Treatment is mainly preventive. If subject to exposure, the patient should select an occupation which is less liable to increase the danger of an attack. Nutrition should be preserved by good food. As long as the condition of the patient permits, out-door exercise should be insisted upon. Tonics, such as iron, strychnin, cod-liver oil, arsenic, should be administered. The bowels should be kept open with salines or laxatives, such as—

℞. Fluidextract of cascara, Glycerin, } each, ℥ j.

Or a pill containing aloin (1 grain), strychnin (1/60 grain), and belladonna (1/8 grain) may be given.

Should indigestion be present, lactopepsin (10 grains) may be given after meals.

℞. Pepsin, Dilute hydrochloric acid, } each, ℥ ij
Compound tincture of gentian, ℥ j
Elixir of curacoa, ℥ iv
Water, add enough to make ℥ iij.
One teaspoonful after meals.

Any of the diuretics mentioned for the acute form may be given if the urine becomes high-colored or scanty.

Hot baths at night may be taken two or three times a week, and followed by thorough massage. Massage aids in breaking up the old adhesions and helps to restore the normal circulation. Vibratory massage may be beneficial. It is well to keep the affected joints wrapped up in flannel. Iodin or blisters may be useful. Sometimes an ointment of ichthyol, mercury and belladonna will prove valuable. Chloral-camphor rubbed in well is effective. Scotch douches and moist compresses (hot and cold) may aid in the treatment. For great pain the actual cautery may be tried. The galvanic current may also be used for a period of 20 minutes 3 times a week. The hot dry air treatment is effective in some cases. Great relief may follow the application of the high frequency current. Of internal remedies not one has been found to be of any distinct advantage. Sometimes an acute exacerbation may be controlled by salicylates. Potassium iodid (10 grains) may be given after meals for periods of 10 days or 2 weeks. Guaiac has been recommended; it should be given in the form of troches. The following prescription is commended:

℞. Guaiac, ℥ iij
Oil of lemon, ♏ vj
Oil of cloves, ♏ ij
Sugar, ℥ j
Acacia, ℥ ss
Confection of rose, a sufficient quantity.
Divide into 30 troches. One after each meal.

See also JOINTS (Diseases).

RHEUMATISM, INFANTILE.—It should be remembered that articular symptoms are relatively less prominent in children than in adults. The same is true of the profuse acid sweating so frequent with the adult. On the other hand, wandering rheumatic pains—the so called "growing pains"—and rheumatic tonsillitis are among the more frequent symptoms of rheumatism in children. Pain, fever, swelling of the joints, and heart symptoms occur, of course, in typical cases of rheumatism, but of these the heart symptoms are chiefly to be dreaded. Pain is quite likely to be slight and more of the nature of tenderness and disinclination to move rather than sharp pain, and hence is often mistaken for a sprain. Fever, as a rule, is neither high nor long-continued, so that the heart symptoms are often the first to attract the attention of the parents. It is not always easy to decide whether we have to do with endocarditis, pericarditis, or both combined; but while it will be found that both are attended with restlessness, labored breathing, and elevated temperature, we expect to find a mitral murmur in endocarditis, systolic, and near the apex (ulcerative endocarditis is attended by fever and chills). Pericarditis usually is more painful than endocarditis, generally gives friction sounds, with the cardiac sounds more distinctly at the base than at the apex.

Diagnosis.—It is by no means always easy to make a positive diagnosis of rheumatism in a child unless there is coincident heart trouble. A rheumatic family history, recurrent tonsillitis, or chorea, may give us valuable hints as to the attack, but antirheumatic remedies are often the best means of differentiation in doubtful cases.

Treatment.—It is of first importance that the child should be clad in a flannel night-gown, put to bed, and kept under blankets until pain and tenderness have disappeared. If the joints are swollen and tender, they should be wrapped in cotton batting after rubbing with liniment; one of efficiency is the following:

℞. Oil of gaultheria, } each, ʒ ss
Spirit of chloroform, }
Soap liniment, ʒ iij.

Of internal remedies the salicylates justly hold the first place, though they sometimes produce hebetude and depression of the heart's action without any appreciable effect in warding off heart complications. Aspirin is usually preferable to sodium salicylate because of its having no by-effects. Da Costa prefers the bicarbonate of sodium in mint-water until the urine becomes alkaline. Quinin sometimes acts well when all the usual remedies have failed, and opiates, especially codein, are permissible for pain. Iodids are the chief reliance in pericarditis and endocarditis. Absolute rest must be insisted upon.

RHEUMATISM, MUSCULAR (Rheumatic Myoitis, Myalgia).—A painful condition of voluntary muscles and their aponeurotic coverings, especially aggravated by motion and pressure. It affects especially large muscles, such as those of the neck, the shoulders, the arms, the intercostal muscles, the back, the thighs, and the calves of the legs.

Etiology and Pathology.—Exposure to cold, and especially to drafts of cool air, as from an open door or window, are the most frequent causes. The acute form, at least, does not wander, but persists in the muscles primarily attacked until relieved. Its true nature is unknown, and whether it is an affection of the muscular substance or of the intermuscular connective tissue or of the minute branches of sensory nerves distributed throughout the muscles is also unknown. Certain forms of muscular rheumatism, especially of the back, are ascribed to gout. An infectious origin has been suggested. It is sometimes associated with articular rheumatism, but has probably a different etiology, though similar exciting causes operate to produce it. Similar pain often succeeds muscular strain, but it is doubtful if this should be called muscular rheumatism. The division of muscular rheumatism into acute and chronic is based upon the duration of the pain and disposition to recurrence. The term chronic is justified for those forms which recur with changes in the weather, and are either excited or relieved by them. It, too, is less localized than the acute. On the other hand, it is not inaptly at times called wandering. It is more frequent in men than in women, because the former are more exposed to its cause.

Symptoms.—The only invariable symptom is pain, aggravated by motion or pressure. Sometimes there is swelling. It is usually rather sudden in its onset, requiring at most but a few hours, and often less, to develop it. It is never accompanied by marked constitutional disturbance. The pulse may be somewhat accelerated and the temperature approach 100° F., but more often there is no fever at all.

Muscular rheumatism is specially named according as it involves certain muscles. Thus, **lumbago** is a painful affection of the lumbar muscles and their tendinous attachments. The attacks come on under the conditions already named, but sometimes suddenly without discoverable cause.

Stiff neck, or **torticollis,** is an affection of the side and back of the neck, forcing the patient to hold his head to one side as the situation of least discomfort, and when he desires to turn his head, he is forced to turn the whole body. Sometimes it becomes chronic and is rather difficult to cure. It is more frequently met with in children and young adults. **Omalgia** is a similar condition of the muscles of the shoulder and upper arm, making motion exquisitely painful. Ankylosis of the shoulder-joint may be caused by delayed motion. **Pleurodynia** affects the intercostal muscles and makes breathing and coughing very painful, while a deep breath becomes impossible, and sneezing an agony. The pectoral and serratus muscles may also be involved when the pain is felt in their locality. It is more frequent on the left side.

The duration of the acute form is brief, seldom lasting more than a few days, though there may be a tendency to relapse. The chronic forms are indefinite in duration.

Diagnosis.—This is easy for the coarser acute forms of omalgia, stiff neck, and lumbago. Muscular rheumatism may, however, be confounded with neuritis and neuralgia. In muscular rheumatism the pain is more diffuse; in neuritis there are pain and tenderness, more localized and along the course of large nerve-trunks. Muscular rheumatism and neuritis are distinctly worse on motion; neuralgia is less so. Rheumatism is commonly relieved by the warmth of the bed; neuritis may be aggravated; while neuralgia is indifferent, though increased by cold winds. Pleurodynia is sometimes difficult to distinguish from intercostal neuralgia, but attention to the points named will prevent mistakes. Neuritis of the brachial nerve-trunks resembles omalgia, but the former is early followed by atrophy, while muscular rheumatism is not. From pleurisy, pleurodynia is easily distinguished by the absence of fever and of physical signs. The lancinating pains of locomotor ataxia and the pains of incipient disease of the vertebræ resemble at first those of lumbago, but the special symptoms of these diseases are soon superadded.

Treatment.—The acute form of muscular rheumatism is occasionally amenable to treatment by the salicylates and salicin. Salipyrin and aspirin have been used with great benefit. The group of muscles treated must be placed at absolute rest, and in the case of the thorax this is best accomplished by strapping the side with adhesive plaster. Rest may, however, be overdone; and in the case of muscles like those of the shoulder, atrophy may result from too prolonged rest. Another measure of great value is dry heat, applied by means of a hot-water bag covered with flannel, or by a warm flat-iron. A flannel cloth should be interposed. With these measures massage may be associated. Of less permanent utility are hot poultices, although they allay pain at least. The same effect is accomplished by moist hot air or vapor (steam) baths, which in special establishments can be localized.

The chronic form is also treated by massage, passive motion, and electricity, either the induced or direct current. Counterirritation by liniments, such as those made with chloroform, ammonium hydrate, or turpentine, have long enjoyed a reputation, but at the present day it is beginning to be questioned as to whether, after all, it is not the friction rather than the liniment itself that produces the good effect. Acupuncture, consisting of the puncture by needles deeply thrust into the skin, is a measure that has some advocates, especially in the treatment of lumbago. Hydrotherapy is more likely to be useful, and here the warm or cold pack is the better method of application. Dry cupping is also often of service. General treatment should not be neglected; cod-liver oil, iron, strychnin, quinin, and good food should be given when the patient is run down (Tyson).

Vibratory massage or the hot dry air treatment may be beneficial. The high-frequency current has given excellent results.

RHEUMATOID ARTHRITIS.—See JOINTS (Diseases).

RHINITIS, ACUTE (Coryza). Varieties.—(1) Simple rhinitis; (2) specific rhinitis.

Etiology. Simple Rhinitis.—(1) Exposure to the cold and wet; (2) inhalation of dust or chemicals; (3) predisposing causes, such as rheumatic diathesis, tuberculosis, and asthma.

Specific rhinitis is due to diphtheria and scarlet fever.

Pathology.—There is vasomotor dilatation with engorgement of the blood-vessels in the mucous membrane, the latter being covered by a mucoserous exudation. The membrane is red and swollen.

Symptoms.—The symptoms are generally ushered in with a severe spell of sneezing, dryness of nasal chambers, hoarseness, headache, and a feeling of chilliness. Large quantities of mucoserous material may be expelled after a few hours, and the choanæ may be entirely occluded by thick, tenacious material. See NOSE (Examination). Often the Eustachian tube becomes clogged up, causing a ringing or buzzing noise, and temporary deafness may be set up.

Prognosis is favorable for simple acute rhinitis.

General Treatment.—Probably the patient would always be cured of his cold quicker if he could be induced to go to bed, or, if not, to remain in a room kept at the same temperature during the day.

Coexisting with the congestion of the nasal mucous membrane there is very likely a partial cessation in the activity of the emunctories of the body; therefore it is most important to use means to promote their activity.

The bowels may be moved by means of fractional doses (1/6 grain) of calomel, salines, Seidlitz powders, or solution of magnesium citrate.

To limit the nasal secretion by contracting the capillaries, Lennox Browne recommends:

℞. Tincture of belladonna, } each, ♏ xx
Tincture of opium, }
Camphor water, ℥ iv.

Two tablespoonfuls 2 hours after meals.

Probably that which may give quickest relief is a hot foot-bath taken at bedtime. The water should be as hot as can be borne, and the limbs should be bathed as high up as the knees. Fifteen or 20 minutes may be well spent in applying this measure of relief, and the process again repeated during the night, and for several consecutive nights if necessary. A small amount of powdered mustard may be added to the bath. Hot drinks, such as lemonade containing a small amount of brandy, may be given after the foot-bath to promote diaphoresis. Quinin (4 to 6 grains) and salol (2 to 4 grains) aid in restoring warmth to the body, and may be used every 3 or 4 hours. Dover's powder (7 grains) is recommended by many good writers.

Local treatment in some cases does good, and in others harm. In the acute stage, if a spray is used at all, only the gentlest force is permissible.

If the anterior naris is entirely occluded, it may be relieved by applying a few drops of a solution of cocain (4 percent) on a pledget of cotton, and the nostril can be subsequently cleansed by

means of some form of douche containing an alkaline solution, such as that advised by Carl Seiler —cold cream (1 ounce) or liquid vaselin containing menthol (4 grains)—may be brushed over the nares to relieve congestion. See also CORYZA.

Treatment of Specific Rhinitis.—See DIPHTHERIA, SCARLET FEVER.

RHINITIS, CHRONIC (Chronic Nasal Catarrh).—**Etiology** is the same as that of acute rhinitis, and it may result from an acute attack.

Pathology. Hypertrophic Form.—Cellular infiltration causes an overgrowth of tissue, giving rise to a spongy condition. The process most often affects the middle and inferior turbinated bones, and may be localized. In many cases deflection of the septum has been found, and nasal spurs are common. The surface is covered with a thick tenacious mucus.

Atrophic Form.—Instead of a hypertrophic condition there may be atrophy of the mucous membrane often involving the bone and giving rise to enlargement of the nasal chamber. On the surface of the mucous membrane a greenish or yellowish and very offensive secretion is usually found, containing various microorganisms. Greenish or mottled crusts may be found scattered over the surface of the nares. This form is also spoken of as ozena. See NOSE (Caries).

Symptoms.—There is generally a feeling of stuffiness or inability to breathe through the nostrils, especially noticeable in the morning; a frequent desire to clear the throat; the voice is harsh, indistinct, or nasal in character; the breath-sounds seem forcible or wheezing; the hearing and taste may become impaired, and from the occlusion of the nares the habit of mouth-breathing may be established.

Often only one nasal chamber is affected, and the patient may complain of being able to breathe only through one or the other side of the nose. A physical examination reveals its character.

In the atrophic form headache may be more common, and the secretion, instead of being mucoserous, has a greenish or purulent cast, often containing greenish crusts.

Complications.—Deafness is common.

Diagnosis is based on anterior and posterior rhinoscopy.

Prognosis is guardedly favorable. The condition is prone to reappear.

General Treatment.—While the local treatment of the disease is probably of most importance, the general condition of the patient must never be neglected. Careful inquiry should be made regarding the habits, such as inveterate use of tobacco, overloading the stomach, bathing at unseasonable hours or in water too cold, and also the condition of the digestion and state of the bowels.

If the general system is below par, a tonic—such as the elixir of the phosphates of iron, quinin, and strychnin (1 dram)—is advisable, taken after meals.

The constipation should be treated by appropriate remedies. See CONSTIPATION.

Local Treatment.—The nasal chambers should be thoroughly cleansed and kept in as healthful a condition as possible by the use of alkaline antiseptic sprays or douches. A good cleansing fluid is composed of listerine (1 part) and water (2 parts).

The fluid for the spray may also be made by dissolving a tablet, according to the formulas of Dobell or Seiler, in about 2 ounces of water, and used by means of the compressed-air apparatus (preferably) or the glass hand-atomizer. Both the anterior and posterior nares are cleared of mucus and dust by this method. The small glass nasal douche seems to be effective in mild cases.

If the compressed-air apparatus is used, much care should be exercised not to use too great a force, as damage to the sensitive membrane may ensue. Usually, a pressure of from 5 to 7 pounds is sufficient. The nasal chambers may be cleansed in this manner 2 or 3 times a week.

Before using the liquids during old weather it is best to slightly warm them. Carbolic acid should be used with caution about the nasal chamber, as it has been known to produce anosmia.

Subsequent to the cleansing process the following solution feels refreshing:

℞.	Eucalyptol, Menthol,	} each,	gr. j.
	Liquid vaselin,		ʒ j.

Use as a spray.

A drop or two of the compound tincture of benzoin may then be sprayed over the parts to advantage.

Here a word of warning against the indiscriminate use of the nasal douche is appropriate. In cases of nasal hypersecretion due to other causes than inflammation of the nasal and retronasal mucous membrane, sinusitis, deviation of the septum, some new growth in the nasal cavity, etc., it is still common practice to have recourse to the nasal douche. In the majority of such cases this is useless, and it may seriously injure the epithelium of the nasal mucous membrane. In numerous cases the power of smell was lost in this way, and experiment has shown that no active antiseptic solution is free from danger to the sense of smell. The nasal douche is, also, frequently the cause of distressing headaches, probably accounted for by fluid passing into the sinuses. One of the gravest dangers is that water may reach the middle ear through the Eustachian tube and cause suppurative otitis media.

Sprays or douches keep the parts clean but they do not altogether relieve the hypertrophy. This condition may often be relieved by a partial destruction of the tissue by means of the galvanocautery or chromic acid.

Before these caustics are applied the parts are thoroughly anesthetized by means of a solution of cocain (5 to 10 percent). The cautery point is then plunged into the hypertrophied tissue in a direction parallel with the inferior border of the bone. In mild cases this operation, repeated 2 or 3 times, suffices. In the more chronic forms linear superficial cauterizations may also be made. At least a week should elapse from the time of one application to the next.

Hypertrophies on the posterior portion of the turbinated bodies are best removed with the knife, saw, or suture, as, being in close proximity to the Eustachian tube, the cicatrix formed by cautery might produce them. There are many operations for straightening septal deviations. The application of chromic acid to hypertrophies has been advised by a few specialists with good results. The parts are anesthetized with a solution of cocain (10 per cent), and the acid is applied by means of a metal probe. Its use is not altogether free from danger of poisoning. See Nose (Caries, Deformities).

RHINOPHYMA.—See Acne Rosacea.

RHINOPLASTY.—See Nose (Deformities).

RHINOSCOPY. See Nose (Examination).

RHUBARB (Rheum).—The dried rhizome of *R. officinale*, *R. palmatum*, or other species of *Rheum*. It contains three closely related anthracene derivatives, *chrysophan*, yielding chrysophanic acid, *emodin*, and *rhein*, which are the cathartic principles; also several bitter resins, a variety of tannic acid, calcium oxalate, starch, sugar, pectin, and other plant constituents. The species of rhubarb cultivated in the United States are devoid of cathartic power, but their leaf-stalks are used as a fruit. Dose of the powdered root, as a stomachic 1 to 5 grains, as a purgative 10 to 30 grains.

Rhubarb is highly esteemed as a cathartic for children on account of the mildness of its action. The tonic and astringent action following its catharsis makes it a valuable agent in diarrheas due to the presence of irritating matter in the bowel, and to correct atonic indigestion accompanied by diarrhea. For hemorrhoids with constipation its gentle action makes it peculiarly suitable, its astringent after-effect being entirely overcome by from 2- to 4-dram doses of olive oil nightly. It may be combined with a mercurial or with sodium bicarbonate. In small doses the tincture is a very efficient stomachic tonic, improving appetite, increasing the flow of the gastric juice, assisting digestion, and promoting the action of the liver without producing any cathartic results. The preparations most in use for children are the aromatic syrup and the mistura rhei et sodæ.

Incompatible with *rhubarb* preparations are: Mineral acids, catechu infusion, cinchona infusion, galls infusion, lead acetate, lime-water, mercuric chlorid, silver nitrate, tartar emetic, zinc sulphate.

Preparations.—**Extractum R.** Dose, 1 to 10 grains. **Fluidextractum R.** Dose, 10 to 30 grains. **Pilulæ R. Compositæ**, each pill contains of rhubarb about 2 grains, aloes 1 1/2, myrrh 1, oil of peppermint 1/10 grain. Dose, 1 to 5 pills. **Tinctura R.**, has of rhubarb 20, cardamom 4, glycerin 10, alcohol and water to 100. Dose, 1/2 to 3 drams. **Tinctura R. Aromatica**, has of rhubarb 20, cinnamon 4, cloves 4, nutmeg 2, glycerin 10, alcohol and water to 100. Dose, 10 to 60 minims. **Syrupus R.**, has of the fluidextract 10, spirit of cinnamon 0.4, potassium carbonate 1, glycerin 5, water 5, syrup to 100. Dose, for an infant, 1 dram; for older children, 2 to 4 drams. **Syrupus R. Aromaticus**, has of the aromatic tincture 15, syrup 85. Dose, as the syrup. **Pulvis R. Compositus**, has of rhubarb 25, magnesia 65, ginger 10. Dose, a teaspoonful. **Mistura R. et Sodæ**, has of sodium bicarbonate 3 1/2, fluidextract of rhubarb 1 1/2, fluidextract of ipecac 1/3, glycerin 35, spirit of peppermint 3 1/2, water to 100. Dose, 1/2 to 4 drams.

In summer diarrhea of children:

℞.	Aromatic syrup of rhubarb,	ʒ vj
	Sodium bicarbonate,	ʒ ij
	Deodorated tincture of opium,	♏ xxxvj
	Peppermint water, add enough to make	ʒ iij.

To a child of from 4 to 6 years give a teaspoonful every 3 hours.

RHUS GLABRA (Smooth Sumach).—The dried fruit of *R. Glabra*. The leaves and bark have an astringent and bitter taste, and are also used medicinally. It contains tannin, coloring matter, also potassium and calcium malates.

Fluidextractum Rhois Glabræ. Dose, 5 to 30 minims. Sumach-berries form a useful acidulous and astringent drink or gargle in catarrhal pharyngitis, stomatitis, and aphthæ. An infusion (one ounce to the pint) or the official fluidextract may be used as a wash and dressing for ulcers and wounds. Internally the berries are useful remedies for mild catarrhal affections of the stomach and bowels.

RHUS TOXICODENDRON.—See Ivy Poisoning.

RIB, CERVICAL.—See Cervical Rib.

RIBS, FRACTURE.—This is a most frequent injury, occurring more often about the fifth to the eighth ribs, in middle-aged males, and in old persons. Direct violence usually produces fractures on only one side of the body, while indirect violence affects one or both sides or breaks one rib in several places. Fractures may be produced by muscular action, as in coughing and sneezing. They are seldom compound, save from gun-shot injury. Fractures of the ribs may be **complicated** by: An external wound; a wound of the pleura and lung, or pericardium and heart; laceration of a blood-vessel, as an intercostal artery; penetration of the diaphragm; and more rarely by perforation of the peritoneum, and wound of the liver or spleen. Hence they may be followed by emphysema, pneumothorax, hemothorax, hemoptysis, hemopericardium, and later by pleurisy, pneumonia, pericarditis, or peritonitis.

Treatment.—The object of treatment is to so immobilize the fractured rib as to put it in the most favorable state for repair. The erect posture is better than the prone. Displacement outward is corrected by direct pressure, while displacement inward is usually rectified by ordinary breathing or deep breathing brought about by anesthesia. As a temporary expedient only the forcibly applied broad rib-roller may be used. Broad bands (2 inches wide) of adhesive strips, extending from the spine to the sternum, and overlapping freely, applied with the arms held over the head while forced expiration is employed, and being put on from 6 to 7 inches below the seat of fracture successively upward, are commonly used. An inelastic spiral or figure-of-eight bandage may be put over the strips. The strips should

be worn for 3 or 4 weeks; fresh pieces being reapplied about once a week, the chest being rubbed with soap liniment, dried, and excoriations treated, as by zinc ointment. Cold, damp, and drafts are especially to be avoided; the diet should be nonstimulating, and cough should be checked by opiates and expectorants. In those over 60 years of age stimulating expectorants are called for, or a steam-tent may be used several times daily.

Confinement in bed is necessary when fracture of the rib is complicated with dangerous visceral injury. The circulation is to be reduced, the patient treated with adhesive strips as before described, put to bed, and diaphoretics and expectorants—such as a mixture of squill, ipecacuanha, ammonium acetate, chloroform, and opium—employed. When there is emphysema, it usually disappears of itself, but it may be necessary to open the cellular tissue and employ pressure under antiseptic precautions. If a sudden attack of dyspnea comes on, it is then advisable to bleed the patient almost to syncope. Pleurisy ensuing from fracture of the rib is mostly local, and is to be treated the same as ordinary inflammations of such membranes. So severe may be the visceral injury, or the patient's state, that it may be advisable to resect a rib, and on investigation treat such complication as may be found, and drain. Hemorrhage from an internal bleeding point indicates the resection of a rib, finding the bleeding point, and ligation thereof. See PLEURISY.

When the costal cartilages are fractured, an attempt should be made to reduce the displacement: if forward, by drawing back the shoulders; or if backward, by employing deep inspiration. A truss may be employed over the projection caused by a broken cartilage for a day or two to reduce the deformity. The case should be dressed and treated the same as a fractured rib—removing the dressings in 4 weeks.

RIBS, RESECTION.—See PLEURISY (Treatment).

RICINUS.—See CASTOR OIL.

RICKETS (Rachitis).—A disease characterized by nutritional changes, deformities of the bones, weakness of the muscles and ligaments, and various nervous disorders. It occurs especially between the ages of 6 months and 2 years. See BONE (Diseases).

Etiology.—The principal cause of rickets is improper feeding. Unhygienic surroundings, hereditary weakness, and feebleness of the digestive powers are also important factors in producing this disease. Breast-fed babies are seldom affected; but when the mother's milk is scanty and poor, as is likely to be the case when the child is weaned late, rickets may occur. Those suffer most frequently who are artificially fed, who receive their nourishment irregularly, and are fed on improper substances, as starches, condensed milk, cow's milk boiled, unmodified, or of an inferior quality, and the various proprietary foods. As the class that most often rear their children in this manner are also those whose hygienic surroundings are of the worst, naturally it is among them that rickets is most common.

The latest theory is that rickets is a "**deficiency disease,**" due to a *lack of vitamines* in the child's diet. The following facts have been adduced in support of this theory: (1) Rickets is less frequent and milder in breast-fed children; healthy breast milk always contains vitamines. (2) Breast feeding has a favorable effect on rickety children. (3) The nourishment of nursing women is often totally inadequate, and this may lead to deficiency of vitamines in their milk. (4) During the winter months the food supply of cows is often inferior, this leading to an inferior quality of milk. (5) The harmful effect produced on the vitamines of milk by prolonged boiling. (6) The harmful results of feeding children with starchy foods, which are poor in vitamines. (7) The beneficial effect of cod-liver oil, which contains vitamines, and also apparently a substance which aids the metabolism of lime salts in rickety children.

Pathology.—Bronchitis is very common. The stomach and intestines are often dilated; the liver may be enlarged, and enlargement of the spleen is frequently present. The only characteristic lesions of rickets, however, are those found in the bones. There are an increased production of cartilage at the epiphysis and excessive cell growth beneath the periosteum, while the process of ossification goes on very slowly or is entirely arrested, which accounts for the unnatural flexibility present in rachitic bones. Normally the bones contain about two-thirds inorganic and one-third organic matter; but in rickets there is a marked deficiency in the proportion of lime salts, and the proportions mentioned above may in severe cases be reversed—there being present twice as much organic as inorganic matter.

There are also characteristic changes in the form of the bones, the principal ones being curvatures and enlargement of the epiphyses of the long bones, and thickening of the bones of the skull.

Symptoms.—The early symptoms may be so mild as to be overlooked. In more severe cases there will be restless sleep, profuse sweating of the head, digestive and nervous disturbances, and perhaps slight fever.

Bending of the ribs (the rachitic rosary), caused by nodules formed at the junction of the costal cartilages and the ribs, and enlargement of the wrist-joints are the earliest noticeable changes in the bones. Dentition in most cases is delayed or arrested, and the fontanels remain open. The appetite is capricious: constipation, which may alternate with diarrhea, is usually marked, and the abdomen is enlarged (often enormously) and tympanitic.

Most rachitic patients are anemic, fat, and flabby, and they are very liable to suffer from inflammations of the mucous membranes, as gastro-intestinal catarrh, bronchitis, and pneumonia. Tenderness of the epiphyses and bones may be present, but is neither a constant nor reliable symptom, and when present to a marked degree suggests scorbutus rather than rickets.

Nervous symptoms are frequent and important; the nerve-centers are in an unstable condition and discharge on the slightest provocation, giving rise

to restlessness at night, to laryngismus stridulus, tetany, or general convulsions.

The deformities most uniformly found as a result of rickets are flat feet, enlarged epiphyses, bow-legs or knock-knees, a malformed thorax (pigeon-breast), and a large square head. In severe cases the spine may become deformed, and not infrequently there occur deformities of the pelvis.

The course of rickets is chronic, the active symptoms continuing for a period of from 2 or 3 to 18 or 20 months. The earliest symptoms of improvement are a diminution of the nervous symptoms, and of the head sweats, improvement in the anemia, and an increase in the muscular power. When improvement once begins, it usually goes steadily forward, relapses being exceedingly rare.

Diagnosis.—The early symptoms mentioned—sweating of the head, craniotabes, great restlessness at night, and delayed dentition—when occurring together are diagnostic of rachitis, but in cases when these symptoms are obscure, the exact nature of the affection may be doubtful before the bones show the characteristic changes.

Hereditary syphilis presents some symptoms which may be taken for rickets, but the lesions of the skin and mucous membrane and the difference in the character of the bone lesions are diagnostic. When there is enlargement of the long bones in syphilis, it is not confined to the epiphysis but involves the end of the diaphysis, and it often is accompanied by a condition that closely simulates a callus. There is a distinct tendency to fracture in syphilis rather than to the bending that is common in rickets.

The diagnosis between rickets and scurvy is mentioned under the description of the latter disease. See Scurvy.

Prognosis.—Many dangers attend rickets on account of the weakly state of the child. He is especially liable to bronchitis and bronchopneumonia, which are particularly dangerous owing to the weakness of the ribs and the feebleness of the respiratory muscles.

One of the effects of rickets is to stunt the child's growth as well as to leave him with deformities. The lowering of the health produced by rickets may last for many years, but in the majority of cases the symptoms and signs of this disease, if they come under treatment, disappear, and the child may grow up into a healthy adult.

Treatment.—The treatment of rickets is chiefly dietetic and hygienic. When possible, the patient should be taken to live in the country, or better—as the salt air is especially beneficial—at the seashore. He should be kept in the open air as much as possible, guarding against bronchitis by keeping him well covered with a woolen blanket and by keeping his feet warm. The living room should be accessible to sunlight, and the child should be given a daily warm salt-bath, followed by an inunction of cod-liver oil.

The food should be adapted to the child's age, and given in proper amounts and at regular intervals. See Infant Feeding. The sugar and starches should be reduced in the food, and the proprietary infant foods not given. Beef-juice should be added to the infant's diet. This is prepared by taking 1 pound of finely chopped round steak, 6 ounces of cold water, and a pinch of salt; place in a covered jar and stand on ice or in a cold place for 5 or 6 hours. This is now strained and all the juice squeezed out of the meat by placing it in coarse muslin and twisting it very hard. One teaspoonful of this may be given in the milk, or separately before taking the bottle, 3 times a day to a child 6 months old, increasing the amount gradually to 4 to 6 tablespoonfuls daily at 11 or 12 months. From 10 to 18 months there should be added to the diet list eggs, scraped raw meat, orange-juice, and fresh fruits.

Cod-liver oil should be given in all cases, and, except in hot summer weather, it is usually well tolerated. It is best given pure, the dose being from 10 drops to a teaspoonful 3 times a day, according to the child's age and its capacity for digesting it. It may be combined as follows:

℞. Syrup of lactophosphate of lime, } each, ʒ ij
Lime-water, }
Cod-liver oil, ʒ iv.
From 1/2 to 2 teaspoonfuls 3 times a day.

Or with phosphorus:

℞. Phosphorated oil, ʒ ss
Cod-liver oil, ʒ vj.
From 1/4 to 1 teaspoonful 3 or 4 times a day.

For the anemia iron should be given. One or 2 drops of the syrup of iodid of iron may be added to each dose in the above recipes, or it may be given as in one of the following:

℞. Syrup of iodid of iron, ʒ j to ij
Simple syrup, ʒ iij.
One-half of a teaspoonful in a little water 3 times a day.

℞. Citrate of iron and quinin, gr. x
Cod-liver oil, } each, ʒ ij.
Glycerin, }
One-half to 1 teaspoonful 3 times a day.

For the relief of sweating when profuse give 1/800 to 1/200 grain of atropin 3 or 4 times a day.

When digestive disturbances are present, they should receive appropriate treatment. As a rule, such simple remedies as calomel and soda, in small doses, and essence of pepsin will meet the indications.

Many of the deformities resulting from the softness of the bones may be prevented by precautionary measures. The children must not be allowed to sit up before their vertebral column will support them. They must not be carried about in the erect posture nor on the same arm always, and they must be discouraged from walking before their limbs are sufficiently strengthened. When there is craniotabes (thinning of the skull), the weight of the head must, as much as possible, be kept from falling upon that part of the skull. In very many cases slight deformities of the extremities are outgrown. Friction and intelligent manipulation of the ex-

tremities will do much to strengthen the muscles and straighten the bones, but braces should be applied if the deformity does not yield to these measures.

The deformity of the spine may be much benefited by postural treatment. The patient should lie upon a hard bed, no pillow should be allowed under the head; but in severe cases one should be placed beneath the back so that the spine is slightly raised. For a few minutes every day the child should be placed upon the face and the deformity overcome by raising the buttocks while pressure is made upon the spine. Friction and massage should be employed to strengthen the muscles. In severe cases an apparatus, as a brace or plaster jacket, should be worn a few hours every day. Little can be done toward correcting deformed bones by apparatus after the child is 2 1/2 years old, as the bones have then become hardened. After this time surgical treatment is the only means of cure.

RIGGS'S DISEASE.—See PYORRHŒA ALVEOLARIS.

RIGOR.—The phenomena—all referable to the central nervous system—that constitute a rigor frequently portend serious illness. The attack frequently shakes every muscle, the teeth chatter, the face twitches, eyelids and mouth-corners irregularly move or twitch, temperature often rises, and the sensation of intense cold ensues. Besides other motor symptoms, disturbances of function occur. A rigor is sometimes produced by traumatic influence, as after sudden dilatation of the urethra by a catheter; but we are by no means enlightened as to the pathologic state of the central nervous system that produces the rigor preceding the onset of disease.

A rigor occurring during the course of an illness, and not due to malaria, should suggest pus formation or thrombosis. In malarial fever and in acute diseases, especially pneumonia and erysipelas, rigors are usually premonitory symptoms.

The most usual **treatment** of a rigor has been that of stimulation and heat, through the use of brandy and hot water, hot bottles, and blankets. It is the disturbance of the heart that urges the necessity for treatment; and any drug that narcotizes the nerve-centers has a preventive effect on rigors. Chloroform will arrest a rigor, and morphin and quinin will prevent and arrest rigors due to catheterism. Practically, the administration of 1/4 to 1/3 grain of morphin hypodermically, with maintenance of external heat through hot-water bottles, hot blankets, or heated air, and the occasional use of hot alcoholic drinks, will suffice. See CHILL.

RIGOR MORTIS.—The muscular rigidity that occurs shortly after death, due to chemic changes resulting in the production of myosin. See DEATH (Signs).

RINGWORM OF THE BEARD (Tinea Sycosis; Barber's Itch).—A contagious, vegetable parasitic affection, attacking the hairs and hair follicles of the bearded region.

Symptoms.—The disease begins with the appearance of small, rounded, scaly, reddish patches (tinea circinata). The hairs and their follicles soon become invaded, with the production of swelling and induration and the appearance of nodular or lumpy tumefactions. Numerous pustules mark the sites of the hair follicles. These soon rupture and give exit to a yellowish pus, which dries in the form of crusts. The hairs are dry and brittle, and either break off or fall out. The chin, neck, and submaxillary region are the regions most frequently affected. The upper lip is almost never attacked. Itching and burning are present in varying degrees. The disease, when untreated, persists indefinitely. Unless treatment is extremely thorough, relapses are liable to occur.

Etiology.—The disease is due to the invasion of the hair follicles by the ectothrix variety of the trichophyton fungus. The affection is usually acquired in the barber shop. The disease, however, is not infrequently contracted from horses and cattle. When acquired from such sources, it is apt to be more severe.

Pathology.—Both the hair and the hair follicles contain the fungus. As in tinea tonsurans, the spores greatly predominate over the mycelium. Secondary inflammation of the follicles and surrounding tissues, with swelling, infiltration, and suppuration, are present in well-marked cases.

Diagnosis.—The chief affection to be differentiated is ordinary sycosis.

TINEA SYCOSIS.	SYCOSIS.
1. A typical case shows large, lumpy, or nodular tumefactions.	1. A typical case shows small, discrete pustules pierced by hairs.
2. Hairs broken and easily extracted. Roots usually dry.	2. Hairs firmly attached until free suppuration occurs. Roots often swollen with pus.
3. Course rapid. Marked changes from week to week.	3. Course slow. Little change from week to week.
4. Upper lip almost never involved.	4. Upper lip frequently involved.
5. Trichophyton fungus in hairs.	5. Absence of fungus in hairs.

Prognosis.—The disease is at times rebellious to treatment, although most cases get well in 1 or 2 months. Relapses are common.

Treatment.—The treatment consists of epilation and the use of parasiticide applications. Crusts should be softened with bland oils and then removed with soap and warm water, after which the part should be shaved. Shaving and epilation of the diseased hairs should then be practised upon alternate days.

The following applications are all efficient:

℞.	Precipitated sulphur,	ʒ j
	Petrolatum,	℥ j.
℞.	Sodium thiosulphate,	ʒ j
	Water,	℥ j.
℞.	Mercuric chlorid,	gr. j
	Water,	℥ j.

These should be applied 2 or 3 times a day.

RINGWORM OF THE BODY (Tinea Circinata).—A contagious, vegetable parasitic disease, due to the trichophyton megalosporon, or large-spored fungus, or the microsporon audouini or small-spored fungus, and characterized by annular vesiculosquamous patches upon the body surface. Of the trichophyton there are two main varieties, the endothrix which causes the transitory forms of macules, and the ectothrix to which is due the severely inflammatory type of the disease. Ringworm of the general surface for the bearded region is due generally to the ectothrix; that of the scalp is usually caused by the endothrix. In children, however, ringworm of the scalp is as a rule due to the microsporon though occasionally to the trichophyton.

Symptoms.—The disease begins as one or several rounded or irregular pea-sized, hyperemic, scaly patches. In a few days these assume a circular shape with minute papules or vesicles around the circumference.

Peripheral spreading and central healing progress hand in hand, so that the patches when fully developed are distinctly annular or ring-shaped. They are of a dull pinkish or reddish color, with slightly elevated borders, which exhibit a branny desquamation. Itching is usually slight. The face, neck, and backs of the hands are the most frequent seats.

In **tinea cruris** (*eczema marginatum, tinea trichophytina cruris*) the clinical appearances are so much modified as frequently to simulate an eczema intertrigo. The patches are large, diffuse, of a dull or brownish-red color, with a well-defined marginated, and at times slightly elevated, border. Outlying circinate patches are usually present.

The eruption spreads with remarkable rapidity, successively involving the thighs, groins, genitals, mons veneris, and nates. Eczema is apt to complicate the affection. The itching is often severe, particularly at night.

Tinea Trichophytina Unguium (*Onychomycosis, Ringworm of the Nails*).—Occasionally, the nails are invaded by the ringworm fungus. They become opaque, white, thickened, and soft or brittle. Two or three nails are usually affected. The disease runs a chronic course, and is refractory to treatment.

Pathology.—The fungus is found in the epidermis, particularly in the corneous layer. Mycelium is abundant, spores scanty. The former consists of long, slender, sharply contoured, bifurcated, jointed threads. The spores are rounded, highly refractive bodies, varying from 1/1000 to 1/600 inch in diameter.

Diagnosis.—Tinea circinata may be distinguished from eczema, psoriasis, and seborrhea by the superficial character of the lesions, their annular configuration, the history, the course, and, finally and conclusively, by the microscopic examination.

Method of Examining for the Fungus.—Epidermic scales are scraped off with a knife and placed on a microscopic slide with a drop of caustic potash (20 to 40 percent). A cover-glass is then applied, with sufficient pressure to flatten out the scales. The fungus is best studied with an oil-immersion lens, although it can be seen with the dry system.

Prognosis.—As a rule, the affection yields promptly to treatment. Tinea cruris is more rebellious than the ordinary form.

Treatment.—The treatment consists in the use of parasiticide ointments and lotions. Mercury, sulphur, beta-naphthol, resorcin, tar, and chrysarobin are all valuable. An efficient formula is:

℞. Ammoniated mercury, gr. xx to xl
Zinc oxid ointment, ℥ j.

Thiosulphate of sodium (1 dram to 1 ounce of water) and bichlorid of mercury (1 to 3 grains to 1 ounce of water) are useful applications, especially in tinea cruris.

RINGWORM OF THE SCALP (Tinea Tonsurans).—A contagious, vegetable, parasitic disease, characterized by circumscribed areas of partial baldness, with evidence of disease of the hairs.

Symptoms.—The disease begins with small, rounded, reddened scaly patches, occurring upon any portion of the hairy scalp. Soon the follicles become invaded and circumscribed hair-fall results. Typical lesions consist of partially bald, discrete, rounded, coin-sized, slightly reddened patches covered with grayish scales. The follicles are prominent, producing a "goose-flesh" appearance. The hairs are lusterless, and consist of "broken or gnawed-off stumps." They lie loosely in the follicles and are easily extracted.

In rare cases ringworm may affect the scalp diffusely, without the production of circumscribed patches (*disseminated ringworm*).

The only subjective symptom is itching, which is usually of a mild character. The disease occurs almost exclusively in children. In adults it is so rare as to constitute a dermatologic curiosity.

The course of the affection is extremely chronic. When cure results, full restoration of hair takes place.

Tinea kerion is a highly inflammatory ringworm terminating in suppuration. The patches are reddish or yellowish, raised, edematous, and boggy; they are honeycombed with distended openings of hair follicles, through which exudes a yellowish pus. Burning, itching, tenderness, and pain are present in a variable degree. The suppuration of a ringworm hastens its cure, but is apt to destroy the follicles and produce permanent baldness.

Etiology.—The cause of the disease is the trichophyton fungus or the microsporon audouini. Ringworm is essentially a disease of childhood. The affection is communicated from one child to another by means of caps, brushes, combs, towels, etc. It may also be contracted from the lower animals, such as the cat, dog, horse, or ox. Tinea circinata in the adult may produce tinea tonsurans in the child, and vice versa.

Pathology.—The fungus is found in the hair, the hair follicle, and the epidermis. In this form of the disease the spores are extremely abundant in the hair, producing under the microscope a fish-roe appearance. The mycelium is scanty or absent. The hair is prepared by immersion in liquor

potassæ, and is examined without staining. Only broken-off hairs are to be selected for examination.

Diagnosis.—The characteristic features of tinea tonsurans are circumscribed patches of partial baldness, grayish scales, goose-flesh appearance, broken-off stumps of hair, and the presence of the fungus.

These points will enable one to distinguish the disease from eczema, psoriasis, and seborrhea. The differential diagnosis from alopecia areata is here appended:

Tinea Tonsurans.	Alopecia Areata.
1. Slow and insidious onset.	1. Rapid onset.
2. Patches are	2. Patches are
(*a*) Covered with "broken-off stumps."	(*a*) Totally devoid of hair.
(*b*) More or less reddened.	(*b*) Pale and whitish.
(*c*) Rough and scaly.	(*c*) Smooth and soft.
(*d*) Follicles prominent; goose-flesh appearance.	(*d*) Follicles contracted.
3. Trichophyton fungus present.	3. Absence of fungus.
4. Occurs almost exclusively in children.	4. Common in adolescence and in adults.

Prognosis.—As to ultimate cure, favorable. As to duration guarded. Most cases persist from 6 months to 1 1/2 years.

Treatment.—The treatment consists of (1) daily soap and hot water cleansings; (2) epilation of diseased hairs; and (3) application of parasiticide ointments and lotions. The scalp will bear remedies of greater strength than the nonhairy surfaces.

The head should be washed vigorously each day with soap and hot water. For this purpose ordinary soap may be employed or, preferably, a soap containing tar. This accomplishes the double purpose of cleansing the scalp of fungus and scales and of preventing surface extension. The parasiticide effect of the washing may be increased by allowing the soapsuds to remain upon the scalp for from 15 to 20 minutes. The hair should be cut short in order to facilitate the application of the various medicaments.

The diseased hair should be extracted either with a broad-blade epilating forceps or the small end of a spoon and the thumb. Epilation is of value in effecting the removal of a considerable amount of fungus in the hair, in opening the follicle, and permitting the ingress of the parasiticide application.

The choice of the particular ointment or lotion is not a matter of great importance. It is the thorough and persevering use of the same that brings success. Sulphur, mercury, beta-naphthol, carbolic acid, resorcin, salicylic acid, tar, chrysarobin, and a host of remedies have been used, but those above mentioned are the most valuable. The following ointment will be found useful in most cases:

℞. Precipitated sulphur, ʒ j to ij
Petrolatum, ℥ j.

This is to be rubbed into the patches vigorously once or twice a day. One may use, in conjunction, a lotion of sodium thiosulphate, one dram to the ounce. Beta-naphthol is a remedy of great value, and has the advantage of being free from odor:

℞. Beta-naphthol, ʒ j
Petrolatum, ℥ j.

A lotion of the bichlorid of mercury may often be employed with advantage. Beginning with 1 grain to the ounce, one may gradually increase to 4 or 5 grains.

A word as to the prevention of the spreading of ringworm: Towels, brushes, combs, caps, soap, and other articles used by a ringworm patient should never be used by any one else. Physicians should prohibit children affected with tinea tonsurans from attending school until they are entirely cured. It is a great hardship upon a child to enforce its absence from school for a year or more, but it is the only method of stamping out this affection.

RISUS SARDONICUS.—A peculiar expression of the face, in which the features are distorted by spasm of the muscles so as to present the appearance of a painful grin or laugh. It is most usually observed in tetanus. After a full dose of strychnin (1/12 grain), among other symptoms, the face will take on an unmeaning smile, or risus sardonicus. The condition in itself is not to be treated, but its cause demands immediate removal.

RITTER'S DISEASE.—See Dermatitis Exfoliativa Neonatorum.

ROCKY MOUNTAIN SPOTTED FEVER.—An acute infectious disease occurring in Montana, Idaho, Nevada and Wyoming, and characterized by chills, fever, muscular pains, headache and a maculopapular or petechial eruption.

Etiology.—This is unknown; but the disease is spread by the bite of a tick, Dermacentor occidentalis.

Symptoms.—Most cases develop in the early spring, and are marked by a brief period of malaise, followed by chills, fever, headache, and pains in bones, joints, and muscles. On about the third to the sixth day a maculopapular or petechial rash appears; it is generally most marked about the hands and feet, but may occur on the face and trunk.

Diagnosis.—This is made by the location, time of year, and a history of a tick bite. It is to be diagnosed from typhoid, typhus, dengue, cerebrospinal meningitis; but the characteristics of these diseases are so marked that differentiation should not be difficult.

Treatment.—Protection against tick bites is of the utmost importance. Cold sponging, quinin, and later tonics, are indicated.

RODENT ULCER (Jacob's Ulcer; Cancroid Ulcer; Ulcus Exedens; Noli me Tangere).—A peculiar form of superficial epithelioma, almost invariably limited to the upper two-thirds of the face. It occurs in old age, and begins as a little nodule which ulcerates. The ulcer is round, oval, or irregular, with indurated everted edges and a smooth, glossy, pinkish surface; the discharge is

slight, pain is absent, adjacent lymph glands are not involved, metastases do not occur, and the general health is unimpaired except in the later stages, death resulting from hemorrhage or from the local destruction of important organs. The disease progresses very slowly, sometimes lasting 30 or 40 years, and occasionally cicatrizes in spots, the scars later breaking down. The ulcer advances principally along the surface, although in the later stages it extends deeply and destroys everything in its path, including the bones. The disease may originate in any of the epidermal structures. See EPITHELIOMA.

ROENTGEN RAYS.—The discovery by Prof. Roentgen of Wurtzburg of a new form of radiant energy emanating from a Crooke's tube has given rise to the new science of Roentgenology. He found that this new form of energy was capable of penetrating substances formerly considered opaque, in degrees varying with the vaccum in the tube, and the density of the object penetrated.

It affected the silver salts of the photographic plate, and the fluorescent salts spread upon a screen called a fluoroscope with proportionate degrees of intensity and thus lent itself readily to use in diagnosis. He did not invent any apparatus, but showed that the rays he discovered could be applied to physical diagnosis.

Roentgenology is the application to diagnosis and therapy of the unknown (X) or Roentgen rays. This science is subdivided into (*a*) *Roentgenography*, physical diagnosis by means of these rays and the photographic plate, (*b*) *Roentgenoscopy*, their use with the fluoroscope, and (*c*) *Roentgenotherapy*, treatment by this form of irradiation.

The development of apparatus has rendered the rays more powerful and less dangerous to the patient in experienced hands, but more dangerous both to patient and operator in the hands of the inexperienced. Their use must therefore be confined to those who have acquired special knowledge, and only in such hands can valuable results be expected.

The Dangers of the Roentgen Rays.—The advancement in technic and apparatus practically limits the danger to those who have little or no experience. The increase in power, which makes diagnosis now possible by an exposure of only a few seconds, augments the danger in the hands of the inexperienced. Medical knowledge is essential to their valuable application in diagnosis and in therapy; it is needed to appreciate the change produced, and to regulate the dose accordingly.

The series of lamentable, often fatal, accidents to operators has shown the necessity for special training. Though the patient is less liable to injury from the more powerful apparatus, the danger to the untaught operator is greater.

The Apparatus.—The evolution of efficient apparatus has been rapid. The Ruhmkorff coil of the physical laboratory even when improved was crude and difficult to handle. The modern Roentgen generator is more powerful and yet simpler in manipulation. It is a machine, as simple to run as an ordinary electric motor, without the disadvantages and complications of inverse currents, electrolytic or mechanical interrupters, and the constant expense and annoyance attendant upon their regulation and repair. It furnishes an unlimited supply of unidirectional high-potential current necessary to energize the Roentgen tube. It is an efficient and easily controlled mechanism of great power.

The problem of effective technic has, however, become more rather than less complicated, since more efficient modifications in its application have been made, thus rendering diagnosis more accurate.

Such efficient apparatus can be run in connection with any commercial electric lighting or power circuit, but must be adapted to the particular current to be employed.

The Roentgen Tube.—This is a modified Crooke's tube adapted to the purposes of Roentgenology. It is now the most complicated part of the apparatus to understand and requires efficient technic. Since the rays emanating from the Roentgen tube in action vary with its vacuum in penetration and therapeutic value, they must be adapted to the particular form of diagnosis to be made and to the disease to be treated.

Other essential accessory pieces of apparatus have been developed, the *milliamperemeter* to measure the amount of current passing through the tube; the *static voltmeter* to measure the tension of the current and the relative vacuum of the tube, *i. e.*, the penetrating power of the rays while the tube is in operation; filters, which by removing undesired rays have increased the safety and efficiency of the rays in diagnosis and treatment.

These contrivances, while reducing the time of exposures in diagnosis from minutes to fractions of a second, have rendered technic essential and yet more involved.

In practice Roentgenology is divided into diagnosis and therapy.

Roentgenography is a method of physical diagnosis by means of the Roentgen rays and the photographic plate. A *Roentgenogram* is a photographic negative produced by this method upon which tue Roentgen diagnosis is based. A Roentgenogram can be produced by any one who can run the apparatus, but one upon which a valuable diagnosis can be based can only be made by a medically educated operator knowing the essential special technic. For diagnostic purposes there is desired not a picture, but a Roentgenogram which shows the tissues in which a lesion is supposed to exist.

The value of the Roentgen diagnosis is dependent upon the medical training of the operator, his technical ability in employing this method and his clinical experience in translating the resulting data.

The tube must be placed in proper relation to the part to be examined and the photographic plate; the quality of rays must be adapted to the tissues to be studied; the exposure must be correct, in order to determine the presence or absence of the supposed pathologic lesion. Anatomical,

clinical and special technical knowledge combined with experience are therefore essential to an accurate Roentgen diagnosis.

Stereoroentgenograms are pairs of Roentgenograms so made that when each is viewed by one eye of the observer in the stereoscope the effect of a true perspective is produced. By this method the distortion produced by the divergence of the rays emanating from the tube is corrected and transformed into a true perspective or a realization of the third dimension. It has the advantage of showing the lesion in its true anatomic relations, not as a shadow, but, as it were, within a semi-transparent body. Thus the position of the bones in dislocations, the fragments in fractures, the location of foreign bodies, or the minute masses of tubercle in tuberculosis of the lungs are seen in their true anatomic relations to the surrounding normal structures.

The development of more efficient apparatus has shortened the time of exposure, so that voluntarily movable organs can be shown in sharp detail after exposure of a fraction of a second in most examinations; while no exposure, except in very stout individuals, should exceed 15 to 20 seconds, unless taken with portable apparatus. The examination of patients in their homes is easy and practical, but necessitates less powerful apparatus and longer exposures.

Applications of Roentgenography.—In internal medicine it has rendered diagnosis more accurate by clearly demonstrating the size, position, and form of aneurysms, aortic dilatations, changes in the size and position of the heart, mediastinal new growths, and strictures and new growths of the esophagus. In the lungs it locates and shows all macroscopic, pathologic changes, while in tuberculosis of the lungs it definitely determines the presence, position and size of areas of congestion, consolidation, softening and cavity formation, as well as the effect of adhesions and contractions upon the mediastinal viscera and the diaphragm. Early enlargement of the peribronchial lymph nodes can be shown before they can be detected by physical signs, while stereoscopic pictures reveal minute clusters of tubercle scattered throughout the lung.

The application of this method to the stomach after a bismuth meal has been given, reveals its normal or pathologic position and the presence or absence of motor insufficiency, pyloric obstruction, malignant disease, pathologic stricture of the stomach and intestines, or ptosis of these organs.

In the kidney, enlargements, displacements, abscesses, new growths and calculus formations can be revealed by this method. In renal calculus it is admittedly the most accurate method known. It determines the size, position and number of the calculi present in the kidney, ureter, or bladder, and no surgical intervention or expectant treatment is sanctioned without its employment. The differentiation between sthenic and asthenic forms of arthritis is another very valuable aid to internal medicine.

In surgery it is of great value in locating foreign bodies, in definitely determining the lines of fracture, the position and number of the fragments, the efficiency of reduction and of fixation appliances. The same is true of dislocations, while its value in excluding such injuries should not be overlooked.

It differentiates between the several forms of bone disease, showing the location, extent, and nature of cysts, tuberculosis, osteomyelitis, syphilis, malignant diseases.

In orthopedic surgery it is peculiarly adapted to the determination of the extent, location and character of bone defects, distortions and necroses, differentiating, for example, between achondroplasia and osteomyelitis, and elucidating the extent and character of the deformity present. It detects supernumerary bones and shows congenital malformations, defects and dislocations.

In otology and rhinology it reveals disease of the accessory sinuses, and the presence of abscesses and bone absorption in the mastoid cells.

Medicolegal Value.—The Roentgen rays produce a visible picture of pathologic conditions which could formerly be expressed only in the mental pictures formed by other methods of physical diagnosis. In medicolegal testimony it has the advantage of being evidence which can be seen and the meaning of which can be demonstrated to a jury. The question of interpretation is the only one capable of argument, and for that reason it is essential that expert testimony should be on hand for both sides, when any question of interpretation can be raised. In the majority of cases, especially of bone injury, the interpretation is obvious. This method possesses an additional advantage in that it shows not only the present condition, but also the extent of the original injury—a point which should always be brought out in malpractice suits. Its power to demonstrate the absence of any bone injury is particularly valuable when such an injury is falsely made the basis of a suit for damages.

Since this method has been admitted to be of scientific value and permitted as evidence in courts of justice, its employment in all cases of fracture forms the greatest safeguard to the surgeon against suits for malpractice. It furnishes evidence of the condition before treatment, the seriousness of the bone lesion, and if plates are made after the fracture is set and immobilized, demonstrates that efficient treatment has been instituted. The inference that the injury to function is proportionate to the distortion shown in the Roentgenogram is erroneous, for bones united with apparent distortion are frequently found after injury in limbs that have perfect function. The fact that the injury to ligaments and soft tissues is not shown by the Roentgenogram should be made clear, although they may be inferred from the injury demonstrable. It is therefore obvious that the evidence produced by this method cannot form the basis for determining the amount of functional injury sustained by the patient.

Roentgenotherapy.—The treatment of disease by means of the irradiations from a Crooke's or Roentgen tube.

The therapeutic value of the Roentgen rays has been so clearly demonstrated that this department of Roentgenology is firmly established. Pathologic studies have demonstrated that the Roentgen rays have a destructive action upon all tissues of low vitality and hence upon all cells resulting from disease, at the same time stimulating normal cells to greater activity. Thus this agent increases the local resistance of the normal tissues while it devitalizes the pathologic. This local action on metabolism in a measure accounts for the many successful applications of this agent.

The effective application of the Roentgen rays for therapeutic purposes demands careful study and experience. By timidity in their application the diseased cells instead of being destroyed may be stimulated to greater activity. By too severe treatment the normal cells may be injured and the local vitality and resistance so essential to recovery may be destroyed. The difficulties attending the proper use of this method account for divergent reports of success and failure.

The results obtained show that Roentgenotherapy is effective in many serious and especially chronic conditions intractable to other methods.

The field of this therapeutic agent is so wide that only a summary of some of its successful applications can be given.

In malignant disease some remarkable results have been produced. It has cured many inoperable and hopeless cases, while as a palliative measure it is the most efficient in affording, when properly applied, relief from pain. As postoperative treatment, its beneficial effect in malignant cases is shown in the reduced mortality rate of such cases. These results have led to its application in the earlier stages of the disease with proportionately better results.

In epithelioma (*q. v.*) and rodent ulcer it has been shown by many series of permanent results to be superior to other methods of treatment.

In tuberculous cervical adenitis it can be employed efficiently in the early stages of disease, when consent to radical treatment cannot be obtained, and while the patient is under medical treatment.

Successful results have been obtained in cases of recurrence after repeated operations. It produces healing in persistent sinuses and ulcerations that have defied surgical treatment. In these conditions it is therefore the method of choice.

In lupus vulgaris and lupus erythematosus it is the most effective treatment known, and produces permanent results with less scar formation.

In other cutaneous lesions such as acne, eczema, pruritus, ringworm, sycosis, etc., the results are remarkable, especially in the chronic forms that have resisted all other medication; this is especially true of the indurated acne and dry eczemas.

It has also been found valuable in diseases such as the neuralgias and neuroses, goiter (both simple, and exophthalmic), as well as other conditions, affording, in many instances, relief from pain, and permanent cure. To obtain the best results, however, treatment should be instituted in the earliest stages of disease.

ROSE (Rosa).—Represented in official pharmacy by the petals of one species and the volatile oil from another.

Rosa Damascena, *Damask Rose,* is the source of the official oil of rose, which is distilled from the fresh flowers.

Rosa Gallica, *Red Rose,* is the petals of *Rosa gallica,* collected before expanding. They contain an aromatic oil, tannic and gallic acids, *quercitrin,* coloring matter, salts, etc.

Rose water has no strictly medical properties, but is an agreeable excipient for lotions, collyria, and urethral injections. The ointment, commonly termed *cold cream,* is a pleasant emollient and protective agent, generally used for chapped hands and other superficial skin affections. Red Rose is classed among the astringents, as it contains an appreciable amount of tannic and gallic acids. A compound infusion, containing sugar and dilute sulphuric acid, was formerly official, and is used as an agreeable gargle for the throat and mouth in inflamed and ulcerated conditions. The chief uses of the rose preparations are as vehicles for other agents, or to impart flavor and odor to extemporaneous prescriptions.

Preparations.—R. Oleum, *Attar of Rose,* is a volatile oil distilled from the fresh flowers of *Rosa damascena.* It is a pale-yellowish, transparent liquid, having a strong odor of rose, a sweetish taste and a slightly acid reaction, but slightly soluble in alcohol. It consists of an aromatic oxygenated elæopten and an odorless solid stearopten (rose-camphor). Being very expensive it is much adulterated with other volatile oils. It is used chiefly for perfuming cosmetic preparations, ointments and lotions, and as the basis of the following three preparations. **R. Aqua Fortior,** *Triple Rose Water,* is water saturated with the volatile oil of rose petals. An agreeable excipient and flavoring agent. Dose, 1/2 to 4 drams. **R. Aqua** consists of equal volumes of the preceding and distilled water, mixed together immediately before use. It is an ingredient of mistura ferri composita. Dose, 1 to 8 drams. **Unguentum Aquæ R.,** *Cold Cream,* has of stronger rose water 19, expressed oil of almond 56, spermaceti 12 1/2, white wax 12, and sodium borate 1/2. **Fluidextractum R.,** prepared from red rose with glycerin and diluted alcohol. Dose, 5 to 60 minims. **Confectio R.,** has of red rose 8, sugar 64, honey 12, stronger rose water 16, beaten together into a mass. Dose, 10 to 60 grains. **Mel. R.,** *Honey of Rose,* has of the fluidextract 12, and clarified honey to 100. Dose, 1 to 2 drams. **Syrupus R.,** has of the fluidextract 12 1/2 percent. Dose, 1 to 2 drams for flavoring. Red rose is an ingredient of Pil. Aloes et Mastiches. The confection is an ingredient of Pil. Aloes et Ferri.

ROSE COLD.—See HAY-FEVER.

ROSEMARY (Rosmarinus).—The leaves of *R. officinalis.* Its properties are due to a volatile oil and a resinous principle. Rosemary was formerly considered emmenagog, galactagog, and diuretic. It is chiefly used as an external stimulant in liniments and lotions, especially to the scalp, in

alopecia (usually combined with cantharides). R., Oleum, the volatile oil. Dose, 1 to 5 minims.

ROSEOLA.—A rose rash. See ERYTHEMA, RUBELLA, SYPHILIS, TYPHOID FEVER, VACCINATION.

ROSMARINUS.—See ROSEMARY.

ROUGH ON RATS.—A paste for poisoning rats, occasionally used as a means of suicide. The active ingredient in most of these pastes is arsenic, and acute arsenic-poisoning results from its ingestion. See ARSENIC.

ROUND LIGAMENTS.—See ALEXANDER'S OPERATION.

ROUND-WORMS.—See WORMS.

RUBEFACIENTS.—Substances that by irritation of the ends of the nerve filaments of the skin cause distention of the capillaries and reddening of the skin. If left too long in contact with the surface, exudation between the cuticle and true skin may ensue, when the agent becomes a vesicant; or it may destroy the tissue and form a slough, when it is an escharotic. Muscular atrophy may be induced by rubefacients. The following is a list: Mustard, capsicum, camphor, ammonia, mezereon, arnica, alcohol, ether, chloroform, iodin, menthol, oil of cajuput, oil of turpentine, volatile oils, pitch, friction, and hot water. See COUNTERIRRITATION.

RUBELLA (Rötheln; German Measles; Roseola.—An acute infectious disease of a mild nature, and characterized by slight inflammation of the mucous membrane of the conjunctiva, mouth, nose, and fauces; enlargement of the cervical glands; mild fever, and a papular eruption of the skin.

Etiology.—Rubella is contagious, and may occur in epidemics or sporadically. Though probably microbic in origin, the specific organism has not been isolated. It is spread by the cutaneous exhalations and breath and by fomites, especially in hospitals or crowded quarters; it is very contagious, but in family practice it is but slightly so, the cases often confined to a single household. The incubation period is from 10 to 12 days, though it may vary; but as a rule it is longer than in measles.

The stage of invasion is from 1 to 3 days, but in mild cases the appearance of the rash may be the first indication of the disease.

Symptoms.—Usually for a period of a few days before the rash appears there will be chilliness, pain in the legs and back, a dull heavy feeling, and perhaps slight fever. There may be suffusion of the eyes and coryza. Enlargement of the tonsils and of the cervical lymph-glands are common.

Just before or with the appearance of the rash there is a rise in temperature—99° to 100° F., or in severe cases 102° to 103° F. These symptoms in certain cases may be very mild or altogether wanting, the appearance of the rash, as stated, being the first sign of infection. The rash first appears on the face and extends downward over the body. In some cases, however, only one part of the body may show any eruption; in others every part, including the palms of the hands and soles of the feet, may be covered. The roof of the mouth and fauces usually are more or less generally covered with the rash.

The eruption is multiform, confluent, and of a pale or rosy red color. The patches do not have any regular shape or form, and the skin between them may be hyperemic and itching. It reaches its height on different parts of the body in succession, fading in one part while appearing in another. The duration of the rash is from 2 to 5 days. Slight branny desquamation usually appears. A slight brownish pigmentation often follows the rash, but disappears in a few days.

The temperature varies, but usually there is fever—100° to 102° F.—while the eruption is at its height.

Sore throat of greater or less severity is usually present, as is also a dry bronchial cough. In severe cases vomiting may occur during the eruptive period, but, as a rule, the constitutional effects are very slight, the patient with difficulty being kept in bed. The duration is 3 days to a week; when uncomplicated, the convalescence is rapid. The complications that may occur are severe bronchitis, pneumonia, and gastrointestinal catarrh; but they are not frequent, most children escaping any serious consequences of the affection.

Diagnosis.—In sporadic cases there is no rule by which rubella may positively be distinguished from measles, or in certain cases from mild scarlatina.

The milder onset, the character of the eruption, and mild symptoms throughout, with the absence of complications and sequels, will, however, serve to differentiate it from a well-marked case of either of these diseases, with their characteristic onset, rash, and course. The eruption does not last so long as that of measles. There is more distinct mottling than in scarlatina.

The following table will be a guide in distinguishing rubella from erythema and urticaria:

RUBELLA.	ERYTHEMA.	URTICARIA.
Rash occurs first on face.	On hands and feet..	In wheals on arms and legs.
Coryza.....	None.....	None.
No itching at first..	Burning pain.....	Intense itching.
Contagious.....	Not so.....	Not so.
Microbic origin....	Reflex origin.....	Gastric origin.

The prognosis in uncomplicated cases or except when occurring in children weak and debilitated from other causes, is invariably favorable.

Treatment.—The child should be confined to a room with a temperature from 68° to 70° F., and when feverish kept in bed. A daily warm bath or warm sponging, followed by inunctions of cacao-butter, should be given, and the bowels kept open with small doses of calomel, to which, when there are fever and restlessness, should be added phenacetin or acetanilid, 1/2 grain for each year of the child's age, every 3 hours. When there is coryza or sore throat, the patient should be treated with a mild alkaline wash, and for the cough, when present, a mixture as given for measles should be prescribed. The child should be isolated for a period of at least 2 weeks.

RUBEOLA.—See Measles.

RUBUS (Blackberry).—It contains more than 10 percent of tannic acid. It is very astringent, and is highly esteemed in summer and infantile diarrheas. Dose, 10 to 30 grains. **R. Fluidextractum.** Dose, 10 to 30 minims. **R. Syrupus.** Dose, 1/2 to 2 drams.

RUMINATION (Merycism).—A remarkable and rare condition in which patients regurgitate and chew the cud, like ruminants. It occurs in neurasthenic or hysteric persons, epileptics, and idiots. It may be hereditary. Certain persons have the power of returning food from the stomach to the mouth at will.

In several instances recorded the return of the food took place in about 15 minutes after finishing the meal, and usually had no acid taste, and had not undergone any digestion. The medical treatment of the condition consists in the use of ipecacuanha and aloes twice daily, and administration of a tonic before meals.

RUPIA.—A term used to denote a peculiar variety of pustular syphiloderm. See Syphilis.

RUPTURE.—See Hernia.

RUPTURE OF UTERUS.—See Postpartum Hemorrhage.

RUSSO'S TEST.—See Typhoid Fever.

RYE.—See Ergot.

S

SABAL.—The fruit of *Serenoa serrulata*, the saw-palmetto. Sabal is sedative, nutritive, tonic and diuretic. It has been used with much benefit in the enuresis of old men, enlargement of the tonsils, spasmodic croup, chronic sore throat, and gonorrhea. The elixir saw-palmetto and santal compound is highly esteemed in incontinence of urine, vesical catarrh, and urethritis. Dose of the fluidextract, 1 dram.

SABINA.—See SAVINE.

SABROMIN.—Dibrombehenate of calcium. It has the same action as the bromids, but its effect is less rapid and more prolonged. It is said to be free from the disadvantages of the bromids. Dose the same as that of potassium bromid.

SACCHARATE.—Compound of saccharic acid and a base, or compounds of cane-sugar with a base. **S. of Iron** (ferrum oxydatum saccharatum solubile, Ger. Ph.), a compound of cane-sugar and iron, important as an antidote for arsenic. **S. of Lead**, a salt of saccharic acid and lead, used in forming the nitrosaccharate of lead, which has been vaunted as a safe and effective solvent for urinary calculus. **S. of Lime**, a compound of cane-sugar with lime. A syrup charged with it has been recommended as a cure for chronic rheumatism. A solution of this compound is a good antidote in carbolic acid poisoning. **Saccharated Carbonate of Iron**, a greenish-gray powder containing sulphate of iron. **S. Iodid of Iron**, iodid of iron with milk-sugar. **S. Pepsin**, milk-sugar with pepsin from the stomach of the hog.

SACCHARIN. $C_6H_4\langle^{CO}_{SO_2}\rangle NH$.—Benzosulphimid, derived from coal-tar, occurring as six-sided, colorless tablets, melting at 224° C. It is 280 times sweeter than cane-sugar. It is used as a substitute for sugar in diabetes, and is recommended for use in the treatment of corpulency and gout. It is also antiseptic, and has been found useful in erysipelas, septic fever, and gonorrhea. Dose, 1/2 to 5 grains.

SAFFRON.—See COLCHICUM.

SAFROL. $C_{10}H_{10}O_2$.—The methylene ether of allyl pyrocatechol, found in oil of sassafras and other oils. It is used in headache, neuralgia, and subacute rheumatism. Dose, 1 to 10 minims. It is also employed for perfuming soap.

SAINT VITUS' DANCE.—See CHOREA.

SAJODIN.—Monoiodobehenate of calcium. A substitute for the iodids. Although containing a smaller quantity of iodin than potassium iodid, sajodin is claimed to be equally efficient. It is said to have been proven exceptionally free from the unpleasant and deleterious by-effects of the iodids. It is used for the same purposes as potassium iodid. Dose, 15 to 45 grains daily.

SALICIN.—A glucosid occurring in the bark and leaves of willows and some poplars. It forms shining crystals that dissolve easily in hot water and alcohol, and melt at 198° C. Its taste is bitter. It possesses tonic properties, and is used as a substitute for salicylic acid in the treatment of rheumatism. Dose, 10 to 30 grains.

SALICYLIC ACID. $C_7H_6O_3$.—Orthooxybenzoic acid; occurs in a free condition in the buds of *Spiræa ulmaria*, in the oil of wintergreen, and in other varieties of gaultheria. It is also obtained synthetically. It consists of four-sided prisms, and crystallizes readily from hot water in long needles. Is soluble in water, and very soluble in chloroform; melts at 155° to 156° F. It is a powerful antiseptic and is used as such in surgery and dermatology in solution and ointment. It is much used in the treatment of acute articular rheumatism and myalgia. Dose, 5 to 15 grains.

Lithii Salicylas, a white, or grayish-white powder, odorless, sweetish, very soluble in water and in alcohol. Dose, 5 to 30 grains. **Sodii Salicylas**, a white, amorphous powder soluble in 3/4 of water and in 6 of alcohol, also in glycerin. Dose, 5 to 30 grains. **Strontii Salicylas**, a white, crystalline powder, soluble in 18 of water and in 66 of alcohol. Dose, 5 to 30 grains. **Methylis Salicylas**, *artificial oil of wintergreen*, is an ester, produced synthetically; and is the principal constituent of oil of gaultheria and oil of betula. It is soluble in all proportions in alcohol or glacial acetic acid. Dose, 5 to 30 minims, suspended in sugared water. **Phenylis Salicylas**, *salol*, is the salicylic ester of phenyl, and occurs as a white, crystalline powder, odorless and almost tasteless, nearly insoluble in water, soluble in 10 of alcohol, and very soluble in ether, chloroform and oils. On being warmed with an alkali it splits up into salicylic acid 60, and phenol 40. Dose, 5 to 15 grains, frequently repeated, in compressed tablets or in cachets, or suspended by mucilage of acacia or of tragacanth. See SALOL. **Physostigminæ Salicylas.** See PHYSOSTIGMA. **Oleum Betulæ** *oil of sweet birch*, is a volatile oil distilled from the bark of *Betula lenta*, the sweet birch. It is identical with methyl salicylate and nearly identical with oil of gaultheria. Dose, 5 to 30 minims. **Oleum Gaultheriæ**, *oil of wintergreen*, consists almost entirely of methyl salicylate, and is nearly identical with the preceding. See GAULTHERIA.

Sodium Salicylate is more soluble than the acid and less irritant to the stomach, while in doses about 50 percent larger it is equally efficient. It is employed in 3- to 5-grain doses internally after meals, to arrest gastric fermentation and to prevent acidity and flatulence. It is used instead of the acid in acute inflammatory rheumatism, muscular rheumatism, phlebitis, rheumatic neuritis and other irregular forms of rheumatism, with immediate benefit in most cases, and it sometimes gives temporary relief in chronic rheumatism. In

gout and its manifestations, especially migraine and sciatica, it frequently proves highly effective; and it has been used with satisfaction in cases showing a tendency to the formation of gall-stones. It is useful in the glycosuria of gouty subjects, and in the nervous irritability of lithemic persons. It is ranked as almost specific in pneumonia by many practitioners, and is very efficient in non-syphilitic inflammations of the eyeball, whether rheumatic or not, especially interstitial keratitis, if given in large doses. It is highly efficient in quinsy, and has been commended as an alterative diuretic for the removal of serous pleuritic effusions. When large doses are prescribed the patient should be kept in bed, and brandy, strychnin, and digitalis should be administered to counteract its depressant action. The salicylates are contraindicated in meningeal inflammation or congestion, middle ear disease, renal insufficiency, albuminuria, and nephritis.

Lithium Salicylate is believed to be particularly applicable in lithemia, gout, rheumatic arthritis, and the various manifestations of the uric acid diathesis.

Strontium Salicylate is not apt to derange the stomach, but is too slow in its action to be of value when a rapid and powerful influence is desired. In 5-grain doses it is one of the best intestinal antiseptics, giving better results than salol or naphthalene. In 10- to 15-grain doses it is one of the most efficient salicylates for chronic gout and lithemia with intestinal indigestion (Wood).

SALIFORMIN (Urotropin Salicylate).—Saliformin is a genitourinary antiseptic and is recommended as a uric-acid solvent. Its action is similar to that of a mixture of hexamethylenamin and salicylic acid, for it is largely hydrolyzed into its constituents in the presence of water. Dose, 5 to 30 grains.

SALINE INFUSION.—See Infusion of Salines.

SALINES.—See Cathartics, Mineral Waters.

SALIPYRIN.—A white powder, the salicylate of antipyrin, consisting of 57.7 parts of salicylic acid and 42.3 parts of antipyrin. It is readily soluble in water and has been recommended as an analgesic and antipyretic in doses of 10 to 20 grains.

SALIVATION.—An excessive secretion of saliva. It may be produced by certain poisons, by such drugs as mercury and pilocarpin, or by nervous disturbances. See Mercury (Poisoning), Sialagogs.

SALOL (Phenyl Salicylate). $C_{13}H_{10}O_3$.—A white, odorless, crystalline substance. It is used as an intestinal antiseptic and as a substitute for salicylic acid, being less irritating to the stomach. Dose, 5 to 15 grains. It is decomposed in the intestines into salicylic acid and phenol. On this account it has been employed to test the motor power of the stomach. A few grains are given in capsule and the urine is tested at intervals for the decomposition products of salicylic acid.

Salol is one of the most efficient remedies for duodenal catarrh, catarrh of the bile-ducts, and catarrhal jaundice; also in the bilious form of sick headache, and in some forms of neuralgia. It is a remedy of very great value in typhoid fever; disinfecting the ulcerated intestines, it promotes the healing process therein and hinders reinfection. It is highly recommended in dysentery, in cholera, and in infantile diarrhea. Given in the latter affection, a dark staining of the child's diapers is often noticed, which is due to the development of carbolic acid from the remedy. Its greatest power is manifested over acute rheumatism, in which disease many clinicians maintain that it has no superior, if given in 15- to 30-grain doses, up to 2 drams in the 24 hours, and continued for some time after the acute symptoms have subsided. In large doses, however, it is liable to induce symptoms of carbolic acid poisoning, which may be met by administering sodium sulphate or any other sulphate. It proves to be an efficient disinfectant in catarrh of the bladder, its constituents being excreted with the urine, and coming in contact with the vesical mucous membrane for a considerable length of time. It is much quicker in its action upon the urine than ammonium benzoate, as in a day or two, ordinarily, the urine loses its foul odor and alkalinity and becomes clear.

Externally, it is employed as an antiseptic and deodorant powder, against impetigo, eczema, sycosis, and other skin-diseases; and has done good service as an insufflation in the treatment of ozena. In spirituous solutions (5 percent) it is used with various flavoring agents in the preparation of mouth-washes and dentifrices; and it also enters into the composition of soaps, face powders, and other toilet articles.

In cholera morbus:

℞.	Salol,	ʒ j
	Bismuth, subnitrate,	ʒ ij
	Chalk-mixture, add enough to make	ʒ iij.

Two teaspoonfuls every 2 hours.

SALOPHEN.—A derivative of salicylic acid, occurring as minute, white, crystalline scales, odorless and tasteless, insoluble in water, but soluble in alcohol. It is decomposed by alkalies. The actions of salophen resemble those of phenyl salicylate (salol). It is not changed in the stomach, but is broken up in the intestine, liberating salicylic acid and acetylparamidophenol, which is not toxic. Its dose is 5 to 15 grains up to 1 or 1 1/2 drams in 24 hours. It is used as a substitute for salol, than which it is said to be far less poisonous. It can be very effectually combined with phenacetin in the treatment of neuralgia. In long-standing sciatica a 10 percent solution hypodermically into the gluteal muscles has given good results. It has been employed with decided benefit in intestinal dyspepsia with flatulence. See Salol.

SALOQUININ.—(Salochinin.) The salicylic ester of quinin. It is a tasteless, crystalline powder, insoluble in water. It is said to possess the virtues of quinin as well as those of salicylic acid, and is used efficiently as an antipyretic and antineuralgic. Dose, 5 to 30 grains.

SALPINGITIS.—See Fallopian Tubes (Inflammation).

SALTATORY SPASM.—See NERVOUS DISEASES (Examination).

SALTPETER.—Native potassium nitrate. It occurs in colorless, hard, rhombic prisms of sharp, saline, and bitter taste, and is soluble in about 9.5 of water at 59° F., or in 4 of boiling water, but is insoluble in alcohol. The dose is from 20 grains to 1/2 dram, well diluted. It is a refrigerant diaphoretic and diuretic in febrile and inflammatory affections, especially of the trachea and bronchi. It is useful in asthma, pneumonia, and rheumatism.

The fumes of the following burning niter paper are serviceable in spasmodic asthma:

℞. Potassium nitrate, 2 1/2 parts
Powdered belladonna leaves, 1/2 part
Powdered stramonium leaves, 5 parts
White sugar, pulverized, 1/2 part.

Dissolve the niter in just enough water to make a saturated solution, mix with the leaves, dry into a coarse powder, and add the sugar. A small quantity is to be placed on a tin plate, ignited, and the smoke inhaled.

Poisoning.—There is no chemic antidote. Emetics or stomach-pump, demulcent drinks, and emollient enemata, particularly milk, should be administered. Opium is the best antagonist for the subsequent depression. Aromatics and brandy may be given. See POTASSIUM.

SALT RHEUM.—See ECZEMA.

SALVARSAN.—See SYPHILIS.

SANDALWOOD (Santalum).—The wood of a species of *Santalum album* and *S. citrinum*, or yellow sandalwood. It yields oil of santal, an astringent oil, useful in chronic bronchitis and gonorrhea. It is often adulterated with oil of cedar. Dose of the **volatile oil**, 5 to 15 minims, in emulsion or capsule. *S. rubrum*, red saunders, the wood of *Pterocarpus santolinus*, imparts a brilliant red color to ether and alcohol.

SANGUINARIA (Blood-root).—The dried rhizome of *S. canadensis*. It contains the alkaloids sanguinarin, chelerythrin, protopin, and homochelidonin. Dose of the powdered root as an expectorant, 1 to 5 grains; as an emetic, 10 to 30 grains; best given in pill. In large doses it causes vomiting and purging. Toxic doses cause convulsions, and then paralysis; death results from failure of respiration. As a stomachic and hepatic stimulant it is employed in small doses (3 drops of the tincture). It is used as an expectorant in chronic bronchitis. Chronic nasal catarrh, asthma, and acute bronchitis are remarkably amenable to the influence of sanguinaria, particularly when it is given in 10-drop doses of the tincture. It is used as a specific emetic in croup, though its action is uncertain and harsh. It is incompatible with alkalies, tannin, and most of the metallic salts. Its antagonists are amyl nitrite, opium, atropin, and such drugs as antagonize the depression of the circulation and the local irritant action.

Preparations. Fluidextract.—Dose, 1 to 5 minims as an expectorant; 10 to 60 minims as an emetic (cautiously). **S., Tinct.**, 10 percent strong. Dose, 5 to 30 minims as an expectorant; 1 to 3 drams as an emetic. **Sanguinarin**, the alkaloid, unof. Dose, 1/12 to 1/8 grain; as an emetic, 1/2 to 1 grain.

SANOSE.—An albumin preparation, stated to consist of 80 percent of casein and 20 percent of albumose. It is a white, odorless, and tasteless powder, which readily forms emulsions with water. It is used as a food and tonic, preferably in form of emulsion.

SANTALUM.—See SANDALWOOD.

SANTONICA (Levant Wormseed).—The flower heads of *Artemisia pauciflora*, the properties of which are due to a crystalline principle, santonin. The flower heads yield about 2 percent of santonin, which is a very efficient anthelmintic against the round-worm, Ascaris lumbricoides. Dose, 1/4 to 2 grains. The tape-worm is not affected by santonin. Santonin should be given, as are all vermifuges, with preceding catharsis and starvation. Sodium santoninate should not be used, as it is absorbed by the system rather than by the intestinal parasite. The crystals of santonin rather than the powder should be employed. A saline purge should be given, preferably followed in a half-hour by a 2- or 3-grain dose of calomel, if no bowel movement has occurred within 10 hours after taking the santonin.

℞. Santonin, gr.v
Powdered white sugar, ʒ iij
Powdered acacia, gr. viij.
Mix well and add:
Mucilage of acacia, gtt. xvj
Water, sufficient quantity.

Make into 10 troches. Give 1 or 2 as directed.

See ANTHELMINTICS.

In large doses it produces yellow vision and gives a yellow color to the urine. In toxic doses it causes headache, vertigo, sometimes convulsions, and death by respiratory paralysis. **Santonini, Troch.**, each contains 1/2 of a grain of the active principle. Dose, 1 to 5.

SAPO.—See SOAP.

SAPREMIA.—See SEPSIS.

SARCINA.—A genus of Schizomycetes, or bacteria, having spheric or ovoid cells dividing in three directions, thus producing cubic masses of greater or less size. See BACTERIOLOGY.

SARCOMA.—A connective-tissue tumor in which the cells so predominate in number, and often in size, that the intercellular substance becomes a secondary element. It may also be defined as a tumor made up of embryonal connective tissue. Sarcomata are malignant tumors, the small-celled forms and those of soft consistency excelling in this respect. They appear, as a rule, at an earlier age than carcinoma. The problem of their causation is not solved: in many instances it is possible to trace a history of injury. It is probable, however, that the trauma merely acts as a predisposing cause. To the naked eye sarcoma appears, as the etymology of the word indicates, flesh-like. Microscopically, the picture varies with the variety of tumor, whether it is a round-cell, a spindle-cell, or a giant-cell sarcoma, or one

of the other derivative forms. Sarcomata are well supplied with blood, which, however, is not contained in true vessels, but in spaces lined by endothelium. They are often combined with other new growths, especially with the so-called mixed tumors and with certain congenital neoplasms, as the rhabdomyoma. The most frequent seats of sarcoma are the connective tissue of the skin, periosteum, intermuscular septa, tendons, subserous connective tissue, and the eye.

Treatment.—Operable growths should be early and thoroughly excised. Inoperable growths have been treated by inoculations with the streptococcus of erysipelas by reason of the fact that an attack of erysipelas sometimes has effected a cure. Recently a number of inoperable cases have been decidedly benefited by injections of Coley's fluid (a sterilized culture of the streptococcus of erysipelas and the bacillus prodigiosus).

"The initial injections are preferably made remote from the tumor, either in the pectoral regions or buttocks. After the susceptibility of the patient has been determined, if the tumor is easily accessible, best results are usually obtained by alternating with local injections. For the remote injections, it is important that the minimum dose should not be over 1/2 minim, and for the local injections (made into the tumor itself) 1/8–1/4 minim is sufficient to start with. Accuracy of the dose may be obtained by diluting the toxins with 3 to 4 times the amount of freshly boiled water. The dose should be increased by 1/2 minim daily up to the point of producing a marked reaction, temperature 102° to 104° F., after which 3 to 4 treatments a week should be sufficient. If due care is taken to secure asepsis, and if one is careful not to give too large doses, or initial dose, the toxins are practically devoid of danger. In a very few cases irritation of the kidneys developed, and it is therefore well to have regular analyses of the urine made during the period of treatment.

"Coley's last paper, read before Brussels Congress in 1913, contains a report of 80 personal cases successfully treated with the toxins, as well as a tabulated list of 102 cases successfully treated by other men. Of the personal cases successfully treated with the toxins, 59 have remained well over three years, namely:

13 well from	15–20 years
5 well from	10–15 years
25 well from	5–20 years
16 well from	3– 5 years

"The tables of other men's cases treated with the mixed toxins, show 63 having remained well over three years:

4 well from	15–20 years
8 well from	10–15 years
19 well from	5–10 years
32 well from	3– 5 years

"It is worthy of note that all types are represented in this series of cases, but the type least favorably influenced by the toxins, is the melanotic.

"It is a noteworthy fact that seventeen of Dr. Coley's successful cases were lymphosarcomas; this is especially interesting, inasmuch as there are no cases on record of a cure of lymphosarcoma either by surgery or X-ray, after more than one gland had become involved. Coley believes that the most promising field for the toxins lies in the routine administration immediately after primary operation, keeping the injections up for a number of months. He also advocates the preliminary use of the toxins in sarcomas of the long bones, before amputating, in the hope of saving the limb, and reports upward of 20 cases in which the limb as well as the life of the patient had been saved by such preliminary treatment" (Potter).

The X-rays have proved curative in a number of cases of sarcoma. See Carcinoma, Tumors, Bone (Diseases).

SARSAPARILLA.—The dried root of *Smilax medica*, and several other species of the smilax family, native to tropical America. It contains an essential oil and several extractive principles, and is diuretic, tonic, and alterative. It has mild alterative properties and is a good vehicle for potassium iodid. It is used somewhat in tertiary syphilis, scrofula, and similar diseases.

Preparations. Fluidextractum S.—Dose, 20 to 60 minims. **Fluidextractum S. Compositum** has of sarsaparilla 75, glycyrrhiza 12, sassafras 10, mezereum 3, glycerin 10, diluted alcohol to 100. Dose, 20 to 60 minims. **Syrupus S. Compositus** has of the fluidextract 20, fluidextract of glycyrrhiza 1 1/2, fluidextract of senna 1 1/2, sugar 65, oils of sassafras, anise and gaultheria, each 0.02, water to 100. Dose, 1 to 8 drams.

SASSAFRAS.—The root bark of *S. variifolium*. Its properties are due to a volatile oil. It is aromatic and a stimulant diaphoretic. **S. Oil,** the volatile oil. Dose, 1 to 4 minims. **Mucilago S. medullæ.** Dose, about 4 drams.

SATURNISM.—See Lead (Poisoning).

SAVINE (Sabina).—The tops of *Juniperus sabina*; its properties are mainly due to a volatile oil which resembles turpentine, but is more irritant. Dose, 5 to 10 grains. In large doses it produces violent purging and vomiting. It is used as an emmenagog. Externally, it is useful to prolong the discharge from blisters and to stimulate ulcers to cicatrization. **S., Fluidextract.** Dose, 2 to 10 minims. **S., Ol.,** the volatile oil. Dose, 1 to 2 minims.

In amenorrhea:

℞.	Oil of savine,	♏ viij
	Mucilage of acacia,	ʒ j
	Camphor water,	ʒ iij

Two tablespoonfuls 3 times daily.

SAW-PALMETTO.—See Sabal.

SCABIES (Itch).—A contagious, animal, parasitic disease due to the sarcoptes scabiei (acarus scabiei), characterized by burrows and a multiform eruption, and attended by severe itching.

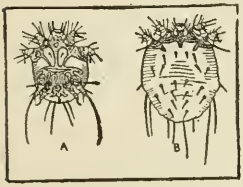
Symptoms.—The itch-mite in burrowing into the skin produces at the point of entrance a small papule, vesicle, or pustule. Later, a burrow or cuniculus is formed at this site. The burrow is a straight, tortuous or zigzag, grayish or blackish,

linear, epidermal elevation, varying in length from 1/8 to 1/2 inch.

In a well-marked case of itch there may be seen, in addition to the burrows, a multiform eruption consisting of papules, vesicles, pustules, crusts, excoriations (scratch marks), and thickening, occupying certain definite regions where the skin is thin; these are the interdigital spaces, the flexor surface of the wrist and arm, the anterior and posterior axillary folds, the breasts and nipples (in women), the umbilicus, the buttocks, the penis, the inner side of the thighs and legs, and the toes, (particularly in infants). The face is exempt except occasionally in infants.

The eruption is attended by intense itching, which is distinctly worse at night. The irresistible scratching leads to the production of the secondary inflammatory symptoms. In children and individuals with sensitive skin the eruption may reach a high grade of inflammation. In predisposed subjects an eczema may be superadded to the scabies. The disease develops rapidly in the course of from 1 to 2 weeks. It is progressive, exhibiting no tendency to spontaneous cure. In untreated cases it may last many months.

Etiology.—The disease is due to the invasion of the skin by the sarcoptes or acarus scabiei. It is highly contagious. The disease may be transmitted by direct bodily contact or through the intermediation of such articles as the bedclothes. It occurs at any age, and is particularly common among the lower classes.



SARCOPTES SCABIEI. *A*. Male. *B*. Female.—(*Braun*.)

Pathology.—The burrow consists of a narrow tract through the epidermis made by the penetration of the impregnated female acarus. The mite deposits a half dozen or more eggs and specks of excrement along the course of the tract, and, after reaching the mucous layer, perishes. The ova hatch out in 8 to 10 days, and, effecting their egress from the burrow, start cuniculi of their own. The itch-mite is a yellowish-white ovoid body, just visible to the eye. The female is twice the size of the male.

Diagnosis.—Scabies consists of the burrows plus an artificial inflammation of the skin, produced by the parasite and by the scratching. The characteristic features of the disease are the presence of the burrows, a multiform eruption distributed in a peculiar manner over the surface of the body, the intense itching—worse at night—and the history.

Scabies may be distinguished from vesicular or pustular eczema by the presence of the mite and the burrows, the peculiar distribution of the lesions, the progression of the eruption from day to day, and the history of contagion. From pediculosis corporis the disease may be differentiated by the character of the eruption and the regions affected.

Prognosis is favorable. The disease, no matter of what duration, is speedily durable.

Treatment.—The objects of treatment are twofold—to kill the parasite and to subdue the accompanying dermatitis. The itch-mite is easily destroyed by such remedies as sulphur, beta-naphthol, balsam of Peru, styrax, tar, staphisagria, etc.

Sulphur is one of the most reliable remedies, and is best applied in ointment form. It may be used in conjunction with balsam of Peru, as in the following formula:

For adults or those of nonirritable skin:

℞.	Precipitated sulphur,		℥ j
	Balsam of Peru,		℥ ss
	Beta-naphthol,		℥ ij
	Lard, Petrolatum,	each,	℥ iv.

Make into an ointment.

Beta-naphthol possesses the advantage of being free from odor and more cleanly. It may be used alone (1 dram to 1 ounce) or combined with sulphur.

Styrax is less irritating than suphur, and is useful in the itch of children:

℞.	Styrax,	℥ ss
	Lard,	℥ jss.

The treatment should be inaugurated by a protracted hot bath, with the vigorous use of soap. The body from neck to feet is then to be thoroughly smeared with the ointment. This may be rubbed in twice a day for 3 days, or nightly for 1 week. At the end of this time another bath should be taken, and the underclothing and bed-linen changed and sterilized. Ordinarily, such treatment will suffice to produce a cure; occasionally, it must be repeated.

Care should be exercised not to *overtreat* cases. The persistence of itching is not always an index of the continuance of the scabies, but is more likely to result from the dermatitis, which is, perhaps, aggravated by the parasiticide application. In such a case a sedative ointment or lotion should be substituted.

SCALDS.—See BURNS.

SCALP, DISEASES.—**Abscess** may occur above the aponeurosis, between the aponeurosis and the pericranium, or beneath the pericranium. It is generally the result of an injury, but may be due to the breaking down of a gumma, diseases of the bones, etc.

Cellulitis of the scalp is usually due to a wound, and is described under SCALP (Injuries) (*q. v.*).

Erysipelas of the scalp is common, and may occur idiopathically or as the result of a wound. In the so-called idiopathic cases, however, it is probable that there is generally some scratch or abrasion through which the specific micrococcus gains admission. The inflammation spreads with great rapidity, but is accompanied by very little redness and swelling on account of the tenseness of the parts. It is likely to be attended with headache, drowsiness, or delirium, consequent upon the hyperemia extending to the pia mater. See ERYSIPELAS.

Nævi are also common on the scalp. When large and situated over the anterior fontanel, they should

be dealt with cautiously, lest the membranes of the brain are injured and meningitis results.

Rodent ulcer and **epithelioma of the scalp** require no special mention here.

Sebaceous cysts are very common on the scalp, where they are at times hereditary. They are frequently multiple, and as they increase in size the hair covering them falls off, and they appear as bare, rounded tumors. The mass of granulations which sometimes protrudes from the walls of these cysts (*fungating ulcer of the scalp*) closely resembles epithelioma, from which, however, it may generally be distinguished by the absence of induration and glandular enlargement, and by the history of a sebaceous cyst having been previously present. Congenital and dermoid cysts are met with.

Seborrhea.—See ALOPECIA, SEBORRHEA.

SCALP, INJURIES.—The scalp presents certain anatomic features of considerable surgical importance. The skin in the first place is so closely bound down to the aponeurosis beneath that mere cutaneous wounds never gape, and superficial inflammation is never attended by much swelling or redness. For the same reason contusions often cause what apparently are incised wounds. Further, the chief vessels lie between the aponeurosis and the skin, and are embedded in such dense tissue that when they are cut they cannot retract, and can hardly be tied. On the other hand, beneath the aponeurosis the tissue is so loose that blood or pus may collect until the skin floats as on a water-bed, bounded by the zygoma, the eyebrows, and the superior curved line; and the scalp can be stripped off and hang in flaps. Sloughing, however, owing to the position of the vessels, is rarely caused in this way. Finally, the pericranium is easily separated from the bone, except at the sutures; it only supplies the outer table, not the diploe or the inner, so that when necrosis occurs from this cause, the sequestrum is usually superficial. It is peculiar also that it seldom produces any new bone to repair an injury.

Contusions.—The blood may be extravasated (1) in the scalp itself; (2) in the subaponeurotic layer, or (3) between the pericranium and the bone.

The first, owing to the denseness of the tissue, is always insignificant. The second may be either diffuse and of enormous extent, or circumscribed, and then very often it is curiously deceptive. The blood around the margin coagulates into a hard, dense ring, the niner edge of which is sharp and well defined, while the outer is beveled off; in the center it remains fluid, so that when the finger is pressed upon it the margin stands out as clearly as the edge of a depressed fracture, for which it may easily be mistaken. The ring, however, is distinctly raised above the level of the surrounding bone, and it can always be indented. Abscesses sometimes give rise to the same kind of impression, and it must be remembered that the presence of a hematoma does not exclude the existence of a fracture.

The third (**cephalhematoma**) only occurs in infants, and nearly always from injuries received at birth. It is most common on the parietal bone —though it has been seen on the occipital—and is easily recognized by the way in which it is limited to one bone; it never extends over the sutures. Like the former, the margin becomes hard, and a certain amount of organization, and even ossification, takes place; the center remains fluid, and for a long time gives rise to a sensation of parchment crackling when pressed upon. Absorption in all these cases is slow; but, unless inflammation sets in, they should never be incised, and aspiration is rarely necessary. The cephalhematoma of infants should not be operated upon; in other cases lead lotion may be applied at first, or, if the patient will lie down, an ice-bag, to check the extravasation and hyperemia; afterward, well-applied pressure is the most efficient remedy.

Wounds.—These, like contusions, may be superficial, involving the skin only; or extend into the subaponeurotic layer; or lay the bone bare. The first are rarely of any extent; in the second, if the hair is entangled in machinery, or the head caught under a cartwheel, the whole scalp may be detached and hang down in a flap, but it rarely sloughs; in the third, there is an additional danger, for the bone is exposed, and is often bruised or scratched. Hemorrhage from the torn vessels is often abundant, but neither ligation nor torsion is of any use. Pressure stops it at once. Acupressure may be used, but a bandage is nearly always sufficient; care, however, is necessary, as it may be applied so tightly as to cause a slough.

Treatment.—Scalp wounds require no special treatment: the same principles must be followed as elsewhere; the only peculiarities are the extraordinary vitality of the skin, and the ease with which inflammation, if it once occurs, spreads in all directions. Therefore no portion of the scalp should ever be sacrificed, no matter how bruised or dirty it is; and perfect cleanliness and perfect drainage must be insisted on. If this is carried out, they may be treated like other wounds, and with exceptional success.

The head must be shaved about the injury, the wound carefully explored, washed out thoroughly with an antiseptic, all oozing stopped, and any bagging or collecting of fluid prevented. Counter-openings may be made and drainage-tubes inserted, if there is a dependent pouch; but in most cases it is sufficient to support the skin well against the skull so as to keep it at rest and insure early adhesion. Then the edges of the wound may be dusted over with iodoform and covered with an absorbent dressing, such as wood-wool, or a sponge wrung out of carbolic solution. There is no objection to the use of sutures, if care is taken; but if the wound is tightly sewed up, and suppuration allowed to take place beneath, serious consequences must ensue. Even if half the scalp is stripped off and hangs down the back of the neck, or over the face, it may be treated in this way, and often will adhere at once. If it does not, the under surface throws out granulations and union takes place by the third intention. In all cases of severe injury the patient should be confined to bed, and kept perfectly quiet, on low diet; and care must be taken that the bowels do not become consti-

pated. It must never be forgotten that, in addition to the scalp wound, there may be very great injury to the brain.

So long as there is no pain nor fever, the wound should be left alone. If, however, one spot is tender, or if the temperature rises, or if there is any shivering, the wound must be exposed at once and carefully examined; it nearly always means that some of the secretion is pent up. As a rule, it is sufficient to introduce a probe or to loosen a suture—a drop or two of fluid escapes, and the symptoms are relieved at once (Moullin).

SCAMMONY.—A purgative gum-resin, the dried juice of the root of *Convolvulus scammonia*, a Southwestern Asiatic plant. It is generally given in combination with other drugs. Its properties are due to an active principle, jalapin. It is a drastic cathartic, and is contraindicated when there is a tendency to true inflammation of the bowels. It is anthelmintic against the tapeworm, and in overdoses produces a high degree of irritation. It is used as a drastic purgative for children with calomel or potassium sulphate. Treatment suitable for gastroenteritis may be necessary if poisonous doses have been administered. It is best given with colocynth or some similar drug. Dose, 1 to 10 grains. S., Resina. Dose, 1 to 5 grains.

SCAPULA, CONGENITAL ELEVATION OF.—See Sprengel's Shoulder.

SCAPULA, DISLOCATION.—The acromion may be dislocated from the scapula upward or downward. The conoid and the trapezoid ligaments are strong enough to make both injuries unusual, and the former very rare. A fall or blow is the most common cause; carrying heavy weights may be causative. This dislocation is easy to reduce, but very difficult to keep in place. Drawing the shoulder back and pressing the clavicle down will restore the joint, but the deformity recurs on removal of pressure. Velpeau's dextrin band and Holland plaster are the most successful methods of treating this dislocation. Sloughing of the skin is to be carefully looked for. A pad over the acromial end of the clavicle may be strapped down by means of a broad webbing band carried over it and under the point of the elbow. When the deformity is the first consideration, the patient should be placed perfectly flat on the back for a week or 10 days, the scapula fixed, the weight of the limb taken off, and the trapezius relaxed. See Shoulder (Dislocation).

SCAPULA, FRACTURES.—The scapula is so much covered with muscle, and its connections with the trunk allow so much yielding on the application of external force, that fractures of this bone are extremely uncommon

Varieties.—The injury may occur to its **body**, its **inferior angle**, its **neck**, to the **acromion process**, or to the **coracoid process**.

Symptoms.—In fracture of the **body** of the bone the shoulder will be depressed and forced forward, and there will be marked irregularity between the ends of the fragments. Fracture of the **inferior angle** is marked by preternatural mobility, by displacement of the smaller fragment, and by acute pain at the seat of injury. In **fracture of the neck** the acromion is unusually prominent, the head of the humerus is felt in the axilla, the shoulder is flattened, the limb is lengthened, the coracoid process is found below the clavicle, severe pain and numbness are experienced in the axilla, and distinct crepitation is perceived on rotating the arm upon the scapula. In fractures of the acromion and of the **coracoid** the symptoms are somewhat similar to those presented by the fracture of the neck.

Treatment.—When the **body** is broken, a broad roller must be passed around the trunk, over a large flat pad placed over the scapula, and a few turns made around the arm so as to fix it to the side and prevent motion. Rest and quietude are required. Or a broad strip of adhesive plaster should be applied across the scapula, extending from the spine to the sternum, care being taken to press it well down along the anterior and posterior borders of the bone before the portions in front and behind the chest have been attached. Then place the arm in a Fox apparatus, and allow it to hang vertically along the side of the body, at the same time lifting the elbow by securing the straps to the ring on the opposite shoulder.

In **fracture of the neck** the shoulder must be supported by the sling and bandage that are used for fracture of the clavicle; but the pad should not be so thick, nor so large, and in addition a short sling should be used, going from the axillary pad on the injured side to the opposite shoulder. Opium, rest, leeches, and purgatives may be necessary for the contusion with which this fracture is accompanied. At the end of 4 weeks passive motion must be made to establish the functions of the joint.

In fracture of the **acromion** the bandages are to be applied so as to raise the elbow thoroughly, so that the head of the humerus may be lifted up against the acromion and keep its place. A pad must *not* be placed in the axilla, otherwise the broken part will be pushed outward too much.

When the **coracoid process** is fractured, the humerus must be brought forward and inward, so as to relax the coracobrachialis, and must be confined to the trunk, with the forearm bent on the chest.

SCARIFICATION.—The operation of making superficial incisions or punctures to allow the escape of serum or blood or gases. According to circumstances they may be deep or penetrate through the skin alone. In conjunctival chemosis, in early acute tonsillitis, in edema or engorgement of the glottis, and in congestions and certain acute inflammations of the uterus, in inflamed ulcers, and those in danger of gangrene, and, indeed, in almost any condition of great tension, the procedure will give relief.

SCARLET FEVER (Scarlatina).—An acute infectious disease, characterized by sudden onset, with vomiting, high fever, sore throat, and an erythematous rash. Serious complications and sequels are not uncommon. It is contagious from the beginning of the attack until desquamation has ceased, and under certain conditions after this time. One attack is rarely followed by subsequent ones.

Etiology.—While believed to be due to a microorganism, none has as yet been demonstrated as

the specific one. Streptococci have been found in the blood by many observers, and less frequently the staphylococcus aureus and the influenza bacillus, but these are probably present as a result of mixed infection. Scarlet fever occurs epidemically, and occasionally sporadically, the epidemics being most common in the fall and winter. As it is most contagious late in the disease (during desquamation), epidemics spread slowly.

The skin seems to be the chief source of infection, but it may be conveyed by the discharges from the mucous membrane of the nose, mouth, or throat, and by the urine, feces, or perspiration, and later, even after desquamation has ceased, by purulent discharges from rhinitis, otitis, suppurating glands, etc. The carpet and furniture of the sick room, and toys, books, and clothing, which may have been in contact with the patient, are often a medium of contagion, as may also be the attendants or nurses. Air may convey the infection for a short distance, and the usual route of infection is the respiratory tract. It may, however, enter by way of the digestive tract. Domestic animals may transmit the disease, and it has, in a number of cases, been spready by food—particularly milk. Children are much more susceptible than adults, but in either the susceptibility to scarlatinal infection is much less than to that of measles.

Pathology.—The parts primarily affected are the throat and skin. Lesions of other organs are rare, but, when present, are due to the fever and septic condition. The principal pathologic lesions due to complications are of the ear and cervical glands; the chief ones from sequels are those of the kidneys and heart.

The scarlatinal throat consists of an erythematous condition of the mucous membrane with the usual changes of a catarrhal inflammation. The skin is hyperemic, inflamed, and swollen, causing death of the epidermis, which is cast off during desquamation.

Symptoms.—The period of incubation is short —1 to 5 days—during which time there are no symptoms to indicate the onset of a disease.

The invasion is sudden: the first symptom in the majority of cases being vomiting. The child complains of chilliness, headache, and sore throat. The temperature will be high from the first (103° to 104°F.) and the pulse rapid and wiry. Prostration is usually well marked, and there may be slight delirium, and, in young children, convulsions. The skin is hot and dry, the face flushed, and the eyes bright.

On inspecting the throat, the tonsils, pharynx, and fauces will be found red and congested, and there will be seen on the hard and the soft palate minute macules of a darker red color than the intervening mucous membrane. An exudate resembling follicular tonsillitis, or even the membrane of diphtheria, may appear upon the tonsils.

At the end of from 12 to 36 hours after the onset the efflorescence appears, and in most cases is first seen upon the front of the neck and the upper part of the chest, but rapidly extends all over the body and face, being fully developed in the course of from 12 to 24 hours. The rash is of a bright scarlet color, and when viewed at a short distance, the whole surface of the body appears to be uniformly covered; but examined closely, it consists of great numbers of red points corresponding with the hair follicles; these points are surrounded by zones of erythematous redness, which, joining one another, give the general diffuse red appearance to the skin.

In some cases the rash consists of the points only, without the erythema; in others it may appear in patches with normal skin between. Rather rarely the rash is hemorrhagic, small extravasations of blood taking place into the skin; this may occur in mild, but is much more common in malignant, cases. With the eruption at its height there is intense itching or burning of the skin, and often considerable swelling, which is most noticeable upon the hands and face. The eruption remains at its maximum intensity for about 3 days and then fades in the order in which it appeared.

The temperature, which has remained high from the first, gradually declines after about the fourth day, or as the rash begins to fade, reaching the normal in 5 or 6 days. The tongue, which for the first few days was covered with a thick white fur, as the disease progresses becomes reddened with enlarged and prominent papillæ, the appearance giving rise to the name "strawberry tongue." The lymphatic glands at the angle of the jaw are usually enlarged and tender.

The constitutional symptoms during the eruptive period are marked by loss of appetite, constant thirst, somnolence with delirium or restlessness, with more or less nervous manifestations. The bowels may be either constipated or loose; the urine scanty, high-colored, and often containing albumin. Not infrequently the urine and stools are passed involuntarily. The respiratory tract is not often affected, though there may be a mucous discharge from the nose and in some cases a dry cough, due to the irritation in the throat. With the fading of the rash and the decline in the temperature the tongue clears, the throat becomes less congested, and the appetite improves; and, by the end of the first week, convalescence should be established; feverishness after this time would suggest some complication, as suppurating glands, purulent otitis, etc.

Desquamation begins soon after the rash fades —about the seventh day—and continues for a period of 2 to 5 weeks. It is usually first seen upon the chest and neck, and is composed of very fine scales. Desquamation upon the face is usually slight, or it may not occur at all. That which follows on other parts of the body, especially where the skin is thick and hard—as upon the inside of the fingers and hands and the soles of the feet—is composed of large scales, and a cast of the part may be thrown off like the finger of a glove. The hair, nails, and teeth are usually also affected. The hair breaks off after scarlet fever; the nails show indentations, and sometimes are shed; and the forming teeth are more or less affected.

While the foregoing description is that of a typical form of scarlet fever, in practice many cases are seen which vary from the mild form—when the child may make no complaint of being ill, the rash, and that often not well marked, being the first symptom—to the malignant form, when the onset is severe, with marked nervous symptoms, high fever, very rapid pulse, diarrhea, and marked glandular swelling and cellulitis, the child dying during the first 24 hours, or lingering for 2 or 3 weeks, when death results from exhaustion or from septicemia.

Complications and Sequels.—The inflammation of the throat may be so severe as to constitute a serious complication. The soft palate may slough, and all the soft parts be destroyed. The inflammation may spread to the larynx, making, in some cases, tracheotomy necessary. Purulent **otitis media** is a common complication, and is caused by extension of infection through the eustachian tubes. It may occur either during or following the active stage, and it is the most frequent cause of continued fever after the rash has disappeared.

Following severe cases, **adenitis** may occur, often accompanied by suppuration and ulceration of the cervical lymph-glands; cellulitis of the neck may occur. Septic cases may be complicated by **bronchopneumonia** or **pleurisy,** and also by **endocarditis** and **myocarditis.**

Arthritis, septic, rheumatic, or tubercular, sometimes occurs with or following scarlet fever.

Rarely nervous affections may arise as complications, such as meningitis, cholera, hemiplegia, convulsions, progressive paralysis.

Nephritis is the most frequent complication, and may occur in an otherwise mild and favorable case. Besides the transient albuminuria, which is nearly always present during the febrile stage, two forms—septic and post-scarlatinal nephritis—occur. The septic form occurs in severe cases complicated by sloughing tonsils and soft palate and much glandular involvement. The urine contains large quantities of albumin, and, postmortem, a pyemic kidney may be found, but dropsy or other renal symptoms are seldom discovered.

Postscarlatinal nephritis occurs during the third or fourth week. The child, who had recovered from the fever, will again become feverish, restless, and thirsty, have a quick hard pulse, and pass small quantities of dark-colored urine containing albumin and casts. The face becomes pale and puffy, and there may be edema of the feet and scrotum or general dropsy.

In mild cases by the end of a week improvement will take place, and the child go on to recovery. In others, however, uremic symptoms may supervene, the pulse becomes slow, the temperature subnormal, and vomiting and marked nervous symptoms appear. Dilatation of the heart is a frequent result of the kidney affection. Recovery takes place in the great majority of the cases of nephritis following scarlet fever, but it may be prolonged for weeks or, rarely, for months.

Diagnosis.—The diagnosis of the usual type is not difficult—the symptoms mentioned above all occurring together in no other disease. In some cases, however, the rash may appear not unlike measles; in others, the throat symptoms being prominent may lead to a diagnosis of diphtheria; but in a great majority of cases a mistake is not probable. However, there may be no distinctive eruption, but close watching will sometimes detect signs of desquamation in the shape of branny scales beneath the underclothing or in the stockings. In other doubtful cases the development of nephritis settles the diagnosis.

The following table gives the principal points of difference between these diseases:

	Scarlet Fever.	Measles.	Diphtheria.
Onset	Sudden, with vomiting	Gradual, with coryza and photophobia.	Gradual.
Temperature	High (103° to 105° F.)	High, but drops with appearance of rash.	Low.
Cervical glands	Involved, usually	Not involved	Involved.
Appearance of throat	Mucous membrane of hard and soft palates much congested and red eruption first seen there.	Throat not involved	Dusky red color early.
False membrane	When present, resembles follicular tonsillitis.	None	Characteristic.
Bacteriologic test	Probably find streptococci	Negative	Klebs-Loeffler bacillus.
Pulse	Very rapid and wiry	Full and bounding	Increased, but weak.
Urine	Frequently slight albumin	No albumin	Albumin.
Rash	Scarlet color, first seen on neck and chest, appears within 36 hours after onset.	Darker color, first on face; appears fourth day.	None typical.
Desquamation	Marked, beginning furfuraceous, becomes lamellar, continues 3 or 4 weeks.	Slight, furfuraceous	None.

Certain drugs, as belladonna, quinin, and antipyrin, and digestive disturbances, especially in infants, are often accompanied by a rash, which closely resembles that of scarlet fever. It is, however, of short duration. In diphtheria, influenza, and varicella an erythematous rash is occasionally seen that may cause them to be mistaken for scarlet fever; but when the history of the case, the order of the appearance of the rash, etc., are considered, a correct diagnosis may in most cases be reached.

Prognosis.—The prognosis should be guarded in all cases of young children. The mortality varies greatly in different epidemics, and may be as low as 5 or 6 percent, or as high as 20 or 30 percent,

and in very young children as high as 50 percent. It depends generally upon, first, the severity of the epidemic; second, the age and resisting power of the individual; and, third, upon the nature of the complications. In no disease is the prognosis more uncertain than in scarlatina.

Treatment.—The patient should be isolated for a period of 5 or 6 weeks, or until desquamation is completed. Should there exist such complications as otitis, rhinitis, or suppurating glands, quarantine should be continued until these conditions are cured. Other children in the house who have not been exposed to the disease should be sent away.

After recovery, the patient should, before mingling with others, be thoroughly scrubbed with soap and warm water and washed with an antiseptic solution—*e. g.*, bichlorid of mercury, 1 : 5000—and dressed in clean clothing. The sick room should be on the upper floor; it should be well ventilated, and kept at a uniform temperature of about 68° F. The ideal method of heating is by an open-grate fire.

The room should be stripped of all hangings, carpets, and unnecessary furniture, and a sheet wet with a solution of carbolic acid, 1 : 100, or bichlorid of mercury, 1 : 1000, kept hung over the doorway, and the floor frequently sprinkled with the same solution. All excreta from the patient should be disinfected by carbolic acid, 1 : 20. The nurse should wear a cap covering the hair, and a washable dress, and should not mingle with other members of the family until her hands and face are thoroughly cleansed and her clothing changed.

The same care should be given to the disinfection of all bed-clothing, cloths, eating utensils, etc., as in diphtheria. The physician before entering the sick room should remove his coat and put on a long gown or rubber coat, and after the visit his hands, face, and hair should be washed and disinfected.

If it can be avoided, the physician attending a scarlet fever patient should not attend an obstetric case or other patients with open wounds. When this is impossible, however, he should use the greatest care in disinfecting himself.

Children should be kept in bed for at least a week after the fever has subsided, and on a liquid diet for 2 weeks longer, as this is important in preventing nephritis. Plenty of water should be given to drink, and the addition of 10 or 15 drops of dilute muriatic acid to the glass of water will often prove grateful to the patient.

Systematic bathing and inunctions should from the first be insisted upon, as this reduces the fever and restlessness, keeps the skin active, shortens the course, and prevents complications. The patient should be thoroughly sponged all over daily or when the temperature is high every few hours, with carbolized water (1:100) or bichlorid of mercury (1:8000), or, if preferred, salt water, or alcohol and water. The temperature of the water should be from 70° to 100° F., according to the amount of fever present, using the cooler baths when the temperature is high. Following the sponging there should be applied all over the body cacao-butter, lanolin, or cosmolin, to which may be added 10 grains to the ounce of menthol, or the following:

℞. Carbolic acid, gr. v
Menthol, Thymol, each, gr. x
Lanolin, ʒ j.

The inunctions are agreeable to the patient, relieve the itching and burning, prevent the scales from becoming disseminated through the air, and at the same time protect the surface and render joint involvement less likely to occur. The bathing and inunctions should be continued as long as desquamation exists.

The hygiene and proper treatment of the nose and mouth is also very important, tending to prevent ear complications. The throat should be sprayed or gargled with an alkaline or antiseptic solution 3 or 4 times a day. For this purpose may be used a solution of bicarbonate of sodium (20 grains to the ounce), a solution of listerine, one of the various modifications of Dobell's solution, or—

℞. Hydrogen dioxid, Glycerin, each, ʒ j
Water, ʒ iij.

To a young child who cannot gargle the following may be given:

℞. Boric acid, gr. xx
Salicylic acid, gr. xxx
Peppermint water, ʒ j
Water, ʒ iij.

One teaspoonful every 2 hours until the throat symptoms are relieved.

Or—

℞. Tincture of iron chlorid, ʒ ij
Glycerin, ʒ j
Water, ʒ iij.

One teaspoonful every 3 or 4 hours.

The nose should be sprayed 2 or 3 times a day with a mild alkaline solution, and an oily substance applied to the anterior and posterior nares by means of cotton on a match-stick or probe. For this purpose may be used 5 or 10 grains of menthol in an ounce of liquid albolin. Cold compresses or ice applied to the throat externally is very soothing. If the throat symptoms are severe, adrenalin chlorid sprays may be used as well as inhalations of steam impregnated with oil of eucalyptus or compound tincture of benzoin.

When there is constipation, small doses of calomel should be given to act upon the bowels, and when, as sometimes occurs, diarrhea is troublesome, one of the bismuth mixtures mentioned under diarrhea of infants and children should be given.

The vomiting that was present at the onset seldom persists after the first 24 hours; should it

do so, however, small bits of ice should be given to swallow every 5 or 10 minutes, and camphorated tincture of opium, in 1- to 5-drop doses every 2 or 3 hours, or cocain, 1/20 grain. Food should be withheld while there is any vomiting.

For the nervous symptoms may be given phenacetin or acetanilid (1/2 grain for each year of a child's age), repeated in 3 or 4 hours if necessary. To this should be added 1/2 to 1 grain of quinin to each dose, if the child will take a capsule.

A very weak or irregular pulse or cyanosis calls for stimulants: aromatic spirit of ammonia, 10 drops in water, or brandy or whisky, 10 drops to a teaspoonful according to the child's age; as soon as the urgent symptoms are relieved, discontinue the use of the alcohol, however, owing to its action upon the kidneys.

A useful heart stimulant for these cases is the following:

℞. Camphor water, Tincture of musk, } each, ℥ j.

From 1/2 to 1 teaspoonful in water every 2 hours.

Strychnin (in doses of 1/100 to 1/30 grain according to the age of the patient) or nitroglycerin (in doses of 1/500 to 1/100 grain) are also very useful.

The prevention of complications is of paramount importance. The drum membrane should be watched for signs of bulging and if found, paracentesis should not be delayed. The urine should be examined daily for the onset of nephritis; in order to prevent this complication the patient should be shielded from drafts and kept on liquid diet in bed at least a week after the cessation of febrile symptoms. Urotropin is recommended as a prophylactic remedy.

By the careful hygienic treatment of the nose and throat, and by the baths and inunctions, complications will be much less frequent, but when they do arise, the treatment is the same as for similar conditions when occurring independently of scarlet-fever.

During convalescence iron, cod-liver oil, and general tonic treatment are indicated.

Serum Therapy.—Injections of antistreptococcic serum instituted early in the disease in doses of 20 c.c. have proved markedly valuable for the relief of the complications that occur so frequently as a result of streptococcic infection.

SCHICK REACTION.—See Diphtheria.

SCHISTOSOMIASIS (Bilharziosis).—A chronic parasitic, tropical disease, characterized by hematuria, cystitis, proctitis, due to the eggs of the blood fluke, distomum or schistosomum hematobium. Lesions due to the parasites are found in the kidneys, urethra, bladder, liver, rectum. The ova of the worm are easily detected by microscopic examination of the urine and feces. The parasite probably gains entrance to man through drinking or bathing in or working with infected water, or with some mollusc, fish or vegetable. Treatment is merely prophylactic and palliative.

Schistosomum Japonicum resembles the S. hematobium, but is smaller and the eggs have no spines. This infection is characterized by enlargement of liver, spleen and mesenteric lymph glands, anemia, diarrhea, enteritis. The eggs, which resemble those of ankylostomum duodenale, are found not in the urine but in the feces.

SCHLEICH'S INFILTRATION ANESTHESIA.—See Infiltration Anesthesia.

SCHLEICH'S MIXTURE (for General Anesthesia).—See Anesthetics.

SCHOTT TREATMENT.—The Schott method may be stated briefly as consisting of the systematic use of saline baths of definite strength and temperature, and the coincident or alternative employment of a certain series of resisted movements. The treatment originated in Nauheim, Germany, where the natural springs are strongly saline and heavily charged with carbonic acid gas, their varying temperature and strength making them admirably adapted to therapeutic use. The most important chemic constituents of these baths are sodium chlorid (1 to 3 percent), calcium chlorid (0.1 to 0.3 percent), with a considerable quantity of iron, and a large amount of free carbonic acid gas. Their temperature varies from 81.7° to 95.5° F. In practice the higher temperature and weaker waters are first used, the waters being freed from the carbonic acid gas; a lower temperature, effervescent bath, and greater strength in saline constituents being gradually attained as the treatment progresses. Baths are given daily, rarely more than 3 being taken consecutively, that of the third or fourth day being omitted. While the natural baths are better adapted to treatment, perfectly satisfactory results may be obtained from artificial baths made after the following:

Formulas.—To 40 gallons of water (usual amount required) add sea-salt, 3 to 10 pints (approximate strength 1 to 3 percent); calcium chlorid, pure, 11 to 15 ounces. It is important to note that this latter ingredient is not the commercial chlorid of lime, which, by giving off chlorin, would become a source of discomfort and danger. To introduce or generate carbonic acid gas we may use a soda siphon with conducting tube or the following formulas of Bezley Thorne:

Mild.—$NaHCO_3$, 1/2 pound; HCl (25 percent), 3/4 pound.

Medium.—$NaHCO_3$, 1 pound; HCl (25 percent), 1 1/2 pounds.

Strong.—$NaHCO_2$, 2 pounds; HCl (25 percent), 3 pounds.

The salts are first dissolved; the hydrochloric acid is then added and thoroughly distributed. It has been found that the best agent for adding the acid is a douche bottle and tube, the acid being thus evenly distributed throughout the mixture.

Immersion.—The patient remains immersed from 5 to 20 minutes, the first bath being brief and the period gradually lengthened. If the patient is very ill, he should be carried to and from the bath and spared any exertion. While in the bath he should remain absolutely quiet, breathe

regularly, and refrain even from speaking. Upon leaving the bath he may be rolled in warm blankets, to rest for at least one hour.

Temperature.—The temperature is at first about 93° F., and may be considerably reduced after the 6 or 8 baths have been taken and the use of carbonated baths begun, provided such reduction is considered necessary. Usually, the patient's sensation is a safe guide to the regulation of temperature. The bath should feel pleasant and quite definitely warm throughout the period of immersion, and the patient should be cautioned and told to report at once any tendency to chill.

The movements are very simple Swedish movements, and, as recommended by Schott, comprise 19 exercises, so planned as to bring into action every muscle group in the body. The movements are intended to produce without fatigue the beneficial result of exercises, and are of decided value in the treatment of almost all cases to which the baths are applicable.

Effects of Baths.—(1) There is a fleeting sense of oppression and dyspnea; (2) a feeling of exhilaration and well-being; (3) slowing of the pulse, and, coincidently, a fuller and stronger beat; (4) brightening of skin, nails, and mucous membrane, indicating relief of cyanosis, freer capillary circulation; (5) secondary reduction of pulse tension with maintenance of lower rate; (6) marked reduction in cardiac area, most marked primarily in the right heart, but involving both lateral and vertical dimensions. See HEART-DISEASE (Organic).

SCIATICA.—Pain in the course of the sciatic nerve. This may be confined to the proximal half of the thigh, or may follow the entire course of the nerve and its branches. The pain is constant and gnawing, subject to exacerbations, and occurs most commonly in adults of middle age. Double sciatica is rare.

Causes.—As a rule, neuritis of the sciatic nerve or of its cords of origin exists. Rheumatism or gout, exposure to cold, heavy muscular exertion, or a thorough wetting, cause primary sciaticas, while compression by ovarian or uterine tumors, by lymphadenoma, the fetal head, or occasional lesions of the hip-joint induce secondary sciaticas.

The duration and course are variable, but chronic sciatica usually lasts for months, or, with remissions, for years.

Diagnosis requires a distinction between primary sciatica and the secondary affection due to diseases of the pelvis or spinal cord. Pelvic tumors and lumbago should be excluded. Hip-joint affections cause no tenderness along the course of the nerve, and sacroiliac disease has usually radiating pain. When the nerve-trunks of the cauda equina are pressed upon, there are bilateral pain and disturbances of sensation. The severe lightning pains of tabes are easily distinguished.

Treatment requires that careful and systematic pelvic examination be made, and that constitutional conditions should receive appropriate attention. Salicylates are useful in rheumatic cases, when the onset has been acute and accompanied by fever. Potassium iodid will remove a suspicion of syphilis, and salines improve gouty cases. Rest in bed with fixation of the limb on a long splint will relieve obstinate and protracted cases. Warm or mud-baths are sometimes satisfactory.

Quinin, antifebrin, and antipyrin are of doubtful use. Local applications of a hot iron, thermocautery, or blisters may temporarily relieve pain. Cocain, in doses of 1/8 to 1/4 of a grain, may be used by deep injection into the nerve. An acupuncture needle may be thrust into the painful spot for a distance of 2 inches, and left there for from 15 to 20 minutes. Injections of distilled water or normal saline solution into the nerve may relieve the pain. Electricity is uncertain, and morphin should be withheld as long as possible or until the pain is unbearable.

Nerve stretching, in very obstinate cases, is sometimes successful, but often the condition recurs. The incision is begun at the gluteal fold and carried down the back of the thigh for 4 inches. The nerve is exposed, properly cleaned from the surrounding tissues, and then raised with a blunt hook on the forefinger. It should be stretched both centrifugally and centripetally, maintaining the traction for about 5 minutes. The surgeon must decide the amount of force to use in each case by the size of the nerve. Experiments show that the breaking strain of a healthy sciatic nerve is never under 80 pounds.

SCILLA.—See SQUILL.

SCLEREMA NEONATORUM.—Sclerema is a rare disease, which occurs in the early days of life, and affects those, chiefly, who are weak and feeble, born in cold weather and in poor hygienic surroundings. It is characterized by hardening of the skin and subcutaneous tissues.

The causes of sclerema are generally not local, the most important etiologic factors being great feebleness, with lowering of the body temperature, and, in consequence, hardening of the subcutaneous fat.

Symptoms.—Soon after birth spots of circumscribed hardness appear on the skin. These are often first seen on the feet or calves of the legs, but soon spread over the greater part of the body. The skin has a waxy and glistening appearance, and is hard and cold; the limbs becoming thick, stiff, and misshapen. The temperature is subnormal—reaching in some cases 83° to 86° F. in the rectum. The infant soon grows weak, somnolent, and refuses to take its food. The breathing becomes rapid and superficial, and no pulse can be felt.

The duration of the disease is 3 or 4 days, and death occurs slowly and quietly. If recovery takes place, there is gradual improvement in the circulation and nutrition, and later a disappearance of the areas of induration.

The treatment should consist of artificial heat—the child should be placed in an incubator. Inunctions of hot oil with massage should be given, and the nutrition kept up by stimulants and careful feeding.

SCLERITIS (Episcleritis).—Inflammation of the scleral tissue characterized by a purplish injection

of the ciliary, deep pericorneal, and conjunctival vessels.

Symptoms and Diagnosis.—If the conjunctival vessels are kept empty by gentle pressure, the bluish scleral vessels are seen more clearly. There is considerable pain on pressure and some local swelling. Carefully examined, a flat nodule made up of minute vesicles is seen lying about 3 mm. from the edge of the cornea (episcleritis). The disease is intimately connected with rheumatic disorders, syphilis and tuberculosis. The diagnosis is easily made, and depends upon the characteristic local condition and rheumatic, gouty, syphilitic or tuberculous history. Most cases are rheumatic in origin. The course of the disease is protracted, sometimes one nodule after another being formed until a large portion of the sclera is occupied by blotches. Relapses are frequent, and are closely connected with general rheumatic paroxysms. The pain is more or less severe, and for the time the eye is practically useless for near work.

Treatment is general. Salicylates and the ordinary rheumatic treatment should be instituted; or if syphilis or tuberculosis is defined, the respective treatment should be inaugurated. Ordinarily, local treatment should be avoided, but in chronic cases massage with yellow ointment may be tried. For the relief of the pain, moist heat and pressure are advised. If the choroid is involved, atropin is indicated. See Tuberculosis (Ocular).

SCLERODERMA (Hide-bound Disease).—A disease characterized by circumscribed or diffuse induration, rigidity and stiffening of the integument, terminating in atrophy.

Symptoms.—The disease is exceedingly rare. The skin manifestations may be preceded or accompanied by disturbance of cutaneous sensibility, such as pain, prickling, tingling, formication, etc., and muscular cramps. The disease begins as a pronounced stiffening or hardening of the skin, which progresses gradually, or more rarely rapidly, until marked induration results. In some cases an edematous stage may precede the induration. When the disease is typically developed, the skin is thickened, tense, hard, and immovable, acquiring in an advanced stage the feel of frozen skin, leather, or even wood. It is bound down to the structures beneath, and is incapable of being lifted. There is usually pigmentation of a yellowish or brownish hue.

After a variable duration the stage of induration passes on to the stage of atrophy. The skin then becomes thinned, shiny, and tensely stretched over the bony prominences. The phalangeal joints are apt to become ankylosed in a semiflexed position (sclerodactylia).

The course of the disease is chronic, although in rare cases it may be acute. The general health is, as a rule, not compromised. The parts most affected are the neck, face, forearms, chest, and lower extremities.

Etiology.—Scleroderma occurs chiefly in early adult and middle age, and is far more common in women than in men. Exposure to cold and wet, rheumatism, and nerve shocks have been causal in many cases. The disease is brought about through the implication of the nervous system.

Pathology.—The chief changes noted in scleroderma are an increase and condensation of the connective tissue in the corium and subcutaneous tissue, an increase in the elastic tissue, and a diminution in the caliber of the blood-vessels. Later there is atrophy of the subcutaneous tissues.

Diagnosis.—The peculiar immobile, indurated, tightly adherent condition of the skin is highly characteristic of the disease. Morphea is looked upon by most writers as a circumscribed form of scleroderma.

Prognosis should be guarded; in some cases the disease undergoes spontaneous involution; in many it persists throughout life.

Treatment.—Internal treatment is to be based upon general principles, arsenic, quinin, and cod-liver oil being frequently of value. Locally, baths, massage with oily substances, and electricity may be employed with benefit.

SCLEROSIS, CEREBROSPINAL.—See Disseminated Sclerosis.

SCLEROSIS, SPINAL.—See Amyotrophic Lateral Sclerosis, Lateral Sclerosis, Paraplegia.

SCLEROTOMY.—See Glaucoma.

SCOLIOSIS.—See Spine (Curvature).

SCOPARIUS (Broom).—The dried tops of the common broom plant, *Cytisus scoparius*. Its properties are due to a neutral principle, scoparin, and an alkaloid, spartein. It is diuretic and laxative; in large doses it is cathartic and emetic. It is a favorite remedy in cardiac dropsy and kidney complaints. Dose, 5 to 30 grains. There are no official preparations.See Spartein.

SCOPOLA.—See Hyoscyamus.

SCOPOLAMIN.—See Hyoscyamus.

SCOPOLAMIN-MORPHIN ANESTHESIA.—See Anesthetics (Anesthetic Mixtures).

SCORBUTUS.—See Scurvy.

SCORPION BITES.—See Bites and Stings.

SCOTOMA.—See Field of Vision.

SCREAMING, NIGHT.—See Nightmare.

SCROFULA (Tuberculous Adenitis; Lymphadenitis; King's Evil).—A morbid condition, usually constitutional, and frequently hereditary, characterized by glandular tumors having a tendency to suppuration, and leaving indolent ulcers very stubborn to treatment. It is now generally accepted as a manifestation of tuberculosis. The term is gradually falling into disuse.

Etiology.—It is most generally seen in children and young adults, especially those who suffer from nasopharyngeal catarrh. It is very common in the negro race. The bacillus of tuberculosis is the specific cause of the disease.

Pathology.—The cervical glands are those most frequently enlarged. The tubercles form first in the lymphoid follicles, finally breaking through the capsule. Generally, caseation ensues with subsequent liquefaction, and suppuration begins, with the establishment of a sinus.

Symptoms.—There is usually a history of tuberculosis in the father or mother, or a neglected

nasopharyngeal catarrh. One gland may be first affected, becoming enlarged and painful. Usually the gland is hard, the color of the skin overlying being unaltered. Soon the lymph-channels convey the virus to neighboring glands, which become diseased, break down, and suppurate. Often the process of liquefaction does not come on until late, and the gland may seem to remain of one size indefinitely. The temperature is variable—from normal to 102° F.; the child seems peevish, and endeavors to protect the affected side by inclining the head in the opposite direction. The body is often greatly emaciated, and signs of grave anemia are very prominent.

Diagnosis.—

Scrofula.	Hodgkin's Disease.	Lymphatic Leukemia.	Lymphoma.
1. Most common in children and young adults; cervical glands most frequently enlarged.	1. Not common in children; principally cervical or submaxillary glands.	1. Middle life.	1. Early life; all glands involved.
2. Glands often painful.	2. Glands not tender.	2. Glands not tender.	2. Glands freely movable, not especially tender.
3. Glands suppurate.	3. Glands rarely suppurate.	3. Glands rarely suppurate.	3. Glands rarely suppurate.
4. Blood may show evidence of anemia.	4. Blood shows signs of moderate anemia.	4. Marked persistent increase of white blood-corpuscles. See Leukemia.	4. Blood shows signs of simple anemia.

Prognosis.—If the disease is located in the cervical region or near the external surface in any portion of the body, prognosis is favorable.

Treatment.—The best of hygienic surroundings, with good and nutritious food, are demanded. Tonics are valuable, such as the iron iodid (5 to 15 minims) 3 times a day. The elixir of the phosphates of iron, quinin, and strychnin (5 to 30 minims), according to age.

An emulsion of cod-liver oil is also very valuable:

℞.	Syrup of the iodid of iron,	℥ vj
	Cod-liver oil,	℥ iv
	Whisky,	℥ j
	Bitter-almond water,	ʒ ij
	Cinnamon water,	℥ ij
	Yolks of two eggs,	
	Water, enough to make	℥ x.

Beat up the eggs in a mortar for 15 minutes and gradually add the oil; then the other ingredients, the whisky being added last.

Two teaspoonfuls 3 times a day.

If suppuration ensues, the glands must be excised.

Tabes Mesenterica.—This is an involvement of the retroperitoneal lymph-glands, and is common in young children. The limbs and trunk are greatly wasted, and the belly becomes very prominent from tympanites. There is often diarrhea, with offensive stools, yet the bowels are not generally the seat of tuberculosis. There may be infection of the peritoneum, also giving rise to an uneven, nodular, tender, and painful enlargement, easily detected on palpation.

SCROTUM, DISEASES.—Edema may occur in nephritic subjects, causing great swelling; and a similar affection, generally inflammatory, is occasionally seen in infants.

Inflammation is quite common, but unless associated with extravasation of urine, or unless the nutrition is much enfeebled, as in specific fevers, sloughing and gangrene rarely occur. Inflammation of the scrotum may arise from injury, eczema, irritation of urine, retained perspiration, or may spread from neighboring tissues. The swelling is much greater proportionately than the pain, heat, and redness. See Testicle (Inflammation).

Elephantiasis.—Enormous hypertrophy of the tissues of the scrotum may be caused by lymphatic obstruction or by repeated attacks of inflammation, as in cases of urinary fistula. The skin and subcutaneous tissues only are affected, the cellular elements and the fibrous tissue being immensely increased, while all the interstices are filled with lymph, or, in rarer cases, with a mixture of lymph and chyle. Hydrocele is usually associated with elephantiasis, and the skin of the penis may become involved, but the testes are never affected.

Epithelioma is of interest from the fact that its origin can nearly always be traced to local irritation; it formerly was often called chimney-sweeps' cancer, from the frequency with which it occurred in chimney-sweepers as the result of irritation of soot. It begins as a wart or nodule, which slowly spreads at the margin as it decays and ulcerates in the center. Induration is its chief feature. The edges are raised, hard, and ill defined; the base is covered with decaying epidermis and florid granulations which discharge a thin, offensive fluid, and the tissues around are swollen and edematous. At first it can be pinched up from the structures beneath, and merely feels like an induration in the skin; soon it infects the lymphatic glands in the groin, spreads to the rest of the scrotum and the penis, and involves the testicles as well. Fortunately, its character is so well known among those liable to it (soot may cause it in other parts of the body, and there is reason to believe that tar may do the same), and its progress (for epithelioma) is so slow, that removal in time is usually possible. Even if the inguinal glands are enlarged and broken down, the whole of the disease may sometimes be successfully eradicated.

Examination of Scrotal Swellings.—Swellings of the scrotum are divided into those that occupy the canal as well as the scrotum, and those that are confined to the latter situation. The distinction is made by feeling the cord immediately below the pubes; whether it is the natural size, with all its

components distinct, or whether it is thickened or concealed in any way.

Swellings that Occupy the Canal as well as the Scrotum.—Those that are *reducible* are:

Bubonocele and *scrotal hernia*, which may be recognized by the way in which they disappear whether they consist of intestine or omentum.

Varicocele, diagnosed by its characteristic feel, the way in which it disappears when the patient lies down and the scrotum is raised, and refills in spite of the pressure of the finger on the ring.

Congenital hydrocele, known by its translucency. As the neck of the canal is often long and narrow, reduction is not always easy.

Those that are *irreducible* are:

Hernia, which cannot be returned because it is *strangulated* (in which case there is no impulse on coughing), or because it is *irreducible—i. e.*, so altered in shape or so tied down by adhesions that it cannot pass back. In strangulation constitutional symptoms are also present.

Infantile Hydrocele.—The neck of the tunica vaginalis is obliterated only at the internal abdominal ring, and a collection of fluid extends from the bottom of the scrotum along the inguinal canal. The slow formation, commencing below and extending upward, the translucency, and the absence of true impulse (if it extends really into the canal, there may be a kind of shock transmitted) are distinctive.

Inflammatory Affections of the Cord.—In urethral epididymitis this is sometimes swollen to a considerable size; in tubercular disease the vas only is thickened, and all the structures of the cord can be isolated.

Growths on the Cord.—The most common is *encysted hydrocele*, a small, round, and tense fluid swelling, due to incomplete obliteration of the funicular portion of the tunica vaginalis. It is movable in the canal, but cannot really be reduced, and it is adherent to the cord, forming part of it and moving with it.

Lipoma, *sarcoma*, and other growths may occur, but they are very rare. Secondary infiltration is always present in malignant disease of the testis, if the gland is not speedily removed. *Hematocele* of the cord has been described. See Hematocele.

Swellings Confined to the Scrotum.—*Of those connected with the scrotum itself* are:

Edema.—In Bright's disease the whole scrotum sometimes becomes enormously distended without the legs being much affected.

Elephantiasis.—In the tropical variety there can be no hesitation, but occasionally a greatly thickened and hardened condition, not so plainly recognized, occurs as a result of neglected stricture.

Lipoma, *epithelioma*, and other varieties of new growths may occur.

Those connected with the testis and its coverings may be solid or fluid. The former include inflammatory diseases and tumors of the testis. The chief difficulty occurs with hematocele and old hydrocele, the walls of which may be so thick that they are practically solid. The latter may be connected with the tunica vaginalis (hydrocele or hematocele), the testis or epididymis (encysted hydrocele), or the lower end of the cord (hydrocele of the cord); or they may be independent cysts—dermoid, for example, or hydatid. Some difficulty may arise from what is known as hydrosarcocele, a collection of fluid in the tunica vaginalis surrounding and concealing an enlargement of the testis, and the diagnosis may remain uncertain until the fluid is drawn off (Moullin). See Testicle (Diseases).

SCURVY. (**Scorbutus**).—A constitutional disease, characterized by a spongy condition of the gums and by a tendency to hemorrhages into the gums, muscles, joints, and internal organs. The blood shows the same characteristics as seen in the secondary anemias.

Etiology.—It is principally due to eating too much salt meats or corned meats, and not enough of fruits and vegetables. It is most often observed in sailors, soldiers, miners, and in remote habitations, where there is a limited amount of proper food.

Pathology.—The gums are soft and spongy, often being ulcerated to such a degree that the teeth drop out. There may be hemorrhages into the mucous surfaces, as into the gums. Often ecchymotic spots are seen on the external surfaces, and occasionally in the serous membranes.

Symptoms are usually of slow development and in early stages they are manifested by fatigue, by a craving for acid foods, and by constipation. There is an anemic appearance of the skin, or it may have a yellowish appearance. The gums are congested, and bleed on the slightest touch, and hemorrhagic spots are found dotted over the mucous membrane of the mouth, principally of the gums.

Prognosis is good.

Treatment.—Prophylactic treatment consists in a diet including onions, limes, lemons, oranges, canned vegetables, etc. Fractional doses of calomel (1/4 of a grain) should be given every hour until 6 doses have been taken, followed by a saline purge, if necessary. Subsequently, the diet should be principally composed of fruits and vegetables.

When convalescence is established, a tonic containing iron may be given:

℞.	Arsenous acid,	gr. j
	Strychnin,	gr. ss
	Mass of carbonate of iron,	ʒ iij.

Divide into 30 pills. One pill after meals.

Or—

℞.	Tincture of ferric chlorid,	ʒ iv
	Aromatic elixir,	ʒ iv
	Water, enough to make	ʒ iij.

One teaspoonful after meals.

SCURVY, INFANTILE.—Infantile scorbutus is a constitutional disease associated with imperfect nutrition due to some prolonged error in diet. It is manifested by rapid and progressive cachexia, profound anemia, etc.

Etiology.—The cause of scorbutus is probably of chemic origin, due to the continued use of food that either lacks some elements required for the child's

nutrition or which furnishes them in such a form that the child cannot assimilate them.

Scurvy occurs nearly always between the sixth and twenty-fourth months, and in nearly all cases in babies who are artificially fed. It occurs in the well-to-do as well as in the poor and neglected—more frequently in the former, as in the latter class the diet is, as a rule, more varied, and although not in every respect suited to proper nutrition, it contains the antiscorbutic elements. A large majority of the cases reported have occurred in babies exclusively fed on condensed milk, sterilized milk, or on the various proprietary foods combined with sterilized milk, or on these foods prepared without the addition of the proper proportions of milk and cream.

Pathology.—Hemorrhages occur frequently in the skin, mucous membranes, muscles, viscera, and subperiosteal tissues of the bones. Extensive ulceration of the gums, with exuberant granulations often overlapping the teeth, are common in advanced cases. The blood presents all the characteristics of anemia, such as a diminution of the red blood-corpuscles and a decrease in the percentage of hemoglobin.

Symptoms.—The onset is gradual; the child becomes anemic, and suffers with more or less severe attacks of gastrointestinal disturbances. The appetite is diminished or irregular; the stools may be normal, but are often irregular, pasty, and gray in color; sweating of the head, as in rickets, has been noticed, and the child is often feverish. These are simply symptoms of indigestion, which generally, but not always, precede for a variable length of time the symptoms of scurvy.

The first symptom which suggests the true nature of the disease is a sensitive condition of the bones, the infant crying when the affected parts are touched. It will also be noticed that the gums are congested and bleed readily. As the disease progresses, the limbs become swollen. Only the legs are usually affected, but the forearm may also become swollen and tender. The enlargement of the limbs may continue until they become double their natural size. The swelling is not usually accompanied by any local heat or discoloration, but the skin has a white, transparent appearance. When the child is not disturbed, it will often lie for hours in one position, the legs being kept extended or slightly flexed, but absolutely motionless; but when it is disturbed or handled, there is apparently intense pain, which is indicated by piercing screams.

Ecchymoses may occur upon the skin over the swelling or upon other parts of the body, especially about the eyes. Intraorbital hemorrhage may give rise to exophthalmos. The gums are not affected when the teeth have not appeared; but when any of the teeth have been erupted, the gums about them become swollen, spongy, and bleeding, and may ulcerate; the teeth may become loosened and fall out, and the mouth may be filled with a bloody and foul-smelling secretion.

Diagnosis.—In certain cases rickets may resemble scurvy, but in rickets there occur curvatures of the bones and enlargement of the epiphyses, while the swelling of the shaft of the bones, the gingivitis, and the purpura are absent. The immobility of the limbs has led to a diagnosis of paralysis; the swelling and the pain to diagnosis of rheumatism, hip-joint disease, fracture, osteosarcoma, etc.; but errors in diagnosis may be avoided by attention to the associated symptoms of swelling and tenderness of the extremities, to the fungous and bleeding condition of the gums, and to the cachexia and anemia. Whenever any doubt exists as to the nature of the affection, the results of treatment will speedily establish the diagnosis.

Prognosis.—The course is slow and progressive, and when left untreated, the child may finally die of exhaustion. On the other hand, cases which receive proper treatment early never develop the graver forms of the disease, and in them the prognosis is invariably favorable.

Treatment.—The treatment of infantile scorbutus consists of substituting for the improper diet one of fresh milk modified according to the child's age. See INFANT FEEDING, MILK (Modified). The juice of one orange, or even more, should be given in the 24 hours. Children usually take this readily; but should they refuse to do so, they should be forced to take it. Beef-juice, a teaspoonful added to the milk, or given alone, should be given 3 times a day, and 1 to 3 grains of the ammoniated citrate of iron in the orange-juice 3 times a day. The child should receive a warm salt bath daily, and should be in the fresh air and sunlight as much as possible.

SCUTELLARIA.—Skullcap. The dried plant *S. lateriflora;* with reputed properties as a tonic nervine in tremors, chorea, hysteria, etc. Dose, of the fluidextract, 10 to 30 minims.

SEA-BATHING.—Sea-bathing may be regarded as a powerfully stimulating cold-water bath, from which it differs only in the action of its ingredients. A question often asked is: Does sea-bathing differ from a salt-water bath taken elsewhere? It differs in the admixture of organic and inorganic mechanic particles in the water; in its varying degree of wave-motion; and in producing an effect, otherwise unattainable, by the alternation in exposure of the body to water and to air. Sea-water is more equable in temperature than the surrounding air, and is, as a rule, warmer in winter and cooler in summer than other water. Its temperature varies during the day and from day to day, but in a less degree than air. Sea-water holds in solution an amount of salts varying according to locality. Mediterranean water is richest in salt. The waters of the Baltic Sea are less salty, containing about 0.5 percent. Five-sixths of the salts in sea-water consist of sodium and magnesium chlorids. The sulphates and carbonates of calcium, magnesium, and potassium constitute the principal other salts. Artificial salt baths cannot give the motion of sea-water, which varies constantly and according to the size and force of the waves; and the effect of sea-bathing is to a great degree dependent upon this point. Waves in any degree powerful expose the upper part of the body to their coming, and the lower part to

their receding; and cutaneous nerves are not only influenced by the temperature, but also by the force of the water and of other substances, such as sand, mixed with it. The alternate exposure to air and water occasioned by waves is peculiar to sea-bathing, and produces its impression on the cutaneous nerves.

The time of day for sea-bathing depends on the weather, the season, the individual, and the tide. As a rule, it is inadvisable to bathe when the stomach is empty, and never after a full meal. Delicate persons particularly should be warned on these points. The duration of a bath is to be measured by the constitution of the bather, the force of the waves, and the temperature of the water. Five minutes are sufficient for weakly persons, while immersion for 1 or 2 minutes may suffice. A good rule is to leave the water as soon as reaction manifests itself.

The warm sea-bath is to be recommended with advantage when the cold sea-bath is unattainable. Such baths are analogous to warm, common-salt baths. The tepid swimming bath of sea-water is sometimes appropriate, can be used in winter, and offers the advantage of combination with muscular exercise. The physiologic effect of sea-baths is similar to that of sea-air. The usual effects are increased appetite and increased weight of body. When loss of appetite, headache, digestive disturbances, and loss of weight ensue from sea-bathing, the shock of the bathing is too great, or the baths are too long continued or too frequently taken, or possibly the increased demand upon the system is too great.

There are cases unsuited for sea-bathing. Persons affected with certain diseases of the heart (see SCHOTT TREATMENT, HEART-DISEASE (Organic)), diseases of the blood-vessels and lungs, angina pectoris, epilepsy, organic diseases of the nervous system, enlargement of the liver, or other organic disease of the abdominal viscera should avoid bathing in the open sea. Violent palpitation and dyspnea extending over many months may ensue, as well as general sleeplessness, loss of appetite, and emaciation. Except on warm days and in quiet water, old persons, especially those with feeble circulation, should avoid bathing in the open sea. Recent rheumatic joint affections are injured by sea-bathing, and it is hazardous in cases of chronic pneumonia, with pleuritic effusion, and in tuberculosis of the lungs.

Cases benefited by sea-bathing are those with weakness or atony of the skin—*e. g.*, with a tendency to profuse perspiration, and who take cold easily on exposure to winds or drafts. In scrofulous complaints there is often more advantage in sea-bathing than in climatic treatment. In muscular rheumatism sea air, combined with the moderate use of sea-bathing, is most useful. So-called nervous rheumatism is often benefited by the use of gentle sea-bathing. Functional diseases of the nervous system are much benefited by sea-baths adapted to the individual case. Persons with a tendency to neuralgia, to nervous asthma, or to certain forms of hysteria are often unable to stand sea air for a long period of time.

According to Kruse, the prevalent objections to sea-bathing in anemia are not justified. The untoward results are attributable to the injudicious employment of the baths. Lack of care in cold bathing is accountable for acute cardiac dilatation, additional weakening of the heart-muscle, which in anemia is less vigorous than normally, and which explains the faintings, weaknesses, etc., after prolonged baths.

Cold sea-baths are contraindicated in anemia complicated with diseases of important organs, such as ulcer of the stomach, chronic inflammatory processes in the uterus and its appendages, etc., or in anemia which has led to great debility and anorexia. The latter is soon relieved by sea air.

The following rules are recommended:

1. Anemic patients should not bathe for two days after arrival at the seashore.
2. They should never bathe when fasting.
3. They should not take baths every day.
4. The first baths must not last over 1 minute; later on they may be extended to 3 or 4 minutes, but never longer.
5. The bather should undress rapidly and dip into the waves immediately, without waiting for the body to cool.
6. The patient should not move about, but remain as passive as possible while in the water.
7. No baths are to be taken in stormy weather, to avoid overexertion.
8. After each bath the skin must be carefully dried and rubbed.
9. The patient should not exercise, but should rest in bed for an hour after each bath.
10. As a rule, anemic patients should not bathe oftener than every second day.
11. No object is attained by beginning the sea-bath treatment with warm baths. They may do harm. An exception to this rule is in parametric exudations; in these warm sea-baths may be used, with warm wet packs on the abdomen during the night, associated with abdominal massage. These, together with prolonged stay in the sea air, prove efficacious.
12. The patient should not exercise much at the seashore; even sitting there for an occasional hour proves sufficiently tiring.
13. Patients with profound anemia should limit walking to the absolutely necessary; they should sit or lie, well wrapped, in the open air for the greater part of the day.
14. The insomnia that often sets in while at the seashore is most frequently due to overexertion.
15. Preparations of iron assist, especially in the beginning, and are in most instances well borne at the seashore. The most desirable form in saccharated ferric carbonate; but the use of ferruginous waters at the seashore is not appropriate in anemias.
16. The patient should not yield to the extreme appetite which often sets in at the seashore, lest the stomach soon become unable to perform its functions.
17. Alcoholic stimulants should be used most sparingly; patients should be warned against brandy and heavy wines. Alcohol promotes fatty degen-

eration of the muscles, and particularly of the heart.

Three hundred cases treated by Kruse with the above precautions proved the efficacy of sea-baths in anemia.

Many states of weakness manifesting themselves in various ways unsuitable for classification, such as inability to sustain mental or bodily efforts, tendency to abortion, leukorrhea, etc., are greatly benefited by judicious and well-timed sea-bathing.

The fear of sea-bathing during menstruation is a teaching handed down to us from by-gone generations. However, any healthy woman may bathe in moderately warm water during menstruation, if she takes proper precautions against subsequent cold. Mirouiff states that alkaline baths at 27° or 28° C. during menstruation by patients suffering from gynecologic troubles act as excellent sedatives. Moreover, the quantity of blood lost is not increased or affected, save possibly to be slightly diminished. In addition, pain is soothed and any accompanying inflammation of the genitals mitigated. Salt baths are, therefore, of real benefit during the flow. Sea-baths, far from deranging, favor menstruation. Unless there is grave uterine disease, sea-baths prolong the period of sexual activity and increase fruitfulness.

SEA-SICKNESS.—The nausea and vomiting affecting certain persons at sea, or those who are subjected to any undulating motion, like that of a vessel.

Etiology.—The exact cause of the condition has never been definitely settled. Very likely no one cause is active in every case. Cases seem divisible into those primarily of nervous origin and those of gastric origin. Imagination alone may cause mal de mer. Disturbances of equilibrium and exaggerated conceptions of the relationship of space, may result in nausea and vomiting. Eye-strain may be provocative of an attack. Some believe that sea-sickness is due to hyperemia of the semicircular canals; others that it results from disturbance of the endolymph. Congestion of the cord and medulla is also regarded in the etiology. The same phenomena may be caused by swinging or by traveling, and even by landing after voyaging. An important point to bear in mind is that the mere fact of a patient's being on a vessel does not preclude the possibility of volvulus, appendicitis, intestinal obstruction, or other complication requiring prompt and urgent attention.

Treatment.—In genuine sea-sickness the bromids furnish a means of prophylaxis. From 5 to 10 grains should be given 3 times daily for several days before sailing. After sea-sickness has begun, they are best given in an effervescing mixture—*e. g.*:

℞. Citric acid, ʒ ij
Distilled water, ʒ iv.
Mix and add:

℞. Potassium or sodium bromid, ʒ j
Potassium bicarbonate, ʒ j
Distilled water, ʒ iv.
Take a tablespoonful of each and drink while effervescing.

Bromural is highly recommended as a prophylactic.

For an hour before embarking strychnin sulphate, arsenate, or hypophosphite, 1/120 grain, may be taken every quarter of an hour; or the combination of 1/120 grain of each of above compounds of strychnin may be taken for 3 days, 3 times daily, with 1/2 grain of podophyllum each night.

For 3 days before sailing, and for 3 days thereafter take:

℞. Extract of taraxacum, } each, gr. xx
Compound extract of colocynth, }
Extract of hyoscyamus, gr. iij
Extract of nux vomica, gr. v
Mass of mercury, gr. xv.
Divide into 20 pills. Take 1 or 2 each night.

The diet must be simple and fluids must be avoided. The recumbent posture should be kept upon deck.

For the vomiting of sea-sickness 5 drops of a 4 percent solution of cocain may be given 3 times daily; or—

℞. Chloroform, } each, gtt. x
Tincture of nux vomica, }
Compound tincture of lavender, ʒ j
Water, ʒ x.
A teaspoonful every hour until the vomiting and nausea cease, the bottle to be shaken each time a dose is given.

Chloral, amyl nitrite, nitroglycerin, and antipyrin may also be mentioned as useful. A spinal ice-bag may relieve the headache.

From many years' experience, P. K. Taylor makes the following summary of the treatment: Rely chiefly, in nervous cases, on morphin and atropin, given by preference hypodermically; and on calomel and Rochelle salt for disturbed digestions. Bromocaffein will often relieve the headache, and cocain will sometimes be of great benefit in overcoming nausea, if given by the mouth. Avoid the bromids of potassium and sodium, as they do more harm than good, by upsetting the digestion. A belladonna plaster over the nape of the neck and a large capsicum plaster over the epigastrium will often be all that is needed to secure immunity from headache and nausea. If, when the ship is pitching much, a person instinctively holds his breath as he sinks to the hollow of each wave, insist on his "breaking step," so to speak. A determined effort to breathe regularly, and not in rhythm with the motion of the vessel, will quickly be successful in overcoming a muscular contraction of the diaphragm which, unchecked, would speedily lead to emesis. As regards diet, it is best to let patients choose for themselves to a great extent; that suited to one patient may not be tolerated by another. Liquids should be restricted in amount. Solids, like toast or dry unsweetened biscuit, with a little iced champagne or brandy

and ginger ale, are less likely to be rejected by the stomach than are the usually administered beef-tea and chicken broth. Do not insist too much on the value of fresh air on the deck. A day or two in bed with restricted diet is sometimes of more benefit than fresh air secured at the expense of one's reserve fund of energy. When there is an opportunity to advise prospective voyagers, always insist on careful diet for several days before going to sea; and upon a liberal calomel and saline purge about 48 hours before sailing. See CALAGE.

SEA-WATER INJECTIONS.—Sea-water especially collected and prepared carefully with aseptic precautions is injected preferably behind the great trochanter in adults, in infants over the scapula. Marked and rapid tonic effects are reported by the French advocates of this treatment as regards the bodily functions and general condition. This treatment is said to be valuable in gastro-intestinal disorders, especially in infants, in skin diseases, in varicose ulcers, anemia, chlorosis and tuberculosis, etc. The initial doses are generally 20 to 50 c.c., depending on the disorder. The results obtained are discredited by American observers who have found this treatment of no greater value than simple injections of normal saline solution.

SEBACEOUS CYSTS.—These are most common during middle life, and occur on any portion of the body, though most generally upon the scalp, back, shoulders, and face. They are mostly movable, superficially situated, and adherent to the skin. The contents are usually of yellowish, curdy material. They probably are formed by dilatation of a hair follicle, with sebaceous secretion. If untreated, they frequently become inflamed, suppurate, and occasionally calcify. Papillomata, horns, and epitheliomata may arise from their internal surfaces. Sebaceous cysts are to be differentiated from dermoid cysts, which lie under the deep fascia, the skin being freely movable over them; a sebaceous cyst lies in the corium, and moves with it or is adherent to it.

Treatment.—Sebaceous cysts should be removed before they become inflamed, by a linear incision through the skin down to, but not into, the tumor, separating the cyst with the scalpel-handle from the connective tissue surrounding, and removing without evacuating the contents. In any case, the cyst-wall must be removed. Fatty tumors are sometimes mistaken for sebaceous cysts or wens, but the treatment is the same in either case, and a distinction is immaterial.

SEBORRHEA (Dandruff; Pityriasis).—A disorder of the fat-producing glands characterized by an increased and altered secretion of sebum, producing an oily or scaly condition upon the skin.

Symptoms.—There are two forms—*seborrhœa oleosa* and *seborrhœa sicca*.

Seborrhœa Oleosa.—This form manifests itself as an inordinate oiliness of the skin. The parts usually affected are the forehead, cheeks, and nose. The mouths of the follicles are dilated, and there is often an enlargement of the superficial blood-vessels. The face is dirty and begrimed owing to the adhesion of particles of dust to the skin.

Seborrhœa sicca (dandruff) manifests itself as an accumulation of yellow or grayish scales, occurring upon the scalp or nonhairy regions. When the face is involved, the eyebrows and beard are usually affected first.

Upon the scalp this condition is generally associated with falling of the hair (*defluvium capillorum*).

The *vernix caseosa* is an intrauterine seborrhea, physiologic in character. The *smegma præputii* is also a seborrhea. As a result of the decomposition of the secretion, balanitis sometimes develops.

Etiology.—The causation is obscure. The disease occurs most frequently at the age of puberty. It is more common in women than in men, and in dark-complexioned persons than in blonds. It may be idiopathic, but is frequently met with in persons affected with tuberculosis, chlorosis, general debility, and gastrointestinal disorders.

Diagnosis.—Oily seborrhea can scarcely be confounded with any other affection. Seborrhœa sicca is to be distinguished from psoriasis, eczema, erythematous lupus, and ringworm. These are all characterized by redness and by more or less thickening.

Pathology.—There is overaction of the sebaceous glands and of the sweat-glands, at times accompanied by a slight degree of inflammation. Some observers consider the affection as microorganismal in character.

Prognosis.—Favorable. Long-standing cases affecting the scalp lead to baldness.

Treatment. Constitutional.—Tonics, such as arsenic, iron, strychnin, and quinin are often indicated. Duhring recommends calcium chlorid in doses of 1/10 to 1/5 grain. Gastrointestinal disorders should receive appropriate treatment.

Local.—The indications are first to remove the crusts and scales, and then to use stimulating and astringent applications, with a view to favorably influencing the glandular secretions. Resorcin, sulphur, and salicylic acid are the three sovereign remedies.

To soften adherent crusts upon the scalp:

℞.	Salicylic acid,	gr. xx
	Olive oil,	ʒ iv.

This may be followed by the use of the tincture of green soap to remove the epithelial débris. One of the following preparations may then be employed:

℞.	Resorcin,	ʒ jss
	Castor oil,	♏ xx
	Alcohol,	ʒ iv.

(If an aqueous lotion is required, the castor oil and the alcohol may be replaced by glycerin and water.)

℞.	Fluidextract of pilocarpin	ʒ j
	Tincture of cantharides,	ʒ ss
	Soap liniment,	ʒ ijss.

Rub the scalp well with this lotion daily.

℞. Sulphate of quinin, ℥ jss
Rectified spirit of wine, ℥ iv
Tincture of capsicum, Tincture of cantharides, Aromatic spirit of ammonia, each ℥ ss
Glycerin, ℥ iv
Water, enough to make O j.
Apply locally.

Upon nonhairy regions, or when there is but little hair upon the scalp, salves may be used:

℞. Precipitated sulphur, gr. xx to xxx
Petrolatum, ℥ ss
Oil of bergamot, ♏ xx.

Or—

℞. Salicylic acid, gr. x
Petrolatum, ℥ ss.

Ammoniated mercury, calomel, carbolic acid, and other remedies are also employed, but the foregoing will be found to give the best results.

For oily seborrhea use equal parts of alcohol and ether.

Or—

℞. Boric acid, gr. xxx to ℥j
Alcohol, ℥ ij.

Or—

℞. Tannic acid, gr. xxx to ℥j
Alcohol, Water, each, ℥ j

SECALE.—See Ergot.

SECTION.—See Abdominal Section, Cesarean Section.

SECUNDINES.—The placenta, cord, and membranes expelled from the uterus after the birth of the child. For their management, see Labor.

SEDATIVES.—Agents that exert a soothing influence on the system (or upon a part) by lessening functional activity, depressing motility, and diminishing pain. *General sedatives* include the narcotics and anesthetics, while *local sedatives* include aconite, opium, ice, etc. *Pulmonary sedatives* are hydrocyanic acid, veratrin, the nauseants, and the emetics. *Spinal sedatives* are physostigma, gelsemium, and potassium and sodium bromids. *Stomachic sedatives* include arsenic, bismuth, silver nitrate, and sodium bicarbonate. *Vascular sedatives* are digitalis, tobacco, aconite, veratrum, and the emetics. Among *nervous sedatives* are potassium and sodium bromids, tobacco, lobelia, and the group of spinal depressants. *Constitutional sedatives* overlap therapeutic divisions. The type is distinctly narcotic and anesthetic. Of *local sedatives*, cold, in the form of ice or ether spray, deadens the sensibility of the skin. Aconite, opium, cocain, belladonna, veratrin, and blisters soothe the sensory nerves and influence the circulation of the parts. The local sedatives are useful in rheumatic or neuralgic pain, in superficial inflammation, and to allay itching in prurigo, eczema, and skin affections. Diluted hydrocyanic acid, carbolic acid, chloroform, borax, and chloral hydrate are examples.

SELF-ABUSE.—See Masturbation.

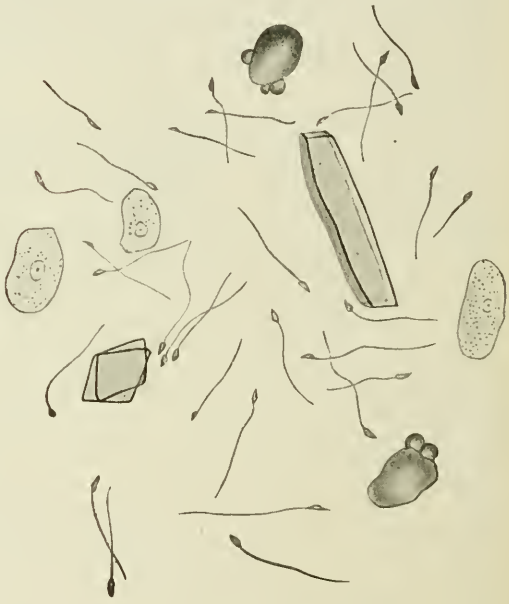
SEMINAL EMISSIONS.—See Nocturnal Emissions.

SEMINAL STAINS.—In all cases of alleged rape the underclothing of the victim should be carefully examined for seminal stains, which stiffen the fabric on which they are deposited in the same way that gum or albumin does. Moistened with warm water, seminal stains give off a characteristic odor.

Lassaigne's test for semen is as follows: The seminal stain is moistened with a solution of lead oxid in liquor potassæ and dried at 68° F. There is no yellow color developed, as would occur in albuminous fluids. However, semen diluted with an albuminous secretion develops a yellow color.

The only positive proof, however, of semen is the discovery of spermatozoa by microscopic examination. A drop of mucus from within the vagina may be placed upon the slide, or the stains may be dissolved and mounted.

The old method of soaking and washing a fabric for seminal discharges often gives unreliable results. The following rules for the



Normal Semen.—(*Webster.*)

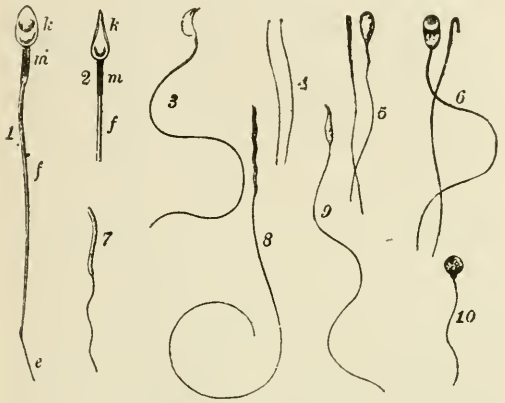
microscopic examination of supposed seminal stains are offered by Hamlin:

If the stain is upon any thin cotton, linen, silk, or woolen fabric, cut a piece about 1/8 inch square, lay it upon a slide previously moistened with a drop of water and let it soak for half an hour or so, renewing the water from time to time as it evaporates; then, with two needles, unravel, or fray out the threads at the corners, put on the glass cover, press it down firmly, and submit to the microscope. If the fabric is of such thickness or nature that it cannot be examined in this way, fold it through the center of the stain, and with a sharp knife shave off the projecting edge thus made, catching upon a slide moistened with water

the particles removed. After soaking from 5 to 10 minutes, the powdery mass will sink down through the water and rest upon the slide. The cover-glass may now be put on and the preparation examined. This latter method will serve well for semen on hairs. A circle of marine liquid glue run around the cover-glass will temporarily preserve the specimen. Carbolic acid or chloral hydrate may be added to the water, as a preservative.

A spermatozoon resembles somewhat the flagellate infusoria. It consists of an ovoid head tapering into a filamentary appendage, or tail, about 10 times as long as the head that, in fresh specimens, vibrates with astonishing rapidity. Spermatozoa vary in number and size, measuring, on an average, between 1/600 and 1/500 inch. The only living animalcule that might be mistaken for a spermatozoon is the trichomonas vaginalis, occasionally found in the vaginal mucus of unclean females. It, however, has a large ciliated head and a shorter tail.

The remarkable vitality of human spermatozoa is a well-recognized fact. The movements of the



SPERMATOZOA.—(*Landois.*)

1. Human (× 400), the head seen from the side. 2. On edge. *k.* Head. *m.* Middle piece. *f.* Tail. *e.* Terminal filament. 3. From the mouse. 4. From bothriocephalus latus. 5. From the deer. 6. From the mole. 7. From the green woodpecker. 8. From the black swan. 9. From a cross between a goldfinch and a canary. 10. From cobitis.

spermatozoa may be observed for as long as 72 hours at a suitable temperature. Piersol remarks that at a temperature of 8.5° C. a few of the elements showed movement after being kept for 9 days. These facts have certain medicolegal bearings.

SENEGA.—The dried root of *Polygala senega* (called also Seneca snakeroot), with properties due to a glucosid, senegin, which is identical with saponin, and closely allied to digitonin. Dose, 10 to 30 grains. It is expectorant and diuretic; in large doses a gastrointestinal irritant, and is useful in bronchitis, asthenic pneumonia, asthma, etc.

Preparations.—**S. Fluidextractum.** Dose, 10 to 30 minims. **S. Syrupus.** Dose, 1 to 2 drams. **Syrupus Scillæ Compositus,** contains 8 percent of senega.

SENNA.—The dried leaflets of *Cassia acutifolia* and *C. angustifolia.* Senna contains an amorphous glucosid, cathartic acid; other constituents are sennapicrin, sennacrol, cathartomannit, and chrysophanic acid. It is an excellent cathartic for children and infants. Senna acts chiefly on the small intestine, is not irritant in medicinal doses, and leaves no after-effect. However, it may cause hemorrhoids and hemorrhagia, if long continued. Its odor and taste are disagreeable, particularly in infusion. The least disagreeable of its preparations are confection of senna and compound licorice powder.

Preparations.—**Fluidextractum S.** Dose, 10 to 60 minims. **Syrupus S.,** has of the fluidextract 25, oil of coriander 1/2, syrup to 100. Dose, 1/2 to 2 drams. **Confectio S.,** has of senna 10, cassia fistula 16, tamarind 10, prune 7, fig 12, sugar 55 1/2, oil of coriander 1/2, water to 100; is sold under the trade names *Tamar Indien,* and *tropical fruit laxative.* Dose, 1/2 to 2 drams. **Infusum S. Compositum,** *black draught,* has of senna 6, manna 12, magnesium sulphate 12, fennel 2, boiling water 80, cold water to 100. Dose, 2 to 6 ounces. **Pulvis Glycyrrhizæ Compositus,** *compound licorice powder,* contains 18 percent of senna. Dose, 1/2 to 1 1/2 drams. See GLYCYRRHIZA. **Syrupus Sarsaparillæ Compositus,** *compound syrup of sarsaparilla,* contains 1 1/2 percent of the fluidextract of senna. Dose, 1 to 8 drams. See SARSAPARILLA.

SENSATION, DISORDERS.—These affect nerves of special or common sensibility, the lesion being either in the end-organ, in the afferent or efferent nerve, or in the ganglionic nerve-center. These sense of touch comprises the sensations of contact, pain, temperature. and muscular activity.

Hyperesthesia, as commonly understood, expresses increased sensibility only to painful impressions, and is better called hyperalgesia. The affected skin is sometimes so tender that a light touch will produce more or less exquisite pain, and the hyperesthesia is usually associated with excess of sensibility to heat and cold and a diminution of the sensibility to touch proper. In gunshot wounds of the nerves it is seen in its most severe form. Hyperesthesia is observed in connection with peripheral and central diseases of the nervous system, and is an accompaniment of neuritis; it is usually expressed in heightened sensibility to temperature.

Treatment.—The lesions causing the expression of perverted function must be discovered and treated. Local moist heat, as by fomentations or poultice; cold, by means of ice; dilute veratin ointment, atropin ointment, or hypodermic injections of morphin, may mitigate the condition. Spongiopilin sprinkled with a liniment of chloroform and belladonna (1:3), or equal parts of either, volatile salt, laudanum, and cologne water, may be applied. Lint soaked in chloroform and covered with oiled silk, or rubbing the part with camphor-chloral and vaselin in equal parts, may suffice.

Anesthesia may result from local abstraction of heat or from exposure to cold. Handling soda used in laundries and the various chemicals used in the

arts may induce anesthesia. In herpes zoster the skin between the groups of vesicles is often anesthetic. In leprosy the senses of temperature and of pain are often abolished. Pressure upon sensory or mixed nerves, as by syphilitic tumors or other growths, may produce anesthesia. Simple mechanic pressure will often excite an inflammation that is followed by anesthesia of the distributive area. Trauma may cause pain followed by anesthesia. Severe nervous trophic disorder is usually associated with anesthesia. Before attacks of neuralgia the skin of the part surrounding is anesthetic; and during attacks of sciatica, and in cervicobrachial neuralgia, there is much diminution of tactile sensibility.

Approaching hemorrhage is often heralded by cutaneous anesthesia. Sudden and increasing numbness in one side of the face or in the limbs of one side may be shortly followed by apoplexy or coma. This anesthesia remains as a subjective feeling of numbness, but the extent bears no relation to the amount of motor paralysis. Recovery proceeds downward, the fingers retaining slight anesthesia for some time after the arm is restored to normal sensation. Cerebral tumors, abscesses, or lesions of the spinal cord or of its membranes may give rise to cutaneous anesthesia. Cutaneous anesthesia affecting the soles of the feet occurs in tabes dorsalis.

It is extremely important to remember that cutaneous anesthesia connected with spinal disease is likely to result in bed sores and in trophic and vasomotor nerve affections. In peripheral neuritis anesthesia is of frequent occurrence. Auræ are often manifested by spots of local anesthesia.

Loss of the sense of muscular activity is especially noticeable in locomotor ataxia. It also occurs in general paresis, in hemiplegia, and in hysteria. As to diagnosis, the most important consideration is whether the causative lesion or disease is central or peripheral.

Treatment.—This is bound up with the treatment of the underlying cause. When the sensory nerves fail to conduct impressions for some time after the lesions that caused the anesthesia have healed, electricity, derived from an induction machine or the negative pole of a continuous-current battery may be employed. Static electricity is a valuable means of combating anesthesia of this kind.

Paresthesia.—The varieties of this disorder are very numerous. Heat may be felt as cold; a faradic current (intolerable to the healthy) may be felt as cold; pricks or pinches may be felt only as touches; feelings of burning, numbness, tingling, creeping of ants, or actual numbness are other manifestations. The senses of contact, pain, and temperature may be in abeyance. Movements may be guided by the muscular sense aided slightly by sight, etc.

SEPSIS.—Sepsis, or "blood poisoning," is a term used to designate sapremia, septic intoxication, septicemia, and pyemia. The former two are due to the presence of toxins alone in the blood (*toxemia*), and the latter two to the presence of toxins and bacteria (*bacteremia*). These toxins and organisms may be of any variety, but in the following paragraphs the terms septic intoxication and septicemia are defined in their restricted sense as referring to pyogenic toxins and pyogenic bacteria.

Sapremia is due to the absorption of the products of putrefaction; hence, properly speaking, autointoxication from decomposing intestinal contents is sapremia. Saprophytic organisms are rarely found alone in surgical affections, consequently a pure form of sapremia is rarely seen. The best example is that due to the absorption of ptomains from a decomposing placenta after childbirth, although a more or less pure form may be seen as the result of putrefaction of blood clots, wound secretions, or large tumors. Since sapremia is so frequently linked with other septic processes, and is clinically indistinguishable from septic intoxication, the term should be discarded.

Septic intoxication (*pyogenic toxemia*) is due to the absorption of pyogenic toxins. The usual cause is pus under pressure, *e. g.*, an unopened abscess or a badly drained, suppurating wound. As granulation tissue blocks lymphatic spaces, toxins are not readily absorbed from its surface, unless pressure be added; thus in a completely drained abscess there are no constitutional symptoms; if the drainage be defective, however, or if the lymph spaces be opened by curettage, absorption takes place. *Chronic septic intoxication* is hectic fever.

The **symptoms** appear usually in from one to three days, and vary in degree according to the character and virulence of the toxin, the amount of absorption, and the resistance of the individual. They manifest themselves as *fever*, or *pyrexia*, which is a syndrome characterized by a rise in temperature (often preceded by a chill), quickening of the pulse and respirations, headache, backache, diffuse muscular soreness, general weakness; by disordered secretions, causing dryness of the mouth, coating of the tongue, thirst, impaired appetite (sometimes vomiting), constipation or diarrhea, scanty high colored urine containing an excess of urea and urates, dryness of the skin or sweating; and by nervous disturbances varying from delirium to coma. There is a leukocytosis unless the intoxication is slight or overwhelming, but no organism in the blood. In the young and robust the symptoms are apt to be active (*sthenic fever*); in the debilitated, in the old, and even in the young (when protracted), they are apt to be of a low type and associated with marked exhaustion (*typhoid state, asthenic or adynamic fever*). The *local symptoms* are those of inflammation, and, if there be a wound, usually a copious and foul smelling discharge.

Septicemia (*pyogenic bacteremia*) is septic intoxication plus the presence of living pyogenic bacteria in the blood stream, and differs from pyemia only by the absence of secondary abscesses. The organisms gain entrance to the blood by the lymph vessels as the result of pressure in an abscess (*secondary septicemia*), or possibly in some cases pass directly into the open capillaries without the existence of suppuration (*primary septicemia*).

Cryptogenic septicemia presents no wound or focus of suppuration; a forgotten needle puncture, or an abrasion on the skin or one of the mucous membranes may be responsible for these cases, which become fewer as the surgeon increases in experience and investigates with more care. Bacteria in the circulating blood are devoured by the leukocytes, or dissolved by the bacteriolytic action of the blood serum, thus terminating the process; or, if sufficiently numerous or virulent, and especially if the individual has not sufficient resistance to manufacture antibacterial serums or opsonins, they multiply, continue to elaborate toxins, and are distributed to various parts of the body, where they may cause secondary or metastatic abscesses (pyemia); some are eliminated by the excretory organs, and some are destroyed by the tissue cells. There is no specific microorganism of septicemia, any one of the pyogenic bacteria seemingly being capable of producing the condition, although the streptococcus bears the worst reputation in this respect.

The symptoms may be noticed a few hours after a wound, or not for several days. There is usually a chill, with a rapid rise in temperature to 104° or 105° F.; the fever persists, being less in the morning and greater in the evening; in many cases there are violent chills at irregular periods, followed by high temperature and drenching sweats. The pulse increases in rapidity and decreases in tension. In severe cases the pulse rate reaches 150 or more, finally becoming so rapid and weak that it cannot be counted. There is often marked depression of the nervous system, the patient being stupid and quiet (typhoid state); or delirium, restlessness, picking at the bed clothes and twitching of the tendons; in either case coma precedes death. Although the respirations are quickened, signs of imperfect oxygenation of the blood are often seen in the face, which may be cyanotic. The tongue is dry, coated, red at the edges, pointed at the tip, and sordes are present upon its dorsum and upon the lips. There are loss of appetite, occasionally vomiting, often diarrhea. Petechiæ may appear in the skin and mucous membranes, and, owing to the disintegration of red blood cells, hematogenous jaundice may develop. The skin may present eruptions also in the form of vesicles or pustules, or simulating urticaria, measles, or scarlet fever. The urine is scanty, high colored, and contains albumin, toxins, and frequently bacteria; the spleen and often the liver are enlarged, and there may be leukocytosis. Bacteria may be discovered in the blood by cultural methods.

The local manifestations vary from slight inflammation to the graver forms of cellulitis and are not always characteristic, although in many cases the wound discharges a thin pus, while the activity of the lymphatic vessels is shown by red lines of lymphangitis running to the nearest lymph glands, which are swollen and tender, or even suppurating. The veins about a suppurating wound may become inflamed, and blocked with coagulated blood (thrombophlebitis). Bacteria may invade and soften this thrombus, portions of which may be washed into the blood stream as emboli.

Pyemia is septicemia plus secondary or metastatic abscesses, due to the bacteria lodging in various parts of the body, or to septic emboli the result of a thrombophlebitis; these abscesses may be found in any part of the body, but are most frequent in the bones, where bacteria are readily deposited from the capillaries owing to the slowly moving blood current, and in those organs which have terminal arteries, such as the brain, spleen, kidney, and lung. Emboli arising in the area drained by the portal vein lodge in the liver. Compared with preantiseptic days, pyemia is comparatively rare at the present time, but is especially prone to follow thrombophlebitis of the facial veins in infections in this neighborhood, thrombophlebitis of the lateral sinus the result of middle-ear disease, and pylephlebitis the result of inflammations about the rectum, appendix, etc.

The symptoms are those of septicemia, plus the secondary abscesses, which usually appear during the second week; they are generally announced by an additional chill, but may develop insidiously, sometimes without even pain or tenderness, and they are commonly small and multiple. Pyemia may run its course in a few days (*acute pyemia*), or it may last a number of months (*chronic pyemia*). It is usually fatal, although recovery has occurred despite the presence of secondary abscesses in the internal organs. In pyemia there is said to be a characteristic sweet odor not unlike that of hay.

Surgical scarlatina is the name given to the scarlet rash, probably the result of vasomotor disturbance, seen in cases of sepsis. True scarlatina may, however, occur after operations and accidental wounds, especially in children. Since the period of incubation is shorter than in the nonsurgical form, it may be that the microorganism of scarlet fever enters through the wound. Scarlet rashes may occur likewise from the absorption of ether, bichlorid of mercury, carbolic acid, and iodoform.

The diagnosis of sepsis is made by finding the causative lesion and excluding other febrile maladies. The *causative lesion* is sometimes difficult to locate, particularly in the so-called cryptogenic or spontaneous form, in which it may be necessary to review the entire body before finding the source of infection. Regions especially liable to be overlooked are the ear, teeth, throat, urethra, rectum, in women the pelvic organs, and in children the bones, particularly the tibia. An insignificant wound that has healed may be the starting point of even the gravest forms of sepsis, and, on the other hand, a wound, even if suppurating, may be complicated by other forms of fever. Here it should be noted that tonsillitis may be the cause, and pneumonia, endocarditis, etc., the result of sepsis. The *exclusion* of aseptic fever is made by the healthy appearance of the wound and the brief duration of the fever, of autointoxication by stimulating the excretory organs. When there is marked depression of the nervous system and general exhaustion, typhoid fever (Widal reaction, leukopenia) and miliary tuberculosis may be

simulated, while the occurrence of chills is often wrongly interpreted as malaria; in the last a blood examination will reveal the presence of malarial parasites. The occurrence of skin rashes, particularly in children, will bring up the question of the acute exanthemata, especially measles and scarlet fever. The *form of sepsis* is toxemia (sapremia or septic intoxication) if, in the presence of an inflamed or suppurating wound, the symptoms promptly subside after thorough drainage and disinfection. If the wound does not show evidences of irritation, the constitutional disturbance may be due to septicemia, but is more probably the result of some medical complication. The continuation of fever after the opening of an abscess or wound, excluding medical complications, usually means inefficient drainage, that is, a continuation of the septic intoxication, or, if the wound is perfectly drained, septicemia. In the latter instance, the absorption of bacteria may be evidenced by red and tender lymph vessels coursing along the surface and ending in inflamed lymph glands; the constitutional symptoms are more severe than in septic intoxication, and chills are more likely to occur. A positive diagnosis can be made only by recovery of the organisms from the blood stream, or from the excretions, particularly the urine. Leukocytosis occurs in all forms of sepsis, as does also iodophilia. The diagnosis of pyemia is made by the metastatic abscesses, which, when superficially situated, are easily detected; but when deeply seated in the viscera, they are apt to be small and numerous, and often their presence can only be suspected.

The treatment of sepsis is first *prophylaxis*. All wounds accidentally received should be carefully disinfected and the most scrupulous antiseptic or aseptic precautions taken during operations and the delivery of pregnant women. After labor the placenta should be carefully inspected to make sure that none of it has been left behind, after miscarriage curettage of the uterus is often done with the same end in view. It is important before operations also to increase the resistance of the patient by suitable treatment.

The local treatment is that of the causative lesion, viz., inflammation, suppuration, gangrene, etc. Uncomplicated sapremia or septic intoxication rapidly subsides if the local cause be found and removed. If the symptoms continue, all the putrefying material has not been removed, drainage is not efficient, or bacteria are elaborating toxins in the blood stream (septicemia). In the last the outlook is always grave, although, as has already been indicated, destruction of bacteria and recovery may follow. In pyemia secondary abscesses should be incised and drained, but unfortunately, in the viscera, this is often impracticable owing to their multiplicity. An accessible vein, the subject of thrombophlebitis, should be excised, or (*e. g.*, lateral sinus) opened, the clot removed, and the cavity packed with gauze; in order to prevent the further dissemination of septic emboli, the vein may be tied between the thrombus and the heart; in the extremities amputation may be required.

The general treatment is (1) specific, (2) eliminative, (3) symptomatic. (1) *Specific treatment* aims to destroy bacteria in the blood stream or to neutralize their toxins. Unfortunately, pyogenic bacteria in the blood stream are inaccessible. The *injection of antiseptics* into the circulation, in sufficient strength to be of value, is dangerous. *Antistreptococcic* serum, which at first seemed to give much promise, has been found to be ineffectual; it may, however, be employed in 10 c.c. doses repeated every 3 or 4 hours, particularly if bacteriological examinations prove the infection to be due to streptococci; like diphtheria antitoxin, which, too, has been used in septic conditions without success, it may produce erythematous or urticarial eruptions and pains in the joints, and several cases have been reported in which sudden death followed the injection of the serum. *Vaccine* treatment is still on trial. Quinin, iron, and large doses of alcohol (whisky or brandy) are regarded by many as almost specific in septic processes. (2) The most efficient means of combatting sepsis is by *elimination* of the microorganisms and their products. *Purgation*, especially by calomel and salines, lowers the blood pressure, drains off toxins through the bowel, and clears the intestinal tract of material which may be absorbed and aggravate the symptoms. If nature has anticipated the physician by the production of a diarrhea, such should not be checked unless excessive. *Diuretics*, such as calomel, caffeine, squill, sweet spirit of niter, acetate of potassium, and large quantitites of water by mouth or rectum, are of great value in removing toxins from the blood, in lowering temperature, and in reducing blood pressure. When both the stomach and rectum are irritable, the same principle may be utilized by injecting salt solution into the subcutaneous tissues, or, exceptionally, directly into a vein. *Diaphoretics* are not often used, as when they are indicated in septic conditions profuse sweats are generally present. *Venesection* is occasionally employed to lessen the amount of toxin in the circulating blood, especially when followed by the intravenous injection of salt solution. It should never be used in infancy, old age, or in the debilitated. (3) *Symptomatic treatment* depends upon the indications. Rest in bed, predigested liquid food, and proper nursing are always required in severe cases of sepsis. The best *anodyne*, if the condition is to last but a short time, is opium or one of its derivatives. In most surgical inflammations pain severe enough to prevent sleep calls for incision and drainage of the affected part. Nervousness is best met by the bromids, and sleeplessness not caused by pain, by sulphonal or trional. The cold-tar products and choral, because of their depressing effects, are usually to be avoided. The best *antipyretic* is an ice cap on the head, and general sponging with ice water, or equal parts of alcohol and water; drugs should be rarely employed. Persistent fever usually means that further search for the source of infection, with proper incisions, disinfection, and drainage, should be carried out. In many cases *stimulants*, such as alcohol, strychnin, ammonium carbonate, and

digitalis will be needed. (Stewart.) See Suppuration; Colon Bacillus Infection.

SEPTICEMIA.—See Sepsis.

SEPTIC INTOXICATION.—See Sepsis.

SEPTUM, NASAL.—See Nose (Deformities), Rhinitis (Chronic).

SEQUESTROTOMY.—See Bone (Disease).

SERPENTARIA (Snakeroot).—The roots of *Aristolochia serpentaria* and A. *reticulata*. Its properties are due to a volatile oil, a camphor-resin, and a bitter extractive. Serpentaria is a stimulant expectorant and a tonic; also a cardiac stimulant, a diaphoretic, diuretic, emmenagog, aphrodisiac, and somewhat of an antiperiodic. Its taste is warm and pungent, its odor characteristic. Dose, 10 to 30 grains. Large doses are irritant, causing nausea and vomiting, vertigo and headache, colic, borborygmi, rectal tenesmus, flatulent distention, and frequent but not watery stools. The irritant action seems to produce gas rather than fluid. Pruritus ani and hemorrhoids are occasionally caused by its use. Serpentaria is chiefly employed as a vehicle for other stimulant drugs.

Preparations.—S., Fluidextract. Dose, 10 to 30 minims. **S., Tinct.,** 20 percent in strength. Dose, 1/2 to 2 drams. **Compound Tincture of Cinchona** has 2 percent of serpentaria.

SERPENT VENOM.—The active principle of serpent venom is a toxalbumin analogous in character to the bacterial toxins. When taken by the mouth it is harmless. Venomous serpents are almost immune to serpent venom, non-venomous ones share this immunity in a less degree, and the mongoose and some other animals possess it in marked degree, probably by inheritance from many generations of bitten ancestors. Sewall in 1887 showed that pigeons can be immunized against crotalus venom by successive and increasing inoculations of the poison. Calmette discovered that the blood-serum of an animal so immunized is protective against the effects of the bite of a venomous serpent, and Fraser found that when immunization is performed with cobra venom the resulting serum is protective against the virus of several other serpent species.

Calmette's Antivenene is the recognized serum for serpent bites, and has been used successfully in many cases. While particularly effective against cobra venom it is less efficient against that of the crotalus and other vipers. Martin has shown that it is of no service for Australian serpents and McFarland for American snakes. The dose is 20 to 40 mils repeated frequently, but other recognized measures should not be neglected. A ligature should be applied above the wound, which should be laid open, well sucked, and surrounded by injections of an aqueous solution of calcium chlorid.

SERUM DISEASE.—See Serum Therapy and Vaccine Therapy.

SERUM THERAPY AND VACCINE THERAPY.—Serum therapy proper is the prophylactic and curative treatment of certain infectious diseases by the subcutaneous or intravenous administration of a blood-serum containing an antibody (antitoxic, bactericidal, etc.) which is specific to the particular disease. As generally used, however, the term includes also the treatment of some of these affections by vaccines and by the toxic products (toxins) of attenuated cultures of their respective microbes; but these toxins, though sometimes grown on blood-serum, may be produced on other media, and are never administered in a blood-serum, as the antibodies invariably are.

Antigens are substances which, when introduced into the organism, cause it to produce *antibodies*, which confer active immunity on the subjects against that particular antigen for a varying period of time; and in the case of the antitoxins, this blood-serum introduced into another individual, confers passive immunity on the latter. The antibodies now recognized are the antitoxins, bacteriolysins, opsonins, agglutinins and precipitins, the last two having no immunizing or therapeutic action, though of great value for diagnostic purposes.

Toxins are specific poisons produced by bacterial growth in suitable media, and when circulating in the organism they are the immediate causes of many of the symptoms of the acute infectious diseases. After the discovery of the bacillus tuberculosis other micro-organisms were found constantly associated with certain infectious diseases, notably tetanus, diphtheria, cholera, pneumonia, erysipelas and typhoid fever. The specific microbes of these affections were at first believed to be the immediate cause of their respective disorders, but later researches have shown that such diseases are due to the action of chemical poisons (toxins) produced by their specific bacteria growing on suitable soils either within the animal organism or outside it. The toxin produced by any particular bacterium varies greatly in power through very slight circumstances. It may be weakened or increased in virulence by the cultivation of its bacteria on different culture media or on the same media with different surroundings as to oxygen, temperature, etc.; also by passing successive generations of these organisms through a definite series of animals, chosen for their natural insusceptibility or susceptibility thereto. The pathogenic microbes of several diseases may be cultivated in test-tubes, forced to acquire an increased or lessened degree of virulence or toxin-producing power as required, separated from the poisonous products of their metabolic life-work, and by the inoculation of either their progeny or their chemical products (toxins) the corresponding diseases may be reproduced upon healthy animals in almost any desired degree of intensity.

The treatment of infectious diseases by their toxins is based upon the theory that the latter cause the organism to produce substances which are inimical to the bacteria producing them. The treatment of tuberculosis by Koch's tuberculin and the inoculations of Haffkine against cholera are examples of true toxin treatment. The vaccinations of Jenner for variola and of Pasteur for rabies are of the same nature when employed as remedial methods, the material being obtained from a morbid product of the disease in the one case and from the diseased tissue itself in the other,

the culture medium in both being the blood and tissues of the infected animal organism. Bacterial vaccines (Bacterins), contain some toxins, modified by heat, in addition to the killed bacteria. It has been frequently observed that patients afflicted with malignant disease have been greatly benefited by an intercurrent attack of erysipelas, in consequence of which the tumors seemed to undergo retrogressive changes. This has suggested the employment of the toxins of streptococcus erysipelatis and bacillus prodigiosus (Coley's fluid) in inoperable sarcoma, and may lead to the treatment of other diseases by the toxins of bacteria hitherto unassociated with them.

The injection of a toxin, in gradually increasing doses at proper intervals, will confer active immunity upon the animal so treated against the corresponding disease and its particular bacteria. This immunity may be passively transferred to another animal by injecting into its cellular tissue the blood-serum of the immunized one, and this serum will also act remedially on a subject of the disease if administered early in its course (Behring). The immunizing and curative action of the serum is believed to be due to the existence of an antibody in the blood of the inoculated animal, elaborated by the living cells of its tissues as a defence against the action of the toxin. These facts and hypotheses form the basis of the treatment of certain diseases by antitoxic and bactericidal sera.

Antitoxins are produced in the blood by the cells of the organism when certain bacterial toxins are injected into it at definite intervals and in increasing quantity. They are highly specific, *i. e.*, effective only against the particular toxin producing them, which they neutralize *in vitro* as well as in the organism, by combining therewith according to the law of multiples. This action is best explained by Ehrlich's side-chain theory, which is briefly as follows: Every toxin molecule consists of a *toxophore* or poisonous part, and a *haptophore* or combining one. The latter unites with the albumin molecule (receptor) of the cell, with which it has the greatest affinity, forming a side-chain thereof. By the frequent repetition of this process the cell is stimulated to excess production of receptors, which, uncombined with toxin, are thrown off into the blood and tissues. These excess receptors constitute the antitoxin, which circulate in the blood and are ready to combine with fresh toxin on its introduction or formation in the body, before it is able to damage the cells of the organism.

The discovery that the blood-serum of an immunized animal may be successfully employed for curative as well as prophylactic purposes against its particular disease upon other animals of the same or different species, was made by Behring in 1891. This was no chance discovery but was the legitimate result of logical reasoning and hard work, and is formulated under the title *Behring's Law*, as follows: The blood-serum of an animal which has been artificially rendered immune against a certain infectious disease, when injected into the body of another animal, has power to protect the latter individual against the same disease and to cure the disease after infection has occurred.

The chief representatives of the antitoxic sera are those of diphtheria and tetanus, though antitoxins for other disease are recognized, and have been used with varying effect. Among the latter are antitoxins for hay fever, tuberculosis, symptomatic anthrax, snake venom, spider and scorpion poisons, and certain poisons in fish and plants. The only antitoxins official in the U. S. P. are those of diphtheria and tetanus.

An antitoxic serum is prepared as follows: A highly virulent culture of the specific micro-organism of the particular disease, or still better, a strong toxin of tested strength prepared therefrom, is injected into the cellular tissue of a suitable animal, generally a horse, at first in very small quantity. The effect is soon shown by the onset of fever and other symptoms of acute disease, which are known as the "reaction." After an interval of time sufficient for recovery from these symptoms, the injection is repeated with a stronger toxin or with a culture of greater virulence, or with a larger quantity of the original toxin. This process is continued for several months, or until the animal no longer "reacts" to the poison, and then sufficient antitoxin is presumed to exist in its blood to render it immune to the toxin and to the disease. After each inoculation the animal's blood-serum is tested as to its value by experiment on guinea-pigs of definite weights. When the desired degree of immunity is reached the animal is bled from the jugular vein under strict aseptic precautions, from 6 to 12 pints being taken from a horse, according to his size and general condition. The blood is received in sterilized flasks, which are carefully stoppered and stored on ice until the clot has separated from the serum. The latter is tested to determine its value in antitoxin, has phenol added to it in the proportion of 0.5 percent, and is bottled in vials which contain in each the dose for one patient. The vials are labeled with a statement of the number of normal antitoxin units per c.c. of the contents, expressed in multiples of a standard normal serum.

Serum Intoxication.—The use of therapeutic serum is sometimes attended by certain unpleasant and even alarming symptoms, due probably to the introduction of a foreign serum and not to any specific action of the antibodies contained. It is probable, therefore, that the magnitude of the dose injected bears no relation to the occurrence or severity of such by-effects. In about 20 percent of all the cases in man the injection of serum produces a temporary intoxication in which any or all of the following symptoms may be present: fever, itching, urticaria and other skin eruptions, glandular enlargements, pains in the joints, edema and albuminuria. These symptoms develop in from 8 to 12 days after the injection. They occur after the first injection, whereas anaphylaxis (in animals) manifests itself only after the second injection. Previous injections, however, predispose an individual to "*serum intoxication*" or "*serum disease*," as it is called, in direct proportion to the number of previous injections. The symptoms of serum disease subside in a short time and leave no bad effects.

Anaphylaxis.—Serum disease is not to be con-

founded with the condition called *"anaphylaxis"* or *"allergie."* If a guinea-pig is injected with a small quantity of horse serum and, after the expiration of a certain interval, is again injected with horse serum, the result will probably be fatal. The first injection has sensitized the animal in such a way as to render it abnormally susceptible to the second injection. Other proteid substances, such as egg albumen, have the same effect as normal serum. Anaphylaxis may be defined as a hypersensitive condition induced by the injection of normal, foreign horse serum or other proteid substance. The hypersensitive condition is manifested after the second injection, separated from the first injection by a certain interval which may be called the period of incubation, and death may sometimes result. The first injection itself produces no symptoms, and, as stated, the condition is not identical with serum intoxication, which develops after a first injection of serum. The very rare instances of sudden death following a single injection of diphtheria antitoxin are sometimes attributed to anaphylaxis, but no sufficient proof in support of this explanation has been furnished. The extreme rarity of the accident—about one case in 400,000 injected with diphtheria antitoxin —would appear to indicate that death is due to some extrinsic cause, such as fright or congenital hypersensitiveness to the trauma of the injection, rather than to any toxic property of the serum, or else to some as yet undiscovered biologic reaction. Diphtheria antitoxin, even in massive doses, is in itself absolutely harmless.

Bacteriolysins form one division of the Cytolysins, antibodies which possess the property of dissolving cellular elements under particular conditions, and occur in the blood as a result of the reaction following the injection of cellular elements as antigens. The dissolving action of the bacteriolysin depends on the presence of two bodies, the *complement* (alexin, cytase), also present in normal blood-serum, and the *amboceptor* (immune body), which is present in the immunized serum, and acts to prepare the bacteria so that the complement can act dissolvingly upon them. Usually there is not enough complement present in the immunized serum to effect bacteriolysis, and more is added by mixing normal serum with the immunized serum before administration.

Opsonins (Bacteriotropins) are chemical substances existing in the blood-serum of animals immunized against streptococci, pneumococci, etc., which have neither an antitoxic nor a bacteriolytic action, yet confer immunity against the same infection when introduced into the blood of other animals. Denys (1895) showed that bacteria treated with sera containing these substances are taken up and digested by the leucocytes. Wright (1903) found similar substances in normal blood-serum, and called them *Opsonins*, because they prepare the bacteria for the devouring action of the phagocytes. He devised a method of ascertaining the opsonic value of any particular blood-serum, which, when compared with that of normal serum, gives the *Opsonic Index* of the individual for any particular infectious disease. He also made the important discovery that the opsonic power of the blood in infectious disease may be raised and maintained at a high level by injecting a killed (sterilized) culture of the same bacteria that are doing the mischief. This is the basis of the modern vaccine-therapy, the so-called *Bacterial Vaccines* of today being suspensions in salt solution of the same bacteria which have caused the patient's infection, and have been killed (sterilized) and accurately measured as to the number present in the vaccine. The determination of the opsonic index is technically very difficult for the general practitioner, and is subject to such variations that it is not available usually as a diagnostic or prognostic guide, and even among trained bacteriologists there is considerable skepticism as to its practical value, though it undoubtedly gives a clue to the probable infecting agent in obscure cases.

Bacterial Vaccines (Bacterins).—The term *vaccine* was originally applied to the infective virus or antigen of vaccinia (cow-pox), but in modern usage has been extended to include the antigens of all infectious diseases. In the preparation of stock vaccines the pathogenic bacteria are grown in pure culture, then killed by heat, suspended with their toxin in sterile physiological salt solution, protected from contamination by an antiseptic, and standardized to contain a definite number of bacteria in each milliliter. They are used by injection, subcutaneously or intravenously, to develop in the patient's body a condition of active immunity against the corresponding pathogenic germs or their toxins, by raising the opsonic value of his blood, and thereby promoting the phagocytosis of invading bacteria. The advantage of this active immunization for prophylactic purposes depends on the facts that these vaccines are incomparably cheaper and simpler to prepare than the sera, and that the active immunity conferred by them is more durable than the passive immunity produced by the latter. On the other hand their immunity does not set in immediately as is the case with the passive form, but only after 8 to 14 days of treatment.

This method of immunization was first tried by Ferran in 1884, who attempted protective vaccination with artificial cholera cultures during a great epidemic of cholera in Spain, but with poor results. Haffkine, using pure cultures attenuated by warmth, conferred immunity against cholera on many thousands of persons in India. Pfeiffer and Kolle placed the method of vaccination with killed bacteria on a scientific basis and put it to practical test against cholera in Japan in 1902.

The prophylactic use of bacterial vaccines has been most successfully applied against anthrax (in domestic animals), symptomatic anthrax (rauschbrand), and the infections of typhoid fever, cholera and plague. Its therapeutic employment is applied to those diseases which are combated by phagocytosis and not by bacteriolytic or antitoxic action, including the infections caused by the staphylococcus, streptococcus, pneumococcus, gonococcus, and the bacilli of tuberculosis, influenza, and the colon bacillus. Vaccine therapy has met with success in gonorrheal arthritis, also in pneu-

mococcic and staphylococcic infections, especially the latter, and is of value in pulmonary tuberculosis with mixed infection.

Stock vaccines must be used in cases of tuberculous and gonorrheal infection, because of the technical difficulties encountered in growing their germs; and stock vaccines of the staphylococci will, in most cases, give about as good results as personal (autogenous) ones. For all other germs the latter are superior to the stock vaccines.

Recently an improved type of vaccine has been brought forth and spoken of as a sensitized vaccine. In its preparation the bacteria are treated with the serum from animals immunized against the same organism. Sensitized bacterial vaccines are claimed to be more efficient in producing active immunity which occurs more quickly and lasts longer and the local and general reactions are greatly reduced or eliminated (Besredka).

The blood, then, has three principal methods of resisting bacterial invasion: (1) an antitoxic action, (2) a bacteria dissolving (bacteriolytic) action, (3) a phagocytic action; so that it opposes the pathogenic germs by neutralizing the toxins generated by some varieties, by dissolving others, and by destroying other bacteria by the devouring action of the white blood-cells. The Antitoxins effect the first method, the Bacteriolysins accomplish the second, and the Opsonins promote the third. The principal affections which have been found eligible to the prophylactic or therapeutic influence of these agents are considered under the titles of these diseases. See Diphtheria, Tetanus, Tuberculosis, Sarcoma, Streptococcus Infections, Staphylococcus Infections, Gonococcus Infections, Pneumococcus Infections, Cerebrospinal Meningitis, Typhoid Fever, Cholera Asiatica, Plague, Rabies, Syphilis, Serpent Venom, and Mallein.

Normal Serum.—The injection of normal horse serum will check hemorrhage when other methods have failed, supplying in hemophilia the principle which promotes coagulation. Its use in hemorrhagic conditions is not based upon any specific immunity content but rather upon the supplying of some material necessary to promote coagulation. Its injection is followed, in some instances, by urticaria, subnormal temperature, rapid pulse, rapid breathing, and in some instances cyanosis and collapse. It may cause a fatality, although this event is rare. It is more common for a slight urticarial rash with joint pains to occur from a few days to two weeks after the injection. Dose, 10 to 50 mils subcutaneously. And see Immunity.

SEWAGE DISPOSAL.—Sewage consists of human excreta, solid and liquid, together with house, factory and street waters and impurities. The mixture of feces and urine undergoes rapid putrefaction, resulting in gas formation (marsh-gas, ammonium sulphid, sulphuretted hydrogen, etc.). The urea of the urine is rapidly transformed into ammonium carbonate and then into ammonia. The bacteria present are chiefly the spirillum rugula, spirillum amyliferum; bacillus butyricus, bacillus putrificus coli, bacillus proteus sulphureus, bacillus proteus vulgaris, bacillus sulphureus, bacillus lactis aërogenes; and the micrococcus ureæ. Pathogenic microorganisms, such as the bacillus typhosus, choleræ, dysenteriæ (Shiga) and streptococci and staphylococci, may be present.

No crude sewage should be discharged into a stream or river. Though in time such sewage would be purified if largely diluted, the water would be rendered unfit for drinking purposes. In towns on the sea coast sewage may be discharged directly into the sea, provided precautions are taken to prevent its being cast up by the tide or carried by currents along the coast. To obviate such dangers the outfall should be so placed that the currents may carry the sewage away from the town, the mouth of the outfall sewer being guarded by a valve and opening below the level of the water. In low-lying towns where any fall for sewage is impossible, one of the pneumatic methods of removing sewage is advisable. The Shone system acts by means of compressed air sent out from a central station. The sewage is received into ejectors into which, when full, the compressed air is admitted by a valve and forces out the sewage. In the Liernur and Berlier systems the motive power is suction; a vacuum is produced at the central station and the sewage is sucked through an air-tight system of sewers to the central reservoir.

Methods of Application to Land

(1) **Broad Irrigation.**—This consists in the distribution of sewage over a large area of soil and is applicable to towns which can procure land of adequate size (one acre to every 100 to 200 people) and of suitable quality. Percolation of the sewage through the soil is provided for and stagnation is prevented by subsoil drains, unless the land is very porous. The sewage must be applied intermittently so as not to interfere with aeration of the soil. Large crops of Italian rye grass, roots (mangold) and cabbage may be obtained from a sewage farm.

(2) **Filtration.**—The increasing cost of land has led to the use of an equally effective but cheaper method—that of intermittent downward filtration on a small surface of especially porous land called a bacterial bed. The best soil is one rich in lime or alumina or hydrated iron oxid. The land is underdrained with porous tile drains and divided into sections, each of which receives screened sewage for 6 hours and rests the other 18 hours of each day. The process is that of oxidation and nitrification by microorganisms through the mechanical filter of the soil. This method is applicable to the sewage of considerably less than 1000 persons per acre. Usually the land is divided into ridges, upon which vegetables are grown, and furrows, down which the sewage flows.

If there is not sufficient land available to provide one acre for the sewage of each 1000 persons, preliminary treatment is necessary before the disposal on land:

Sedimentation and Chemical Precipitation.—The sewage is treated with lime (about 12 grains to the

gallon of sewage), or protosulphate of iron (2 to 5 grains per gallon), or sulphate of aluminum (about 5 grains per gallon) in settling tanks, having preferably a conical bottom, in order to remove suspended matters. The supernatant liquid is then applied to the land, or passed intermittently through special filters of sand, coke, coke-breeze, etc., or discharged into a large river or the sea. The sludge is generally partly rid of moisture by hydraulic filter presses and drying machines and used as manure. By this treatment the sewage of 2000 to 5000 persons can be disposed of on one acre of land. In London before the sewage is discharged into the sea it is treated with lime and sulphate of iron. Combinations of iron and alum, or alum and lime are also in use.

Biologic Purification.—Depending on the principle that the decomposition and purification of sewage, which is chiefly organic matter, is essentially due to the action of microorganisms, newer methods than chemical treatment and land application have been adopted. These have the advantages of greater efficiency and marked reduction in the amount of sludge and in the expense and labor involved.

In the changes occurring in sewage there are mainly two stages. The first is a process of digestion in which the anaerobes (microorganisms living without oxygen) play the chief rôle—the solid organic matter becomes liquefied, nonnitrogenous matter is reduced, albuminoid substances are peptonized; the second stage is one of oxidation, mineralization and nitrification, the ultimate result being mineral matters and gases—in this stage the work is done largely by the aerobes (oxygen-requiring microorganisms). The various types of installation in use at present are based upon the principle of separating these stages, with a view to placing the two main groups of microorganisms in the most favorable conditions for work. The first stage is allowed to take place in a digestive tank under strictly anaerobic conditions, while the second stage is effected during the passage through one or more aerating contact or filter-beds. Aerating filter-beds known as "streaming filters" are preferably constructed of coke, clinkers, flint, burnt ballast, coal, refuse pottery, and, less effectively, of sand or gravel. They have open outlets and afford the best means of securing efficient oxygenation of the effluent.

Before entering the installation the sewage must always be passed through a "grit chamber" to be freed from all large mineral particles. When the crude sewage is highly offensive as a result of wastes from breweries, preliminary treatment in slate beds is advisable.

The Scott-Moncrieff installation includes two or more "cultivation tanks" filled with large stones at the bottom and small above. The sewage passes to a false bottom on the floor of the tanks and escapes at the top. The effluent flows into a series of nitrification channels filled with large stones and exposed to the air. A modification of this system has a series of perforated trays containing filtering media over which the effluent slowly falls.

The Sutton System advocated by Mr. Dibdin consists of straining, then downward filtration through coarse beds of burnt ballast 4 feet deep. The effluent passes into five filters 4 feet deep where it rests for 2 hours. These contact beds are emptied slowly and then allowed to rest several hours. By this intermittent application aeration is provided for. In a modification of this system the sewage rests 4 hours in the coarse beds and 2 hours in the fine beds (treatment in a series of which is more effective to that in merely one).

The Septic Tank Method.—The sewage enters a covered tank where it remains for a day under anaerobic conditions (rest and absence of air and light) and becomes liquefied. The effluent passes through the outlet and along a trough or aerator over the edge of which it falls in a thin film, combining with air to a certain degree, upon a series of coke-breeze filter-beds 4 1/2 feet deep. Each filter is filled in 6 hours, then after 6 hours of rest it is emptied in a half hour and then left empty for aeration the remainder of the 24 hours. Small septic tank disposal plants have been installed effectively for the sewage of large houses.

Antiseptic Methods.—A purified effluent should be inodorous and not liable to undergo putrefaction. It is always potentially dangerous, however, for pathogenic organisms may still be present. Therefore prior to being thrown into a running stream, it is generally passed from the installation through a special sand filter or applied to land. Even then if discharged into waters where watercress is grown or oysters or other shell fish are laid, there is danger of contamination. The question of sterilization of the effluent has given rise to considerable study. Antiseptics and deodorants are advised and may be used to advantage if they do not interfere with the work of the microorganisms. In the A B C process alum, blood, clay and charcoal are used. Manganate of sodium and sulphuric acid are advocated. The Amines process consists of the addition of milk of lime and herring brine. Chlorin, either as chlorid of lime or gas, seems to be the most practical antiseptic. In the oxychlorid method, sea water or salt solution is decomposed electrically. In one hour 3 1/4 gallons are said to partially sterilize 1000 gallons of effluent from a biologic instillation. This treatment is claimed to render sewage effluent practically free from intestinal organisms.

SHINGLES.—See HERPES ZOSTER.

SHOCK.—Shock is a general prostration of the vital powers the result of injury or emotion. *Local shock* is numbness or anesthesia of a part which has been injured, and is seen most frequently in gunshot wounds. *Collapse* is the final stage of shock, or sudden profound shock coming on acutely. *Exhaustion* presents similar symptoms to shock, but comes on gradually, often following some exhaustive disease, such as carcinoma or tuberculosis.

The causes of shock are afferent impulses transmitted along the sensory or sympathetic nerves, or

in emotional shock along the nerves of special sense, to the vital centers, especially the vasomotor centers, which are thus weakened or exhausted (shock), or paralyzed (collapse); consequently there are marked lowering of the blood pressure, weakening of the propelling force of the heart and arteries, collection of the blood in the veins, especially the large abdominal veins, and anemia of the brain, lungs, and superficial parts of the body.

The **symptoms** vary in intensity according to the severity and situation of the injury, the psychical condition, age, sex (women are more susceptible) and previous general condition of the patient, and according to various other factors, such as hemorrhage, exposure to cold, etc. In *torpid* or *apathetic shock* there are marked pallor of the skin and mucous membranes, cold clammy perspiration, elongated, pinched, expressionless face, half open mouth, half closed shrunken eyes, lusterless cornea, dilated pupils reacting slowly to light, weak and rapid pulse, accelerated (occasionally slow) shallow and irregular respirations, mental apathy, subnormal temperature, impaired sensation of the skin, retention of urine, and sometimes incontinence of feces. If the shock is due to or aggravated by hemorrhage, there may be great restlessness and other symptoms commonly associated with the loss of a large quantity of blood. During the period of reaction there may be vomiting, great restlessness or excitement, and even delirium (*erethistic shock*), particularly in conditions like extensive burns, in which a toxic factor is added. Shock which does not appear for several hours (*delayed* or *secondary shock*) is most frequently seen after railway accidents, alcoholic intoxication, and severe emotional storms. After operation *delayed shock* is almost always due to hemorrhage.

The symptoms of hemorrhage are practically identical with those of shock, in fact the condition after hemorrhage is shock due to loss of blood. In concealed hemorrhage one does not see the blood, and the question arises whether the symptoms are due to shock alone, or to shock the result of hemorrhage. In hemorrhage there is apt to be greater restlessness, and instead of torpidity, great anxiety and foreboding on the part of the patient who complains of loss of sight, asks for water, and gasps for air; the skin and mucous membranes are excessively pale, and the pulse, although very frequent, is likely to be larger and more compressible than that of shock. The hemoglobin is greatly lessened in hemorrhage (but not for a number of hours) and unreduced in shock. The most reliable signs are those of fluid in a cavity, *i. e.*, in the chest or abdomen. In case of doubt, especially after an abdominal operation or injury, an exploratory incision should be made.

The **prophylaxis** of shock is possible in surgical operation. In addition to reassuring a nervous patient, the physical condition may be improved. With the patient in poor condition, shock may be anticipated by the application of warm water bags, the hypodermatic injection of strychnin and atropin, the careful covering of the patient during operation, the avoidance of excessive purgation and prolonged abstention from food before operation, and by celerity, gentleness, and careful hemostasis during the operation. The part to be operated upon may be placed in a slightly higher position than the rest of the body in order to lessen hemorrhage. The use of a local anesthetic for the prevention of shock in extensive operations is of doubtful value, as the fright of the patient, and the increased time necessary for the performance of the operation, owing to the struggles of the patient more than counter-balance any depressing influence of a general anesthetic. In head operations Crile applies a temporary clamp to the carotid, places the patient in a pneumatic rubber suit, and elevates the upper part of the body 45°. In operations on the dangerous area of the larynx, in which sudden collapse may follow from reflex inhibition of the heart and respiration as the result of stimulation of the superior laryngeal nerve, he advises a preliminary dose of atropin, or the application of cocain to the nerve endings in the pharynx; in the extremities he blocks the nerve trunks by injecting into them cocain.

The **treatment** of shock consists in raising the feet and lowering the head; the application of carefully protected warm-water bags; the hypodermatic injection of ether 1 dram, brandy 1 dram, strychnin grain 1/20, digitalin grain 1/10, atropin grain 1/100, ergotin 10 minims, or camphorated oil 1 dram, inhalations of ammonia, alcohol, or oxygen; the rectal injection (enteroclysis) of hot coffee 1 pint, whisky 1 ounce, or turpentine 1/2 ounce with salt solution; and autotransfusion, hypodermoclysis, or intravenous infusion of adrenalin chlorid in the strength of from 1 to 50,000 to 1 to 100,000 in salt solution. As a rule from 10 minims to a half dram of a 1 to 1000 solution is dropped into two quarts of salt solution, which is slowly injected into a vein. *Autotransfusion* is the application of bandages to the extremities for the purpose of driving the blood to the vital centers. Crile uses the same principle by the application of a rubber suit, which is blown up with a bicycle pump. Mustard plasters may be put over the heart and on the extremities, and stretching the sphincter ani has been recommended. If the respirations fail despite stimulation, artificial respiration should be performed. Transfusion of blood and massage of the heart have been employed in a few cases. Operations are not, as a rule, performed during the presence of shock, unless it is known that the shock is being increased by the condition for which the operation would be performed, *e. g.*, hemorrhage, perforation of a hollow viscus, and some cases of crushed extremities (Stewart). See COLLAPSE; EXHAUSTION; and INFUSION OF SALINE SOLUTIONS.

SHOULDER, AMPUTATION. The Flap Method.—The patient is placed on a firm table, with the arm well raised and projecting beyond its edge; the subclavian artery being compressed, the operator enters a long, narrow, straight bistoury at the anterior margin of the deltoid muscle, if it is the right arm, an inch below the acromion. From this point he thrusts it through the muscle, across

the outside of the joint, and brings it out at the posterior margin of the axilla. If the left arm is operated on, the knife must be entered at the posterior margin of the axilla and brought out at the anterior margin of the deltoid. Then, by cutting downward and outward the external flap is made. The arm is then brought down to the side and forcibly adducted; the origins of the biceps and triceps and the insertions of the infraspinatus and supraspinatus are cut through and the joint laid open. Finally, the blade of the knife, being passed through the joint and placed on the inner side of the head of the bone, is made to cut an inner flap of the same shape, but rather shorter than the outer one.

Oval Method.—In order to control hemorrhage, pins similar to those already described for amputation of the HIP-JOINT (*q. v.*) are now employed: one to be passed through the pectoralis major muscle and brought out in front of the acromion process; the other passed through the latissimus dorsi muscle and brought out back of the acromion. The points are to be protected by cork. The rubber band is to be put on above the line of operation, and is to be removed as soon as the limb is amputated and the vessels secured. Make a straight incision immediately beneath the acromion process, and a little toward the anterior border of the axilla, with a moderate-sized amputating knife, which should reach down to the bone, and should be between 2 1/2 and 3 inches in length; from the lower end of this incision two others are prolonged, the first passing in a curved direction downward and backward, and the second forward toward the folds of the axilla, the blood-vessels and the inner or axillary aspect of the arm remaining untouched. The flaps are then dissected back, including the muscles and exposing the joint. The head of the bone is then disarticulated by cutting upon the tuberosities, the arm being rotated inward and outward The arm is then adducted, throwing the head of the humerus outward, and the knife is passed to the inner side and carried downward close to the bone, an assistant at the same time compressing the artery. Then the tissues between the axillary folds are divided by an oblique cut from within outward so as to form part of the internal incision.

The axillary artery and branches of the anterior and posterior circumflex and of the suprascapular arteries are to be tied.

SHOULDER, DISLOCATION.—Shoulder-joint dislocations are quite frequent, and are usually readily diagnosed, but sometimes evade recognition.

Forward luxation of the humerus is the most frequent of the shoulder dislocations, and, according to the degree of displacement, is described as **preglenoid, subcoracoid,** and **subclavian;** the degree termed subcoracoid is most common. Sometimes the dislocation is somewhat forward and downward (infraglenoid) primarily, and becomes subcoracoid by a secondary displacement.

Forward displacement may result from direct violence, as a sharp blow on the shoulder from the side and behind; but generally results from indirect violence, as pushing the elevated arm powerfully backward. Occasionally, muscular action (hurling a stone) may produce it.

The symptoms of subcoracoid dislocation are characteristic: the head of the bone is absent from the glenoid fossa and presents beneath the coracoid process; the rounded outline of the shoulder has disappeared, the acromion hanging over and forming an angular projection; the long axis of the arm passes under the coracoid process instead of beneath the acromion; as a result, the arm is held abducted; the elbow can be pressed against the body, but on being released springs back immediately to its abducted position (elastic fixation). The outer contour of the arm is no longer almost straight, but forms an angle opening outward, with its apex at the humeral insertion of the deltoid. Voluntary movements are much restricted and passive movements are limited and painful.

Injuries to the blood-vessels are rare; the nerves are put on the stretch, and are sometimes injured, especially the circumflex nerve, resulting in serious injury to, and sometimes atrophy of, the deltoid muscle.

In making the **diagnosis** the following conditions must be differentiated:

Paralysis of the deltoid, with descent of the arm; fracture of the acromion; upward dislocation of the acromial end of the clavicle; fracture of the neck of the scapula; and fracture of the neck of the humerus.

Treatment.—Kocher's method is always to be attempted: first, without an anesthetic; and, if unsuccessful, then with an anesthetic. It is uniformly successful except in cases of very extensive laceration of the capsule. This procedure is as follows: The elbow, fixed at a right angle, is pressed closely against the side; the forearm is next turned as far as possible away from the trunk, causing external rotation of the bone-head; the elbow is next carried across the chest, forward and upward, the external rotation of the bone-head being meanwhile maintained; and, finally, the hand is placed on the opposite shoulder, producing inward rotation. It may be useful to have an assistant press the head outward with the fingers during the latter manipulation. The classic method of Sir Astley Cooper is also of service in some cases (traction upon the arm in the longitudinal direction, with simultaneous pressure of the foot—unshod—in the axilla, making direct pressure on the head).

After reduction, the arm should be fixed by slings or bandages (Velpeau's) so that the head of the injured side rests on the opposite shoulder.

Upward (supracoracoid) dislocation is extremely rare, and is always associated with fracture of the coracoid process.

Downward (subglenoid or axillary) dislocation is usually the result of a fall upon the hand or elbow with the arm raised. The appearance is characteristic: the bone-head can be felt in the axilla, and

when the arm is raised at right angles, the change in axial line, together with the empty socket and the overhanging and prominent acromion, make the condition evident.

A subvariety of this injury is the *luxatio erecta*, in which the arm is directed upward, with the forearm held behind the head to avoid pain. Reduction is easily effected by traction on the arm, together with direct outward pressure against the bone-head.

The following useful table (Pick) will aid in diagnosing the various forms of dislocation of the shoulder:

	Direction of the Axis of the Limb.	Alteration in the Length of the Limb.	Presence of the Head of the Bone in New Situation.
Subcoracoid.	The elbow is carried backward and slightly away from the side.	Very slight lengthening.	The head of the bone cannot easily be felt; if it can, it is found at the upper and inner part of the axilla.
Subglenoid..	The elbow is carried away from the trunk and slightly backward.	Very considerable lengthening.	The head of the bone can easily be felt in the axilla.
Subspinous..	The elbow is raised from the side and carried forward.	Lengthening intermediate in degree between the subglenoid and the subcoracoid.	The head of the bone can be felt and be grasped beneath the spine of the scapual.
Subclavicular.	The elbow is carried outward and backward.	Shortening....	The head of the bone can readily be seen and be felt beneath the clavicle.

Backward (retroglenoid, subacromial, subspinous) dislocation is very rare, and is usually the result of direct force. The prominence of the bone-head in its new position and the projection of the coracoid process make the diagnosis easy. Traction, together with adduction and direct pressure, effects reduction.

Irreducible Dislocations.—When dislocation is accompanied by fracture of the humeral shaft or fracture below the anatomic neck—as by the separation of the tuberosities, or by a dislocation of the long head of the biceps, with its twining about the humeral head—primary reduction may be accompanied by insurmountable difficulties. Under these circumstances there can hardly be a question about the propriety of immediate operation. The very brilliant result obtained by McBurney and others by the use of a bone hook inserted into the upper fragment through an open incision, thereby making reduction of the dislocated head feasible, will in the future justify like procedures in all similar cases. In unreduced dislocations of older date the question of operative interference must be entirely determined by the degree of disability entailed. When this is slight, and the patient is able to gain a livelihood, and when pressure-symptoms produced by the dislocated head are absent, the advisability of operative interference must be questioned, particularly if the dislocation is one of more than two or three months standing. Positive indications for operative interference are pressure upon the vascular or nerve-trunks with which the head of the humerus has formed new relations.

The present status of the question of operative interference in shoulder luxations may be summarized as follows (Ransohoff):

1. Immediate operative interference is indicated when the ordinary methods by manipulation under anesthesia have failed.

2. In irreducible dislocations operations should not be delayed until irremediable changes have taken place in the capsule and about the humeral head. In comparatively recent cases arthrotomy offers the best results.

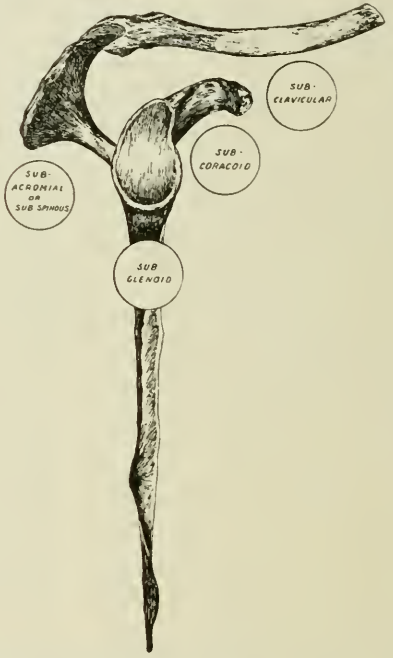


Diagram of Most Common Varieties of Dislocation of the Shoulder.—(*Thomson and Miles' Manual of Surgery*).

3. In long standing cases the conditions found must determine the choice between arthrotomy and resection.

4. In unrecognized dislocations of long standing—one year or over—only grave compression symptoms must be recognized as indications for interference.

5. Special attention must be given to the prevention of sepsis, since, in a very large proportion

of cases recorded, sepsis has been either the cause of death, or, by the destruction of the humeral head or obliteration of the joint cavity, has frustrated the very object of the operation.

SHOULDER, EXCISION.—This may be required for injury or disease. Ankylosis is compensated for so thoroughly by the mobility of the scapula that it is a question whether operation is advisable. It has also been performed for unreduced dislocation in which the head of the bone was resting upon the brachial plexus, and for tumors in connection with the upper extremity of the humerus.

The usual incision is vertical, between 3 and 4 inches in length, beginning just outside the coracoid process, on a level with it, and carried through the skin, fascia, and deltoid, down to the bone. If the arm is rotated outward and the soft part drawn to the sides, the tendon of the biceps is exposed at the bottom. This should be preserved, if possible; sometimes it is in a pulpy condition, or has already been eroded, and occasionally it is fixed firmly to the bone in its groove, and the upper end of it is lost. The capsule is then freely opened and the condition of the parts examined before determining how much it is necessary to take away.

So far as the subsequent utility of the limb is concerned, there is no doubt that the more of the bone that is left, the better. Partial resections (in which some of the head is left, the rest being gouged away) give better results than when the anatomic neck is divided; and this is to be preferred to the surgical neck. The entire diseased process must be removed (in cases of tumors springing from the head of the bone, one-third, and in some cases even more, of the shaft has been excised, preserving the elbow and the hand); but consistently with this, as little as possible of the healthy bone. The question of subperiosteal excision is still open, but there is ground for believing that when it is practicable, the results are superior to the other method. If the surgical neck requires division, the arm must be strongly rotated outward by the assistant as soon as the capsule is opened, in order that the tendon of the subscapularis may be cut; and then inward for the short external rotators. As soon as this is done the head of the bone rises well up into the wound, and may be either sawed off with a narrow-bladed saw *in situ*, the soft parts being protected and held aside by retractors, or thrust bodily out. The glenoid fossa very rarely requires more than the application of a gouge.

A counteropening at the back of the joint is usually advisable for drainage. The wound is thoroughly cleansed; the margins drawn together with sutures; a large tube placed across it; and the cavity of the axilla, the space behind the shoulder, and the outer side and front of the arm thoroughly packed with wood-wool. Stromeyer's elbow cushion should be used as long as the patient is in bed, and passive motion commenced as soon as the condition of the wound allows it, the fingers and wrist being exercised from the first (Moullin).

SIALAGOGS (Ptyalagogs).—Agents which increase the secretion and flow of saliva and buccal mucus, either by reflex action from local irritation produced when anything is taken into the mouth, or by stimulating the glands during their elimination. The principal sialagogs are divided into two groups: (1) *topical sialagogs* acting by reflex stimulation; the chief of which are: Acids and alkalies, ether, chloroform, mustard, ginger, pyrethrum, mezereon, tobacco, cubebs, capsicum, rhubarb, horse-radish; (2) *general sialagogs*, acting through their systemic influence on the glands or their secretory nerves; the chief of which are: Pilocarpus (jaborandi), muscarin, physostigma, mercurials, iodin compounds, antimonials, tobacco, ipecacuanha.

Agents which diminish salivary secretion are called Antisialagogs (*q. v.*).

SICK-ROOM.—Every home of any pretensions should contain a room especially arranged and kept ready for the use of sick members of the family. Such a room should be on the upper floor, and preferably in the southeast corner, so as to have the best sunny exposure; or still better, should be itself the upper floor of a two-story annex, separate from the main building, but joined thereto by a light, latticed bridge. It should have no upholstered furniture, a bare but painted floor, and rough-plastered and painted walls and ceiling, without pictures or paper, curtains or hangings. It should contain a bath room nearby and should communicate with the kitchen by a dumb-waiter, or preferably have connected with it a smaller room, furnished with a gas-stove and the other requirements of a diet-kitchen. It should contain everything requisite for nursing a case of typhoid fever, scarlatina, diphtheria, measles or small-pox; and all its arrangements should be supervised by the family physician. The possession of such an adjunct to the home would enable the owner to defy the mandate of a Health Officer, in regard to removing an inmate thereof to a public pest-house, as it could be shown to the satisfaction of any reasonable court, that a case of infectious disease could be better isolated and more humanely treated in such a room than in any "pest-hospital" yet erected by our political administrators of health laws (Potter).

SIDEROSIS.—Pigmentation of the lung tissue due to inhalation of metallic particles.

SIDONAL.—Quinate of piperazin. It is used in uricacidemia, gout, rheumatism in doses of 5 to 20 grains in the form of powder or solution, 75 grains being given in 24 hours.

SIGHT.—See Vision.

SILK AND SILKWORM-GUT.—See Ligature.

SILVER (Argentum).—Ag = 108; quantivalence 1. A malleable and ductile metal of brilliant white luster. It tarnishes only in the presence of free sulphur, sulphur gases, and phosphorus. It is an excellent substance for vessels used in pharmacy and for sutures used in surgery.

Therapeutics.—Internally, the silver salts are used in dyspepsia with vomiting of yeasty fluid; chronic gastritis and gastric ulcer; dysentery of chronic type, especially if rectal ulcer (the nitrate

internally and by enema); the diarrhea of phthisis and typhoid fever (nitrate with opium); chronic spinal inflammations causing locomotor ataxia or paraplegia; and epilepsy (in the latter affection the nitrate has occasionally given good results).

The **oxid** has been used internally for gastric neuralgia, irritative dyspepsia, pyrosis, gastric and pulmonary hemorrhages, and menorrhagia.

Used locally, the **nitrate** of silver is caustic, excitant, astrigent, and hemostatic. Strengths of nitrate of silver sufficient to prove astringent are also apt to be irritative. Thus, when used on mucous surfaces, the agent is liable to excite the mucous glands, if not to increase the inflammation. Under other conditions the irritating quality of the drug acts to advantage, and it is often selected when an excitant, and at the same time astringent, effect is desired. Nitrate of silver is a weak caustic on the most delicate tissues, but is a futile one on tough, resistant tissues. It is an astringent and hemostatic through the direct constricting effect it exerts on the caliber of the smaller vessels, and in the pressure exerted on them by the hygroscopic albuminate created by the salt.

In gastric catarrh:

℞. Silver nitrate, gr. v
Extract of hyoscyamus, gr. x.
Mix and make into 20 pills. Take one 3 times daily, a half-hour before meals.

In typhoid fever:

℞. Silver nitrate, gr. vj
Extract of opium, } each, gr. ij.
Extract of belladonna, }
Divide into 24 pills. One pill 3 times daily after taking food.

Poisoning.—Given internally in small doses, silver salts increase secretion, stimulate the heart, promote nutrition, and act as a nerve tonic. Their continued use produces symptoms which are collectively termed *argyria*, and are as follows: Gastrointestinal catarrh; tissue waste; uremia; albuminuria; fatty degeneration of the heart, liver, and kidneys; hemorrhages; fluidity of the blood; a slate-colored line along the margin of the gums and a similar discoloration of the skin and mucous membranes, with centric impairment of the nervous system, producing extensive paralysis, loss of coordinative power, convulsions, and, finally, death by paralysis of respiration. Large doses produce violent gastroenteritis; also ulcer of the stomach from thrombosis of its veins and destruction of the gastrointestinal mucous membrane.

Common salt freely used in the antidote, precipitating the silver as the insoluble chlorid and acting as an emetic. The nitrate is exceedingly sensitive to organic material and light, which decompose it readily. Incompatibles are all the soluble chlorids (hence it should be used in distilled water), most of the mineral acids and their salts, alkalies and their carbonates, lime-water, and astringent infusions. A course of silver medication should be regulated by suspending the remedy after 5 or 6 weeks' use, and then promoting elimination by purgatives, diuretics, and baths. To prevent the general discoloration, potassium iodid should be given conjointly with the silver, and baths of sodium thiosulphate should be used frequently.

Preparations.—There are three official salts, the nitrate, cyanid, and oxid.

Argenti Nitras, $AgNO_3$, occurs in colorless rhombic crystals, of bitter caustic taste and neutral reaction, soluble in 0.6 of water and in 26 of alcohol. Is best given in pill with kaolin, or in distilled water; never with tannin or a vegetable extract, lest an explosive compound result. Dose, 1/6 to 1/2 grain; if watched, up to 1 grain may be given. When melted with 4 percent of hydrochloric acid, it makes: **A. Nitras Fusus,** *Lunar Caustic*, for local use as a mild caustic and astringent. **A. Nitras Mitigatus** is the same salt melted with twice its weight of potassium nitrate. It is used locally by opthalmologists. **A. Cyanidum,** AgCN, has no medicinal use except for the extemporaneous preparation of hydrocyanic acid. **A. Oxidum,** Ag_2O, a brownish-black powder, nearly insoluble in water and insoluble in alcohol. It is liable to decompose with violence when mixed or triturated with readily oxidizable or combustible substances as creosote, phenol, potassium permanganate and many others. It should not be brought into contact with ammonia. Dose, 1/2 to 2 grains in pill with kaolin. It is not a dangerous internal remedy. **A. Citras,** called also antiseptic Credé. See Itrol. **A. Lactas,** see Actol. See also Argonin; Argyrol.

SINAPIS.—See Mustard.

SINGULTUS.—See Hiccup.

SINUSES, ACCESSORY, DISEASES.—See Nose (Accessory Sinuses).

SIX HUNDRED AND SIX.—See Syphilis.

SKIAGRAPHY.—See Roentgen Rays.

SKIASCOPY.—See Retinoscopy.

SKIN-DISEASES, DIAGNOSIS.—Skill in the diagnosis of diseases of the skin requires not only a sound knowledge of the principles of medicines, but also an acquaintance with the pathology of cutaneous disorders; it is, besides, necessary to be familiar with the physiology and minute anatomy of the integument.

It should be remembered that the same pathologic conditions that are found acting elsewhere on the economy are also present in the skin; and that, therefore, this organ is equally subject to such processes as anemia and hyperemia, atrophy and hypertrophy, inflammation, new growth, and infection from animal and vegetable parasites; but it should also be recalled that while many, perhaps the majority, of these alterations are local in character, some of them are the result of general states, although not to the extent, and not even in the manner, that our humoralistic predecessors imagined.

With so much premised, it is but just to say that the difficulties of diagnosis in this branch of medicine have been considerably exaggerated—the result in part, perhaps, of undue refinement in classification and unnecessary pedantry in nomenclature. Experience has shown that many of these difficulties may be minimized, and the way made smoother, if some systematic method of examination is followed.

However, before entering into details, attention may be directed to the importance of endeavoring, first, to establish the diagnosis from the objective symptoms present in a given case. Until he has made the diagnosis as far as it is possible to make it by these visible and tangible signs of disease, the physician should keep himself as free as may be from preconceptions arising from the patient's statements or his own interpretations of past events. For example, it is seen often enough that, when the examiner presumes, rightly or wrongly, that a patient has had syphilis, his whole investigation is tinctured by that presumption. This mental attitude is all the more pronounced in those with but scant experience in dermatology. Of course, it is not always possible to draw a sharp line in these matters, and the scheme to be presented is to be regarded merely as suggestive.

Light.—In examining the skin for evidences of disease, artificial light should be avoided, and the first examination, at any rate, should be made in the daytime. Only in this way can slight differences in shades of color be detected—a matter at times of no slight importance: as, for example, in syphilis, tinea versicolor, and certain pigment anomalies.

Temperature of the Room.—If a patient is undressed in a cold apartment, upon exposure the skin will become mottled from congestion, and will take on an appearance simulating closely certain erythematous disorders, especially the early erythematous syphilid, or other like conditions. Consequently, an examination should always be conducted in a pleasantly warmed room. Having thus arranged the surroundings of the patient, attention may next be turned to the patient himself.

General Inspection.—The physician should never rest contented with the patient's statement in regard to the character and location of an eruption: as, for instance, that a certain patch on the abdomen is exactly like one on the face, etc. On the contrary, the examination should be thorough, and as much of the surface of the body inspected as possible; and even in the case of women, this may readily be effected by examining different portions of the skin successively. As a matter of course, this practice may be neglected in conditions obviously localized; but in generalized eruptions or in doubtful cases it is an absolute necessity to satisfactory diagnosis. By way of illustration, the fact may be cited that the nature of an ill-defined lesion of psoriasis on the face may be fully established by more characteristic types of the same disease if the elbows and knees are inspected. Again, the differential diagnosis between eczema and scabies may be made, both affections having certain features in common, if, upon a general survey of the body surface, the eruption in the latter disorder is found to occupy the classic sites of scabies: viz., between the fingers, at the wrists, the axillæ, the pubic region, especially the penis in the male, under the breasts in women, the buttocks, the inner sides of the thighs, and, in fact, wherever there are heat and moisture.

Extent of Surface Involved.—In making the general inspection just recommended, attention must also be paid to the amount of surface involved and to the localities occupied by the eruption. In addition to the illustration just given, it should be recalled that the exanthems usually cover the whole body; that the early syphilids are widely distributed; that acne is seated upon the face and shoulders; that psoriasis is likely to be symmetrically disposed; and that tinea versicolor is found on the trunk, xanthoma on the lids, lupus and epithelioma generally on the face, and lupus erythematosus on the nose and cheeks.

Arrangement of Lesions.—It is important to know whether the lesions occupy one or both sides of the body, and whether they possess any special arrangement. For example, in zoster the eruption is unilateral and the eruptive elements follow the course of cutaneous nerves, displaying clusters of vesicles on a red base. In ringworm the lesions affect a ringed arrangement, and extend at the periphery while clearing in the center. This disposition is also to be noted in psoriasis and in some syphilids; herpes iris is annular. Moreover, the eruption in syphilis is often grouped—a feature also to be observed in dermatitis herpetiformis; but the first-mentioned affection presents no marked subjective symptoms, whereas in the latter there are intolerable itching and burning.

Color.—The color of an eruption is often at least an auxiliary aid to diagnosis. The brownish-red or ham color of some syphilids differs from the underlying brighter red of psoriasis, and it also may be said that the thick greenish crusts of syphilis are fairly characteristic. The favus cups are sulphur-yellow; the patches of tinea versicolor are of a fawn tint; keloidal tumors are pinkish; and the new growths of xanthoma are buff-colored. In the same way the shade of color presented by an inflammation of the skin will measurably indicate its acute or chronic character.

Touch.—The affected skin should also be pinched up between the fingers, in order to get as accurate an idea as possible of the amount of infiltration present, the special tissues involved, the temperature, the presence or absence of fluctuation, etc. An account of the symptoms revealed by the educated touch will often determine whether a disease is superficial or deep-seated, and thus eliminate whole groups of disorders from the field of discussion.

Odor.—The odors arising from certain diseases of the skin are at times helps to their diagnosis. Favus has a peculiar mouse-nest smell; syphilitic ulceration emits a nauseating stench that is suggestive; while the smell of gangrene is well recognized.

Acute or Chronic.—The objective aspect of the disease is indicated by these terms rather than the time occupied in its development, the latter point receiving notice more particularly when the previous history of the case is under inquiry. For example, an eczema may have an acute appearance although a long time in existence, while a syphilid may be of recent origin yet lack all evidence of acuteness. Any changes that may have occurred, such as crusting, scarring, and the like, should be carefully noted, and the extending or outer margin of a patch should be especially observed, as often in this way we may detect the primary lesions (*e. g.*, in lupus) of an eruption that has been disguised by complications or treatment.

Individual Lesions.—It so happens that diseases of the skin, whatever may be their cause or nature, impress themselves upon the integument by certain elementary forms called primary lesions, which have been justly termed the alphabet of dermatology; and there are also to be observed certain other manifestations that are partly the sequels of the initial processes or are the effect upon them of traumatism—these are termed secondary lesions.

The primary lesions consist of macules, papules, vesicles, blebs, pustules, tubercles, wheals, and tumors.

Macules are discolored patches of skin, of variable shape and size, without elevation or depression.

Papules are circumscribed solid elevations of the skin, varying in size from that of a pinhead to that of a pea.

Vesicles are pinhead-sized to pea-sized circumscribed elevations of the epidermis, containing clear or opaque fluid.

Blebs are round or irregularly shaped pea-sized to egg-sized elevations of the epidermis, containing clear or opaque fluid.

Pustules are circumscribed, flat, or acuminate elevations of the epidermis, containing pus.

Wheals are edematous, circumscribed, irregular, pinkish elevations of the skin, transitory in character.

Tubercles are circumscribed, solid, deep-seated elevations of the skin attaining or exceeding the size of a pea.

Tumors are variously sized and shaped prominences, having their seat in the corium or subcutaneous tissue.

The secondary lesions comprise scales, crusts, excoriations, fissures, ulcers, scars, and stains.

Scales are dry epidermal exfoliations shed from the surface of the skin.

Crusts are brownish or yellowish masses of dried exudation.

Excoriations are epidermal denudations, usually the result of local traumatism.

Fissures are linear cracks or wounds in the epidermis or corium due to disease or injury.

Ulcers are round or irregular losses of tissue involving the skin and subcutaneous tissue.

Scars are connective-tissue new formations occupying the region of former losses of tissue.

Stains are discolorations of the skin left after the disappearance of cutaneous lesions.

While it is absolutely necessary for one desiring a knowledge of dermatology to know thoroughly these pathologic processes, it is not claimed that the recognition of a primary or secondary lesion will immediately give a clue to the diagnosis; for it is well known that these lesions are due to the most varied morbid states, and that the same kinds of lesions will often be found in very dissimilar diseases. If, however, the type of the lesion has been determined, at least the field of investigation has been considerably narrowed. For instance, it is of decided advantage to be aware that in herpes zoster there are vesicles and not tubercles; that in a disorder presenting macules we have not to deal with pemphigus or acne or urticaria, for these affections are characterized by an entirely different order of lesions. The same reasoning holds good, in a measure, for secondary lesions, such as crusts, ulcers, scars, scales, etc.

Macules occur in chloasma, eczema, erysipelas, roseola, rubeola, scarlatina, rötheln, erythema, ephelis, leukoderma, melanoderma, tinea versicolor, syphilis, xanthoma, purpura, nævus pigmentosus, and morphea. When a large portion or the entire skin is involved by change of color, it is known as a discoloration: such, for example, as is seen in Addison's disease, leprosy, and argyria.

Papules are observed in acne, milium, comedo, eczema, lichen, prurigo, in certain kinds of purpura and urticaria, and in variola, keratosis pilaris, ichthyosis, and miliaria papulosa. The eruptions of measles and rötheln are really maculopapular in character. In syphilis the papule is often surmounted by a scale.

Tubercles are found in connection with syphilis, leprosy, parasitic sycosis, acne, molluscum epitheliale, and lupus.

Tumors exist in carcinoma, sarcoma, syphilis, elephantiasis, angioma, keloid, lipoma, fibroma, and erythema nodosum.

Vesicles are present in eczema, herpes, vaccinia, sudamina, miliaria, varicella, dermatitis, dysidrosis, scabies; vesicopustules are observed in impetigo contagiosa, the vesicular syphilid, etc.

Blebs occur in pemphigus, hydroa, erysipelas, herpes iris, leprosy, syphilis, and dermatitis.

Pustules are encountered in acne, variola, ecthyma, equinia, impetigo, scabies, syphilis, sycosis, dermatitis, and pustula maligna.

Wheals are found in connection with irritable states of the skin, such as occur from the bites of insects, and most typically in urticaria, and also in some degree with purpura and erythema multiforme.

Scales are observed in psoriasis, eczema, pityriasis rubra, exfoliative dermatitis, scarlet fever, measles, seborrhea, the vegetable parasitic affections, and ichthyosis.

Crusts are to be found in eczema, syphilis, scabies, ecthyma, scrofuloderma, leprosy, syphilis, impetigo, carcinoma, seborrhea, herpes zoster, and sycosis.

Fissures occur in eczema, psoriasis, syphilis, ichthyosis, verruca.

Excoriations are to be seen in pruriginous disorders, such as eczema, pruritus, pediculosis, scabies, etc.

Ulcers appear as sequels to the lesions of syphilis, lupus, boils, carbuncles, eczema, herpes zoster, scrofuloderma, epithelioma, sarcoma.

Scars come in the wake of ulcerative skin-diseases: *e. g.*, lupus vulgaris, syphilis, and lupus erythematosus.

Having now closely observed all that the eye, the touch, the sense of smell, etc., can reveal—in other words, having made, free from preconceived notions, a thorough study of the objective symptoms present—we are better prepared to ascertain the general history of the case, to obtain an account of the patient's own sensations, and, finally, to make use of the various collateral methods of diagnosis that science has placed at our disposal.

Locality.—Many diseases have distinct predilections for special localities. Psoriasis elects the scalp and the extensor surfaces of the elbows and knees. Eczema may occur anywhere, but prefers the flexor surfaces. The excoriations of pediculosis corporis are seen across the shoulder-blades and around the waist. Acne attacks the face and chest. The lesions of scabies are quite constantly present on the webs and sides of the fingers, the flexor surfaces of the wrists, the anterior and posterior axillary folds, the nipples, the umbilicus, the penis, the buttocks, the insides of the thighs and legs, and the toes (in infants). The face is always exempt, except in infants. Erythema multiforme attacks the face, the neck, and the backs of the hands and feet. Erythemá nodosum is usually situated on the anterior surfaces of the tibias.

The proneness of common affections to attack special localities is indicated in the following list:

Scalp.—Eczema, ringworm, pediculosis capitis, favus, seborrhea, alopecia areata.

Face.—Acne, eczema, lupus vulgaris, lupus erythematosus, syphilis, impetigo, sycosis.

Chest.—Tinea versicolor, seborrheic eczema, macular syphiloderm, acne.

Shoulders and Back.—Acne, carbuncle, pediculosis corporis.

Buttocks.—Furuncles, scabies, congenital syphilis, eczema intertrigo.

Genitals.—Eczema, pruritus, herpes simplex, scabies, syphilis.

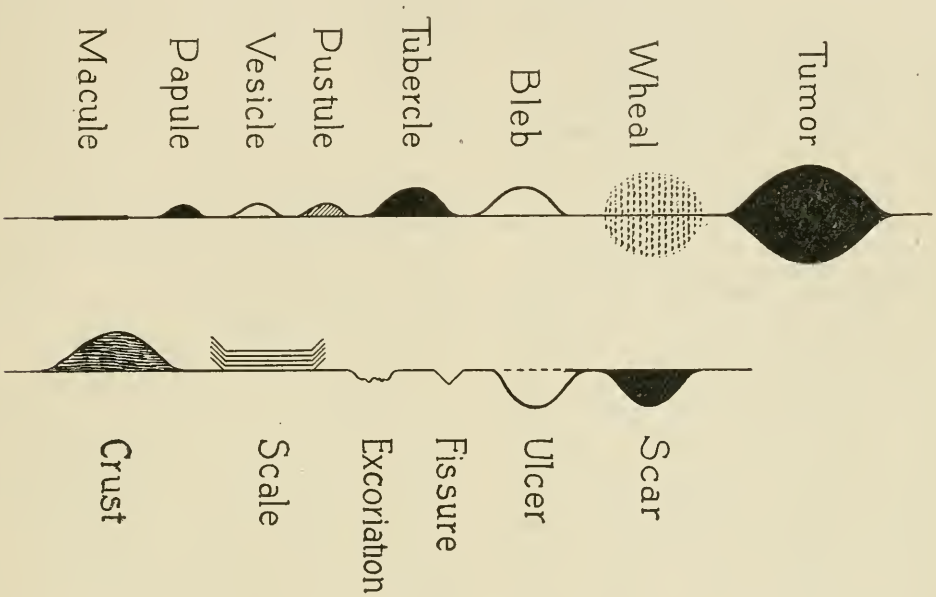

Diagram of Skin-lesions.

Lower Extremities.—Purpura, ecthyma, eczema rubrum, erythema nodosum.

Age, Sex, and Social Condition.—Some diseases of the skin are more prone to attack children than adults, and vice versa. Epithelioma usually appears first in middle or advanced life, while lupus vulgaris nearly always dates from childhood. Neither acne nor tinea versicolor is common in children, but ringworm of the scalp shows a predilection for that age and usually spares the adult. Ichthyosis is practically congenital. Lupus erythematosus is more frequent in women, and epithelioma of the lower lip is generally an affection of the male.

A knowledge of the occupation is sometimes a help in diagnosis. Bakers, grocers, bricklayers, plasterers, and barkeepers suffer from eczema, and artisans who handle chemicals and other irritants exhibit various grades of dermatitis. Hostlers may contract glanders, and wool-sorters become

infected with anthrax. Pediculosis is more common in the poor and unclean than in the upper classes of society.

Antecedent History.—The past history of the case will inform us as to former attacks of cutaneous or other diseases; and if the information is judiciously elicited, may throw much light on the present condition. This is of prime importance, especially in syphilis.

General Symptoms.—The general symptoms of the patient must not be neglected. His facial expression, his gait, the color of his skin and conjunctivæ, the state of the tongue, stomach, and bowels, etc., must be thoroughly investigated. The thermometer will show the body temperature, and microscopic and chemic investigation will determine the condition of the blood and urinary secretion, thus proving or disproving the existence of diabetes, nephritis, and malaria, each of which may be potent factors in the etiology.

Microscope.—Aside from the employment of the microscope in the conditions just mentioned, this instrument is an invaluable aid in dermatologic practice. With it the character of tumors may be determined and information furnished as to the nature of obscure pathologic processes. It is of especial utility in recognizing the presence of fungi or of animal parasites, and in the investigation of the rapidly extending class of bacillary diseases.

Drug and Feigned Eruptions.—The ingestion of various drugs produces in many persons diverse lesions of the skin, and a careful inquiry should always be made in that direction. The same observation may be applied in regard to certain foods: *e. g.*, urticarial and erythematous rashes are often due to the eating of strawberries or buckwheat, and eczemas are sometimes at least indirectly connected with the free eating of oatmeal. Many plants set up severe dermatitis, and heat and cold and the X-rays are also responsible for similar conditions. The physician should also be fully aware that feigned or artificial eruptions are not infrequently produced upon themselves by hysterics and malingerers. See Drug Eruptions.

Subjective Symptoms.—The merely subjective symptoms of a patient are not of paramount importance in diagnosis; still, one must not put aside as of no importance the statements of intelligent persons in matters relating to their own experiences of pain, itching, burning, or other sensations. Very often such statements may be verified by the condition of the integument itself; for example, if itching is severe, the presence of scratch marks will testify to its existence.

SKIN-GRAFTING.—See Plastic Surgery.

SKULL, DISEASES. Hypertrophy.—In ostitis deformans the vault of the cranium is usually immensely thickened. The inner surface becomes irregular, and is marked all over by arborescent grooves; the outer surface remains smooth and even; the diploe disappears, and on section the bone is hard and dense, like ivory. Beyond a gradual increase in the circumference of the head, it does not appear to give rise to any symptoms; no treatment is of any avail. Other forms of enlargement are described under Bones (Diseases).

Craniotabes.—A peculiar form of atrophy of the inner table, known as craniotabes, is occasionally met in infants suffering from rickets. It affects especially the posterior inferior angles of the parietal bones and the tabular part of the occipital bone, probably because of the recumbent position of the child, for a certain flattening of that part of the head is not infrequently noticed at the same time; and in one or two instances in which the disease existed before birth, a similar change has been found on the inner surface of the vertex. The sulci for the cerebral convolutions are unusually distinct, and here and there are marked in their course by little conic pits, which in some places are so deep that nothing but a parchment-like layer of dura mater and pericranium is left; the whole thickness of the bone is absorbed. Sometimes, in addition, there is a granular deposit of new bone under the pericranium on the outer surface, and occasionally a very considerable amount around the fontanels and along the sutures—enough to be felt plainly through the scalp. In all probability it is due to the effect of continued pressure acting on softened hypervascular bone. It certainly may occur independent of hereditary syphilis, although it is often associated with it (*e. g.*, Parrot's nodes), and a few instances are recorded in which other evidence of rickets was unusually slight. The diagnosis can only be made in well-marked cases by the peculiar parchment-like yielding on pressure with the fingers. No special treatment is required.

Caries and necrosis of the bones of the cranium are not uncommon. They are generally the result of syphilitic periostitis or injury, or, very rarely, of tubercle or fevers. The external table is the most often affected; but whether the external or the internal table is involved, the disease seldom extends beyond the diploe, as the two tables have a distinct blood supply. At times, however, complete perforation of the skull occurs. Caries and necrosis in this situation are likely to be followed by septic or infective inflammation of the diploe and its consequences; by suppuration between the bone and dura mater; by meningitis and abscess of the brain; or by thickening of the dura mater, resulting in persistent headache or even in epilepsy. When the skull is completely perforated, the hole is not filled up by bone; and when necrosis occurs, the sequestrum is not invaginated.

Treatment.—Beyond keeping the parts aseptic, providing free exit for the discharges, and removing loose sequestra, little, as a rule, is required. Should pus collect between the bone and dura mater, it must be released by the trephine; and a portion of necrosed inner table may also require the trephine for its removal. Appropriate constitutional remedies for syphilis or tubercle will, of course, also be necessary.

Meningocele and encephalocele are rare congenital tumors, formed by a protusion of the membranes of the brain through an unossified part of the skull. They are believed to be dependent upon hydrocephalus, the excess of fluid in the subarachnoid space or in the ventricles of the brain

leading respectively to a protrusion of the membranes alone (*meningocele*), or of the brain also (*encephalocele*). In the latter instance the dilated ventricle may extend into the protruding portion of the brain, a condition further distinguished as *hydrencephalocele*. The protrusion is most common in the occipital region, just behind the foramen magnum, between the four centers from which this part of the occipital bone is ossified; next, at the root of the nose, between the frontal and nasal bones; but it may occur in any situation in the course of the sutures, and may even project into the nasal fossæ or into the pharynx.

Symptoms.—In the occipital region these tumors are generally pedunculated and of large size—sometimes nearly as large as the child's head; at the root of the nose they are usually small and sessile. The skin covering them is generally normal. They swell up when the child cries, and can be completely or partially reduced on pressure, the reduction sometimes producing convulsions or other brain symptoms. When they contain fluid only (*meningocele*), they are soft, fluctuating, translucent, and completely reducible on pressure; they rarely pulsate, and are generally pedunculated. When they contain brain matter (*encephalocele*), they are doughy, nonfluctuating, opaque, and only partially reducible; they pulsate, and are usually sessile. They may be mistaken for other tumors of the scalp, but especially for congenital dermoid cysts and degenerative nævi. However, their intimate connection with the bone, their situation in the course of the sutures, and their partial or complete reducibility, together with the facts that they swell up on expiratory efforts and occasionally pulsate synchronously with the brain, will usually serve for their diagnosis. Further, the hole in the skull may at times be detected and brain symptoms may be produced by pressure.

Treatment.—As a rule, they should be let alone, or merely supported by a pad or bandage. A meningocele, when pedunculated, and apparently communicating with the interior of the cranium by a small aperture only, may be injected with Morton's fluid, or, under exceptional circumstances excised.

Fungous tumors, generally of a sarcomatous nature, and springing either from the tissues of the scalp or pericranium, or from the diploe or dura mater and then penetrating the bone, are occasionally met, and may be mistaken for inflammatory affections of the pericranium or bone, or for syphilitic gummata. Their rapid growth, resistance to syphilitic remedies, the escape of blood only on puncture, and the concomitant loss of weight and strength of the patient, will usually serve to distinguish them; but an exploratory incision may in some cases be necessary to clear up the diagnosis. Secondary tumors which pulsate and have the structure of thyroid gland tissue are also occasionally met in cases of malignant goiter.

Treatment.—When there is no evidence of dissemination, and the tumor is small and fairly circumscribed, it may be removed. When growing from the scalp, this can usually be done without much difficulty; but when the growth arises from the bone or dura mater, a much more serious operation will, of course, be required, since a considerable portion of the skull will have to be cut away and the dura mater probably opened. It need hardly be said that the strictest antiseptic precautions must be observed (Walsham).

Osteomata.—Those tumors growing from the outer table are sometimes called exostoses; those from the inner table and the diploe, enostoses. Most of the latter are, however, inflammatory, and probably syphilitic. Cancellous exostoses upon the cranium are rare; ivory exostoses are more common, growing chiefly from the frontal bone and in the external auditory meatus. Sometimes they are multiple and symmetric. As a rule, they are of very slow growth, and require no treatment; but when they grow in the frontal sinus, they may cause the most fearful disfigurement from displacement of the eyeball, or even more serious symptoms from pressure upon the brain; while in the ear they may lead to deafness, and ultimately to complete obstruction of the meatus, with its consequences (acute suppurative ostitis and meningitis), if the secretion collects behind and decomposes. Fortunately, it frequently happens that the necks of these growths are much more slender than would be imagined from their size, so that they have even been known to break off. As a rule, they can be detached with a drill fitted to a surgical engine; but very great care is required in the selection of proper instruments. In one or two instances the growths have detached themselves, like the antlers of a stag, the vascular canals in the neck gradually becoming smaller and smaller until at length the blood supply is altogether cut off.

SKULL, FRACTURES.—Fractures of the skull are usually due to direct violence. The vault of the cranium generally receives the blow, and hence is most often fractured. If, however, the force is diffused over a wide area, the skull is compressed, the most inelastic and unyielding part gives way, and a fissure is produced which generally runs across the base as well as the vault.

Simple Fractures of the Vault.—Of themselves, simple fractures of the vault are of little or no consequence: contusions, fissures, and fractures without displacement do not admit of proof, and even when the bone is comminuted and the depression considerable, the diagnosis is often only a conjecture, owing to the amount of blood extravasated. Their gravity arises from the fact that serious injury to important structures is so often associated with them. Concussion or contusion of the brain, hemorrhage between the membranes, or, especially if the course of the fissure traverses the middle meningeal artery, between the dura mater and the bone, rupture of the venous sinuses, and laceration of the membranes are of frequent occurrence after simple fractures; more rarely the contents of the cranium (the cerebrospinal fluid at least) find their way out, and form a soft, fluctuating, and pulsating swelling underneath the aponeurosis—cephalhydrocele. Later, especially in cases in which the bone is severely contused,

inflammation may set in, although it is very rare in comparison with compound fractures. It may be either acute or chronic.

Compound Fractures of the Vault.—In the majority of instances the nature of the injury can be seen at once. There is a fissure, appearing as a thin, red line, out of which blood continues to ooze, contrasting with the white bone around, or the bone is plainly comminuted and driven in, or the broken edge of a knife or other foreign body can be seen upon the surface. The wound must be carefully and thoroughly explored with the finger, and its extent and the depth and character of the displacement must be made out as accurately as possible, especially in the case of punctured wounds.

Serious complications are much more common in compound fractures. The more nearly a fracture approaches the punctured form, the more dangerous it becomes; it does not matter so much if the depression is wide and extensive, or if, owing to the softness and elasticity of the bones, there is little or no splintering; the dura mater is not injured, and symptoms of compression, merely from displaced bone, are exceedingly rare; but when the inner opening is fringed with a circle of little spikes projecting vertically inward, and tearing, and irritating the membranes and the brain, inflammation is almost certain. In addition compound fractures are always exposed to the risk of decomposition. Blood is extravasated into the diploe, and between the dura mater and the bone; the fracture is often comminuted; there are numerous little spaces and fissures between the fragments which cannot drain, and the wound is frequently filled with dirt and other foreign substances. Under these circumstances, unless steps are taken to prevent it, inflammation must follow, and though fortunately it often remains limited to the wound and merely causes necrosis of the broken fragments, it may at any moment spread into the surrounding bone, or, especially if the dura mater has been pricked, into the membranes of the brain, and set up fatal meningitis.

Treatment. *Simple Fractures.*—Unless there are definite symptoms of compression, either growing worse or refusing to clear up, nothing should be done. But if associated with concussion and contusion of the brain, the patient must be placed in a darkened room with the head shaved, and an ice-bag, or, better, Leiter's coil, applied; every source of irritation or excitement should be excluded, the bowels should be opened, preferably with a calomel purge, and nothing but the simplest diet allowed. Rest in bed must be strictly enforced for at least 3 weeks, and the patient must be carefully watched for months. The great fear during the first few days is that hyperemia and inflammation of the brain may occur; after that the chief risk comes from the bone, which may inflame and cause necrosis, meningitis, or pyemia; still later, even years after, symptoms of cerebral irritation may make their appearance, sometimes merely undue excitability or fits of temper, especially if there is any indiscretion in diet or abuse of stimulants; occasionally, but fortunately very rarely, more serious disturbance, such as epilepsy and even insanity.

Compound Fractures.—The wound in the soft parts should be treated as already described; the hair should be shaved off, the scalp well washed, the hemorrhage arrested, foreign matter and dirt carefully removed, and then all the part that has been exposed thoroughly washed out with corrosive sublimate or some other antiseptic. It should then be well dried, the edges dusted over with iodoform and brought together with sutures (catgut is especially useful when there is no tension), leaving suitable openings for the escape of the lymph, and, if necessary, one or two tubes may be inserted. Then it should be carefully covered over with a thick layer of some dressing sufficiently absorbent to soak up any discharge at once, and bandaged to avoid displacement and secure rest. Simple linear fissures, not depressed and not caused by the impact of a sharp weapon, may be covered in at once, the pericranium being replaced if it is torn off. There is no splintering in such a case, no fear of spicules irritating the dura mater and the brain, and the sooner the fracture is converted into a simple one, the less the risk of decomposition and suppuration. Punctured fractures, on the other hand, should always be trephined, the wound in the outer table being included in the circle of the instrument. It is impossible to ascertain the condition of the inner table; in nearly every case it is "starred" and the splinters driven inward; the operation adds nothing to the gravity of the case, and deep punctured wounds passing through strata of different consistence can neither be cleaned nor drained.

In compound depressed fractures portions of bone that are detached or loose or driven into the substance of the dura mater must be picked out, avoiding any unnecessary violence or persistence. If there are symptoms of compression, or if the size and depth of the wound make it probable that the inner table is splintered, the bone must be elevated and, if necessary, part of a circle removed with the trephine, the pin resting on the uninjured margin. See BRAIN (Injuries).

Fracture of the base of the skull is sometimes the result of direct violence—when, for example, a revolver is discharged into the mouth, or a stick is forced through the roof of the orbit, or the condyle of the jaw is driven through the glenoid fossa. More often it is caused by a fissure extending from the vault. The fracture starts from the point that is struck, and generally passes across the base of the corresponding fossa, sometimes when the force is great involving more than one. The middle fossa suffers the most frequently, as may be expected, and a very common course for the fissure to take is across the petrous portion of the temporal bone and the internal auditory meatus. Occasionally it is produced in other ways. The skull, for example, may be driven down on the vertebral column, just as a hammer-head is forced onto the shaft, with such violence as to break the bone around the foramen magnum; or, as it falls upon the head, the vertebral column may be driven against the skull. In fracture by *contre-coup* the

injury is on the opposite side of the head, at the other end of the diameter. The orbital plate of the frontal bone, for example, is sometimes fissured from a fall upon the occipital region. The skull is suddenly shortened in its anteroposterior diameter, and correspondingly widened in its lateral and vertical ones; both the frontal and the occipital regions are flattened out; but the former, being the thinner, more brittle, and less regular in its elasticity, gives way first. It must not be forgotten that fractures extending into the ear, nose, and pharynx are really compound.

Symptoms.—Sometimes there are no distinctive signs, and the condition is overlooked. It is often confused with drunkenness. Generally, however, there are present the symptoms of compression or other severe lesion of the brain. The signs considered especially diagnostic are (1) the escape of cerebrospinal fluid from the ear, nose, or mouth, or from an open wound if it exists; (2) the similar escape of blood; (3) effusions of blood under the conjunctiva, about the mastoid process or suboccipital region; (4) injury of one or more cranial nerves.

Prognosis is always grave, the cases generally, but not always, terminating fatally from concomitant injury or inflammation of the brain.

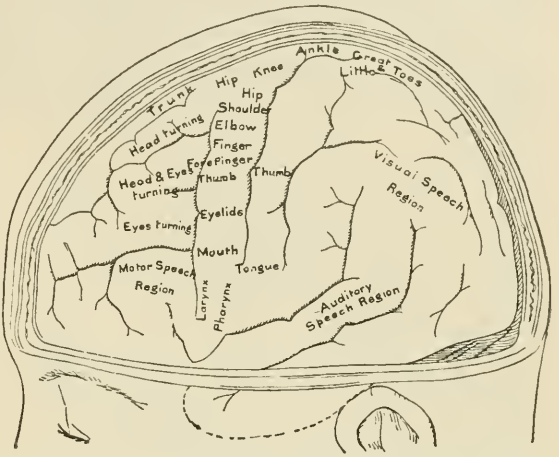
Treatment.—Fractures of the base of the skull must be treated in the same way as fractures of the vault; the brain is always severely in ured, and the greatest care must be taken tojward off any source of irritation. If the cribriform plate of the ethmoid is comminuted, an attempt should be made to remove the fragments, either through the orbit or the nose, for fear of the dura mater being injured, and to insure more perfect drainage. The discharge is certain to become purulent—unless drained and antiseptically irrigated—and is usually exceedingly offensive, especially if the injury is followed by necrosis. In the case of the ear, the meatus should be gently syringed out with an antiseptic, and then covered with a large pad of absorbent cotton, renewed as often as required. The fracture is compound, but meningitis rarely follows. Callus is scarcely every thrown out, the parts lie absolutely quiet, and there is no irritation; in many cases union is by fibrous tissue only; and the edges of the fracture become smoothed down and absorbed to some extent, so that the fissure, when the skull is macerated, appears much larger than it really was. See SKULL (Surgery).

SKULL, SURGERY.—Conditions calling for cranial surgery are cerebral abscess, tumors, injuries, hydrocephalus, idiocy, general paralysis, and severe cephalalgia and intracranial hemorrhage.

The tumors are glioma, psammoma, localized tubercular lesions, syphilitic scars that drugs cannot absorb, scar tissue and cystic formations following injury, and parasitic cysts. Sarcomatous and carcinomatous growths are usually too extensive for removal, or are multiple from the first. Moreover, since they have no capsule they are not sufficiently distinguishable from the surrounding brain-substance to insure their complete excision and their nonreturn in the scar.

Symptoms.—The chief signs of a cerebral tumor are vomiting, persistent headache, optic neuritis, localized spasms or paralysis, and epileptiform convulsions, and convulsive seizures usually starting in the part connected with the cortical area involved in the growth (Jacksonian epilepsy).

Localization.—Among the symptoms that may enable the surgeon to localize the growth are the following: (1) If at the beginning of the epileptiform fit there are: (*a*) Pain, peculiar sensation,

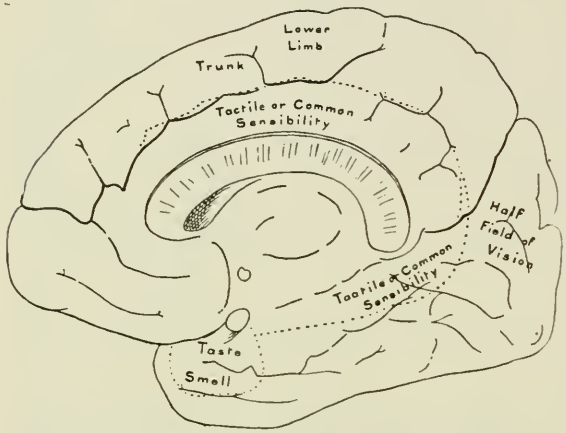


AREAS ON THE CONVEX SURFACE OF THE CEREBRUM.—(*Horsley and Russell.*)

flexion, or hyperextension of the great toe, a lesion of the leg area on the opposite side of the cortex about the upper end of the fissure of Rolando close to the middle line is indicated; (*b*) movements of the shoulder, a lesion near the upper part and in front of the fissure; (*c*) flexion of the thumb, a lesion about the genu of the fissure; (*d*) turning of the head and eyes to the opposite side, a lesion about the hinder portion of the superior and middle frontal convolutions; (*e*) movements of the mouth and tongue, a lesion about the lower end of the fissure of Rolando. An epileptiform movement starting in one of these parts may be followed by loss of power in the part for some time after the fit. (2) Aphasia indicates a lesion of Broca's convolution. (3) Loss of half the fields of vision in both eyes points to a lesion of the angular gyrus of the side opposite to the lost fields of vision. (4) Loss of hearing suggests a lesion of the two upper temporosphenoid lobes. (5) Aid to localization may also be derived from the involvement of the cranial nerves (Walsham).

When, from a consideration of the foregoing symptoms, a tumor or new growth is believed to be fairly circumscribed and in an accessible situation the skull should be trephined, a sufficient portion of the bone removed to fully expose the growth, by a Hey's saw, Gigli saw, Hoffmann's, Keen's, Dahlgren's or Hudson's forceps, or the surgical engine, and the growth cut away by making

perpendicular incisions into the brain around it, and raising it by means of a sharp spoon. Many experienced brain surgeons, notably Horsley and Krause, make use of the osteoplastic flap method, which consists in raising a flap composed of both soft tissues and bone, the latter being cut through along the line through which the former are incised, and the base then fractured by leverage and raised with the superficial tissues. It is frequently advisable to do the operation in two stages, allowing an interval of six to fourteen days between the formation of the flap and the removal of the tumor. When the operation is thus done, the flap is replaced and held in position by means of deep sutures. Whenever the operation is begun with the intention of completing it at one sitting a rim of bone at least one centimeter in



Areas on the Mesial Aspect of the Cerebrum.—(*Horsley and Russell.*)

breadth must be cut away (Krause). In order to prevent bony union the blood-pressure should be taken at the beginning of the procedure and every few minutes while the surgeon is operating; any decided fall should be considered a danger signal and the operation either hastily completed if it be already almost done, or abandoned to be finished at another time. The mortality in operations for cerebral tumors is high under all circumstances, but statistics show it to be less in those cases in which the operation is done in two stages than in those in which it is completed at one séance.

The removal of a portion of the cortex will be followed by loss of function of the area removed, but this will be regained to a great extent by the aid of the surrounding areas, especially as regards the coarser movements. The finer movements of the fingers and thumb will not be completely regained; hence in this region the removal of cortex should be as limited as is consistent with success. Parasitic cysts should be drained.

In focal epilepsy, that is, epilepsy without obvious gross lesion—when the fits become very frequent—for example, more than one an hour—and the mental processes are becoming further impaired, the focus in the cortex representing the initial movements may be exposed, the exact spot for the initial movements found by exciting the brain with the faradic current, and this area of the cortex excised. After such an operation a diminution in the number of fits as well as an improvement in the health of the patient may be expected.

In general paralysis trephining in a few cases has been of some benefit in the early stages of the disease. Thus the hallucinations, have disappeared, and the patient has so far improved as to be fit to be set at liberty.

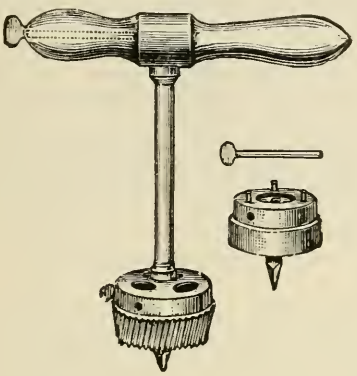
In severe cephalalgia, incapacitating the patient for work or preventing sleep, trephining may give relief. In such cases an exostosis, a spicule of bone, an enlarged Pacchionian body, or a fibrous tumor or cyst of the dura mater has been found, and its removal has been followed by complete recovery. In other cases when a tumor, etc., of the brain that did not permit of removal has been discovered, the relief of pressure has freed the patient from the excessive pain or threatened blindness.

Hydrocephalus, especially when accompanied by fits, when progressive atrophy of the optic nerve threatens, or when dementia or coma supervenes, may be treated by tapping the ventricles at intervals and applying slight pressure to the skull, or, if this fails, by continuous drainage of the ventricles.

Microcephalus combined with idiocy, due, it is thought, to too early synostosis of the cranial sutures, especially the sagittal and coronal, may be benefited by craniectomy—*i. e.*, the removal of a strip of bone on either side of the middle line of the skull. The aim of the operation is to allow the brain, the development of which has been prevented by the early synostosis, to expand. See Craniectomy.

Trephining.—Trephining is an operation required for the relief of (1) injury; (2) abscess, especially following ear disease; (3) tumors, including cysts; (4) trigeminal neuralgia. *After injury* it is required for (*a*) All cases of compound depressed fractures, including punctured wounds, gutter fractures and grazing of the skull by bullets. (*b*) Simple or subcutaneous depressed fracture in children if at all marked, whenever over the region of the sensorimotor areas, also for depressions occasioned during birth which tend to cause irritation and epilepsy. (*c*) Localized intracranial hemorrhage, particularly from rupture of the middle meningeal artery. (*d*) Signs of increasing intracranial tension or of suppuration, whether localized or not. (*e*) In late results of injury, localized pain and tenderness, and for focal epilepsy. If a wound of the scalp exists, it should be enlarged, otherwise a large semicircular flap of the scalp should be turned down, so that when it is replaced after the operation, the trephine hole is completely covered. The pericranium having been turned back from the bone, the trephine, with the pin protruded 1/10 of an inch, should be applied, and steadily worked, clearing the teeth

from time to time with an aseptic sponge or the brush provided for the purpose in the trephine case. A good groove having been formed in the bone, the pin should be withdrawn. When the diploe is reached, which may be known by the bone-duct being soft and red, greater caution must be used, and a quill or probe introduced into the goove at intervals to ascertain whether perforation has taken place at any situation. When the crown of bone is loose, it should be removed with the sequestrum forceps, and if it is intended to replace it, it should be kept warm in some weak antiseptic solution, and at the end of the operation cut into small pieces and placed in the hole, and the flap laid down over it. If more room is necessary, the trephine hole may be enlarged by a Hey's



saw, Hoffman's or Keen's forceps, or by the surgical engine. The strictest antiseptic precautions should be used throughout. Thus, the whole scalp should be shaved, and washed with soap and hot water, then with ether, turpentine, or ammonia, to remove all grease, and afterward with perchlorid of mercury or other antiseptic. Healing by first intention should be obtained if possible by accurately uniting the wound—except perhaps at its lowest part, which may be left open for drainage—and by applying a dry antiseptic dressing, and over it an ice-bag to prevent inflammation. The trephine should not be applied, as a rule, over a suture, an air or venous sinus, or over the middle meningeal artery, unless the operation is undertaken with a view to secure that vessel. The conic trephine of Walsham will be found a safer instrument than that in ordinary use, as with it the dura mater is less likely to be injured, and the handle also is more comfortable to work with. It can now be had with a metal handle and the improved button-pin. Before trephining for the removal of a cerebral tumor morphin should be given, as it causes contraction of the small blood-vessels, and so has a tendency to lessen the hemorrhage. See Craniometric Points.

SLEEP, DISORDERS.—See Insomnia, Nightmare, Somnambulism, Sleeping Sickness, etc.

SLEEP, TWILIGHT.—See Twilight Sleep.

SLEEPING SICKNESS, Definition.—The humantrypanosomiasis endemic in Africa, the terminal stage of which is characterized by somnolence, torpor, and coma.

History.—Sleeping sickness was known and described in Africa as far back as 1800 A. D. The disease at that time was confined to a few endemic areas, but of late years it has become widespread on account of the opening up of new areas of trade and travel over tropical Africa. Prior to 1903, the disease was known by its clinical symptoms only. In 1901, Forde discovered an intracellular protozoal organism in the blood of an Englishman, who had spent 6 years on the Gambia river in British West Africa. Dutton recognized and described the parasite as a new species of trypanosome infecting the blood of man. In 1902, Dutton and Todd found the parasite in 6 cases out of 1043 natives in the Gambia. In 1898, Brault had suggested that sleeping sickness might be caused by a trypanosome, but the relation between the two was not made until 1903, when Castellani demonstrated the trypanosome in the cerebro-spinal fluid of patients suffering from sleeping sickness. Since Castellani's discovery, the disease has been investigated by numerous Commissions, whose reports cover in great detail every phase of the subject.

Geographical Distribution.—Sleeping sickness has not been discovered outside of equatorial Africa. The limits of the disease on the west coast are the Senegal on the north and Mossamedes in Portuguese West Africa on the south. Along this coastal territory, the distribution is decidedly irregular. In some places a large percentage of the native inhabitants are infected, while other districts are comparatively free. The basins of the Senegal, Gambia, Niger, Congo, and head waters of the Nile rivers are infected. No cases have been reported from the Zambesi. In the interior whole tribes have been destroyed. Around Lakes Albert Nyanza and Victoria Nyanza the majority of the native inhabitants have perished. The east coast of Africa is free from the disease and no cases have originated within 400 miles of the coast. Outside of the endemic area both natives and Europeans have been diagnosed as suffering from the disease, but inquiry has always led to a history of residence within the infected area. Within this area there are many places endemically free. The low-lying banks of streams and shores of lakes of those localities, whose native inhabitants live near the water, harbor the infection in a particularly virulent form. In the West Indian slave trade days, there were many cases of sleeping sickness among the West African negroes imported from Africa, but the disease never became endemic and no cases of sleeping sickness are known to have occurred in any native born West Indians.

Predisposing Causes.—Before any series of exhaustive observations had been made, it was believed that the natives alone were liable to infection. This has been disproved and it is now known that all races and both sexes are equally liable, providing exposure to the infecting agent has taken place. The white inhabitants of an infected district are less liable to contract the disease than a native on accout of the protection rendered by his clothing and different mode of life.

but there is a large series of cases on record now of the disease in both white men and white women. Age seems to have no influence upon liability to infection, and among natives of an infected area, all ages are seen suffering with the disease.

Etiology.—Prior to the establishment of the fact that sleeping sickness is the terminal stage of human trypanosomiasis, many theories had been advanced to explain the disease, and it had been considered at various times by different observers, a manifestation of bacterial, filarial, strongloides, and hook-worm infections. Chronic food poisoning had also been incriminated. Castellani's discovery in 1903, of the trypanosome in the cerebrospinal fluid of sleeping sickness patients has been confirmed by many workers, and now the entire cycle of infection with the transmitting agent is known, with the exception of a few minor points.

The Parasite.—After the recognition of the parasite in Forde's case it was named trypanosoma gambiense. Nepveu had first seen the parasite in the blood of man, but his description is imperfect. Castellani gives its dimensions as from 16 to 24 microns long, and from 2 to 5 microns broad. Anteriorly it is either pointed or rounded and along one border is an undulating membrane, which is a thickening of the ectoplasm. This is continued posteriorly into a free flagellum. The origin of the undulating membrane takes place from a minute spot of nuclear material of oval shape, called the kinetonucleus, situated near the anterior end of the trypanosome. About the middle of the body of the parasite is an oval mass of nuclear material, irregularly shaped, called the trophonucleus. A few chromatin granules may be seen posterior to the trophonucleus, and the cytoplasm is continued in a narrow diminishing band for some distance along the flagellum. In Castellani's report in the Reports of the Royal Society on Sleeping Sickness are pictured besides the ordinary forms, multinucleate, polyflagellate, and nonflagellate forms.

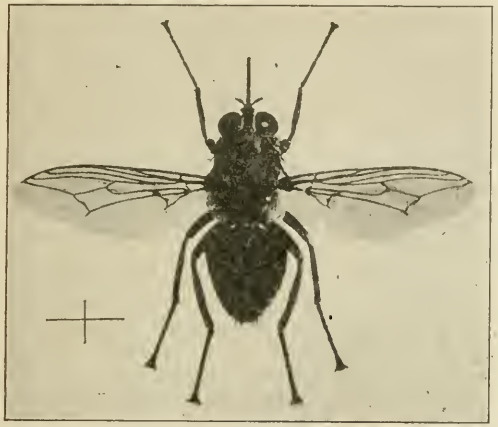
Occurrence of Parasite in Man.—The main facts of the life cycle of the parasite have been worked out but there are still a number of unknown points. In man the trypanosome is found in the peripheral circulation, the cerebrospinal fluid, and the lymph nodes of cases of sleeping sickness at various times during the progress of the disease. The majority of observers believe that the parasite is found in the peripheral circulation and lymph glands during the early stages (the so-called trypanosomatic fever); and that the invasion of the cerebrospinal fluid marks the beginning of the later stages. Various methods have been devised for demonstration of the trypanosome in the blood of man. Unless the trypanosomes are quite numerous they will be overlooked in the ordinary fresh blood preparations; the use of a large hanging drop, searching from 10 to 15 minutes, will give positive results in a larger percentage of cases in the early stages. The trypanosome may be located first with the low power of the microscope by the movements of the red blood cells as they are lashed by the flagellum of the parasite. Further investigation should then be made with the high power. The surest method of demonstration in fresh blood preparations is by the use of the centrifuge. About 10 c.c. of blood are drawn in the usual manner from a vein at the bend of the elbow. This is drawn in 1 percent sodium citrate in normal salt solution to prevent coagulation, centrifuged three times and the third or fourth residue examined. For staining blood preparations the various modifications of the Romanowsky stains give very good results. Koch, in his work on Lake Nyanza used a heavy drop of blood, which he stained with a dilute solution of Giemsa's stain. In the hands of experts, this is a very reliable method, but one or two trypanosomes may be overlooked on account of their being concealed by red blood cells and fibrin. During the latter stages of the disease, the trypanosomes may be demonstrated by examination of the cerebrospinal fluid obtained by lumbar puncture. In examining the cerebrospinal fluid, fresh and stained preparations are made and if these are negative, the fluid is centrifuged and the sediment examined. The lymph nodes and channels contain the trypanosomes at a very early stage of the disease and puncture of an enlarged lymph gland is the most certain method of demonstrating the parasite. A technic of gland puncture used by Grieg and Gray has given most satisfactory results. An enlarged gland of the posterior cervical chain is grasped between the thumb and index-finger and punctured by a sterile hypodermic needle. Then the barrel of the instrument is placed on the needle and the latter withdrawn. The drop of gland juice may thus be expressed upon a slide and examined as a fresh or stained preparation. Artificial culture of the trypanosome of sleeping sickness has not been successful, although they were kept going for 68 days by Thomas and Breinl.

The Transmitting Agent.—After the discovery that the trypanosome was the cause of sleeping sickness, it was soon noted that the distribution of the disease in the endemic foci was limited to those areas in which a certain species of the tsetse fly was found. There are ten species of this fly in Africa, but only one species, *Glossina palpalis*, has been proved to be the transmitting agent of the Trypanosoma gambiense of man. In appearance, *Glossina palpalis* is a dark colored fly, about 8 to 12 mm. long. A point of recognition is the arrangement of the fly's wings in the resting position. They overlap like a pair of scissors. This point differentiates the tsetse fly from other blood-sucking diptera with which it is associated.

Distribution.—The tsetse flies are limited to Africa. The *Glossina palpalis* is found along the west coast from about 13° to 15° south of the equator. In the interior it is not found farther north than 8° in the Anglo-Egyptian Soudan, nor farther south than 12° on the Luapula river in northeast Rhodesia. It is found in Angola, Congo State, The Gambia, Gold Coast, Ivory Coast, Lagos, North and South Nigeria, Prince's Island, Sierra Leone, Anglo-Egyptian Soudan, Uganda, Northeast Rodesia, Togoland, Senegal, Niger, French Guinea, French Congo, Dahomey,

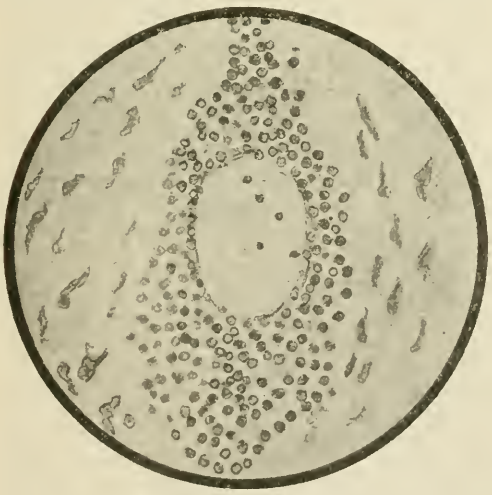
and the Gaboon. It is very numerous on Lakes Victoria Albert and Albert Edward. Lake Tanganyika and Mveru. It is not found on the east coast nor within approximately 400 miles of it.

Habitat, Habits, Method of Propagation.—All of the glossinæ are typical sanguiverous diptera, and



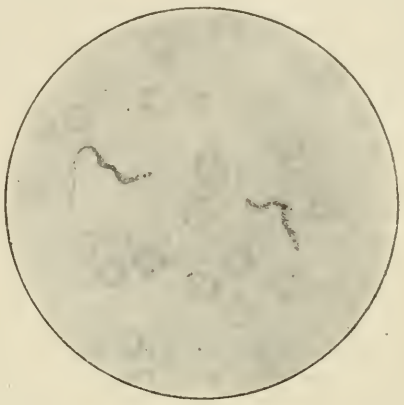
Glossina Palpalis.—(*Adapted from Wellcome Research Laboratory Reports.*)

they bite all mammalia. In examining the intestinal contents of a large number of *Glossinæ palpales*, Koch found red blood cells from crocodiles most frequently, and from man next. Avian blood was found very rarely. The flies only bite



Perivascular Infiltration of Lymphocytes in Sleeping Sickness.—(*Mott. B. M. J.*, Dec. 16, 1899.)

during the daytime from sunrise to sunset. The Portuguese Commission working on Prince's Island reported that they were less liable to bite during the mid part of the day, but observers in other parts of Africa lay no stress upon this point. Both male and female flies bite, and they seem to prefer a dark to a light surface. The optimum habitat of the fly is a loose soil, well shaded, bordering a lake, stream, or pool, with a temperature range of 25° to 30° C. and a high degree of humidity. It is not found in the dense jungle where the ground is always shaded nor in clear places where there is no shade. It has not been found above an



Trypanosoma Gambiense in Human Blood.—(*Schleip.*)

altitude of 4000 feet. Hodges considered that the natural range of the fly was about 30 yards with a following range of very long distances. The native boats and caravans distribute these flies over a wide area by mechanical transmission and it is by this method that human trypanosomiasis has been so widely spread during the

Forms of Trypanosoma Gambiense seen in Blood and Cerebrospinal Fluids.—(*Adapted from Manson's Tropical Diseases.*)

past 10 years. Dutton and Todd, on the Congo believed that the natural flight of the fly was a considerable distance, and Roubaud on the same river reported that it would attack passengers on boats a mile from shore. The flight of the fly is swift and there is a buzzing sound. Clothing is a fairly adequate protection against the bite of the

fly, but observers report that it can bite through socks, white drill or duck, khaki, and flannel shirts. There is little or no pain accompanying the bite, and little or no irritation follows. The female *Glossina palpalis* gives birth to a larva every 9 or 10 days. This larva buries itself in the loose soil, crevice of a tree trunk, or decaying mass of vegetation, and changes to the pupal stage. Both larvæ and pupæ are killed by prolonged exposure to water, and if shade is removed, they die under the direct rays of the sun. In 32 or 33 days the pupa hatches.

Cycle of Trypanosoma Gambiense in the Fly.—The French Commission working in the Congo believes that for the transmission of the trypanosome over long distances, the *Glossina palpalis* is necessary, but for the transmission from one individual to another, such as would take place in a native family inhabiting the same hut, other biting insects may mechanically transmit the trypanosome. Bruce, working with Nagana, the trypanosomiasis of cattle, could discover no trace of the trypanosomes in the proboscides of tsetse flies later than 1 hour after they had bitten infected animals. Munchin, Gray, and Tulloch found no trace of trypanosomes in the bodies of infected flies later than the third day after infection. During the 3 days after infection, trypanosomes were found in the midgut of the fly. Kleine, working with *Glossina palpalis* and Trypanosoma gambiense on experimental animals concluded that *Glossina palpalis* is a true host of the trypanosome. Some of the flies were able to infect laboratory animals immediately after biting. They lost this ability to transmit the trypanosome for about 18 days, when they were able to infect experimental animals again. The duration of the period of infection is unknown. Two years after the native population had been removed from the shores of Lake Victoria, the British discovered that the tsetse flies were still infective to experimental animals. There is a possibility in this case of the flies finding new infection in natives. If this source could be barred, there would remain the possibilities of (1) a reservoir of human trypanosomiasis existing in some animal, (2) the life of a tsetse fly extending over 2 years, (3) and hereditary transmission of the trypanosome in the fly. Both dogs and monkeys are infective and the disease runs a fairly rapid course of about 2 months in the former and about 12 months in the latter. In the laboratory animals, the infection runs a more chronic course.

Symptoms.—For purposes of description, the course of the disease is divided into three stages. During the first stage the parasite is present in the peripheral circulation and in the enlarged glands; the second stage is marked by an invasion of the cerebrospinal fluid; and in the third stage, the symptoms of serious nervous involvement are seen.

First Stage.—In blacks there may be no symptoms. In a reported case of a European, there was fever, irregular in type, accompanied by irritability, insomnia, headache, and loss of strength. This persisted for 15 to 20 days, then there was an improvement. The fever persisted, however, coming on at irregular intervals, with a tendency to rise at night. During this stage there is an acceleration of the pulse, which is distinct from the febrile rise. The pulse rate at this stage is often 120. During the second and third months, Kérandel's sign of deep hyperesthesia is noted. Kérandel in describing this symptom said that ordinary contact with objects, such as would pass unnoticed in a normal individual caused very severe pain. In Europeans, an erythema appears which may have an irregular distribution. This skin eruption may not be noticed in the blacks. Fugitive and painful patches of transitory edema on face and ankles may be present. Loss of sexual power in men, and amenorrhea in women are common. Anemia, loss of flesh, headache, itching, may be present. Iritis and cyclitis have been noted and blacks complain of photophobia and sensations of mist. Vomiting, colic, bloody diarrhea may occur. Adenitis is sometimes absent, but in the majority of cases there is a painless enlargement of the cervical glands. Polyadenitis may be present.

Second Stage.—The symptoms of the first stage are accentuated. The anemia is more pronounced, the headaches more frequent and severe. Patches of edema are more constant. The febrile attacks occur oftener and finally there is a daily afternoon rise of temperature. During the course of the disease, the temperature seldom arises above 103° F. There is a gradual change of character, with intellectual apathy and a tendency to drowsiness. Fibrillary tremors of the tongue appear, which may interfere with speech. Tremors in the arms, when extended, may be present. Zones of anesthesia and hyperesthesia and muscular atrophy are reported. There are attacks of giddiness and the gait may be hesitating. It is reported that during the first part of this stage, Romberg's sign is absent, later it is present, and finally the patient must stand upon both legs with eyes open to keep from falling. Martin, Guillain, and Darré describe a medullary (spinal) and a cerebrospinal form, in the former there being loss of sensation and motion, and in the latter, mania and hallucinations.

Third Stage.—In the final stage the nervous symptoms show that serious structural changes have taken place in the cerebrospinal axis. The intellectual apathy is extreme and somnolence has given place to torpor. There are tremors, and convulsions may take place similar to Jacksonian epilepsy. The patient lies in coma toward the end. The axillary temperature at this time is usually subnormal. Death takes place while in coma, or from some intercurrent disease, such as pneumonia, dysentery, or tuberculosis. It is the third stage which gave the name sleeping sickness to the disease.

Duration of the Disease.—This is uncertain. In one case reported, a European, there was an interval of about one month between known exposure to infection and beginning symptoms. The first stage may last from a few months to a few years. During the second and third stages, careful nursing will prolong life considerably.

The length of life of Europeans, after definite symptoms appear, varies from 1 1/2 to several years. In untreated blacks, it may be shorter.

Blood.—All observers agree that there is a relative increase in the lymphocytes. The French Commission reports the following as an average differential count:

Polynuclears,	49.04
Lymphocytes,	36.6
Large mononuclears,	6.36
Eosinophiles,	6.24
Transitional,	.76

The eosinophilia was caused by filariasis. There are no reports of a leukocytosis in uncomplicated cases of human trypanosomiasis.

Pathology.—Bruce reports that the gross appearance of the brain is fairly characteristic of sleeping sickness. He says that "upon removing the calvarium, a great deal of fluid escapes. The dura mater is not adherent and as a rule presents nothing abnormal. On reflecting it, the convolutions on the surface of the brain are found to be flattened and the sulci filled with opaque looking subarachnoid fluid, giving a ground glass appearance. The vessels on the surface are injected. On section, the brain appears normal, but the lateral ventricles are dilated and contain an excess of fluid." The microscopic pathology was worked out by Mott. He reported that the specific lesion was a meningoencephalitis in which there was a perivascular infiltration of mononuclear leukocytes around both large and small blood-vessels of the brain and cord. Bruce concludes that "human trypanosomiasis is essentially a disease of the lymphatic system, and the irritation and proliferation of the lymphocytes is probably due to a toxin, secreted by or contained in the bodies of the trypanosomes. The characteristic symptoms of the disease are no doubt due to the accumulation of these lymphocytes in the perivascular spaces of the brain, compressing the arteries and so interfering with the normal nutrition of the brain cells. The progressive weakness of the body, the tremulous conditions of the muscles, the feeble, rapid pulse, the weak voice and uncertain gait, the rise of temperature, would all be accounted for by this obstruction or interference with circulation, giving rise to degenerative changes in the nerve cells and proliferation of the neuroglia."

Diagnosis.—A tentative diagnosis may be made upon the clinical symptoms; but the absolute diagnosis depends upon the discovery of the trypanosomes in the enlarged cervical glands, in the peripheral circulation, or cerebrospinal fluid, according to any of the methods described under the **"parasite."** Numerous observers have reported an autoagglutination of red blood cells in cases of human trypanosomiasis, and African workers regard this as a very suggestive sign.

Treatment.—Besides general hygienic measures, which seem to prolong life only, a specific treatment with arsenical derivatives with or without some of the anilin dyes has been made use of. This specific treatment is based on animal experimentation, some of the arsenical derivatives, notably atoxyl, destroying the trypanosomes in the blood of infected animals. Breinl states that the injection of atoxyl and mercury, atoxyl and antimony, and arsenophenylglycin will produce cures in infected monkeys provided careful general treatment is carried out. He concludes that in man, atoxyl by itself affects a permanent cure in comparatively few and exceptionally favorable cases of sleeping sickness. The trend of medical opinion inclines now to a combined treatment with atoxyl and mercury, salts of antimony or some of the anilin compounds, such as trypan-red. Nattan-Larrier gives the results of treatment of eight Europeans. Of those who received general treatment only, one remained well for 17 months and then relapsed, another had a relapse with cerebral symptoms, and the third remained without symptoms two years. Of 5 treated cases, 3 received weekly hypodermic injections of 0.5 G. of atoxyl. There were two relapses and the condition of the third is doubtful. Another case, which relapsed, received atoxyl by mouth and injections of mercury. A case treated with atoxyl and strychnin improved. Atoxyl occasionally causes partial or total blindness. Soamin, a trade name for sodiumaminophenylarsenate is recommended as possessing all of the beneficial effects of atoxyl with none of its deleterious action. Yet cases are reported of optic atrophy from the use of this drug as well.

Prognosis.—The consensus of opinion seems to be that there is a slight prospect of cure provided the case is seen in the very earliest stages, but in the vast majority of cases, there is a fatal termination that may be only temporarily halted by proper nursing with administration of atoxyl or some other arsenical derivative.

Prophylaxis.—This may be either personal or general. Individuals who are obliged to enter the infected districts should wear clothing and face nets which will protect against the bites of the *Glossina palpalis*. The British, French, Germans, and Portuguese are endeavoring to rid their African territory of sleeping sickness by measures, which include the segregation and treatment of infected natives and the destruction of the *Glossina palpalis*. The British removed the natives from the infected areas around the Victoria Nyanza and established sleeping sickness camps where cases might be observed and studied. Koch rid an island in the lake of the tsetse flies by deforestation. The larvæ and pupæ of the fly will not develop unless they are shaded. Deforestation, however, is impracticable, except in certain localities. Travel between infected and noninfected districts has been regulated, and there is some prospect that eventually, the disease may be limited to certain foci.

SMALLPOX (**Variola**).—An acute, contagious disease, epidemic, characterized by an eruption that makes its appearance first as a papule, then is converted into a vesicle, finally becoming pustular, with the formation of a crust. See also VACCINATION.

Varieties.—(1) Discrete; (2) confluent; (3) hemorrhagic; (4) varioloid.

The period of incubation is from 7 to 12 days.

Etiology.—The specific microorganism of smallpox is probably an intracellular protozoon. Unicellular bodies are formed near the nucleus of the epithelial cell; and its final spores are considered by Councilman to be the true agent of infection. The virulent poison seems to be more abundantly present in the crusts. At this stage it is most highly contagious, is capable of being carried by fomites for great distances, and has the power of causing the disease after long periods of time. The disease is modified by a previous vaccination. One attack generally confers immunity, but subsequent attacks may occasionally take place.

Pathology.—The eruption consists at first of a small, hard, red papule, surrounded by a red areola. Within a short time liquefaction necrosis begins, forming a vesicle depressed in the center. The papules seem to originate in the epidermis immediately over the papillæ; it is here that liquefaction necrosis occurs. At the same time there is an exudation of a lymphoid material, through which are seen threads of denucleated cells dividing the vesicle into distinct divisions. In the stage of maturation the rete malpighii is filled with leukocytes and the products of coagulation necrosis. If the suppurative process extends through the cutis, scarring is inevitable. The eruption is very frequently seen on the soft palate and mucous membrane of the mouth and on the tongue. The red blood-corpuscles are greatly diminished; the leukocytes are not affected until the pustular stage; they are then increased.

Internal Organs.—The lungs and spleen are congested. The liver and kidneys occasionally show a degree of parenchymatous degeneration.

Symptoms and Clinical Course. Discrete Smallpox.—The onset is usually marked with a chill, intense frontal headache, and lumbar pains, often nausea and vomiting. In young children convulsions are frequent. The fever rises rapidly to from 103° to 104° F. within the first 48 hours, where it remains until the third or fourth day, or until the papular eruption appears, when it falls several degrees. The eruption is first noticed about the forehead at the junction of hair and on the wrists. The pulse is rapid and full.

The temperature remains low until about the eighth or ninth day, when the pustular stage arrives and there is a secondary rise of temperature—105° F. or more—proportionate to the severity of the attack. There is now great swelling about the face, and the eyelids may be entirely closed. Intense pain is present over the affected area. At this stage a peculiar odor is detected. If the case terminates favorably, toward the twelfth day desquamation begins with restoration of the diseased epidermis.

The Eruption.—It may be said, with due allowance, that the eruption for 3 days remains a papule, 3 days a vesicle, and 3 days a pustule. The papules are at first hard to the touch, and can be rolled around under the skin like a shot. The vesicle is depressed in the center (umbilicated) and is divided by the meshes into distinct compartments (loculated) which, if incised in one portion, all of the fluid will not escape, but only in the mesh in which the incision is made.

Confluent Smallpox.—The onset is the same as in the discrete form—with the papules at first discrete or separate, but later run together. The primary rise of temperature is higher, as a rule, than in the discrete form; and the same is true of the secondary fever, which may also be very irregular. With the rise of secondary fever the suffering becomes more intense, and there may be delirium and stupor, with rapid pulse.

Hemorrhagic Smallpox (Malignant Smallpox).—The primary symptoms are all exaggerated, and instead of the eruption first appearing, there are seen small punctiform hemorrhages about the groins and conjunctivæ, which gradually increase in size until large areas are affected. Hematuria, hemoptysis, and hematemesis are very common. Death usually occurs from the fourth to the seventh day. In this form there is usually no distinct eruption.

Varioloid.—This is a modified form of smallpox occurring in a person who has been previously vaccinated. The symptoms come on very suddenly, with a rise of temperature, headache, and severe pains in the back. The papules, as in discrete smallpox, appear on the forehead and arms on the third or fourth day. As a rule, they are fewer in number than in discrete smallpox. The papules become vesicles within a day or two, then pustules, and finally desquamate; the whole process frequently is completed within a period of 5 or 6 days. See Vaccination.

Complications.—Bronchopneumonia (most common), laryngitis, pleurisy, iritis, keratitis, conjunctivitis, boils, convulsions.

Diagnosis.—With the appearance of the perfect papule all doubt in the diagnosis of smallpox generally ceases. Ignorance of the initial rashes, measly and scarlatinal, has often led to errors of diagnosis. On the other hand, the resemblance of the eruption of measles to smallpox has also given rise to errors, the result of which has been no less serious; because in consequence, cases of measles have more than once been sent to smallpox hospitals, with disastrous consequences. Never, in measles, is there so severe a pain in the back as in smallpox, while the early cough and coryza are only found in measles. The lesson taught is to defer a positive diagnosis because less serious mischief may result from an error thus occasioned than as the result of an opposite course. The possibility of mistaking relapsing fever for smallpox has been alluded to in considering the former disease. Cerebrospinal fever may also be simulated by the hemorrhagic form of smallpox. Pustular syphilids and accidental croton-oil eruption have been mistaken for smallpox, as has also chicken-pox.

Prognosis depends upon whether or not the person has been vaccinated, upon the character of the epidemic, and upon the season of the year. If there has been a previous vaccination, the prognosis is always good. Occasionally, there is a type of smallpox which is virulent in certain epidemics.

The summer season is always favorable to smallpox, as the room can be kept well ventilated, more

comfortable, and there is less danger of complications.

The hemorrhagic type is the most fatal. In young children the prognosis is very unfavorable.

Ominous Symptoms in Smallpox.—Eliot has always noticed, in moving a patient to the hospital, that those who voluntarily covered their faces and heads, without any suggestion to do so, invariably died. When the face of a white patient assumes a dark leaden hue during the first days, death may be predicted almost with certainty. Those patients who present great swelling of the face and head in the beginning always suffer from severe attacks. There is a peculiarity of the walk which is very ominous: the patient lifts the feet high, as if he were ascending stairs, and this applies to the early eruptive stage. The general mortality is from 15 to 30 percent.

Prophylactic Treatment.—The patient should be isolated. If in the summer, a tent answers very well; or a house should be chosen that can subsequently be thoroughly disinfected. Nothing should remain in the room that cannot be boiled and washed in a solution of mercuric chlorid, 1:2000. The bed-clothes and bedding should be burned. The furniture, walls, and ceiling should be thoroughly scrubbed with soap and water; then with the solution of mercuric chlorid; 1 : 2000; and all furniture that can be moved should be sunned for at least a week. All sweepings, cloths, and waste around the yard should be swept up and burned. Burning sulphur and scattering a few drops of carbolic acid about an infected place is a primitive custom, and does no good unless the cause of the evil is removed. Formalin is a good disinfectant. See DISINFECTION.

The physician should wear such outside garments as can be thoroughly washed, and should always change the clothing before attending other cases. His clothing should be kept in an unoccupied room from which all drapery has been removed. It should subsequently be disinfected. After a visit to a patient with smallpox, the face, hair, and hands should be thoroughly scrubbed with soap and water; then with a solution of mercuric chlorid—1:1000 on hands and 1:4000 on face and hair—taking care that the liquid does not come in contact with the eyes. All persons in the immediate vicinity of the patient should be vaccinated. See VACCINATION.

Medicinal Treatment.—In mild cases few drugs are indicated. In no other disease are careful nursing and the proper hygienic precautions more necessary. It is always well to begin the treatment with calomel, 1/4 grain being taken every hour until 5 or 6 doses have been taken, followed by 1/2 of an ounce of Rochelle or Epsom salt. The kidneys should be kept active, and probably there is nothing better than potassium bitartrate, 20 grains of which may be given every 3 or 4 hours. Acetanilid or phenacetin may be given for hyperpyrexia. A light nutritious diet should be given. If the temperature rises above 102.5° F., it may be reduced by the administration of 5 grains of phenacetin; or the following formula may be given:

℞. Antipyrin, ʒ jss
Tincture of digitalis, ʒ ij
Peppermint water, ʒ iij
Water, enough to make ʒ ij.

One teaspoonful every 3 or 4 hours, if necessary, to reduce fever.

These antipyretics, besides reducing the temperature, mitigate the pain and render the patient more comfortable. If the temperature cannot be satisfactorily controlled, one should not hesitate to use the cold tub-bath. Cold drinks, such as lemonade, assuage the thirst fairly well.

As a diuretic:

℞. Solution of potassium citrate, ʒ ij
Sweet spirit of niter, Elixir of curacoa, each, ʒ iv
Water enough to make ʒ iv.

One tablespoonful every 3 or 4 hours.

If the nervous system begins to suffer, or if the heart is weak; 1/2 ounce of whisky may be given every 3 or 4 hours. Frequently morphin, 1/4 of a grain hypodermically, may be given to relieve pain and to produce sleep.

Finsen's red light treatment has proved effective in preventing suppuration.

Antistreptococcus serum is recommended in the stage of pustulation.

To Prevent Pitting.—Apply cold cream or vaselin on lint to affected parts. Schamberg found the most efficient treatment to be painting with iodin. Romero advocates picric acid applications (picric acid 30 grains, alcohol 1/2 ounce, water 6 1/2 ounces; or as an ointment). Lint dipped in a solution of mercuric chlorid, 1:3000, may also be applied.

Quarantine should be enforced for at least 2 weeks.

SNAKE-BITES.—See BITES AND STINGS.

SNAKEROOT.—See CIMICIFUGA, SENEGA SERPENTARIA.

SNEEZING.—The causes of excessive sneezing may be broadly classified as extrinsic and intrinsic. Tobacco-snuff and pollen are instances of the former, while the latter occur in association with various affections, as whooping-cough, asthma, hay-fever, gout, hysteria, disordered menstruation, derangement of the sexual functions, and pregnancy. A bright light or an intense color may cause excessive sneezing in some persons. The ingestion of pungent substances may cause violent sneezing. Some individuals exhibit special idiosyncrasy to certain articles of food. For instance, in some, chocolate, eaten or drunk, will provoke sudden sneezing. The initial sneezing in the beginning of an ordinary "cold" needs no mention here. Impacted cerumen may be a reflex cause. Sexual excesses may act similarly.

Treatment.—An attack may be cut short by pressure on some branch of the trigeminal nerve. A mustard poultice to the back of the neck, an emetic, an astringent nasal inhalation or a spray of creosote, iodin, or menthol, or an application to the nasal mucosa of a solution of cocain (3 percent)

may suffice. The head may be immersed in cold water. Irregularity in the function of any affected organ should be rectified. One drop of Fowler's solution 3 times daily may be given in paroxysmal sneezing allied to asthma. Potassium iodid, 10 grains several times daily, and iodin inhalations are sometimes used. In incessant sneezing, with profuse watery discharge from the eyes and nose, camphor powder snuffed and an alcoholic solution of camphor inhaled are also recommended. See Asthma, Hay-fever.

SOAMIN.—Sodiumaminophenylarsonate. One of the new arsenical compounds used in the treatment of syphilis. It is almost identical with atoxyl though it is claimed to be more stable and hence safer; but it is less stable and more toxic than arsacetin. Cases of optic atrophy, however, have been reported from its use. Dose, 1 to 5 grains. See Arylarsonates.

SOAP (Sapo).—A chemic compound made by the union of certain fatty acids with a salifiable base. It is used for washing and cleansing purposes. A table is appended showing the composition of the chief soaps of pharmacy, as analyzed by M. Dechan.

Therapeutics.—Soap is a laxative, antacid, and antilithic. Externally, it is a stimulating discutient, and is used for cleansing the skin, removing fatty substances, and softening the epidermis; but if too long applied, it may prove decidedly irritant. It is a good antidote in poisoning by acids, and should be administered freely in such cases until more energetic alkalies can be obtained. In aqueous solution it makes a useful enema for constipation, or a plug of soap may be inserted into the rectum. Soft soap is a powerful detergent stimulant, and is much employed in skin-diseases, especially eczema rubrum, in which the tincture is well rubbed on, the diseased skin well washed and then covered with a bland ointment. The tincture is the most desirable form for use, and may be diluted with 3 parts of alcohol for shampooing the scalp. The liniment is used with friction in sprains, bruises, and stiff joints, being a little more stimulating than camphor liniment. It makes a good basis for extemporaneous liniment prescriptions.

Preparations.—**Sapo** (*white castile soap*) is soap prepared from sodium hydroxid and olive oil; a whitish solid, hard, yet easily cut when fresh, of faint, peculiar odor free from rancidity, a disagreeable alkaline taste and alkaline reaction; readily soluble in water and in alcohol. It is an ingredient of three of the official pills, and two plasters. **Sapo Mollis,** *soft soap, green soap,* is soap prepared from potassium hydroxid and linseed oil; a soft, unctuous mass, of a yellowish-brown color, soluble in about 5 of hot water and in 2 of hot alcohol. The name green soap is a misnomer, as it is not green in color. Insoluble soaps are combinations of the oily acids with earths and metal oxids, as the soap of lime, official as linimentum calcis, and the soap of lead monoxid, the former lead plaster. **Emplastrum Saponis** has of soap 10, lead plaster 90, water *q. s.* **Linimentum Saponis** has of soap 6, camphor 4 1/2, oil of rosemary 1, alcohol 72 1/2, water to 100. **Opodeldoc** is a similar preparation. Soap liniment is an ingredient of chloroform liniment. **Linimentum Saponis Mollis,** *tincture of green soap,* has of soft soap 65, oil of lavender 2, alcohol to 100.

Variety.	Fatty Acids.	Combined Alkali.	Free Alkali.	Silica.	Sulphates and Chlorides.	Insoluble Matter.	Water.	Insoluble in Alcohol.
Hard soap (*sapo durus*).	81.5	9.92	0.08	....	0.28	0.20	10.65	0.50
White Castile soap (*sapo Cast. alb.*).	76.7	9.14	0.09	....	0.36	0.90	13.25	0.60
Mottled Castile soap.	68.1	8.9	0.19	0.15	0.63	0.80	21.70	1.30

SOAPBARK.—See Quillaja.

SODA-WATER.—See Carbon Dioxid.

SODIUM.—Na = 23; quantivalence, 1; sp. gr., 0.972. A metal of the alkaline group, characterized by its strong affinity for oxygen. It has a silver-white luster, and is softer than lead. It decomposes water, forming sodium hydroxid.

The action of the sodium salts is similar to that of the potassium salts, except that the former are feebler as alkalies, are not so depressant, and are not so poisonous to the cardiac muscle or the nerves. They are diffused more slowly, are neither absorbed nor excreted so readily, and have not so marked diuretic action. Locally applied in large doses to muscular and nervous tissues they are paralyzant, but not so powerfully as potassium salts. **Sodium urate** is not soluble like the urates of lithium and potassium, and is therefore much less readily excreted, forming the masses called chalk-stones in gouty subjects. **Soda** is a less active escharotic than potash, having less affinity for water. **Liquor sodii hydroxidi** renders the blood and secretions more alkaline, but does not alter nutrition to the extent that the potassium solution does. The **acetate** is converted into the carbonate in the blood, and is a less active diuretic than the corresponding potassium salt. The **carbonate** is irritant to the stomach, and is chiefly used in the preparation of the other salts. The **nitrate** is mildly purgative and diuretic, and in solution is solvent to false membranes. The **ethylate** is antiseptic, and a powerful but almost painless escharotic. **Sodium bicarbonate** has the same action as the corresponding potassium salt, except that it is more slowly absorbed and is less depressant. It is antacid, antipruritic, and analgesic, the latter being probably due to the increased alkalinity imparted by it to the blood. Internally in small doses it is neutralized by the hydrochloric

acid of the gastric juice; in medium doses it is solvent to the gastric mucus, slightly irritant to the stomach, and sedative to the gastric nerves; in large dose it renders the stomach contents neutral or alkaline and stops the gastric digestion.

Preparations.—**S. Acetas,** $NaC_2H_3O_2 \cdot 3H_2O$, diuretic, a good saline draft. Dose, 5 to 30 grains. **S. Arsenas,** Na_2HAsO_4, used in preparing liquor sodii arsenatis. **S. Benzoas,** $NaC_7H_5O_2$. Dose, 10 to 30 grains. **S. Bicarbonas,** $HNaCO_3$, "saleratus," "baking soda;" antacid; 20 grains neutralize 16.7 grains of citric acid or 17.8 grains of tartaric acid. Effervescent. It is much used for the aeration of bread. Dose, 10 to 30 grains. **S. Bicarb., Troch.,** each contains 3 grains of the salt. **S. Boras,** $Na_2B_2O_7$, BORAX (*q. v.*). **S. Bromidum,** NaBr. Dose, 10 to 30 grains. **S. Cacodylate.** See CACODYLIC ACID. **S. Carbonas, monohydratus,** Na_2CO_3, antacid; 20 grains neutralize 9.7 grains of citric or 10.5 grains of tartaric acid. Effervescent. Dose, 1 to 7 grains. **S. Chloras** $NaClO_3$, the basis of an agreeable gargle. Dose, 1 to 10 grains. **S. Chloridum,** NaCl, common salt. Dose, 10 grains to 1 dram. **S. Cinnamas.** See CINNAMIC ACID. **S. Citras.** Dose, 5 to 30 grains. **S. Ethylas,** C_2H_5NaO, caustic alcohol, unof., in contact with water breaks into caustic soda and alcohol. **Sodium Glycocholate,** an excellent cholagogue, markedly stimulating the digestion of fats. Its dose is 2 to 5 grains. **S. Hydroxid,** Na(HO), "caustic soda," very alkaline and powerfully escharotic. **S. Hydroxid. Liq.,** solution of soda. Dose, 5 minims to 1/2 of a dram well diluted with water, contains 56 parts of the hydroxid in 944 of distilled water. **S. Hypophosphis,** $NaPH_2O_2$ used in preparing syrupus hypophosphitum **S. Iodidum,** NaI. Dose, 3 to 10 grains. **S. Nitras,** $NaNO_3$, "cubic niter," "Chili saltpeter." Dose, 5 to 30 grains. **S. Nitris,** $NaNO_2$, used in preparing sweet spirit of niter. **S. Oleas,** antacid and mild laxative. Dose, 2 to 20 grains. **S. Perboras,** antiseptic and bactericide. A substitute for hydrogen peroxid. **S. Phenolsulphonas,** $NaC_6H_5SO_42H_2O_2$, (sodium sulphocarbolate). Dose, 10 to 15 grains. **S. Phosphas,** Na_2HPO_4, sodium orthophosphate. **S. Pyrophosphas,** $Na_2P_2O_7$, sodium pyrophosphate. **S. Salicylas,** $NaC_7H_5O_3$, sodium salicylate. Dose, 10 to 15 grains. **S. Santonas,** $Na_2C_{15}H_{18}O_4$, a vermifuge for thread-worms. Dose, 5 grains. **S. Sulphas,** Na_2SO_4, "Glauber's salt," a mild purgative. Dose, 5 to 20 grains; as a purgative, 1/2 to 1 ounce. **S. Sulphis,** Na_2SO_3, sodium sulphite. **S. Thiosulphas,** $Na_2S_2O_3+5H_2O$, an antiseptic salt.

SOFTENING OF THE BRAIN.—A disease of the cerebral tissue dependent upon inflammation or blood failure, the symptoms varying according to the part affected, but consisting of loss of function, partial or complete. According to the appearances presenting, the softening has been distinguished as red, yellow, or white. See PARALYSIS (General).

SOLUTION.—See LIQUOR; PERCENTAGE SOLUTIONS.

SOMATOSE.—A preparation in which the albuminoids and nutritive constituents of flesh are converted into soluble albumoses, 5 parts of somatose representing 30 parts of beef in nutritive value. It forms a pale yellowish powder, which is readily soluble in water, forming an almost odorless and tasteless solution. It is employed as a food for patients afflicted with weak digestion, 1/2 to 1 ounce being given in milk, cocoa, or soup.

Iron Somatose (Ferrosomatose).—A preparation of somatose containing about 2 percent of iron in organic composition, and forming a light brown, inodorous, and tasteless powder, readily soluble in warm fluids; it does not attack the teeth or constipate. Dose, 1 to 3 drams daily.

Milk Somatose.—A tasteless, inodorous, strength giving food-product in powder form, prepared from milk. It contains the albumoses of milk in soluble form with 5 percent of tannic acid organically combined. It is used in chronic diseases of digestive organs such as are connected with inflammation of the stomach and with typhoid conditions. Daily doses for children, 1 or 2 teaspoonfuls; adults, 2 or 3 tablespoonfuls.

SOMNAL.—A hypnotic formed by the union of chloral, alcohol, and urethane. It acts like chloral, but is more pleasant. It occurs as a colorless liquid, resembling chloroform in its behavior with cold water, forming globules and refusing to dissolve or mix. It is soluble in hot water, in alcohol, and in alcoholic solutions 3 : 1. The advantages claimed for it are that in 20-grain doses it induces a quiet sleep, within a half-hour, lasting for 6 to 8 hours, and with no unpleasant after-effects. Doses of 45 or even of 60 grains do not depress the heart. Doses of 30 grains in solution with syrup of tolu or whisky are well borne and without deleterious effects. Its effects are more striking than urethane and less depressing than chloral. There is no vertigo, as after sulphonal. It is not powerful enough to control delirium tremens, maniacal delirium, or severe pain, but manifests its best hypnotic and sedative action in insomnia of convalescence from acute disease. In whooping-cough, in spasmodic laryngitis and in asthma, in the so-called "nervous cough," in chorea, in melancholia, and in mental depression, it is of much use. It is said to be injurious in general paralysis, and to be contraindicated in cases of impaired digestion.

SOMNAMBULISM.—The condition of half sleep, in which the senses are but partially suspended; also termed sleep-walking. Also the type of hypnotic sleep in which the subject is possessed of all his senses, often having the appearance of one awake, but whose will and consciousness are under the control of the operator. Charcot calls this simply **somnambulism,** which constitutes the third type of the hypnotic state. The second he calls **catalepsy,** produced by the gong suddenly sounded or the electric light suddenly brought before the subject's eyes; the eyes are wide open, and the muscles acquire the curious waxy condition designated as *flexibilitas cerea.* The subject seems to have no mental communication with the outside world. This latter characteristic also distinguishes **lethargy,** or the first type of the hypnotic state, in which there are unconsciousness, irresponsiveness of the senses to stimulation, and a fixed position of certain muscles. See CATALEPSY, HYPNOTISM.

Somnambulism is practically confined to childhood and youth. Idiots and imbeciles are rarely affected. There may be no definite symptoms of ill health in the simpler cases. A neurotic temperament or a tendency to disturbances of the nervous equilibrium, such as epilepsy, hysteria, chorea, or migraine may exist. Other cases may be accompanied by mere chagrin, anger, or surprise.

The eyelids are usually closed, but may be open, and the pupil is dilated. The sense of touch is much exalted, and a sleep-walker seldom runs against furniture, chairs, etc. Some subjects hear well, others do not. The sense of smell varies with the subject. A sleep-walker may enjoy a meal and not remember the fact of having eaten.

Sensibility to pain may be entirely suspended. The muscular system is intact, and permits of extraordinary exploits. The ordinary mental processes are active in somnambulists, and elaborate work may be performed. A dream in all probability precedes and accompanies the action taken. Occasionally, the particular dream may be recalled. Vivid hallucinations may arise, determining the particular act to be performed. Speaking and singing are not uncommon.

Treatment.—Treatment is limited to regulating any indiscretions in diet and correcting any gastric disturbance. The best hygienic surroundings for quiet sleep should be obtained. See Insomnia.

SOMNIFACIENTS.—See Hypnotics.

SOMNOFORM.—A mixture of ethyl chlorid 60, methyl chlorid 35, ethyl bromid 5, said to be more rapid in action than ethyl chlorid.

SORBEFACIENTS. (Discutients).—Agents promoting absorption. They may be divided into two classes: (1) those which stimulate the lymphatics to the removal of morbid or inflammatory deposits, (2) those which promote the imbibition of nutritive or medicinal material into the system. (See Alteratives.) These agents include the following: arsenic, mercury, iodin, iodids, cadmium, ichthyol, lanolin, oleic acid, cacao butter, massage, vapor bath, hot water bath, poultices, counter-irritation, galvanism.

SORE THROAT.—See Laryngitis, Pharyngitis, Tonsillitis.

SPANISH FLY.—See Cantharis.

SPARTEIN.—A volatile liquid alkaloid not containing oxygen. It occurs in *Scoparius*, and is a colorless, thick oil, boiling at 311° C. It is narcotic. It stimulates the action of the vagus, and acts more quickly than digitalis, but not so powerfully. It is an uncertain diuretic and cardiac tonic, but is often efficacious when digitalis fails. Dose, of the sulphate, 1/5 grain. See Scoparius.

SPASMS, INFANTILE.—See Convulsions (Infantile).

SPEARMINT.—See Mentha Viridis.

SPECIFIC GRAVITY.—The comparative weight of bodies of equal bulk. It is ascertained by weighing the bodies with an equal bulk of pure water at a given temperature and atmospheric pressure, which is taken as the unit.

To obtain the specific gravity of a body, it is only necessary to balance it with an equal bulk of the standard and to ascertain how many times the weight of the standard is contained in its weight. For example, a fluidounce of water (standard) weighs 455.7 grains; a fluidounce of lime-water weighs 456.3 grains; $456.3 \div 455.7 = 1.0015$: that is, the lime-water weighs 1.0015 times more than water, bulk for bulk. In other words, its specific gravity is 1.0015. A fluidounce of alcohol weighs 422.8 grains; $422.8 = 455.7 = 0.928$, specific gravity.

This general rule may be given for finding specific gravity: Divide the weight of the body by the weight of an equal bulk of water; the quotient will be the specific gravity.

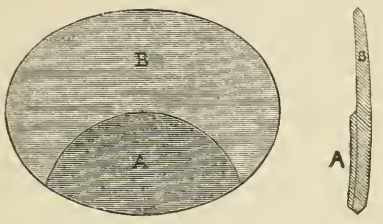
SPECIFICS.—Agents which have each a selective curative influence on a particular disease. Mercury is said to be specific to syphilis, quinin to malaria, and other drugs are more or less specific to certain affections, but they have so many actions and uses that they are usually placed in other groups. The true specifics are the various animal extracts and sera, though even these are being found remedial in other than their specific diseases. The most important of these agents are the thyroid and suprarenal glands, and antidiphtheritic serum or diphtheria antitoxin, which are official but many other animal extracts and sera are used in medicine.

SPECTACLES AND EYE-GLASSES.—The fitting of spectacles and eye-glasses is a most necessary adjunct to the art of ophthalmology. Spectacles should always have stout temple-pieces, to maintain their shape and stay in proper position by their weight. To prevent jarring while walking or running, the sidepieces should fit closely to the face and temples; in fact, it is sometimes preferable that they should exert sufficient pressure to slightly groove the skin. By this means a definite and fixed support is given. Fourteen-karat gold is to be preferred, and stout steel should be the second preference. Although silver does not rust, it cannot be made of sufficient rigidity. Delicate wires, either of gold or steel, should not be accepted, as they can only maintain their position by uncomfortable pressure behind the ears and on the nose.

Spectacles are preferable to eye-glasses whenever there is astigmatism, or when the nose is not properly shaped for the ready adjustment of eye-glasses. Hooks are to be preferred to straight temple-pieces when the glasses are to be worn constantly. Reading-glasses are sometimes more convenient with straight side-pieces, particularly in women, on account of the abundance of hair about the temples. For constant use, lenses should be slightly inclined at a compromise angle between the straight position and the inclination preferred for a reading-glass. Of course, the occupation of the patient must be taken into consideration in adjusting the glass. In high defects the glasses should be fitted closely to the eyes, and, if necessary, the lashes should be trimmed from time to time. Glasses should be worn constantly in high defects, in astigmatism, and in all cases in which there are asthenopic or reflex symptoms.

Bifocal glasses are particularly valuable for a presbyope or for a myope of high degree who is compelled to use different glasses for reading and for distance. The improved form, with a reduced

curved segment cemented on the distance glass, is far more satisfactory than the old straight Franklin bifocals. The lower segment should be about 2 cm. wide, and the upper edge should be more curved than the lower. If the occupation of the patient subjects him to high degrees of heat or steam, the lower segment should be inserted into a groove in the bottom of the distance glass instead of being cemented on. Although it takes the patients some little time to become accustomed to bifocal glasses, they ultimately give far greater satisfaction, and are more convenient than two different pairs of glasses.



Bifocal Lens.
B. Distance lens. *A*. Reading lens, cemented to the Distance lens.

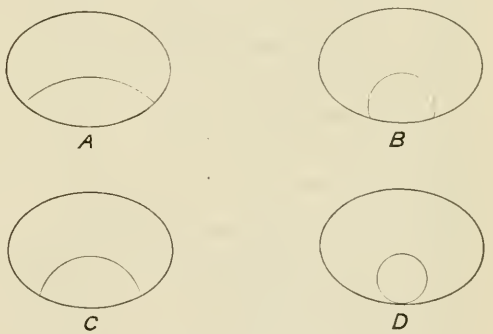
"In another form of bifocal glass the small supplemental lens is *countersunk*, that is to say, is cemented into a corresponding concavity ground in the distance glass. Or the distance glass may be composed of two full-sized plano-convex lenses with their plane surfaces in apposition, each of these surfaces being ground out at its lower part, so as to house the small supplemental lens between them. These two forms admit of a reduction of weight and the abolition of chromatic aberration in the heavy glasses required in aphakia. To accomplish the latter purpose the distance lens is made of crown glass and the supplemental lens of flint glass. In this form they are called *achromatic bifocals*. Their advantage lies in the expense of their manufacture.

"*Fused bifocals* are a variant of the countersunk supplemental lens. In their manufacture a small lens of flint glass is let into a large lens of crown glass by countersinking. Instead of cementing the supplemental lens in position, however, the lenses are heated to the point of fusion of the glass, when its two portions unite. The surfaces of the glass are then reground. One surface of the small supplemental lens is exposed to the grinding and is reduced to the same curvature as the corresponding surface of the main lens. The necessary difference in the refraction of the upper and lower portions is dependent on the difference in index of refraction of the crown glass of which the main lens is composed and the flint glass of the supplemental lens" (Phillips).

Before discharging the patient, the adjustment of the glasses should be carefully examined and the correctness of the lenses verified by neutralization. The good effects of many a careful diagnosis of refraction are ruined by maladjusted and decentered glasses.

Tinted glasses of any kind should never be ordered for constant use, but only temporarily prescribed in inflammatory conditions, during mydriasis, for use at the seashore, etc. Once formed, the habit of wearing tinted glasses is difficult to overcome. Photophobia is usually due to uncorrected or improperly corrected ametropia. It is a well-known fact that tinted glasses are most used in countries in which the importance of eye-strain in comparatively low defects is unrecognized. During mydriasis, London smoked plano-lenses should be worn. Coquilles generally have some spheric or cylindric effect on an irregular surface. See Lenses.

The Care of Spectacles.—"Spectacle frames will last longer and perform their function better if the wearer is instructed to exercise care in handling them. In putting them on and off, the hooks should be lifted from or into their position behind the ears; both hands being used, so as to avoid straining the temples widely apart or otherwise bending them. They should be folded together as little as possible, and when not in use should be laid in a safe place, open, and resting on the edge of the lenses, to avoid scratching the surfaces of the latter. For cleansing them nothing is better than a piece of clean old linen, or, if very much soiled, a little ammonia and water may be used, except on cemented bifocal glasses. While cleansing, the frame should be grasped by the end piece and not by the bridge, and in replacing the glasses on the eyes care should be taken not to crush them against the lashes and thus soil the refracting surfaces at once. When cylindrical or prismatic glasses are worn, patients may return after a time with the statement that the spectacles are unsatisfactory, when the trouble will frequently be found to be due to bending of the frame; or a lens may have fallen out and been replaced upside down, or with the wrong edge inward. It is well to have such persons report periodically to have their glasses readjusted" (Phillips).



Forms of Bifocal Lenses.—(*Phillips.*)

SPEECH-DEFECTS.—The importance of speech as a factor in the mental and physical growth of our race is not generally appreciated. Speech has been defined as "a system of articulate words adopted by convention to represent outwardly the internal process of thinking;" but not only does it represent the process of thinking, but it is

so closely interwoven with it as to be essential to its highest development. Speech is also one of the essentials to the highest physical development, for its use tends to expand the chest and aerate the blood. The faculty of speech is presided over by delicate and complicated cerebral areas inciting to action and working in harmony with peripheral organs having other important bodily functions in addition to those of voice and speech production. Defective speech, therefore, having its origin in a defective action of some of these important central areas and peripheral organs, is a serious malady, and deserves most careful consideration.

For convenience of study, these defects may be divided into two classes: in the first class are all those cases in which the defect is the chief cause for complaint; and in the second, those in which it is merely a symptom of some more alarming condition: as, for example, cerebral abscess or intracranial pressure, from whatever source.

It is convenient, also, to make two divisions of this class; and of the terms that have been used to designate them, the best are **dyslalia** and **pseudolalia.** Under dyslalia come those forms of defective speech in which there is difficulty of utterance: as, for example, stammering, or stuttering; and under pseudolalia come all those defects that may be characterized as slight deviations from the normal speech, as the slurring or omitting of certain elements and the substitution of one element for another.

Stammering (Dyslalia)

Stammering may be defined as interrupted speech characterized by a spasm of certain opposing muscles more or less closely related to the vocal or oral articulating mechanism. This spasm is not always confined to the muscles directly concerned with speech, but may extend to any part of the body, especially when great effort is made to overcome the interruption. It is never exactly the same in any two cases, nor does it always remain constant either in degree or location, but it changes with the temperament of the individual. The phlegmatic person will sometimes stand and only stare, and use no apparent muscular effort at all until such time as he thinks he may be able to proceed. This has been called the silent form of stammering, and in it there is but little noticeable spasm. In the majority of cases, however, the tendency is at least to try to speak, and the degree and extent of spastic muscular contraction will be proportionate to the strength of the effort put forth.

A muscular spasm, therefore, of greater or less intensity is the one condition that is characteristic of all forms of stammering. The cause of this spasm is manifestly a result of misapplied energy in the effort to speak, and it has its counterpart in the grimaces of the letter-writer unaccustomed to the occupation, and in the muscular contortions of the beginner on a bicycle. To the expert, the control of a pen or a bicycle becomes automatic, and the nervous energy expended is almost *nil;* but to the beginner, the control must be voluntary, and the amount of nervous energy expended is immense and is out of all proportion to that which is required. So in the normal person speech tends to become automatic and to require the least possible amount of nervous energy; but when something happens to interfere with the development of this automatic action of the organs of speech, and voluntary action attempts to come to the rescue, the result is always more or less of a failure. There is a surplus of nervous energy expended, and this surplus overflows, so to speak, into muscles that may have but little to do with the process of speech production—and the result is a spastic contraction, or a spasm of these muscles.

The overflow takes place along the channels of least resistance, which channels vary in different individuals; and, therefore, the spasm does not occur in the same muscles in all cases, nor, indeed, in any two cases. It may occur in almost any part of the muscular system, and its manifestation is often grotesque in the extreme.

Etiology.—The cause of stammering has given rise to much conjecture, and many superficial observers have supposed that they had discovered it, only to be disappointed upon further investigation. The mistake has been made of supposing that there is but one cause for stammering, and that this cause operates alike in all cases. The fact is, there are many causes, as there are many causes for dyspepsia or any other functional disturbance; and the precise cause in any individual can only be determined after a careful and oftentimes prolonged study of the case.

Among the predisposing causes heredity must be placed first. About 35 percent of the reported cases had relatives who stammered. It is an affliction that belongs to youth, and it begins at, or soon after, the time the child begins to talk. It may continue to old age; but stammerers, as a rule, are not long lived. Statistics show that about 84 percent of all cases seeking relief are males, and this would seem to indicate that sex must be regarded as a factor in the cause of the affection.

A nervous temperament, either inherited or acquired, is a condition common to most children who stammer. This condition may follow one of the infectious fevers or other diseases of childhood, or it may be the result of eye-strain, hypertrophied tonsils, adenoid vegetations, or intranasal pressure from whatever source. About 15 percent date the origin of their trouble to a severe nervous shock caused by fright or injury. One child had his head ducked in a tub of cold water and has stammered ever since. Another was threatened with arrest by a policeman for playing "pussy" on the street. He was thrown into a convulsion, and has stammered from that time. A child fell downstairs and received a slight injury, attended by a great nervous shock, and stammering immediately followed.

The various neuroses are more or less prevalent in stammerers and in their ancestors, and therefore they must be regarded as probable predisposing causes. Not only do glandular enlargements in the pharynx and intranasal hypertrophies and spurs act as causal factors in this affection, indirectly and in a reflex manner through the nervous system, but in so far as they interfere directly with

the free automatic action of the muscles of vocalization and articulation must they be considered as direct causes. Moreover, we find decided evidences of arrested or imperfect development in the articulating organs of a large percentage of these cases. High and irregular palatal arches are more common than in persons having normal speech; bifid uvula is of frequent occurrence, and we often find abnormalities in the various muscles of the tongue. A very large and imperfectly shaped epiglottis may prove to be the cause in some cases. Anything that interferes with the uniform development and harmonious action of the various mechanisms of speech must be placed among the causal factors of this affection.

Treatment.—Few children would be confirmed stammerers if they could have the proper treatment at the very inception of the trouble. Whatever may be the direct or exciting cause in any particular case, the child begins to hesitate in speech during a period of mental excitement. There is a confusion of ideas that leads naturally to a confusion of words and of the elements of which words are composed. It is here that the turning-point is made. Usually, the child is scolded or ridiculed, either of which procedures tends to add to the confusion and to make future attempts at oral expression still more difficult.

If the little patient can be tided over this period of nervous excitement, in most cases the development of the affection is prevented. Most careful and gentle treatment should be employed. Any attempt at speech should be interdicted until mental quietude is fully established. A careful examination should now be made, with a view to discovering the cause of the trouble, bearing in mind that any condition that may add to the nervous excitability of the patient becomes a contributory cause. Especially must the nose, the nasopharynx, and the throat be examined for obstructions. Careful examination of the mouth should also be made, and so far as possible any irregularities of structure should be corrected and glandular enlargements reduced; the general health of the patient should be put in the best possible condition.

During all this time the child should be encouraged to talk but little, and to think of only one thing at a time, and to express his thoughts with the greatest deliberation. The word "stammering" should never be used in his hearing, nor should his attention be directed in the slightest possible degree toward his speech; for the fear of future trouble in speech is easily aroused, and it is one of the greatest obstacles in all cases to the accomplishment of a cure.

The automatic action of the various mechanisms of speech is no longer possible and the patient is equally incapable of voluntary control of these mechanisms. Manifestly, the object to be attained is the reestablishment of the normal automatic processes of speech, and this can only be done, in a great majority of cases, by making use of voluntary control of the vocalizing and articulating muscles, and thus gradually, the unconsciously, leading the patient back to the normal processes of speech. The first step should be to try to discover the cause, and to remove it if possible. It is well to remember, however, that the original cause may have long since ceased to exist, and that only the results may remain. The stammering, for instance, may be the result of a nervous shock received years ago, or of an adenoid growth long since removed; so that the exciting cause of the trouble may not be apparent at the time of the examination. If, however, we can find any condition that may impair the harmonious action of the nervous system, our attention should be directed toward its improvement.

The general health of the patient, his diet and methods of life, should be carefully investigated and regulated in the minutest detail. The organs of articulation and vocalization should be carefully examined, and an attempt made to correct any abnormality, however slight it may be. A short lingual frenum interfering with the normal action of the tongue is often a great hindrance to freedom of speech, and we frequently find an abnormal development in the various muscles of the tongue; and whether it is the cause or the result of stammering, a slight surgical operation, followed by carefully chosen exercises, will assist very materially toward accomplishing the desired result. Irregularities in the structure of the palate are common in these cases. There is great lack of uniformity in the size and shape of the palatal half-arches. This is probably due in a great measure to adhesions that form between the folds of the palate and the tonsil, thus causing these folds to be irregularly bound down to the tonsil and interfering with their normal action in speech. The condition is easily corrected by the separation of the adhesions and a slight cauterization of the cut surfaces of the tonsil, to prevent the formation of new adhesions. The vault of the pharynx must be examined, and catarrhal conditions treated on general surgical and therapeutic principles. Nasal stenosis, while it may not be a common cause for stammering, undoubtedly serves as an obstruction to its cure, both by its interference with normal respiration and its reflex influence on the nervous system. Intranasal pressure, therefore, should be removed by surgical procedures, if necessary.

Having corrected the patient's habits of life, both dietary and moral, and having removed, so far as possible, all other sources of nervous excitability and physical and mental depression; and having put the peripheral organs of speech in the most favorable condition for normal action, the after-treatment should consist in the development of a perfect voluntary control of certain important muscles employed in respiration, vocalization, and articulation; and this, as has been suggested, should be used as a means—and in the majority of cases it is the only means—for the reestablishment of the normal automatic muscular action.

Unfortunately, many stammerers are deficient in will power, and in these cases a voluntary control is difficult to acquire. They not only do not control their speech, but, to use an expression that is common among them, they "stammer in other things" as well. They do not think connectedly nor do

they pursue any line of action to its logical conclusion. These are the cases that are difficult to cure, although they are by no means hopeless. The faculty of the will may be developed by training, just as any other faculty of the mind may be developed; and there are no exercises so efficient for this purpose as those required for the improvement and development of speech.

To gain voluntary control over the organs of speech, certain important muscles that have been considered hitherto as involuntary must be brought under the domination of the will. These muscles belong for the most part to the vocal and respiratory mechanisms. The management of the breath, which is the motor power of the vocal mechanism, is deficient in all cases of stammering, and it is to this point that attention should first be directed.

There is a certain definite and precise action of the great muscles about the lower thoracic and abdominal regions that is necessary to the production and control of voice, and that must be acquired by the patient before any real progress can be made or permanent improvement can take place. Just what the precise action of each one of these muscles is has been the subject of much discussion, and its importance in connection with this work cannot be overestimated. This action is exceedingly complicated, and cannot well be explained within the limits of this article and without a subject for demonstration.

The respiratory muscles must be so used as to bring just sufficient breath upon the vocal cords, and no more than is sufficient, to produce the syllable or word that is required. Not only so, but this little blast of breath must come at exactly the proper instant for the production of the sound. A lack of promptitude at this point is observed in many cases. The voice, of which speech is made, is not present or forthcoming at the instant that the oral mechanism requires it for articulation. The articulating organs try to perform their function, but there is no voice present to be articulated, and the result is a more or less spasmodic hesitancy. The patient dwells upon the initial consonant or repeats it until such time as the vocal mechanism may come to the rescue with the vocal element that is necessary for the completion of the syllable or word.

In other cases it is the oral mechanism that is at fault, and the patient dwells upon the vocal element or repeats it until such time as the articulating organs may be brought into action for the formation of the syllable or word. Suitable exercises must be given to make the action of these two mechanisms entirely harmonious, and this can be done by teaching the voluntary control of the various muscles of that mechanism in which the action is delayed, and then practising this voluntary control daily until the necessary promptitude of action is acquired.

In most cases it is necessary, for the exercise of this voluntary control, to have the patient speak in syllables. Alexander Graham Bell has said that syllabification is the cure for all vocal and oratoric defects. Of course, this is claiming too much for the exercise, but it certainly should have a prominent place in the treatment of stammering. In many cases it is necessary even to divide the syllables into their component parts and to drill the patient on these individual elements. Then, after a certain time, the elements that unite to form each syllable should be practised together and syllabic conversational exercises given, with careful attention to voluntary control over the important respiratory and vocalizing muscles.

In all these exercises there should be an attempt to harmonize the various faculties of the mind, not only with one another but with the exercises themselves. The patient should be induced to think introspectively and to study the impressions that the proper muscular action in the production of each syllable makes upon the mental and physical organisms. Not only should he be conscious through his sense of hearing that the syllable is accurately given, but he should be taught to recognize, by means of the sense of feeling, the physical impressions made by the normal action of the muscles and the resultant vocalization.

The stammerer generally knows how the syllable would sound if properly given, but he has no definite knowledge of how it would feel to give it or what would be the physical and mental impressions. In other words, the mental and physical sensations of speech should be studied and developed in what has been called the kinesthetic center of the brain; and after these sensations are recognized and felt, the patient should be taught to reproduce them.

Pseudolalia

In this division may be conveniently placed all those defects of speech in which there is no spasmodic hesitation. The chief characteristic of this form would be a defective or false utterance of certain syllables or words. In some cases there is a substitution of one element for another. In others there may be an entire omission of the element. In one case that has been reported there was a complete substitution of a language entirely unknown for that which the patient attempted to use; and not a single element of this false language had any resemblance to the element for which it was substituted.

This, however, is unusual, and the majority of these cases give proper utterance to at least one of the elements and thus suggest the syllable or word intended to be spoken. The first element in a word is sometimes omitted, and, as some one has said, the word becomes "decapitated." More often, however, the final consonant is not given, and the word becomes "decaudated;" and when all the elements are mispronounced, the word may be said to be "mutilated." This mutilated speech is characteristic of imbeciles and idiots and all those having a cerebral lesion. That there is some defective cerebration in all these cases must be admitted.

Nice distinctions are not made in the utterance of the various elements of which words are composed. The auditory word center in the brain fails to recognize or to register accurately the exact sound produced by the peripheral organs of speech.

No distinction may be made, for instance, in the physiologic sounds of the consonants *D* and *G* or *T* and *K;* the one being substituted for the other without any conscious recognition of the substitution, or one of these consonants may be omitted entirely and the ear fails to recognize the omission.

Other cerebral areas may be similarly deficient in the performance of their natural functions, or, as is often the case, this auditory center is the only one affected. It must be remembered also that normal cerebral development depends very largely upon the use of the faculty of speech, and therefore that defective mentality which at first glance may seem to be the cause, may in reality be the result, of defective speech.

Pseudolalia, like dyslalia, often has its origin in abnormalities in the structure of the peripheral organs of speech. The slightest irregularity in the organs of articulation may be responsible for the development of mutilted speech in children. It may be said that anything that interferes with the normal action of the articulating organs may result in serious defects of speech. The shape of the hard palate, the dental arch, and the condition of the teeth all affect the character of the speech. A short lingual frenum or any deformity of the lingual muscles not only causes defective speech, but may make speech so disagreeable as to greatly delay its development and thus interfere with the child's mentality. Enlarged faucial tonsils and adenoid vegetations in the vault of the pharynx have long been supposed to interfere in some mysterious way with the mental development of children; but they probably interfere with mental development only so far as they impair the patient's physical condition and obstruct the development of normal speech.

Another common cause of these defects of speech is the paralysis that often follows diphtheria and the various infectious fevers prevalent in children. This paralysis may be of only short duration, and yet if it come during the formative speech period, it is sure to leave its deleterious influence. It is during the earlier years of adolescence that these irregularities in the peripheral organs of speech do harm; and although they may disappear altogether after a few years, as is sometimes the case with hypertrophied tonsils, or they may be removed by surgical interference later in life, yet the defects of speech of which they were the direct cause remain as fixed physical habits until they are corrected by suitable training.

This is well illustrated by those cases having cleft palate. If the operation for the closure of the cleft is delayed until after the formative speech period and until that peculiar speech characteristic of cleft palate is fully established, it will have little or no effect upon the speech, however well the deformity may be corrected. This fact would seem to indicate that it is not so much the cleft palate that causes the defective speech, as the abnormal muscular action that is the direct result of the cleft palate. However that may be, this abnormal muscular action must be corrected after the two halves of the palate are put in apposition if improvement in speech is to be effected.

Treatment.—In discussing the treatment of stammering it was found that the object to be attained was the correction of a faulty coordination between the vocal and the oral articulating mechanisms, and indirectly, perhaps, between the muscles within one or the other of these two mechanisms. In pseudolalia the lack of coordination is entirely within the oral articulating mechanism. There is a faulty action in some of the muscles of the lips, the tongue, or the palate; and whatever may be the cause of this faulty muscular coordination, there is always a corresponding defective action in the nerve centers that preside over these mechanisms.

A careful physical examination of the patient must first be made, with a view to determining the cause of the defect, always keeping in mind that this cause may have existed only in the past and during the formative speech period. All structural peculiarities of the articulating organs should be carefully noted, and any obstructive irregularities corrected or removed. When this is accomplished, muscle training should be given, with a view to correcting the faulty action and establishing correct coordination. A lack of uniformity is often found in the development of these muscles, and this condition may be corrected by suitable voluntary exercises entirely independent of speech. For instance, muscles of the lips or of the tongue that have been entirely involuntary may be brought under control of the will and made to act independently of others, and thus be trained to perform their natural functions. This muscle training is an important factor in all speech defects, not only on account of its value in harmonizing the action of the muscles themselves, but also on account of the fact that it serves as a direct stimulus to the development of the cerebral areas that preside over the muscles, and the general mental development resulting from these exercises is sometimes very marked.

Exercises for the correction of the special defects that may exist in each individual case should follow this muscle training. Speech is voice articulated or molded into certain definite shapes or forms. The vocal mechanism furnishes the voice, and the oral articulating mechanism the molds into which the voice may be regarded as being poured. Each syllable of speech requires a separate and distinct adjustment of the articulating organs, and those syllables that are composed of two or more primary elements require for and during their utterance certain variations in the molds. For instance, the syllable "*m-a-t*" has in it three primary elements, for each of which a separate mold is required; but in the utterance of this syllable these elements follow one another in quick succession and close sequence, and therefore these primary elements must be made to follow one another so closely as to form what is practically one variable mold, upon the structure and formation of which depends the character of the resultant speech.

If any part of this mold is imperfect in its formation, there will be corresponding defect in the articulation of the syllable. For instance, if the first

primary mold required for the physiologic sound represented by "*m*" is omitted, the syllable will be "decapitated;" and if the last sound represented by the letter "*t*" is omitted, it will be "decaudated," and if the three primary molds are improperly formed and coordinated, the syllable will be "mutilated."

The decapitation, decaudation, and mutilation of syllables are phenomena designated pseudolalia, and in the treatment of this affection the proper formation and coordination of the primary molds of speech and their coordination into what have been called the variable molds required for the utterance of syllables and words must be taught. To do this one must have an accurate knowledge of the anatomy and physiology of the organs of speech, and the location of each muscle; and he must be able to form a clear mental picture of the exact position of the organs of articulation required for the formation of the primary molds for the elements of speech and their coordination into the variable molds for the syllables and words.

The patient must be taught the precise voluntary muscular action required for the formation of these molds. He must be shown, for instance, how to shape the lips and where to place the tongue for each element of speech in which he may be found deficient; and thus, by frequent repetition of this voluntary control of the organs of speech, he may be trained to speak automatically with great accuracy.

It will be observed, therefore, that the principle underlying the treatment of all defects of speech consists in the establishment of an accurate voluntary muscular control of the organs, this control to be continued until the faulty processes or habits of speech have been entirely eradicated, and the new and improved methods become habitual and automatic. See APHASIA.

SPERMATIC CORD, DISEASES.—Torsion of the spermatic cord—*i. e.*, a twisting of the cord so that the epididymis is felt in front instead of behind the body of the testis—is occasionally met either in a testis to all external appearance previously normal, or in a testis retained in the inguinal canal. The twisting has been attributed to spasm of the cremaster. If unrelieved, the testicle will atrophy or necrose.

Symptoms.—The torsion is attended by a tender and painful swelling in the groin or scrotum, dull on percussion, irreducible, and without impulse on cough, the symptoms generally coming on suddenly after great strain or exertion. Vomiting is nearly always present, and there may be constipation. Thus, when the testis is retained, a strangulated hernia is very closely simulated.

Treatment.—When seen early, the cord may be readily untwisted if the testis is in the scrotum, the symptoms at once disappearing. If the testis is in the groin or inguinal canal, it should be removed and the canal and ring closed by sutures.

See also HEMATOCELE, HYDROCELE, TESTICLE, VARICOCELE.

SPERMATOCELE.—See HYDROCELE.

SPERMATORRHEA.—See NOCTURNAL EMISSIONS.

SPERMATOZOA.—See SEMINAL STAINS.

SPERMIN.—Spermin has been found in the form of a phosphate in the thyroid and thymus glands, the spleen, the ovaries and the blood, as well as in the testes. Poehl believes it to be an alkaloidal product of the retrogressive metamorphosis of albumins (a leukomaïn), and a most powerful intraorganic restorative of the oxidizing properties of the blood. He states that it should not be regarded as a specific for any particular malady, but should be used as a means of promoting oxidation in the body. It has been employed with decided benefit in ataxia and delirious epilepsy, as a tonic in tuberculosis also in senile marasmus and the nervous affections of the aged. The hydrochlorate is used hypodermically, in doses of 1/8 grain twice daily, in the morning and at noon, avoiding evening administration, as it may cause insomnia. No reaction follows its injection.

SPHACELODERMA (Dermatitis Gangrenosa, Spontaneous Gangrene of the Skin).—See DERMATITIS GANGRENOSA INFANTUM, RAYNAUD'S Disease.

SPHENOIDAL SINUSES, DISEASES.—See NOSE (Accessory Sinuses).

SPHYGMOGRAPH.—See PULSE.

SPIDER-BITE.—See BITES AND STINGS.

SPIGELIA (Pinkroot).—The dried rhizome and roots of *S. marilandica*. A popular vermifuge, generally administered with senna. Should be employed with the usual precautions as to feedings, and a purge should be administered while the worm is narcotized, to carry it out of the bowel. In large doses it is an uncertain cathartic. Poisoning is manifested by palsy of spinal origin, the respiration becoming slow as death approaches, and finally ceasing simultaneously with the action of the heart. Vertigo, dimness of vision, dilated pupils, dyspnea, convulsions, and spasms are lesser phenomena. Dose, 30 grains to 2 drams. **S., Flext.** Dose, for a child, 10 to 20 minims; for an adult, 1/2 to 2 drams. **S., Infus., Comp.,** "worm tea," "pink and senna," unof.; spigelia 15, senna, fennel, each 10, manna 30, water 500. Dose, 1 1/2 to 5 ounces.

SPINA BIFIDA. (Hydrorrhachis).—A congenital deficiency in the bony covering of the spinal cord, or failure of the spinal laminæ to unite, present in about one in every 1000 births. Sometimes there is a small congenital gap in the spine, the cord and membranes remaining in the canal (*spina bifida occulta*); the skin is frequently indented over this defect and the dimple filled with hair. These cases need no treatment unless there are symptoms of pressure on the cord, when the removal of such compression, which may be due to hypertrophy of the skin and subjacent soft parts, would be indicated. In 2 percent of the cases the cleft is wide, the skin is absent, and the cord protrudes through the opening, its central canal communicating with the surface of the body (*myelocele*). This condition is not compatible with existence. In 10 percent the membranes alone escape through the opening (*meningocele*), but in the vast majority (about 75 percent) there is also a portion of the cord in the protuberance (*meningomyelocele*), and very rarely the tumor is the result of a dilata-

tion of the central canal of the cord (*syringomyelocele*). The last variety is often situated laterally. More than one vertebra is usually fissured, and cases have been reported in which all the vertebræ were involved. Rarely the body of the vertebra is implicated (*anterior spina bifida*). One-half of all cases occur in the lumbar region and more than one-third in the lumbosacral or sacral portion of the spine. (Stewart).

The coverings of the sac may be healthy skin, but more commonly normal skin is only found at the sides, the central portion consisting of a thin bluish membrane. Sometimes a slight depression is seen on the lower part of the sac at the spot where the cord terminates in the wall. This is called the umbilicus, and at its bottom the central canal of the cord has at times been seen to open. In some instances there is no protrusion, but rather a depression in the situation of the cleft between the vertebræ (*spina bifida occulta*) the cleft being occupied by the blended membranes, cord, and skin, and the spot covered with a tuft of hair. In obscure paraplegias, contractures, and deformities of the feet the back should be examined, since this condition may be present but has been overlooked by the mother.

Symptoms.—The swelling is usually of a globular or oval shape, translucent, sessile or slightly pedunculated, and flaccid, but becomes tense and distended on coughing or crying. Pressing upon it sometimes causes the fontanels to swell up, and may produce convulsions. When the spinal cord and large nerves are involved, there may be paralysis of the extremities or of the bladder or rectum. The gap between the laminæ of the vertebræ may at times be felt on pressing on the sac. As a rule, these tumors show a great tendency to enlarge, and rupture spontaneously, in which case death usually follows from the draining away of the cerebrospinal fluid and septic meningitis. Death, however, is sometimes due to marasmus and defective nutrition. When a spontaneous cure takes place, it is usually due to the gradual shrinking of the sac.

Diagnosis.—Its congenital origin will at once distinguish a spina bifida from a new growth developed subsequently to birth; and its situation in the middle line, translucency, increase of tension on straining, and the gap between the laminæ, when this can be felt, will usually serve to diagnose it from other congenital tumors.

Treatment.—As there are no means of accurately determining that the spinal cord is not in the sac, it has hitherto not been considered safe to attempt excision or ligation, although these operations have at times been attended with success. Repeated tappings are very fatal. The treatment usually employed, except when the spina bifida is very small or is apparently undergoing a spontaneous cure, when it should be left alone, is to inject the sac with Morton's iodoglycerin fluid. This method when successful causes the tumor to shrink, and most closely follows the process of nature when a spontaneous cure occurs. The injection is best performed when the child is two months old; but it may be done earlier if the sac threatens to burst. The best results may be expected when there is no hydrocephalus or paralysis, and the sac is covered by healthy skin. It is contraindicated when there is advanced marasmus, great and increasing hydrocephalus, and intercurrent disease. The child should be placed on its side, and the puncture made obliquely through healthy skin on one side, and the base of the tumor, and not through the thin and imperfectly formed skin, which nearly always covers the sac in the middle line, the object being to avoid wounding the expanded spinal cord, and the subsequent leakage of the cerebrospinal fluid. About a dram of the iodoglycerin fluid (iodin (10 grains), iodid of potassium (30 grains), glycerin (1 ounce)) should be injected, and the injection repeated in a fortnight if the first trial is not successful. The fluid contained in the sac should not be drawn off before the injection. The advantage of Morton's fluid over tincture of iodin alone is that, owing to the glycerin it contains, it becomes uniformly diffused over the sac-walls. The injection of iodoglycerin is not unattended with danger; therefore, when the sac is small and its walls are thick and it is not increasing in size, beyond protecting it with a metal or leather shield, no further treatment should be attempted. Mayo Robson advocates excision in all cases except when there is well-marked paraplegia, hydrocephalus, or marasmus, or when the tumor is small and well covered by a firm pad of integument. In spinal meningocele he makes skin flaps, removes the sac, ligates or sutures the base, and brings the flaps together by suture. In meningomyelocele he separates the skin from the sac, opens and dissects out the sac, taking care that the lines of suture in the meninges and skin are not opposite.

SPINAL CORD, ANESTHESIA.—See Intraspinal Anesthesia.

SPINAL CORD, DISEASES.—These are considered under their special headings. See Amyotrophic Lateral Sclerosis, Caisson Disease, Friedreich's Ataxia, Locomotor Ataxia, Muscles (Progressive Atrophy, Progressive Dystrophy), Myelitis, Paralysis (Acute Ascending, Bulbar, Infantile), Paraplegia, Lateral Sclerosis, Syringomyelia, etc.

SPINAL CORD, INFLAMMATION.—See Myelitis.

SPINAL CORD, INJURIES. Contusion of the Spinal Cord (Hematomyelia).—Hemorrhage into the substance of the cord is nearly always the result of forced flexion, and occurs naturally in the region in which fracture by indirect violence is most common. Sometimes the similarity of origin is shown by their occurrence together, but independently of each other. It is possible, however, that it may be caused by direct violence. The hemorrhage nearly always lies in the gray substance of the cord, because this is the softest and the most vascular part, and it may occupy an indefinite length. The effect is immediate, becoming intensified later, as the hemorrhage extends. Motion and sensation are lost over a corresponding area; reflex action is suspended for a time, but rarely as completely as when the cord is

crushed; and then later, as the circulation around the injured area becomes more active, hyperesthesia sets in; motor disturbances are rare. The subsequent course depends chiefly upon the degree of the primary injury. The extravasated blood may be in great measure absorbed, leaving a certain degree of anesthesia, with paralysis or spastic rigidity of the muscles corresponding to the part of the cord that has been destroyed; or, on the other hand, red softening and ascending myelitis may follow, the paralysis extend higher, bed-sores and cystitis set in, and, if the injury is in the cervical region, phenomenal temperatures, just as when there is a fracture.

Wounds of the spinal cord are rare in civil practice, but they may be produced by stabs, the weapon passing between the arches of the vertebræ, possibly notching or incising them as it does so; or by gunshot injuries. The symptoms in either case depend upon the seat and the extent of the injury, and only differ from those of crushing of the spinal cord in fractures by their proneness to inflammation and suppuration.

Compression.—This is much more rare; it may be caused by a lamina driven in, though when this occurs the delicate nervous tissue is almost sure to be utterly crushed; or by hemorrhage, either inside the theca or between it and the bones (it is impossible to distinguish one from the other); or later it may result from inflammation, as in Pott's disease. If due to bone, the symptoms are immediate; if to hemorrhage, there is a distinct interval before they commence, and they progress from below upward, affecting the leg first, and then the trunk, until the respiratory muscles are involved. The loss of motion is more marked than that of sensation, but it is rarely so definite as in contusion; pain along the course of the nerves, hyperesthesia extending around the trunk, and muscular tremors are more frequent. In many instances the blood is absorbed again and the symptoms subside; occasionally it accumulates to such an extent as to prove fatal, either from its pressure or from secondary softening and degeneration. See SPINE (Diseases, Injuries).

Concussion.—This injury occurs practically under the same conditions as contusion, and can only be distinguished from it by the symptoms being general, not confined to any one portion of the spinal cord, and by their passing off within a few hours. Afterward, when the immediate symptoms have disappeared, hyperemia may set in, as in concussion of the brain. If there is no contusion, as very rarely happens, this may be merely transient, and under proper treatment subside without leaving behind any serious result; but if the part is not kept at rest, or if there is severe contusion, it may increase, and either run to inflammation or lead to softening and degeneration.

Railway Spine.—Railway accidents are not infrequently followed by a peculiar train of symptoms, which have been grouped together under the name "railway spine," justly stigmatized by Page as absurd. The symptoms do not set in immediately and are not those of any gross lesion of the cord, such as contusion or inflammation. As a rule, they do not appear for 3 or 4 days; then, after lasting some time, they either begin to subside or steadily grow worse. The chief difficulty is to distinguish them from locomotor ataxia and chronic meningomyelitis, both of which may undoubtedly follow injuries to the back. If, however, sufficient attention is paid to objective symptoms, to the distribution of areas of anesthesia, for example, and the electric reactions of muscles, it can usually be surmounted. Railway accidents are always accompanied by an extreme degree of shock that occasionally, but fortunately not very often, grows worse and worse; the patient becomes more feeble, and without being able to assign any definite reason for it, or find any gross lesion, death ensues after a few weeks or months, just as sometimes happens after a severe mental shock. More frequently there is a certain amount of improvement for a time, but not perfect recovery. The extreme depression passes off, but the patient remains weak and feeble, unable to control himself or to exercise deliberate judgment, with mental capacity and bodily vigor alike impaired. The symptoms are of the most varied character. Some, such as palpitation, flushing, alternate sensation of heat and cold, and menorrhagia, may be accounted for by the disordered working of the vasomotor system; others, like sleeplessness, dreaming, headache (often posterior), irritability of temper, emotional display, noises in the ears, and failure of sight, are due to interference with the blood supply of the brain and the organs of special sense. The bodily strength fails; gastrointestinal disturbances are present; the patient becomes worn and emaciated; the cerebral symptoms grow more pronounced, and at last he becomes utterly broken down in health, feeble in mind as well as body, and aged before his time. This history is not in any way peculiar to railway accidents. It may be induced by injuries of all kinds, especially in those who from heredity or for other reasons are in any way predisposed to the occurrence of nervous disorders. It is not uncommon, for example, after severe and prolonged mental worry; it may even follow a single shock, as noted by Moullin.

In another class the symptoms resemble those ordinarily grouped together as hysteric. There may be epileptiform attacks from time to time, with insanity, melancholia, or suicidal impulse. Anesthesia and hyperesthesia may occur, affecting the special nerves as well as those of ordinary sensation. In other instances muscular paralysis, affecting physiologic groups rather than anatomic ones, or spasmodic contraction is present, the electric reaction remaining unaltered. Retention of urine and aphonia are very common; and numerous other symptoms are met from time to time—pains in the joints, for example, of the most excruciating character, without any objective sign, dysphagia, torticollis, closure of the jaws, etc.

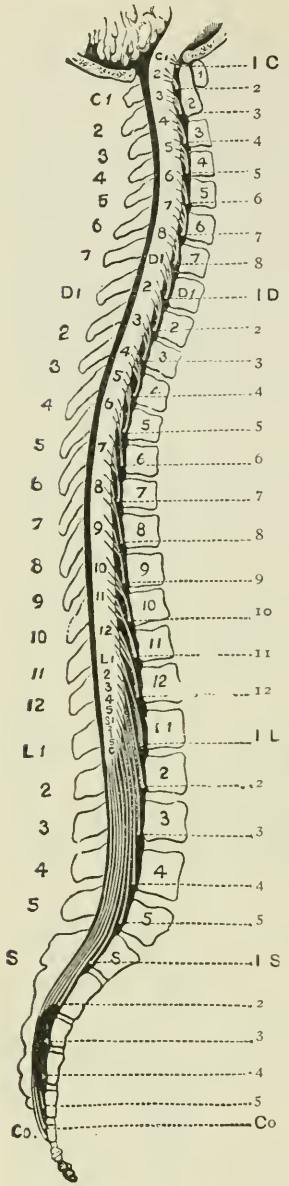
If in any of these groups of cases there is, in addition, a severe sprain of the muscles or ligaments of the neck and back, so that every movement is attended with pain, the difficulty of proving that the injury is limited to external structures, and

that the spinal cord is not involved as well, may be imagined. The local symptoms, the stiffness, rigidity, and pain, grow worse and worse as time goes on. If the hypnotic state continues, each suggests some further trouble, and it is almost impossible to distinguish between the real and the functional disorder. The desire to recover is often not genuine, even when it is present, and it is impossible to obtain any assistance from the patient. If there is even a suspicion of chronic inflammation of the spinal cord, it is a serious matter to propose active measures. Time is thus wasted, and the muscles become more rigid from disuse; the extravasated blood becomes organized; adhesions are formed in all directions; and it ends in leaving a permanently crippled condition.

The diagnosis from chronic inflammation of the spinal cord rests chiefly upon the absence of definite local signs. Stiffness and rigidity of the back are not leading characteristics of chronic meningitis. When this sets in, there are other symptoms, usually of an unmistakable character: There is pain along the course of certain nerves; or anesthesia and hyperesthesia of definite regions; special groups of muscles are wasted or paralyzed; the electric reactions are abnormal; the cutaneous reflexes are enfeebled or lost; in short, there is definite evidence of injury to nerves or centers in the cord, such as does not occur in sprains of the vertebral column alone, however severe the mental depression and bodily weakness may be (Moullin).

SPINAL CORD, LOCALIZATION.—The following table (after Starr) shows the location of function in the different segments of the spinal cord:

Segment.	Muscles.	Reflex.	Sensation.
Second and third cervical.	Sternomastoid; trapezius; scaleni and neck; diaphragm.	Hypochondrium (?). Sudden inspiration induced by sudden pressure beneath the lower border of ribs.	Back of the head to the vertex. The neck.
Fourth cervical....	Diaphragm; deltoid; biceps; coracobrachialis; supinator longus; rhomboid; supraspinatus and infraspinatus.	Pupil. Fourth to seventh cervical. Dilatation of the pupil induced by irritation of neck.	The neck, upper part of the shoulder, and outer part of the arm.
Fifth cervical.....	Deltoid; biceps; coracobrachialis; supinator longus; supinator brevis; rhomboid; teres minor; pectoralis (clavicular part); serratus magnus.	Scapular. Fifth cervical to first dorsal. Irritation of skin over the scapula induces contraction of the scapular muscles. Supinator longus. Tapping its tendon at wrist induces flexion of forearm.	Back of the shoulder and arm. Outer side of the arm and forearm, front and back.
Sixth cervical.....	Biceps; brachialis anticus; pectoralis (clavicular part); serratus magnus; triceps; extensors of wrist and fingers; pronators.	Triceps. Sixth to seventh cervical. Tapping elbow tendon induces extension of forearm. Posterior wrist. Sixth to eighth cervical. Tapping tendons causes extension of hand.	Outer side of the forearm, front and back. Outer half of the hand.
Seventh cervical...	Triceps (long head); extensors of wrist and fingers; pronators of wrist; flexors of wrist; subscapular; pectoralis (costal part); latissimus dorsi; teres major.	Anterior wrist. Tapping anterior tendons causes flexion of wrist. Palmar. Seventh cervical to first dorsal. Stroking palm causes closure of fingers.	Inner side and back of arm and forearm. Radial half of the hand.
Eighth cervical....	Flexors of wrist and fingers; intrinsic muscles of hand.	.....	Forearm and hand, inner half.
First thoracic.....	Extensors of thumb; intrinsic hand muscles; thenar and hypothenar eminences.	.....	Forearm, inner half. Ulnar distribution to the hand.
Second to twelfth thoracic.	Muscles of back and abdomen; erectores spinæ.	Epigastric. Fourth to seventh thoracic. Tickling mammary region causes retraction of the epigastrium. Abdominal. Seventh to eleventh thoracic. Stroking side of abdomen causes retraction of belly.	Skin of chest and abdomen, in bands running around and downward, corresponding to spinal nerve. Upper gluteal region.
First lumbar.....	Iliopsoas; sartorius; muscles of abdomen.	Cremasteric. First to third lumbar. Stroking inner thigh causes retraction of scrotum.	Skin over the groin and front of the scrotum.
Second lumbar....	Iliopsoas; sartorius; flexors of knee (Remak); quadriceps femoris.	Patella tendon. Striking tendon causes extension of leg.	Outer side of the thigh.
Third lumbar.....	Quadriceps femoris; inner rotators of thigh; abductors of thigh.	.....	Front and inner side of the thigh.
Fourth lumbar....	Abductors of thigh; adductors of thigh; flexors of knee (Ferrier); tibialis anticus.	Gluteal. Fourth to fifth lumbar. Stroking buttock causes dimpling in fold of buttock.	Inner side of thigh and leg, to the ankle. Inner side of the foot.
Fifth lumbar.....	Outward rotators of thigh; flexors of knee (Ferrier); flexors of ankle; extensors of toes.	.....	Back of the thigh and leg, and outer part of the foot.
First to second sacral.	Flexors of ankle; long flexors of toes; peronei; intrinsic muscles of foot; perineal muscles.	Plantar. Tickling sole of foot causes flexion of toes and retraction of leg. Foot-reflex. Achilles tendon. Overextension of foot causes rapid flexion; ankle-clonus. Bladder and rectal centers.	Back of thigh. Leg and foot, outer side. Skin over sacrum. Anus. Perineum. Genitals.



Motor.	Sensory.	Reflex.
	Neck and scalp.	
Sternomastoid.		
Trapezius.	Neck and shoulder.	
Diaphragm.		
Serratus	Shoulder.	Scapular.
Shoulder		
Arm musc.	Arm.	
Hand		
(ulnar, lowest).	Hand.	
	Front of thorax.	Epigastric.
Intercostal muscles.	Ensiform area.	
Abdominal muscles.	Abdomen. (Umbilicus, 10th).	Abdominal.
	Buttocks, upper part.	
	Groin and scrotum (front).	Cremasteric.
Flexors, hip.	Thigh — outer side.	Knee-joint.
Extensors, knee.	Thigh — front.	
Adductors. hip.	Thigh — inner side.	
Abductors	Leg, inner side.	
Extensors (?).	Buttocks, lower part.	Gluteal.
Flexors, knee (?).	Back of thigh.	Foot-clonus
Muscles of leg moving foot.	Leg and foot except inner part.	Plantar.
Perineal and anal muscles.	Perineum and anus.	
	Skin from coccyx to anus.	

Diagram and Table Showing the Approximate Relation to the Spinal Nerves of the Various Motor, Sensory, and Reflex Functions of the Spinal Cord. (*Arranged by W. R. Gowers, from anatomic and pathologic data.*)

SPINAL CORD, TUMORS.—The diagnosis of tumors of the cord and its membranes necessitates a knowledge of the symptoms of tumors involving the spinal column. It, therefore, seems appropriate to consider tumors of all these structures under the same general heading.

Tumors of the Spinal Column.—Tumors of the spine resulting from spina bifida and other congenital tumors are discussed under their various heads.

Etiology.—Tumors of the spine are exceedingly rare before the thirtieth year. They are not frequent at any time of life, but are found most commonly during the fifth decade. They occur with slightly greater frequency in the male than in the female. Injury to the spine is undoubtedly the exciting cause in some instances.

Pathologic Anatomy.—Carcinoma—either of the scirrhous or encephaloid variety—osteosarcoma, and sarcoma are the most frequent growths of the spine. Tumors of the spine may be primary or secondary. Cancerous growths of this region may be secondary, especially when the primary lesion is in the breasts, stomach, or mediastinum. According to Gowers and others, primary growths

are more likely to begin in the bodies of the vertebræ. If the bodies of the vertebræ are weakened by the neoplasm, angular curvature of the spine may take place, as in caries. The spinal nerves may suffer by compression, inflammation, or infiltration (Gowers). The spinal cord is rarely, if ever, infiltrated; but it is often compressed by the growth extending into the spinal canal. In nearly all advanced cases the cord is inflamed opposite the seat of the growth.

Symptoms.—These result from involvement of bone, the spinal nerves—which rarely ever escape—and from compression and inflammation of the cord. The latter may appear early or not until late in the course of the disease. The bone symptoms differ from those of caries in that among the former there may be a discoverable tumor, especially in the cervical region, and a greater severity of the spinal pain, well pronounced on bending the spine in different directions.

The nerve-root symptoms, especially pain, which is usually as early symptom, are often pronounced. Radiating pains and areas of hyperesthesia and anesthesia are frequently more marked than in caries or in tumors of the membranes. The cord symptoms are those of myelitis. In some instances complete paralysis takes place within a few days or a few weeks after the first cord symptoms appear.

Diagnosis.—The diseases likely to be confounded are caries and tumor, after the symptoms point unmistakably to organic disease of the spine. The presence of a tumor, when this can be felt, a primary growth in some other portion of the body, the severity of the pain, both bone and nerve-root, and in cases of cancer the rapid progress of the disease, are points in favor of a tumor.

Duration and Prognosis.—Carcinoma of the spine runs a rapid course, and results in death in a few months. . Life is rarely prolonged a year. Slowly growing tumors may run a course of one to several years. Gowers quotes a case that lasted 13 years, death finally taking place from meningeal hemorrhage. Death usually takes place from myelitis. Unless the tumor is so situated that it may be removed, which is, unfortunately, rarely the case, death invariably results.

Treatment.—In inoperable tumors of the spine the treatment resolves itself into prolonging life by giving nourishing food, and in making the patient as comfortable as possible by the judicious use of various anodynes and analgesics, of which, unfortunately, morphin is our main reliance. In cases in which the pains are not too severe, the following formula has postponed the use of morphin until late in the disease:

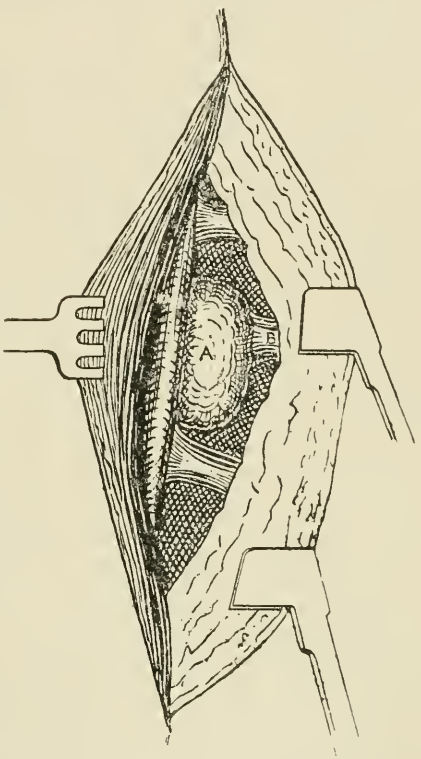
℞.	Extract of cannabis indica,	gr. 1/6
	Sulphate of codein,	gr. j
	Phenacetin or acetanilid,	gr. iij
	Citrated caffein,	gr. ij.

In capsule, and repeated only as often as it is absolutely necessary for the relief of pain.

Codein is much less objectionable than morphin in those cases in which the pain can be relieved by it.

Tumors of the Cord and of Its Membranes

The symptoms of tumors of the cord are so similar to those of the membranes that it will be more convenient to study these together; and in the section on diagnosis to endeavor to bring out the differential points between an unmistakable case of tumor of the cord and one of the membranes. In many cases, especially when the neurologist is consulted, it is only possible from the symptoms present to make a diagnosis of intraspinal tumor, irrespective of the primary seat of the lesion. In others, however, by a careful study



Showing the Relation of the Tumor to the Cord which it had Displaced to the Left.—(*Eskridge.*)

A. Tumor. *B.* Eroded end of fourth rib. The neoplasm had apparently taken its origin on the anterior surface of the body of the fourth dorsal vertebra and extended into the spinal canal, completely separating the end of the rib from the vertebra.

of the history, with especial reference to the initial symptoms and to the manner of development of additional ones, and by thorough, repeated, and systematic examinations, a fairly definite diagnosis can be made between tumor of the cord and of the membranes. Theoretically, the symptoms of tumor in the substance of the cord are such as denote destruction of tissue and abolition of function; while those that result from a growth in the membranes are such as one would expect from irritation of tissue—perversion of function. Practically, however, the early symptoms of tumor of the cord may be irritative in character and in the

advanced stages of tumor of the membranes the function of the cord may be totally abolished.

Etiology.—Intraspinal tumors may occur at any time of life. They are most frequent between the fifteenth and the forty-fifth years. In an analysis of 50 cases Mills and Lloyd found 14 percent before the twentieth year. They are slightly more frequent in the male than in the female. Syphilis and tuberculosis are diathetic conditions that may lead to the development of tumors of the cord or of the membranes. Traumatism has been credited with causing many of the intraspinal tumors. Growths here are often secondary to similar ones in other portions of the body. In the majority of cases no real cause can be found.

Pathologic Anatomy.—In the substance of the cord sarcoma and the different varieties of it, especially glioma, are the most frequent tumors met. Solitary tubercles, syphiloma, and a few other growths may take place here. In the membranes fibroma, sarcoma, fibrosarcoma, myxoma, psammoma, tubercle, syphiloma, and several other varieties occur. Neuromata are found on the spinal nerve-roots and the cauda. The dorsal region is the most common seat of tumors. Fibroma is rarely more than an inch or two in length, and its long axis corresponds with that of the spinal canal. The sarcomata and some other growths may be several inches in length, and in rare instances have extended nearly throughout the entire length of the cord or spinal canal. Tumors may arise from the fatty substance between the bone and dura—especially lipoma—from the external or internal surface of the dura, from the soft membranes, or from the substance of the cord itself. In some instances a tumor takes its origin from the soft tissues outside of the spinal canal and grows inward through the intervertebral foramina. Extradural growths have always been found to be single; the intradural ones, while often single, may be multiple. Tumors of the membranes, while usually small, may be limited in size only by the width of the spinal canal; hence tumors of the cauda often attain a larger size than those occurring higher up in the spinal canal. Tumors of the substance of the cord are usually small, and generally begin unilaterally. Growths of the membranes compress the nerve-roots, the cord, and often give rise to meningeal irritation. The growths are usually unilateral, but in some instances they involve the membranes so as completely to encircle the cord.

Symptoms.—The tissues irritated, compressed, or destroyed in intraspinal tumors may vary so much in different cases that the symptoms are rarely the same in any two. A knowledge of the numerous conditions that may exist within the spinal canal, although apparently at first confusing, will often enable one, by a careful analysis of all the symptoms in an individual case and a minute sifting of the details of the history of the disease, to make a fairly accurate diagnosis.

The early symptoms may be from unilateral irritation of the spinal nerve-roots, sensory or motor; from unilateral irritation of the membranes, or of the membranes and nerve-roots; from unilateral irritation of nerve-roots, membranes, and cord; from unilateral irritation of the cord alone; from bilateral irritation of the nerves and membranes; from bilateral irritation of the nerves, membranes, and the cord, or from bilateral irritation of the cord alone. The symptoms are more decided in character—both of irritation and destruction—in infiltrating than in noninfiltrating growths. The symptoms vary in character according to the region of the spinal canal in which the tumor is situated; they are modified by the structures in which the tumor takes its origin, especially whether the cord is primarily the seat of the growth or is affected by compression; and finally the rapidity with which the symptoms develop depends upon whether the tumor is slow or rapid in its growth.

The symptoms may be divided into nerve-root, meningeal, and cord symptoms. In tumor of the spinal cord the cord symptoms are usually the primary ones. In rare cases in which the growth is situated in the posterior portion of the cord, usually unilateral and involving the nerve-root fibers from the posterior horn, the early symptoms may be of a nerve-root character. Extramedullary tumors give rise to nerve-root and meningeal symptoms before those of the cord are manifest.

Nerve-root Symptoms.—These are usually unilateral and sensory in character early in the course of the disease. If the cauda is affected, the symptoms are bilateral and affect the legs and feet; if the tumor is in such a position as to involve some of the nerves of the lumbosacral plexus, the pain will be felt in one leg; if the brachial plexus is affected, the pain radiates in one arm; if some of the trunk nerves are the seat of the irritation, the early symptom may be pain at the distal portion of one or two nerves, without pain or tenderness in any other portion of those nerves for a while.

In some cases hyperesthesia throughout the distribution of the affected nerve or nerves is well marked; and later anesthesia replaces the hyperesthesia. In those cases in which the nerve-roots become infiltrated by the growth, wasting of the muscles supplied by the affected nerves takes place, and there may be the reactions of degeneration. These phenomena are especially pronounced in the legs in tumors of the cauda. The skin over the area of distribution of the inflamed or degenerated nerves may show changes, such as herpetic eruptions, glossiness, and thickening. Meningeal irritation is evidenced by pain in the back, tenderness on pressure, and muscular twitching. The pain and tenderness in the back are not nearly so pronounced as they are in tumor of the vertebræ, nor are movements of the spine so agonizing. The pain is entirely absent in some cases. Tenderness may not be elicited unless the pressure is firm enough to produce some flexing of the spinal column. Rigidity of the muscles of the back is rarely pronounced except in those cases in which there is considerable involvement of the spinal nerves and usually of the membranes. The nerve-root and meningeal symptoms are among the earliest in extramedullary tumors. They are at first usually unilateral and later bilateral. In those cases in which the tumor is situated in regions of

the canal that are narrow, as in the upper cervical and dorsal regions, the indirect symptoms of nerve-root origin arising from the cord being crowded against the bones of the opposite side of the canal, may be more pronounced late in the disease than those that arise from the direct irritating effects of the growth. Eskridge has seen 2 cases in which the tumor had caused displacement of the cord, and crowded the nerve-roots of the opposite side against the bones of the spinal canal; and in each the indirect symptoms were as great as, if not greater than, the direct ones.

Cord symptoms manifest themselves early in intramedullary growths, and are usually at first unilateral in character, but soon become bilateral. If the tumor begins in one of the posterior horns of the cord, nerve-root symptoms of a sensory nature are the earliest. These symptoms, however, differ from those caused by an extramedullary tumor affecting principally a posterior nerve-root, in that in the former on the opposite side of the body from the one on which the nerve-root symptoms are manifest, and beginning at a level one inch or more below the level of the nerve-root symptoms, some disturbance of sensation, either subjective or objective, will be found, if carefully searched for early in the course of the disease, and cord symptoms develop about the same time that nerve-root symptoms are first complained of. In extramedullary tumors, on the other hand, nerve-root symptoms almost always precede cord symptoms for weeks or months, except possibly in rare cases in which the tumor is small and so situated as not to impinge upon the nerves before some pressure is exerted upon the cord. In such cases the growth might be located anteriorly, posteriorly, or laterally. The tumor under such circumstances would necessarily be a slowly growing one, and the symptoms would be those of gradually increasing compression of the cord, irritative in character, and not indicating destruction of cord tissue for a prolonged period at least. In intramedullary tumors, with the exception noted, the symptoms would probably be unilateral, at first those of irritation, later leading to destruction of cord tissue and abolition of function. Such symptoms would not be preceded by those of nerve-root and meningeal irritation. If the cord symptoms begin unilaterally in intramedullary growths, they soon become bilateral. It is important to bear in mind that in intramedullary tumors beginning unilaterally, while a well-defined case of Brown-Séquard paralysis, loss of motion on the side corresponding to the seat of the lesion, and loss of sensation on the opposite side is rarely seen, yet in nearly all of these the greatest loss of motion and disturbance of the deep reflexes, with weakened muscular sense, occur on the side corresponding to that on which the neoplasm is located; impaired sensation, subjective or objective, and disturbed superficial reflexes are most marked on the opposite side below the seat of the lesion in all those cases in which the tumor is situated above the lumbar enlargement. In some cases, especially in those in which the growth begins in the central canal, the symptoms are bilateral from the beginning. Nerve-root symptoms and rigidity of the muscles of the back are slight or almost entirely absent in intramedullary tumors. Muscular wasting and the reactions of degeneration are more common in intramedullary than in extramedullary tumors, except in those cases in which the growth originates in the cauda, then the symptoms are bilateral from the beginning.

Individual Symptoms. Motor.—Paralysis of more than a few muscles of one side of the trunk or of one limb rarely occurs in extradural tumors until cord symptoms develop. The exception to this is found in tumors of the cauda, in which case the paralysis is bilateral. The paralysis is usually a later symptom than pain in extradural tumors. Motor symptoms may precede the sensory by several weeks. Paralysis of the anal and vesical sphincters may take place early in tumors of the lumbar and sacral portions of the cord and in tumors of the cauda. Retention of urine may occur comparatively early in intramedullary tumors above the lumbar region. Paralysis of the sphincters only results late in the progress of tumors, intra- or extramedullary above the lumbar enlargement, except in rare instances in which the inflammation may descend and involve the lower portion of the cord. The ataxia, sometimes observed in extra- and intramedullary tumors of the dorsal region, is attended by pain in the back and other unilateral or bilateral symptoms of focal lesion of the cord.

Reflexes.—The reflexes in extradural tumors before cord symptoms develop are abolished only in the region of distribution of the affected nerves. When cord symptoms develop either from extra- or intramedullary tumors, the reflexes are affected in the same manner that they are found to be in myelitis of the different portions of the cord. Rigidity of the back muscles is rare in intramedullary tumors, but it is common in extramedullary growths. Muscular wasting and the reactions of degeneration, except in isolated muscles, denote an intramedullary or a caudal tumor.

Sensory Disturbances.—Pain is one of the earliest and most pronounced symptoms of an extramedullary tumor. It is usually at first unilateral, and radiates along the course of one or two spinal nerves. A tender point, or rather localized pain, is usually found at the distal portion of the affected nerves. Pain in the back, often severe in character, but rarely ever as agonizing as in tumor of the vertebræ, is frequently complained of in extramedullary tumors, especially when the patient tries to bend the spine freely in different directions. It is not a pronounced symptom in intramedullary growths. Hyperesthesia at first and later anesthesia are found in the area of distribution of the affected nerves. Dissociation of the sensory phenomena is common in tumors of the cord, and may be found in extramedullary tumors after the cord has become seriously affected by compression. It is not common to have temperature sense abolished over areas in which tactile sense is preserved. Pain and temperature sensations may both be abolished, and tactile sense preserved. Dissociation of the sensory phenomena is rarely so

typical in extramedullary tumors as is the case in neoplasms of the cord.

Vasomotor and Trophic Disturbances.—Either extra- or intramedullary tumors in the cervical region may give rise to inequality of the pupils and unilateral sweating, especially of the neck and head. Dilatation of the capillaries may take place on one side of the body in the parts below the seat of an intramedullary growth. Trophic disturbances may occur in the skin over the area of distribution of the affected nerves in extramedullary tumors. These may consist of herpetic eruptions, dryness, thickening, and harshness of the skin. The most marked trophic disturbances occur in tumors of the cauda and of the lumbar region of the cord. These are pronounced muscular atrophy, with the reactions of degeneration, bed-sores, and cystitis. In intramedullary tumors of the dorsal and cervical regions the trophic changes are largely limited to the parts on a level with the lesion.

Variability of Symptoms.—These occur in both intra- and extramedullary tumors, but are most pronounced in the latter. The symptoms vary considerably in intramedullary tumors, but the changes are never so sudden or so great as those observed in the extramedullary variety. In the former the patient slowly, rapidly, and, in some instances, suddenly, gets worse, so that it becomes apparent that without a change in the course of the disease life cannot long continue. Gradually the patient begins to improve, and this goes on for several weeks. At the end of this time the patient seems to be in nearly as good condition as he was before the change for the worse. Such sudden changes and the pronounced improvement that follows them can only be explained on the theory of acute focal myelitis, which has subsided and been resolved, or of a local hemorrhage which has been absorbed.

Course and duration of intraspinal tumors vary greatly. The course is shorter, and acute myelitis of a destructive character is more likely to occur in intramedullary than in extramedullary tumors. The intramedullary tumors usually progress steadily to a fatal termination more quickly than an extramedullary one. The average duration is from a few months to 2 or 3 years. Some exceptionally rare cases last much longer than this. Most cases steadily grow worse from month to month, although the symptoms may show much variability during a period of several months.

Diagnosis.—The questions to decide are: Is the trouble organic or functional? If it is organic, its character, or, in this instance, is it tumor? What is the location of the tumor: First, with relation to the bone; second, with reference to the cord itself; third, in regard to the membranes; and, lastly, opposite what segment of the cord does it lie? The final questions to determine, if possible are: What is the nature of the growth, and is it operable?

Is the trouble organic or functional? This question in the vast majority of instances will not be difficult to answer even early in the history of the case. In the majority of instances the symptoms are numerous and pronounced. They consist of spinal pain, tenderness, and lessened freedom of movement of the spinal column, radiating pains from the same level, muscular weakness and loss of reflexes at this level, and exaggeration of the reflexes below. All these symptoms first being unilateral in character soon become bilateral. In other words, there would be positive evidences of a focal lesion affecting the spinal column, membranes, nerve-roots, or cord. These are numerous, have been described under the head of symptoms, and are familiar to those who have become expert in examining for obscure affections of the spine and cord.

Is the lesion a tumor? The diseases that should be considered and excluded before arriving at the conclusion that a tumor exists are: Hemorrhage into the cord; a transverse myelitis without compression of the cord; caries; aneurysm; cervical pachymeningitis; neuritis; traumatic injuries of the spine and cord; and, lastly, syringomyelia.

Hemorrhage into the Substance of the Cord.—Hemorrhage that comes on suddenly, and gives rise to paralysis more or less complete in a few minutes, or few hours at most, after the first onset of the symptoms, and commonly ends in death from acute myelitis, may be mistaken for tumor of the cord. Tumor of the cord substance, especially glioma or sarcoma, might be attended by hemorrhage, as is the case with reference to these tumors when situated in the brain. In such cases, however, the history would show that spinal cord symptoms had preceded the paralysis for weeks and months. The history of hemorrhage into the substance of the cord reveals traumatism or freedom from spinal symptoms preceding the hemorrhage, while sudden paralysis from tumor would be preceded by the history of spinal symptoms.

Transverse Myelitis without Compression of the Cord.—In transverse myelitis without compression there are no nerve-root pains, spinal tenderness, or pain on bending the spinal column. The disease begins, in the vast majority of instances, bilaterally, and all the functions of the cord below the seat of the lesion are greatly affected or almost completely abolished soon after the beginning of the initial symptoms. The reverse of nearly all of these phenomena obtains in the case of tumor of the membranes and bones, and in tumor of the cord, except the nerve-root pains and spinal tenderness which are also absent in the majority of cases of intramedullary tumors.

Caries of the Spine.—Pain, limited to one or two vertebræ, tenderness of the spinous process over the same region, nerve-root symptoms, muscular rigidity, and cord symptoms are common to caries and tumor of the vertebræ, membranes, and, to a less extent, to tumor of the cord. The intense, agonizing pain in the back, both when the patient is at rest and while the spine is being moved, is not found in caries. In the latter the nerve-root symptoms are less marked than in tumor of the bone or membranes. They are absent in tumor of the cord. The symptoms are bilateral in caries, except in exceedingly rare cases. In tumor they are almost always unilateral early in the history of the disease. Rapid progress of the morbid process and

failure to yield to rest would point to tumor. Deformity of the spine would exclude tumor of the cord or membranes, but not tumor of the bones. The history of syphilis or of the removal of a tumor from another portion of the body, especially a malignant tumor of the breast, would be in favor of tumor.

Aneurysm.—The advanced age of the patient, except when the subject is syphilitic, would be equally in favor of tumor and aneurysm. If the subject is young and syphilis can be excluded, aneurysm may also be excluded. If, by careful auscultation and palpation over the entire back, no aneurysmal bruit is detected, it is useless to consider aneurysm as a causative factor.

Cervical pachymeningitis and intraspinal tumor have many symptoms in common. Pachymeningitis spreads over a larger vertical extent than does tumor, except in rare instances. The former more usually begins bilaterally than the latter, and gives rise to greater muscular rigidity than does tumor. Muscular wasting in tumor affects at first a limited group of muscles; pachymeningitis causes wasting in several groups. Tumor of the cord is not likely to be mistaken for pachymeningitis, because nerve-root symptoms are almost never prominent in the former.

Traumatism of the Spine.—In those cases in which the symptoms resulting from traumatism are similar to those of tumor the history will show that the symptoms immediately followed injury, and will lead to a careful examination of the spine, showing marked tenderness over a considerable vertical extent. The tenderness is much greater than in tumor of the membranes or of the cord. The history would be the main reliance in differentiating injury of the bones from tumor of the same, except that in the former the spinal tenderness involves a much greater vertical extent of the bones. It must be borne in mind that an injury of the spine may be followed by tumor; but under these circumstances there would be a history of two periods—the one immediately following the injury during which the symptoms will have been indicative of inflammation, and during the other there will have been a set of symptoms that mark the irritation caused by the beginning and development of the tumor. Traumatism of the cord in which nerve root and bone symptoms are absent would not easily be mistaken for tumor of the cord, as the acute symptoms of myelitis following trauma develop a few days after the receipt of the injury, and the patient is most commonly paralyzed immediately after the accident.

Neuritis affecting one nerve may occur from tumor. It may follow the development of tumor in the cervical region of the spinal canal, and affect one brachial plexus. Such a neuritis is due to pressure, and pressure neuritis in its early stage is not attended by tenderness over the trunk of the nerve, below the seat of the pressure, although pain is felt throughout the nerve and is most severe at its terminal end. Tenderness of the entire nerve does not take place until the neuritis descends the affected nerve. Spinal tenderness and pain in the spine on movement would probably be present in neuritis from pressure within the spinal canal. This would be absent in ordinary neuritis.

Syringomyelia, in the majority of instances, is due to a gliosis, or a benign and slowly growing tumor of the central canal of the spinal cord. The symptoms are usually bilateral, the morbid process is spread over a large vertical extent of the cord, and the disease advances slowly, and often lasts many years. Dissociation of sensory symptoms is much more typical and pronounced than is the case in tumors of the cord.

Location of the Tumor.—Is it in the vertebræ, cord, or membranes, and opposite what segment of the cord does it lie? Having satisfied one's self that a tumor exists, the next task is to locate it in some structure.

Tumor of the vertebræ is attended by pain, out of all proportion in severity to that caused by tumor of the membranes or of the cord. The pain after the disease becomes well advanced is almost constant, even while the patient is lying quietly in bed. Movements of the spine greatly increase the patient's suffering. Deformity of the spine, especially when the cervical region is the seat of the tumor, is not rare. Tenderness of the spine almost always exists, but in some cases it is not great unless severe pressure is made. There is marked rigidity of the back muscles, so that the spinal column is constantly fixed in such a position that jars are least likely to affect it. The nerve-root pains are severe, appear early, and last throughout the course of the disease, unless the affected nerves are completely destroyed. The nerve-root symptoms begin unilaterally, and the cord symptoms usually appear before they become bilateral.

Tumor of the cord usually manifests itself by unilateral symptoms. Nerve-root pains are absent, unless the tumor begins in one posterior horn, and affects the nerve-root fibers within the cord. Under such circumstances there will probably be some sensory disturbance below the tumor on the opposite side of the body. Cord symptoms begin unilaterally, unless the tumor is situated near the center of the cord. Bone, nerve-root, and meningeal symptoms are usually absent in tumor of the cord.

Tumor of the Meninges and Cauda.—The most prominent symptom of tumor of the spinal canal, extramedullary in character, is unilateral pain affecting one or two nerves, unless the cauda is involved, in which case they are bilateral from the beginning and affect many nerves of both legs. Bone symptoms, except slight pain in the back, some rigidity of back muscles, and some tenderness over a limited portion of the spine are absent throughout; cord symptoms occur late, but these are likely to appear before the nerve-root pains become bilateral.

After the tumor has been located in some structure—bone, membranes, or cord—it is not difficult to determine opposite what segment of the cord the highest portion of the tumor lies. The safe rule to follow is to ascertain the highest level of sensory disturbance—such as hyperesthesia or anesthesia—and locate the lesion about two spinous processes above this level.

What is the nature of the growth and is it operable? The history of syphilis, or evidences of constitutional infection, such as bone disease, an old iritis, the presence of sores in the mouth, or a tumor of the brain, would be in favor of the spinal tumor being syphilitic. This evidence would be strengthened by rapid development of symptoms. Scrofulous glands, or the presence of tubercles in the lungs, testes, or other portions of the body, would lead one to suspect that the spinal growth was tubercular in its nature. In the absence of syphilis or tuberculosis, tumor in the membranes of a child or young adult would probably be a fibroma or a sarcoma, and later in life a sarcoma or a carcinoma. The most common tumors of the cord are tubercular, gliomatous, syphilitic, and sarcomatous. In regard to whether the tumor is operable, this question cannot always be decided before making an exploratory incision. All tumors of the cord are inoperable—*i. e.*, those that are strictly confined to the cord substance. Some slowly growing bone tumors are removable. In all cases of tumor of the vertebræ an effort should be made to remove the growth if the diagnosis is made early, and it is fairly evident that the neoplasm is not malignant. Theoretically, all tumors of the membranes are operable, and in doubtful cases the patient should be given the benefit of the doubt, unless the contraindications to surgical procedure are too strong.

Prognosis.—Syphilitic growths yield readily to proper medication. If treatment is instituted early and before irreparable damage has been done to the cord, a complete recovery may take place. In all other kinds of growths that are not operable the prognosis is unfavorable. Life may be preserved for several months, or even for years, in slowly growing neoplasms that are not malignant.

Treatment.—Little space need be consumed in discussing the treatment of tumor of the spine, cord, or its membranes. In tumor of the meninges, unless it is quite evident that the neoplasm is not syphilitic, the patient should be placed on increasing doses of potassium iodid and inunctions of mercury pushed to the point of tolerance. In meningeal tumors, if the patient does not show the slightest improvement within 2 or 3 weeks, exploratory operation is advised. In case the symptoms grow steadily worse during this time, it is not safe to defer operating even for 2 or 3 weeks, as the structures of the spinal cord might be irreparably damaged before the expiration of 3 weeks if the tumor is growing rapidly or other conditions suddenly develop that cause considerable pressure on the cord. In inoperable tumors, if thorough antisyphilitic treatment for a period of 6 weeks is not attended by any improvement, it is not probable that further specific treatment will be followed by good results. Tubercular growths of the cord, membranes, or bones may be somewhat benefited by small doses of potassium iodid, by cod-liver oil, arsenic, quinin, iron, and a full meat diet, together with rest in bed. In all cases of tumor of the vertebræ that are not amenable to internal medication, operative interference should be instituted before the cord is seriously affected, unless there is evidence that the neoplasm is malignant. In all inoperable tumors that will not respond to specific or tonic treatment the patient should be made as comfortable as possible by rest in bed, a generous diet, relief of pain by means of anodynes, preventing the formation of bed-sores, and by taking care of the bladder and bowels.

SPINAL SCLEROSIS.—See Lateral Sclerosis (Primary).

SPINAL SCLEROSIS, POSTERIOR.—See Locomotor Ataxia.

SPINE, CARIES (Pott's Disease; Tuberculous Spondylitis).—Inflammation of the vertebra is nearly always tubercular—in children, almost without exception—although it is not impossible that the immediate starting-point of the disease is some slight injury causing an extravasation of blood into the substance of the cancellous tissue. In exceptional cases it may be due to syphilis—perhaps more frequently than is suspected, in the case of adults—and late in life to rheumatism, osteoarthritis, and ostitis deformans. Tubercular ostitis is essentially a disease of childhood, although it may occur at any period of life. Sometimes it is excited by injury, and usually affects but one part of the spine, though several vertebræ, etc., are involved together.

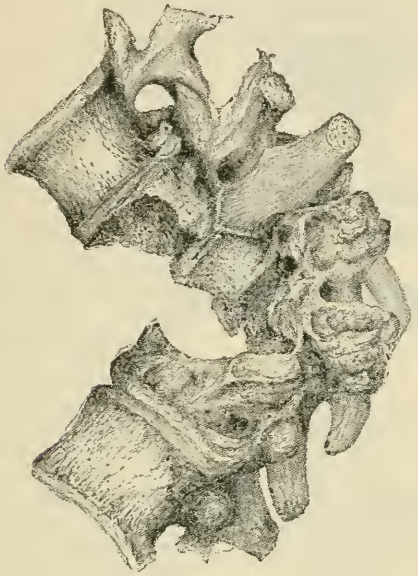
Location.—Like tubercular ostitis elsewhere, it nearly always begins in the cancellous tissue, where growth is more rapid and the blood supply most abundant. The upper or under surface of the bodies of the anterior border is the favorite seat; the spinous and transverse processes are almost never involved at the first, although later they become welded together as the inflammation extends to them; and the articular processes only when, as in disease of the atlas and axis, synovitis precedes ostitis. The most common situation is at the junction of the lumbar and thoracic regions; here the bodies are large, and strains are felt most severely. The cervical vertebræ enjoy much greater immunity; and the two highest—in children, at least—the greatest immunity of all. There is some reason to think that disease of the atlas and axis is proportionately more common in adults. Usually, the intervertebral discs are destroyed with the bones between which they lie, the granulation tissue eating into them and causing their gradual absorption. Sometimes they disappear at a very early period, as if the force of the disease was spent on them rather than on the bodies; very rarely they persist, as when the vertebræ are absorbed by the pressure of an aneurysm.

The pathology does not present any special feature. The disease begins as rarefying ostitis, the bone becoming softer, more open, and vascular, and the bone corpuscles undergoing fatty degeneration. According to the virulence and number of bacilli on the one hand, and the strength and resisting power of the tissues on the other, resolution, caseation, or liquefaction follows.

Disease of the upper two cervical vertebræ always commences as synovitis, and extends from

the articulation to the bone beneath, spreading along the most vascular lines; and, therefore, if it involves the axis, separating the odontoid process from the body.

The deformity depends upon the amount of destruction. If the caries is superficial, involving only the anterior surface of the body, and if repair begins at once, deformity may be entirely absent. If the bodies are softened or destroyed, even if only part of one, the spine sinks forward, the spinous processes project backward, and compensatory curves in the opposite direction are developed above and below. This is most distinct in the thoracic region; the lower cervical rarely becomes



Ankylosis of Dorsal Vertebræ with Great Deformity, Consequent on Caries of the Bodies.—(*Moullin.*)

convex backward; only a little thickening is perceptible, and the lower lumbar practically is not so distorted. Disease between the axis and atlas is peculiar, again, in this; for, owing to the shape of the articulation on the former, the latter, when the ligaments are softened by inflammation, or when the odontoid process is detached from the base on which it rests, slips bodily forward, carrying the head with it, so that when the patient is viewed from one side, it appears as if the head were placed in front of the spine. The effect of this displacement (when it is below the third cervical vertebra) on the diameter of the spinal canal is exceedingly slight; often it is actually enlarged; exceptionally, a wedge-shaped portion is driven backward into the substance of the cord. When the upper two vertebræ, however, are concerned, the atlas slides forward and the anteroposterior measurement opposite the odontoid process may be reduced to less than ⌊1/2 of an inch. This, if it is effected gradually, is not incompatible with life, and the odontoid process may even become ankylosed in its new situation as much as 1/2 of an inch in front of its natural one. The deformity cannot, of course, remain limited to the spine. When the cervicothoracic region is affected, the chin is brought down on the sternum so that the movements of the neck cannot be carried out; and, similarly, when the curvature is lower down, the thorax is crushed together, respiration is carried out by the diaphragm only, and the heart and the abdominal viscera are placed at great disadvantage.

Repair may commence at any time, the caseous material, if any has formed, and the débris being absorbed, dried up, or discharged externally. The vertebræ above and those below fall together; the spines, laminæ, and, in the thoracic region, even the ribs become welded into a solid mass; the sinuses gradually close up; and bony splints are thrown out in proportion to the degree of strength required.

Symptoms.—The most prominent symptoms are pain, rigidity of the back, peculiar posture, and a sense of weakness, which last, even when the child cannot describe it, can usually be recognized from the child's actions.

Pain is rarely local; nearly always it is referred to the distribution of the spinal nerves, not to their origin; thus, in atloaxoid disease it is felt over the back of the head; or, when the thoracolumbar region is concerned, over the pubes. Sometimes there is a sense of constriction around the thorax, and children often describe it as stomachache. Usually, it is worse after standing or after any exertion; lying down, it may not be felt at all. As movement causes pain, the child will guard its spine against jarring by refraining from any violent or unusual action and the surgeon should not resort to jarring of the head and shoulders in the course of his examination.

Muscular rigidity is highly characteristic; every movement of the segment of the back for some distance above and below the seat of mischief is avoided with the greatest care. If the cervical spine is involved, the whole trunk is turned around instead of the head when the patient wishes to look to one side, and it is done with the utmost deliberation. If it is the back, and the child is told to pick up anything from the floor, the hips and knees are bent, the head is thrown back, and the spine is kept absolutely rigid. Sometimes it voluntarily goes on hands and knees. For the same reason the walk is very peculiar, entirely different from the natural mobile gait, and wry-neck and other distortions are not infrequently present. When children are concerned, the weakness of the back must be judged of by their actions. They cease to play and run about; they wish to be let alone; and if they must stand, they try to support the weight of the head and shoulders by resting their hands upon the furniture, or even upon their knees, propping themselves up in a crouching attitude. With adults it is easier, as they can explain the peculiar difficulty they experience in holding themselves upright.

Spinal Abscess (Psoas and Lumbar).—When suppuration occurs, the pus collects in front of the diseased vertebræ in the angle formed by the

falling forward of the upper upon the lower portion of the spine. The anterior common ligament and the periosteum, relaxed by the bending of the spine, yield to the pressure of the pus, and, with the pleura or peritoneum, become thickened and form the abscess wall. The pus, prevented from traveling upward by the overhanging vertebræ, from traveling downward in front of the column by the attachments of the anterior common ligament, and from traveling backward by the posterior common ligament, and by the vertebræ being less diseased behind than in front, makes its way on one or the other side of the column. There it either enters the sheath of the psoas, and, destroying the contained muscle, presents in the iliac fossa or groin as an iliac or a psoas abscess, or it passes backward through or external to the quadratus lumborum, and points in the loin, when it is known as a lumbar abscess. In rare instances the pus may take a different course. Thus Walsham has seen it make its way into the ischiorectal fossa, or pass through the great sciatic foramen, or travel along the course of a rib and reach the surface near the sternum. Occasionally an abscess forms on both sides of the spine at once. In the cervical region the abscess will point in the pharynx (**retropharyngeal abscess**) or in the neck.

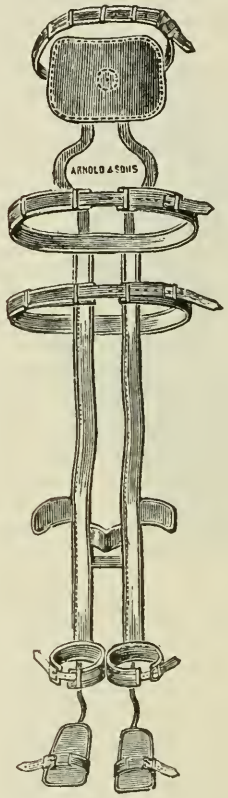
Spinal paralysis, like suppuration, may begin at any period, although naturally it is more common in the later stages of the disease. Loss of motion always precedes that of sensation, and may be nearly complete without the latter being seriously impaired. The gait becomes shuffling; the movements of one or more of the limbs are awkward; and the loss of power becomes more and more evident, with a certain degree of numbness, until at length complete paraplegia follows. As long as the cord is merely compressed, the patient may retain power over the rectum and bladder; but this, too, is not infrequently lost in the later stages. When myelitis sets in there is often severe pain along the course of the spinal nerves, with spasmodic muscular contraction; the skin becomes dry and branny; all power of the sphincters is lost; the limbs are wasted; the joints, generally speaking, are flexed; and the muscles are rigid and not infrequently thrown into violent spasmodic contractions from the uncontrolled reflex irritability of the spinal cord. Occasionally, the inflammation suddenly becomes acute, and extends upward, with symptoms of high fever, to the meninges of the brain. In disease of the cervical spine respiration may be seriously endangered either from displacement forward of the atlas and cranium upon the axis, or, when the disease is lower down, from gradual flattening of the cervical curve, owing to the softening of the ligaments. Under these circumstances any sudden movement of the head, either forward or backward, or even lying in the supine position without a support beneath the arch of the cervical spine, may cause immediate asphyxia.

Diagnosis.—In the early stages caries must be differentiated from neuralgia, rheumatism, lumbago, aneurysm, tumors, and hysteria; in the later stages the angular curvature may have to be distinguished from the kyphotic curvature of rickets.

From **neuralgia, rheumatism,** and **lumbago** it is not always easy to distinguish it. The history of the former rheumatic attack, the effect of remedies, and the absence of the signs described, must then be relied upon.

Hysteria may simulate it very closely. The absence of signs of caries, except pain; the inconstant and more diffused character of the pain; and the presence of other signs of hysteria or of uterine disease, are the points to be attended to.

A careful auscultation of the chest and examination of the abdomen will usually serve to exclude **aneurysm.**



Double Thomas' Splint for Spinal Caries.

From **tumors** of the vertebral bodies leading to the breaking down of the vertebræ caries cannot at first be differentiated, as both give rise to the same symptoms; but the age of the patient and the presence of a carcinomatous growth elsewhere would lead to suspicion of cancer.

The curve of **rickets** is more generally kyphotic, and disappears completely on gently holding the child up by its arms, or on extending it with its face downward across the nurse's knee. There are, moreover, concomitant signs of rickets, and absence of those of tubercle.

Treatment.—The general principles are those of the treatment of tuberculosis. With very few exceptions local removal of the diseased portion is out of the question; all that can be done is to improve the general health and to subdue the local inflammation, in the hope that the tissues may be able to cope successfully with the disorder.

Rest is the first consideration. In most cases it is advisable to confine the patient, for a time at least, to the recumbent position, on a well-made hair mattress, with sand bags as splints. In disease of the upper cervical vertebræ rest is absolutely essential, a bag being placed on each side, coming well down against the shoulder, and a third smaller one under the arch of the spine. If the patient's condition is favorable, this may be kept up for many months without the least deterioration in health; indeed, distinct improvement is not uncommon, especially when the pain has pre-

viously been severe. Later, when the acute symptoms have subsided the back may be incased in some kind of splint, and the patient allowed very gradually to begin to move about. To insure absolute recumbency Walsham uses a double Thomas' splint, modified by the addition of a pelvic band, a support for the shoulders, neck, and head, and two sliding foot-pieces. The two upright bars

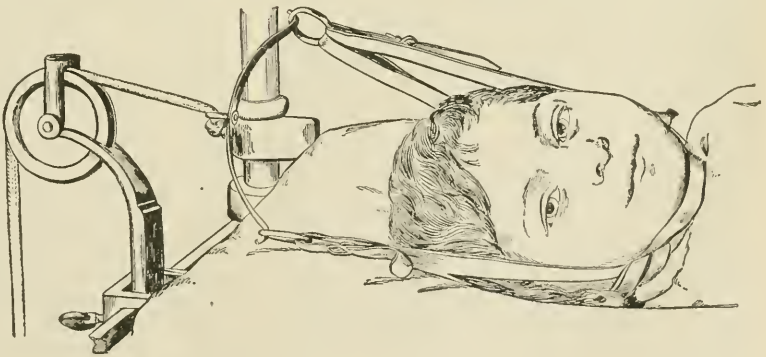
Sayre's Tripod.

which are prolonged to the head support, are made after the shape of a normally formed child when in the recumbent position.

The supports most in use at the present day are Sayre's plaster-of-Paris case and Cocking's poroplastic felt jacket, though some surgeons prefer steel instruments. The plaster-of-Paris case may be applied with the patient either in the upright position, suspended with his heels just off the ground by Sayre's tripod, or in the recumbent position, by Davy's hammock apparatus. A skin-fitting vest having been previously applied, and a line drawn across the back with a pencil at the level of the axillæ, to indicate the upper limit of the jacket, crinoline bandages, impregnated with plaster-of-Paris, are wound round and round the trunk, until a sufficient thickness is obtained, dry plaster being from time to time rubbed in with the hand. The cast should reach from the pencil line to just below the crest of the ilium, stopping short of the great trochanter and the pubes, and may be strengthened, if necessary, in places by inserting strips of perforated tin vertically between the bandages. Before applying the bandages a folded towel should be placed over the abdomen beneath the vest, so that, when afterward withdrawn, space will be left for abdominal respiration (Sayre's stomach pad). When the plaster case is dry, it may be sawed through down the front, removed, and the fronts edged with leather and perforated with eyelet-holes, so that it can be worn laced up, and can be taken off from time to time. To apply the poroplastic felt, the jacket, which is first made to measure, must be put in a steam oven, and when rendered thoroughly plastic, further molded to the patient, who should be prepared and suspended in the same way as for applying plaster-of-Paris. Of steel instruments, that known as Taylor's is perhaps the best. When the disease is in the cervical or upper thoracic region, Sayre's jury-mast may be fitted to the plaster-of-Paris cast or poroplastic jacket; or a cervical collar composed of leather or poroplastic felt may be used; or, better, the combined poroplastic jacket and collar.

The treatment of a tubercular abscess is either expectant or operative. Many of these are readily absorbed when proper mechanical support is afforded and the general health is improved. There are three indications for operative interference, viz.: if the abscess is rapidly increasing in size, if it is interfering with the health of the patient, or if it is pointing, but unless one at least of these is present, a tubercular abscess should be left alone. Aspiration may be employed first to stay the progress of the abscess and possibly to remove it entirely. Force should not be used in aspirating, and it may be repeated frequently provided the trocar be inserted into healthy tissue each time. In these abscesses lavage of the sac with iodin water, followed by injection of iodoform emulsion, is of great benefit. The trocar and cannula used for evacuation should be large enough to prevent clogging during the outflow, and the puncture should be sealed with iodoform collodion laid on a thickness of gauze.

In some cases in which necrosis has been associated with caries success has attended the removal of the sequestrum through a properly planned incision made in the loin. In exceptional cases, in which the paralysis of the lower limbs continues in spite of absolute rest and recumbency, and in



Head Extension for Pott's Disease.—(*Young.*)

port, to improve the outward appearance, and to prevent further deformity. In slight cases they should on no account be used. The exercises employed are directed in part to improving the muscular tone generally, and in part to strengthening those muscles in particular that tend to lessen or straighten the curves. For the former purpose, such exercises as swinging by the hands from a bar, forcibly stretching an elastic cord fixed to the floor, and dumb-bell exercises should be practised. For strengthening the muscles in particular that tend to straighten the curve, the back should be manipulated until that posture is found in which the curves are least marked, and the patient should be made to hold herself in this position as long as possible. At first she will be only able to do this for a few minutes at a time; but by frequently assuming the posture the muscles thus brought into play are gradually strengthened, until at last the improved posture is maintained constantly and without effort. For further improving the tone of these muscles, Busch and Roth recommend exercises similar to the following: The patient's body, held in the improved posture, is brought over the end of a couch or table, and while she is prevented from falling by an assistant holding her legs, she alternately flexes and extends her body at the hips, the surgeon resisting her efforts. Some surgeons use the sloping seat, as recommended by M. Bouvier and Mr. Barwell, in counteracting the curves. A similar effect may be obtained by wearing a thick sole on one boot, and by sitting on the off side of the horse when riding. After the exercises, or twice or thrice during the day, the patient should lie on her back for from half an hour to an hour; and while sitting, her back should be supported by a reclining chair. Walsham has had considerable success in removing rigidity in cases where there is slight osseous deformity by applying a weight to the convexity of the curve, the patient standing with her legs straight and body horizontal, and being supported in this position by her elbows on a chair.

Kyphosis

Kyphosis is a general curving of the spine with its convexity backward or an exaggerated condition of the normal dorsal curve. It depends upon an unequal compression of the intervertebral cartilages and, to a less extent, of the vertebral bodies, which thus become wedge-shaped, with their bases looking posteriorly. It is generally the result of muscular debility, rickets, slouching habits, or occupations necessitating stooping.

Symptoms and Diagnosis.—The chief point of interest is to distinguish it from the serious angular curvature induced by caries. In children and in adults this is generally easy; but in rickety infants, in whom the ordinary test for caries cannot be applied, it is often very difficult. In such a case the infant should be placed across the nurse's knees and gently extended, when the rickety curve will disappear, but the angular curve will remain. The back, moreover, in caries, is rigid, and the child is uneasy in this position and tries to resist the extension by muscular effort, and draws up his legs. In rickets the back is flexible and there are other signs of rickets.

Treatment.—In the infant, recumbency; in growing lads and girls, the correction of stooping habits by the use of muscular exercises and a spinal brace, with partial recumbency and tonics, is the treatment usually indicated. For the confirmed kyphosis of the old, nothing can be done.

Lordosis

Lordosis, or curving of the spine with the convexity forward, is a symptom rather than a disease, inasmuch as it is formed as a compensatory curve to restore the equilibrium of the spine when from any cause its normal antero-posterior curves are disturbed. Thus, it is most common in the lumbar region, where it is merely an exaggeration of the normal curve, and is there produced to counterbalance the tilting forward of the pelvis consequent upon hip-disease, congenital distortion of the hips, rickets, etc.

SPINE, DISEASES.—See Spine (Caries, Curvature), Spondylitis Deformans.

SPINE, INJURIES.—**Sprains** of the spine are exceedingly common, and may be caused by any violent twist or bend of the back. See Back (Injuries).

Dislocation and Fracture.—Dislocation of the spine without fracture is extremely rare; indeed, except in the cervical region, it is said never to occur. Fracture unaccompanied by dislocation is also uncommon; but uncomplicated cases of fracture of the spinous process and laminæ, and, more rarely, of the transverse and articular processes, are sometimes met with. In the majority of cases fracture and dislocation are combined. Thus, usually there is fracture of the body and of the articular processes of one or more vertebræ, with dislocation of the whole of the spine above the seat of injury from the spine below. This common form of injury is known as fracture-dislocation.

Fracture-dislocation is either the result of direct violence applied to the spine, or of indirect violence, as a fall upon the head.

When the result of **direct violence**, which can only be applied to the posterior part of the spine—one or more of the spinous processes may be detached without implicating the vertebral canal. When the violence is very great—as in a fall from a height on the back across a beam or rail, or as the result of a severe blow, as from a crane—the spine is bent violently backward, tearing asunder the structures forming the anterior segment of the column and crushing those forming the posterior segment. Hence the vertebral bodies are generally uninjured, but are wrenched apart, the intervertebral cartilages are ruptured, the anterior common ligament is torn, and the arches of the vertebræ and of the articular and spinous processes are crushed. The vertebræ above the injury are dislocated forward, as, the articular processes being fractured and the intervertebral

cartilages torn, nothing remains to keep them in position.

In fracture from **indirect violence**—such as may be received in a fall from a height upon the head, or catching the head while passing under an arch, or from a weight falling upon the head or shoulders—the spine is bent violently forward, crushing the anterior part of the column and tearing the posterior part asunder. Here one or more of the bodies and intervertebral cartilages are crushed between the vertebræ above and the vertebræ below, one of the fragments of the fractured body being frequently driven backward into the vertebral canal, while the arches and the spinous and articular processes are wrenched asunder. Fracture of the

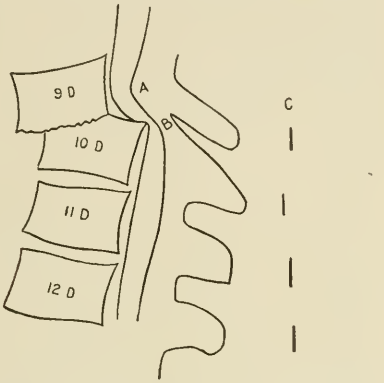


Diagram of Fracture-dislocation of the Spine, showing compressions of the cord by the laminæ of the 9th dorsal vertebra (*A*), and by the body of the 10th dorsal vertebra (*B*). *C*. Spines in same case as felt from the rear.

sternum is occasionally combined with this injury, in consequence, it is said, of the chin coming into violent contact with the sternum as the spine is doubled forward.

Condition of the Spinal Cord.—The importance of fracture-dislocation of the spine lies not so much in the fact that the vertebræ are fractured, as that the cord is generally injured. When the vertebræ are not displaced, the cord may at times altogether escape. More commonly, however, it is compressed; or, perhaps, completely divided; or, again, so bruised that it rapidly undergoes inflammatory softening. When the injury is situated below the second lumbar vertebra, the cord necessarily escapes, as it terminates at that spot; but the nerves of the cauda equina may then be injured.

Symptoms.—The local signs are often but little marked. There may be pain at the seat of injury, or some inequality in the spinous processes; but as often as not these are absent. The general signs depend upon the condition of the cord, and none will be present when it has escaped injury. But when it is compressed or crushed, there will be paralysis of the parts below, more or less complete according to the extent of the lesion. Taking as an example a case of fracture in the lower cervical or upper thoracic region, the most common situation, with severe compression or crushing of the cord, there will be paralysis of both motion and sensation of the whole of the parts below the seat of injury (paraplegia), and perhaps a zone of hyperesthesia immediately above the injured part. The intercostal muscles being paralyzed, respiration can only be carried on by the diaphragm, this muscle receiving its nerve supply through the phrenics that are given off above the seat of injury. Hence, while the chest is motionless, the abdomen rises and falls during respiration. The bladder and rectum and their respective sphincters share in the paralysis, so that there is at first retention of urine and of feces, followed by passive overflow of urine as the bladder becomes distended and will hold no more, and by involuntary passage of feces. Priapism, or involuntary erection of the penis, is frequently present, or is induced by the use of the catheter. The temperature varies: sometimes it may be lower than the normal, but often it is considerably elevated, even reaching as high as 107° F. shortly before death. Consciousness, unless any head injury has been received at the same time, is not affected. The reflexes in the lower limbs are usually at first in abeyance, but may return if the patient does not succumb to the shock of the injury. If the reflexes remain quite lost, the probabilities are that the conducting power of the cord has been completely destroyed. If they return, it is a sign that some power of conductivity is left in certain portions of the cord at the seat of injury. Death occurs, as a rule, in from 24 hours to a few days, from bronchial trouble; but the patient, if the fracture is in the upper thoracic region, may linger from 2 to 3 weeks. The secondary troubles that are then generally met with are bed-sores and chronic cystitis, probably due in part to impaired nerve influence, and in part to slight injury in the passage of a catheter, or to the introduction by the catheter of a microorganism—the micrococcus ureæ.

Such may be taken as a typical example of fracture of the spine as commonly met with in surgical practice. But the nature and gravity of the symptoms will depend upon the situation of the fracture, and upon the amount of injury to the cord. Thus, in some cases of fracture there may be no paralysis; in others, the paralysis may be incomplete: *i. e.*, confined to loss of motion only, or to paralysis of one limb or one group of muscles, or to impairment of sensation over some limited area. Such cases, however, are much less common than that previously described (Walsham). The X-rays should always be employed when possible, to determine the extent and character of the injury to the bony parts.

The prognosis will depend in great measure on the situation of the fracture and on the condition of the cord. Thus, when the fracture is in the cervical region, if death is not instantaneous, the patient may survive from 12 hours to 2 or 3 days; usually, however, death occurs in about 2 hours; when in the upper thoracic region, the patient may linger for 2 or 3 weeks; when in the lower thoracic region, if he survives the period at which the inflammatory troubles commonly occur, he may recover, remaining, however, if the cord is severely injured, paraplegic; when in the lumbar

region, he may recover, with perhaps only partial paralysis of one or other of the lower limbs or of a certain group of muscles, or even without any paralysis whatever. But even when the injury to the cord has been so high as to cause paralysis of the whole body below the neck, patients have been known, in rare instances, to live for several months, or even for years.

Treatment.—In cases in which there is no paralysis, thus showing that the cord is not affected, the indication is to keep the fractured spine at perfect rest, for the purpose not only of obtaining union of the fracture, but also of preventing by any movement displacement of the fragments and injury of the cord. In the more common cases, when there is paralysis, showing that the cord is injured, the indications are to remove any fragments that may be compressing the cord, and subsequently to keep the parts at rest until union of the bones has occurred. When, however, as is too frequently the case, the removal of the fragments is not practicable, or the cord itself has been crushed, all that can be done is to endeavor to guard against the formation of bed-sores and the occurrence of chronic cystitis and its attendant evils. Thus, the patient should be placed upon a water-bed, and his posture gently changed from time to time, so that pressure may not be continuously made on one part, while he must be kept scrupulously clean and dry, and free from urine and feces. The bowels should be cleared, if necessary, by enema, or excessive diarrhea controlled by morphin suppositories or by starch and opium injections. Should bed-sores threaten, the skin should be hardened by sponging with rectified spirit, and dusted with oxid of zinc and starch-powder. If formed, they should be dressed with mild antiseptics, iodoform, balsam of Peru, etc., and all pressure removed from the surrounding skin by the use of water-cushions. To prevent cystitis from occurring, a soft-rubber catheter, thoroughly cleansed in carbolic acid and dipped in carbolic oil, should be passed twice daily. Should the urine become alkaline, the bladder must be washed out with some antiseptic solution, as salol (10 grains to 1 ounce) or boric acid (10 grains to 1 ounce).

Extension of the Spine.—In cases in which, from the marked inequality of the spinous process, there is a probability of fragments pressing upon the cord a cautious attempt to extend the spine and to reduce the displaced vertebræ may be made, and a plaster-of-Paris case may be applied during the extension.

Laminectomy is the operation of removing the posterior vertebral arches. It is performed for the purpose of relieving pressure on the vertebral cord, but is contraindicated when it is likely that disorganization of the cord has been effected. An incision is made down the vertebral spines of the patient, who lies prone, with a firm sand-pillow under the lower ribs. The spinous processes and the laminæ are cleared, and the periosteum is incised and lifted away from the arch. Forceps remove the spinous processes close to their bases, and the laminæ are cut off on each side by rongeur forceps, exposing the dura mater. Fragments may be found exposing the vertebræ, and a blood-clot may exist between the dura and the bone. The dura may be incised and the clot removed, or the dura may be closed with catgut, the wound drained throughout by a tube, the superficial parts being closed with silkworm-gut, and antiseptic dressings applied. In operating, hammers and chisels should not be used, on account of the jarring to the structures.

SPINE, TUMORS.—See Spinal Cord (Tumors).

SPIRILLUM FEVER.—See Relapsing Fever.

SPIRITS.—Alcoholic solutions of volatile substances, which may be solids, liquids or gases. They are officially prepared either by simple solution, by solution with maceration, by gaseous solution, by chemical reaction, or by distillation. The menstruum is alcohol in nearly all instances, 4 having water in addition, and 2 being alcoholic liquors of a specified alcoholic strength (whisky, brandy). The official spirits are 20 in number; those made from volatile oils are frequently called *essences*.

Spiritus ætheris (32 1/2); S. ætheris compositus (32 1/2); S. ætheris nitrosi (4); S. ammoniæ (10); S. ammoniæ aromaticus (9); S. amygdalæ amaræ (1); S. anisi (10); S. aurantii compositus (20); S. camphoræ (10); S. chloroformi (6); S. cinnamomi (10); S. frumenti (37 to 47 1/2); S. gaultheriæ (5); S. glycerylis nitratis (1); S. juniperi (5); S. juniperi compositus (64 1/2); S. lavandulæ (5); S. menthæ piperitæ (10); S. menthæ viridis (10); S. vini gallici (39 to 47). The figures placed after spiritus frumenti, spiritus juniperi comp., and spiritus vini gallici, represent the percentage of absolute alcohol by weight in each; those placed after the others indicate the quantity of the principal ingredient in grammes to each 100 cubic centimeters of the preparation.

SPIROSAL.—The monoglycol ester of salicylic acid. It is an efficient external remedy in rheumatic affections. When rubbed into the skin, it is nonirritant and readily absorbed, and it liberates salicylic acid in the tissues.

SPLEEN, DISEASES. Physical Examination.—The spleen lies in the left hypochondriac region, the internal or concave surface being in close relation with the greater curvature of the stomach and tail of the pancreas; the upper border lying immediately under the diaphragm; the lower border covers the left suprarenal capsule and a small portion of the kidney, to which it is attached by areolar tissue. It extends transversely from the upper border of the ninth to the lower border of the eleventh ribs, and anteriorly to the mid-axillary line. The patient is placed in the recumbent posture. By **inspection,** enlargement of the organ is detected.

Palpation confirms inspection, detects tenderness, position and character of enlargement, whether hard or soft. In the normal condition the organ does not admit of palpation. The spleen is said to be enlarged when the anterior surface can be felt at the free margin of the ribs on deep inspiration, or if it projects beyond the mid-axillary line on percussion.

Percussion.—The patient is placed in the recumbent position on the right side, with the thighs flexed. Deep percussion is necessary, and should begin in the midaxillary region over the lung, gradually going downward in order to detect impaired resonance over a more dense medium. Dulness is usually elicited at the upper border of the ninth rib, and extends downward to the lower border of the eleventh rib, when tympany exists over the region of the intestine. The anterior border is determined by first percussing over the bowel, gradually moving toward the splenic dulness, which is found in health in the midaxillary line. If it projects beyond the midaxillary line, the organ is said to be enlarged.

Morbid conditions of the spleen arise as the result of some general disease, such as malaria, leukemia, syphilis, or by extension of some inflammatory process from a neighboring organ.

Splenitis.—This may be the result of traumatism or extension of a septic process from the stomach, perinephritic abscess, or disease of the diaphragm. It is recognized by enlargement and tenderness of the organ.

Perisplenitis may be due to extension of inflammation from adjacent tissues or from traumatism. The resulting adhesions cause pain during respiration. There may be palpable crepitus over the spleen.

Treatment.—Relief may be obtained by counter-irritant and 10 percent iodin inunctions.

Splenic abscess occurs occasionally during the course of pyemia. It may break into the stomach, intestines, lungs or peritoneal cavity.

Rupture of the spleen is caused by traumatism or pernicious malarial fever. In this condition there is a sudden sharp pain in the region of the spleen, accompanied by evident symptoms of collapse.

Tumors of the Spleen.—The spleen may be the seat of gummatous tumors, or of an echinococcus cyst.

Amyloid spleen occurs as the result of prolonged suppurative process, as in tubercular bone-disease, and may be associated with amyloid liver and kidney.

Echinococcus of the Spleen is associated with similar infection elsewhere. The characteristic hooklets may be recognized in the aspirated fluid. The spleen presents a fluctuating tumor which is distinguished from abscess by the absence of symptoms of sepsis (chills, fevers, etc.) Echinococcus disease may, however, take on a purulent form.

Movable spleen is due to elongation of the gastro-splenic ligament and blood-vessels.

Symptoms.—Absence of the normal splenic dulness, the presence of a movable hard tumor in the lumbar or epigastric regions, accompanied by a dull, dragging sensation in the affected parts may distinguish the condition.

Treatment consists in the application of a pad and an abdominal binder. Prolonged rest in bed is necessary to obtain relief.

SPLENECTOMY.—Splenectomy, or extirpation of the spleen, may be required for rupture of the viscus, and for some forms of enlargement and tumors. It should not be proceeded with if on exposure extensive adhesions are found, since, unless all these can be securely ligatured, fatal recurrent hemorrhage is almost certain to take place. An incision is made either in the left linea semilunaris, or still further to the left, and the spleen having been thoroughly exposed, each adhesion carefully tied, and the organ, if enlarged, drawn out of the wound, the pedicle is then transfixed in several places with strong silk, and the ligatures interlocked and tied. The pedicle is next severed well to the splenic side of the ligatures, the organ removed, the peritoneum thoroughly cleansed, and the abdominal wound united without or with drainage. Great care should be taken not to tear the splenic substance, an accident attended with fearful hemorrhage (Spencer and Gask).

SPLENIC ANEMIA (Splenic Pseudoleukemia).—A chronic anemia characterized by progressive hypertrophy of the spleen, without the glandular enlargement of Hodgkin's disease.

The **etiology** is unknown, but infectious diseases and intestinal infection are believed to be factors.

The **symptoms** and **blood changes** are similar to those of pernicious anemia. These include pallor, dyspnea, palpitation, progressive weakness, enlarged spleen; and later, emaciation, deeper yellow hue of the skin, tendency to hemorrhages, fever, serous effusions, diarrhea. The red blood cells are diminished. The hemoglobin percentage is lowered, but is relatively less than the corpuscles. Later in the disease there is ascites due to cirrhosis of the liver (Banti's disease, *q. v.*). The disease is a protracted one.

Treatment.—Nutritious food, arsenic, iron and bone-marrow are indicated as in other anemias. About 75 percent of recoveries are reported to have followed splenectomy. This operation is contraindicated in profound cachexia. Talma's operation has also been performed in few cases.

SPLENIC EXTRACT.—The substance of the spleen has been recommended in malaria, tuberculosis, typhoid fever, and in various disorders of the blood. The ethereal extract, in the form of an emulsion containing 5 grains to the dram, is the most active preparation. It is given in daily doses up to 4 drams.

SPLENOMEGALY, TROPICAL.—See KALA-AZAR.

SPONDYLITIS (Tuberculous).—Acute osteomyelitis of the spine. A rare infection due to the same causes as osteomyelitis elsewhere. (See under BONE, Diseases.) It is too diffuse and rapid for successful surgical treatment. See SPINE (Caries).

SPONDYLITIS DEFORMANS.—A form of arthritis deformans characterized by a striking rigidity of the spinal column. If not associated with kyphosis it has been called "poker back." It may be accompanied by osteoarthritic changes in the shoulder and hip (Spondylose rhizomelique).

SPONDYLOLISTHESIS.—A slipping forward of the lumbar upon the sacral vertebræ.

SPONDYLOSE RHIZOMELIQUE.—Ankylosis of hip, spine and shoulders, occurring chiefly in old men. See SPONDYLITIS DEFORMANS.

SPONGES.—Marine sponges are especially used in operations on the throat and abdomen—in the

former because mucus adheres, in the latter because the omentum and intestines do not adhere to marine sponges, whereas the reverse is the case with those made of wool or gauze. Owing to the difficulty in preparing and cleaning them, they are not generally used except as above. Marine sponges must first be freed from sand and remains of marine organisms by prolonged soaking and kneading in water. Then they are covered for a day with sulphurous acid 20 percent or 1 in 5, alternatively with hydrochloric acid 8 percent, or with permanganate of potassium 1 in 400, followed by saturated oxalic-acid solution to decolorize. After all acid has been washed away the sponges are placed in a jar covered with 1 in 20 carbolic acid, where they should remain at least a day before use. They may be so preserved indefinitely, merely becoming browner, or the sponges may be counted into linen bags, which are tied, labelled, and then hung up to dry in the air. Such sponges are then ready for use at any time with sterile water. After use, sponges must not be put straight into carbolic acid, but must soak in warm water and be kneaded at intervals for a day or more until all the fibrin of the blood has become dissolved, which it will soon do, unless it has been coagulated by heat or by carbolic acid. When the water in which the sponges are being kneaded remains clear, the sponges are treated with sulphurous acid followed by carbolic acid as above described. But all sponges which have come in contact with infective material should be burnt. (Spencer and Gask.)

SPOROTRICHOSIS.—A subacute or chronic disease affecting chiefly the skin and subcutaneous tissues, due to the sporotricha, which can be identified in culture made from the pus. Nodules or abscesses or ulcers appear which may be mistaken for furunculosis, blastomycosis, tuberculosis, syphilis, etc. Lesions may be found in the bones or joints or the muscles. At times the eyes, nose, throat, or epididymis may be invaded; or the infection may become general, accompanied by pains, fever, and malaise. The affection is curable under iodid treatment in moderate dosage.

SPOTTED FEVER.—See CEREBROSPINAL FEVER TICK FEVER.

SPRAINS.—A sprain is always the result of indirect violence, and is produced when the movements of a joint are carried beyond their physiologic limits, but stop short of a permanent displacement of the articular ends—that is, dislocation. A sprain may be said, therefore, to be the aborted stage of a dislocation. Extensive muscular action may likewise produce a sprain. In many individuals the first injury predisposes to the recurrence of the condition from apparently trivial causes. In the majority of sprains there is a stretching of the capsule of the joint and of one or more ligaments. In severe cases there is a rupture of one or both of these, with consequent laceration of blood-vessels, and often of nerves. Hemorrhage into the joint and the periarticular structure is always present. The ligaments, as a rule, if torn, give way at the point of insertion rather than in their continuity. This is made manifest in milder cases by tenderness at some point above or below the articular line, and corresponding to the point from which the ligament was torn. In the tearing of a ligament from its osseous attachment particles of bone are not infrequently brought away with the detached fibrous structure. In severe cases the bone may be denuded of its periosteum for a considerable distance. In the sprains of childhood and adolescence this condition is not uncommon, owing to the great flexibility of the bone. In adults, on the other hand, the extreme limit of the sprain is the tearing away of a greater or less fragment of bone to which the ligament placed upon the stretch by the trauma has been attached. It is in this way that fractures of the lower end of the radius and of the lower end of the fibula may be considered as severe forms of joint distortion. They are sometimes known as sprain-fractures. In severe sprains the segment of the capsule opposite that which is put upon the stretch may be pinched between the articular surfaces. Thus, in severe sprains of the ankle pain is often felt on both sides of the foot. In very severe cases a rupture of the muscles of the accompanying joints may ensue. This is quite uncommon. When it results, the muscles give way along the line of attachment to the tendon.

The symptoms of a sprain are pain, swelling, ecchymosis, and limitation of joint function. The pain at the moment of accident it often very severe, leading at times to syncope. When an examination of the joint is made, the tenderness will be found most marked over the articular line and over the insertion of the ruptured ligament. The swelling varies greatly in different cases, since it depends upon the hemorrhage within and about the joint. In mild cases it is limited to the periarticular structures, appearing in the form of ecchymoses within the course of two or three days. The ecchymoses, owing to ruptures of muscles, are often found at points considerably removed from the affected joint. The ecchymosis following a sprain is often found at a distance far removed from the joint without rupture of muscle. Often the only ecchymoses seen in sprains of the shoulder appear after the lapse, sometimes, of many days at the point of insertion of the deltoid. As a rule, the swelling attains its maximum within the course of 24 hours. In many cases, however, the hemorrhage into the joint produces a reactional hydrarthrosis, which reaches its maximum in from a week to 10 days. The degree of periarticular or intraarticular swelling depends entirely upon the extent of damage done to the ligaments and the joint capsule.

The frequency with which joints are subject to sprain varies with their nature. The enarthrodial joints, in which the range of movement is widest, are least subject to sprains. On the other hand, joints of the hinge variety are more frequently the seat of such lesions. Sprains occur, therefore, most often in the ankle, the knee, the wrist, and the small joints of the hand.

The clinical history of a sprain varies with the

conditions produced by it. In some cases characterized by the stretching of the ligaments without laceration, the pain and swelling speedily subside, and after a few days or a week the joint functions are restored. In severer cases when hemorrhage into the joint and periarticular swelling indicate extensive laceration, the progress toward recovery is often very tedious, and months may pass before a final restitution to the normal condition takes place. In the severest cases circumscribed tender areas, thickening of the joint capsules, or chronic hydrarthrosis may leave the joint permanently impaired. Atrophy of the muscles is often found to follow upon severe sprain during the first 2 weeks, and is the result of the injury to the articular nerve filaments. This condition is often irreparable.

Extensive hemorrhage into a joint is always significant of a tedious recovery, and frequently renders unfavorable the prognosis, so far as complete restoration of joint function is concerned. In subjects with a tendency to diathetic, and particularly to tubercular, disease, a sprain is often the exciting cause of chronic joint-disease.

Treatment.—In the treatment of sprains absolute rest should at once be secured. Elevation and suspension of the affected limb at a right angle will often relieve the pain at once. This position conduces to the arrest of hemorrhage and, by rapidly depleting the veins, facilitates the absorption of the already effused blood. To further hasten absorption, compression by an elastic bandage may be considered as of prime importance in the treatment of sprains. Cold applications are often of value for the relief of pain. To these may be added the lead and opium wash, or a solution of chlorid of ammonium and opium, or an ichthyol ointment. Internal administration of opiates may become necessary when pain cannot be otherwise alleviated. To secure absolute rest, immobilization of the joint by means of plaster-of-Paris, starch, or silicate of sodium bandages is often indicated. In milder cases strapping the joint with strips of adhesive plaster is often of great value. In sprains of the ankle incasing the joint by well-applied adhesive strips permits the patient to walk within 24 hours. The indiscriminate use of fixed dressings must, however, be condemned, since their unnecessarily prolonged use may lead to irremediable stiffness of the joint. It is preferable to resort to the use of splints, which can be removed daily if required. After the subsidence of the acute symptoms of the sprain, the main object of treatment must be that of the restoration of joint function. Efforts in this direction should never be delayed beyond the second week. The chief agents in attaining this end are passive movements and massage methodically applied. In the severest forms of sprains, in which the intraarticular effusion is not absorbed by this treatment, recourse must be had to aspiration of the joint.

In sprains that are not relieved by one or other of these methods of treatment, singly or combined, counterirritation by means of blisters, or, preferably by ignipuncture, often answers admirably. When there is any thickening under an especially tender point, recourse should be had to free incision. In a few cases hemorrhagic cysts have been drained or granulation masses removed with a curette, thereby permanently relieving the symptoms. Such a subfascial cyst as large as a hazelnut has been successfully drained. It was over the trochanter, and directly under a point that had been extremely tender during two years following a sprain of the hip. See JOINTS (Injuries); ANKLE.

SPRENGEL'S SHOULDER.—Congenital Elevation of the Scapula, Winged Scapula (*scapula alata*). This has been explained as due to an arrested development in the embryonic formation of the shoulder girdle, which prevents the normal shifting of the shoulder girdle from the cervical to the upper dorsal region, the so-called "descensus scapulæ." In fetal life the nerves of the brachial plexus pass out horizontally and the angle of the scapula only reaches the fifth instead of the seventh rib. When thus arrested the muscles—trapezius, rhomboids and levator anguli scapulæ—shorten, and fibrous or bony plates unite the sixth and seventh verte-

CONGENITAL ELEVATION OF THE SCAPULA, SPRENGEL'S SHOULDER.—(*Spencer and Gask.*)

bral spines and the scapula. Thus the upper angle of the scapula has been mistaken for an exostosis.

Treatment.—In early life persistent exercises until the palms meet above the head and the flexor surface of the wrists can be applied to the back of the neck. In later cases a division of contractured muscle and excision of the bony plate may be required before exercises can be carried out (Spencer and Gask).

SPRUE (Psilosis).—A tropical disease, characterized by stomatitis, chronic gastrointestinal catarrh, and atrophy of the liver. Emaciation, tympanites and diarrhea are markedly prominent symptoms. The treatment is chiefly tonic and

dietetic. Rest in bed and an exclusive milk diet should be insisted upon until there is a decided abeyance of the symptoms, then a very gradual return to normal diet. An exclusive meat and beef juice diet is advocated by some clinicians, while others recommend a diet of strawberries.

SPUTUM.—The material discharged from the alveoli of the lungs, bronchi, trachea, larynx, pharynx, and posterior nares.

Characteristics.—The amount of sputum varies both in health and in disease. In certain affections of the lungs, as edema, gangrene, and tuberculosis, the sputum is always increased in amount.

Consistence.—In certain affections, as in early stages of croupous pneumonia, it may be so thick or viscid that in inverting the receptaclei into which it is discharged the fluid may not escape.

The color varies greatly under different circumstances, being at times reddish (pneumonia and pleurisy), greenish (edema and gangrene), blackish (in coal-miners), blood-tinged (phthisis).

Normally, the **odor** is only faintly perceptible, but in putrefactive processes the odor is strong and frequently nauseating.

The specific gravity ranges from 1.015 to 1.026.

Configuration or Character.—(1) Mucoid, (2) purulent, (3) serous, and (4) sanguineous. There may be combinations of these, such as mucopurulent, mucoserous, serosanguineous, sanguinomucopurulent, nummular, etc.

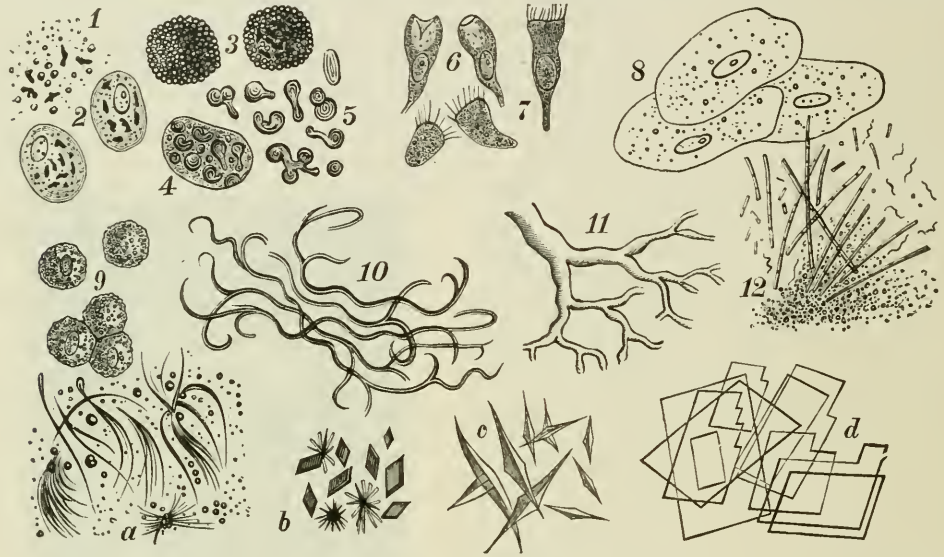
Clinical Significance.—In health the sputum is a transparent, colorless, slightly glutinous liquid, like thin mucilage. It contains mucin, varying quantities of saline matter, and water. The saline matter is abundant in transparent viscid expectoration, deficient in the opaque and less tenacious kind, and least in the actually purulent sputum.

The quantity and viscidity of ordinary mucous secretion is increased in simple catarrhal inflammation of the bronchial membrane. A change occurs when bronchitis has existed for some days, the secretion becoming semitransparent and then opaque, the color changing to a yellow or greenish hue.

The sputum becomes frothy from admixture of air, rusty or prune-juice colored from oozing from the capillary vessels. Fibrinous molds of the bronchial tubes, chalky masses consisting of nspissated and calcified cheesy matter, are sometimes expectorated.

A person having chest complaint, coughing frequently, and expectorating a frothy salivary fluid only may have pleurisy. If the expectoration is glairy, like white of egg, bronchitis may exist. A rusty tinge, like thick gum-water colored with blood, indicates pneumonia. A sudden gush of fetid pus points to abscess or empyema. Purulent expectoration occurs in bronchitis as well as in phthisis, but when long-continued and accompanied by a distinct rhonchus, it invariably comes from a vomica.

In phthisis the expectoration is usually salivary or frothy at first, the result of irritation. Later it becomes viscous, and subsequently dotted and streaked with blood. A pearly aspect next ensues, with whitish opaque spots. These become large, flocculent, and ultimately nummular.



Objects Found in the Sputum.—(*Landois.*)

1. Detritus and dust-particles. 2. Pigmented alveolar epithelium. 3. Fatty degenerated and partially pigmented alveolar epithelium. 4. Alveolar epithelium showing myelin degeneration. 5. Free myelin forms. 6, 7. Desquamated ciliated epithelium, partly changed and deprived of its cilia. 8. Squamous epithelium from the mouth. 9. Leukocytes. 10. Elastic fibers. 11. Fibrinous cast of a small bronchus. 12. Leptothrix buccalis, together with cocci, bacilli, and spirochetæ. *a*. Fatty acid crystals and free fatty granules. *b*. Hematoidin. *c*. Charcot's crystals. *d*. Cholesterin.

Later the expectoration becomes purulent, and just before death is surrounded with a pinkish halo. By the addition of acetic acid, the sputum may be made transparent, and elastic tissue more clearly seen. The experienced eye is the best guide in the selection of those small pinhead-sized flocculi of expectoration in which microscopic particles of lung tissue may be detected.

The existence of carcinoma of the lung may sometimes be detected by the microscope, and from the character of cells found, the same apparatus may indicate the part of the respiratory tract affected and the degree of disease existing.

Treatment may be much guided by a study of the expectoration. An alteration in the nature of the secretion may affect the symptoms, and relieve the cough and dyspnea. If frothy from congestive disorder, warm poultices, turpentine stupes, or hot flannels externally may benefit, while fever may be reduced and irritability lessened by giving salines with antimony or aconite. Lemon-juice, liquor potassæ, and various inhalations give relief if there is a viscid or glutinous expectoration. Iodid of potassium, given with a few drops of wine of antimony, will promote cell and tissue change, and make the secretion less adhesive.

Senega and the gum-resins are indicated when mucopurulent secretion is established. In the form of a lozenge they may be continually used. Benzoin, tolu, and copaiba are of use. Acetic or tannic acid, given in small or frequently repeated doses, reduces the quantity of secretion. Calomel with antimony and guaiac, as in Plummer's pill, is of the greatest service, and calls for much discrimination and care. Inhalation of tar, creosote, or oil of juniper are of benefit to the affected surface of the mucous membranes, while cod-liver oil, iron, and tonics improve the general health.

Macroscopic appearance may present (1) elastic tissue or threads; (2) fibrinous casts, as in pneumonia or certain varieties of bronchitis, diphtheria, etc., Curschmann's spirals, and Charcot-Leyden crystals (see ASTHMA); (3) Dittrich's plugs —yellowish-white or grayish malodorous masses of bacteria, fatty acid crystals and pus found in pulmonary gangrene, follicular tonsillitis, etc.; (4) echinococcus membranes; (5) various concretions or calcareous plugs (broncholiths and lung stones); (6) foreign bodies.

Microscopic Appearance.—The specimen is spread on a glass slide, a cover-glass superimposed; and immediately examined. It may show (1) leukocytes; (2) red blood-cells; (3) epithelial cells; (4) elastic tissue; (5) animal parasites, as echinococcus hooklets; (6) various bacteria.

The chief **bacteria** are tubercle bacillus, pneumococcus, influenza bacillus, actinomycosis, oidium albicans, and aspergillus mycelium. See TUBERCULOSIS.

Crystals in Sputum.—(1) Charcot-Leyden; (2) hematoidin; (3) cholesterin, as in phthisis; (4) fatty acid crystals; (5) tyrosin crystals; (6) crystals of oxalate of calcium and triple phosphate.

Chemically the sputum contains (1) albumins, (2) volatile fatty acids, (3) glycogen, (4) ferments, and (5) inorganic salts.

After examination of the unstained specimen a smear should be made; the preparation should next be dried in the air and stained with Wright's stain for 3 minutes, washed and mounted.

Pathologic Technic.—The following are the principal methods of procuring a concentrated sediment for microscopic examination:

Biedert's Method.—Used in examining sputum that contains few tubercle bacilli. Mix 15 c.c. of the sputum with from 75 to 100 c.c. of water and a few drops of potassium or sodium hydroxid solution. Boil until the sputum is thin. Place in a conic glass vessel, and after two days pour off the supernatant liquid. Stain the precipitated sediment.

Kaatzer's Method.—Mix the sputum with from a 1 to a 3 percent solution of caustic soda or potash. This dissolves the cells and mucus, but preserves the elastic fibers and bacteria. Stain the sediment. Clear the preparation with a dilute solution of acetic acid.

Kühne's Method.—This method is used to overcome the viscidity of sputum and to facilitate the spreading of a thin and even film on the cover-glass. It consists of adding to the sputum an equal volume of a saturated solution of borax. A concentrated aqueous solution of ammonium carbonate will reduce the consistency of less viscid sputum.

Mühlhäusen's Method.—This method is used to render the sputum less viscid. It consists in adding to the sputum from 6 to 8 times its volume of a 2 percent solution of caustic potash.

The resulting mixture may then be centrifuged and examined.

Preserving Sputum. *Savelieff's Method.*—This is a process of preserving sputum for purposes of subsequent examination. Let the patient expectorate in a receptacle containing 95 percent alcohol, in which the sputum may remain for several months, and in which it is hardened by dehydration and coagulation. A few drops of caustic potash solution added to a small lump of the hardened sputum on a slide will liquefy it in a few minutes, and from this the cover-glass preparations are made. When dry, fix the film by passing the cover-glass twice through the flame of a spirit-lamp, wash in water to remove the potash, and then stain according to any of the given methods.

Sectioning Sputum. *Gabritschewsky's Method.*—Place the denser portions of freshly expectorated sputum in Müller's fluid, or some other hardening reagent, and then embed in celloidin. Stain the sections in safranin, alum carmin or hematoxylin eosin. Aronson and Philip treat the sputum first with corrosive sublimate, and, according to Schmidt, it may be embedded in paraffin as well as celloidin.

SQUILL (Scilla).—The sliced dried bulb of *Urginea maritima*. It contains the glucosids—*scillitoxin*, acrid and bitter, the most active principle; *scillipicrin*, acting on the heart; and *scillin*, causing numbness and vomiting; also

sinistrin, a mucilaginous principle. The *scillitin* of the older writers is a complex substance. Dose of the powdered drug, 1 to 5 grains.

In small doses squill is expectorant, in larger doses emetic and diuretic, and in overdoses it is a violent irritant poison, producing nausea, vomiting, purging, gastroenteritis, strangury, bloody urine, perhaps suppression of urine, paralysis and convulsions, with death by paralysis of the heart in systole. Medicinal doses slow the heart, making the pulse stronger and slower, raising the arterial tension, and increasing the flow of urine (like digitalis). Its active constituents diffuse into the blood, and its systemic effects follow on its application to the skin and seem to be exerted upon the lining of the secretory organs, especially affecting the bronchial, gastrointestinal and genitourinary mucous membranes.

Squill is employed in medicine for its expectorant and diuretic effects. It is especially applicable in cardiac dropsy, combined with digitalis or the saline diuretics, and in chronic bronchitis, in which it may be associated with ipecac, ammonia, asafetida, or benzoin. It is used in croup, but is usually combined in this affection with some other emetic, as tartar emetic in the compound syrup, a mixture which may produce very depressing effects and should be used with caution. In whooping-cough and other irritant coughs with tickling sensations in the throat the syrup or vinegar is often of great service.

In dropsy:

℞.	Powdered squill,	gr. x
	Powdered digitalis leaves,	gr. xx.

Make into 10 pills. Give 1 pill after meals.

In subacute bronchitis:

℞.	Wine of ipecacuanha,	ʒ j
	Tincture of squill,	ʒ ij
	Syrup of tolu,	ʒ v
	Water,	ʒ j.

Give a teaspoonful every 3 or 4 hours.

Preparations.—S., **Acetum**, "vinegar of squill," 10 percent in strength. Dose 5 to 30 minims. S. **Flext.** Dose, 1 to 5 minims. S., **Syr.**, has of vinegar of squill 45, sugar 80, water sufficient quantity. Dose, 10 to 60 minims. S., **Syr., Comp.**, fluidextract of squill and fluidextract of senega, each 80, tartar emetic 2, sugar 750, water to 1000. Dose, 10 minims to 1 dram, for children as an emetic; 20 to 45 minims, for adults as an expectorant. Commonly known as Coxe's Hive Mixture. S., **Tinct.**, 10 percent. Dose, 5 to 30 minims.

SQUINT.—See Eye-muscles (Strabismus).

STAINING.—See Pathologic Technic.

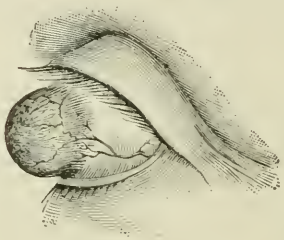
STAMMERING.—See Speech Defects.

STAPHISAGRIA (Stavesacre).—The ripe seed of *Delphinium staphisagria*. Its properties are due to an alkaloid, delphinin, and other extractives. Dose, 1/2 to 2 grains. It is a violent emetic, cathartic, and parasiticide. It lowers the activity of the heart, producing adynamia. It is used internally in asthma and rheumatism, and externally for itch and lice. S. **Fluidextract,** Dose, 1/2 to 2 minims. S. **Ung.**, unof., 1 part of powdered seeds with 2 each of olive oil and lard. **Delphinin**, unof. Dose 1/12 to 1/4 grain.

STAPHYLOCOCCUS.—See Suppuration.

STAPHYLOCOCCUS INFECTIONS have been treated with both sera and vaccines, but with little success, except in furunculosis, carbuncle, and suppurating acne, in which the vaccines have given satisfaction whenever they have been employed. The initial dose is from 50 to 100 million for acne to 300 million for carbuncle. Staphylo-vaccine, as an adjuvant to tuberculin in tuberculous cases of mixed infection, has been of value. A polyvalent staphylo-vaccine, containing the three types of staphylococci (*S. albus*, *S. aureus*, and *S. citreus*), is preferred by some clinicians, and is on the market; but the vaccines of *S. albus*, and *S. aureus* are also furnished separately by the manufacturers.

STAPHYLOMA OF THE CORNEA.—A bulging forward of a corneal scar with an adherent iris. It is caused by the weakening of the corneal tissue, which gives way to the intraocular pressure, pushing the iris and even the lens forward. Secondary glaucoma is not an uncommon complication. The staphyloma may be partial or total. The pain, loss of vision, and repulsive disfigurement associated with this affection render the patient a great sufferer.



Complete Staphyloma.

Treatment.—Unless the condition is only that of a simple prolapse of the iris, the treatment is of no avail. When possible, abscission of the staphylomatous projection, forming a suitable stump for a glass eye, is to be preferred to enucleation, particularly in young children, in whom the presence of orbital contents is necessary for the symmetric growth of the face. If there are signs of infection or internal disease, enucleation is peremptorily demanded.

STAPHYLORRHAPHY.—See Cleft Palate.

STARVATION.—See Fasting.

STATUS EPILEPTICUS.—See Epilepsy.

STATUS LYMPHATICUS (Lymphatism).—A hyperplasia of the thymus, spleen, lymphatic glands and lymph tissues, including bone marrow, occurring usually in children. It is associated with a marked tendency to sudden death, either without tangible cause or subsequent to operation, anesthesia or antitoxin administration. The patient is anemic and the tonsils and thyroid are usually enlarged. In several cases a section of the enlarged thymus has been excised. There may be hyperplasia of the heart and aorta, and rickets.

STENOCARDIA.—See Angina Pectoris.

STERILITY.—In considering the causes of sterility it should be remembered that the husband is at fault in about 30 percent of all sterile marriages. Bilateral epididymitis is a potent factor in male sterility. Imperfect development of the

sexual organs is an important cause of sterility in women. The ovaries may be undeveloped, in which case ovulation is imperfect or absent; the uterus may be very small, or the vagina may be so narrow that complete sexual intercourse is impossible. Obstruction in some part of the genital tract may cause sterility. All cases of atresia of the vagina, cervix, or fallopian tubes would come under this class. The two former conditions are usually congenital, the latter is usually the result of inflammation. Tumors and polypi may act as sources of obstruction, as may also displacements of the uterus. Chronic inflammatory conditions of the tubes and ovaries, uterus, and vagina are frequent causes of sterility. Inflammation of the ovary may prevent ovulation by destroying the glandular substance, or by causing thickening of the capsule, which prevents rupture of the follicle and escape of the ovum. Inflammation of the uterine and vaginal mucous membrane causes sterility mainly on account of the leukorrheal discharge that accompanies it. This is particularly true of inflammation due to gonorrhea. Cancer of the cervix obstructs the cervical canal, and at the same time produces a profuse leukorrhea.

The treatment will, of course, consist in eliminating the cause whenever this is possible. If the condition is due to errors in development, little or no hope of cure can be entertained. Atresia or congenital narrowness of the cervix or vagina may be treated by incisions or dilatation. If displaced, the uterus must be replaced. Tumors and polypi require removal.

Inflammatory conditions require appropriate treatment. If the tubes and ovaries are affected, little good can be accomplished; if the inflammation is confined to the uterus and vagina, treatment is very effective. In a certain small percentage of sterile marriages the sterility is undoubtedly the result of incompatibility. These cases are usually not benefited by treatment.

STERILIZATION.—The condition of rendering sterile, infertile, or incapable of reproducing. In bacteriology the destruction by heat of the spores or mature forms of bacilli, micrococci, or other forms of microscopic life. In most instances a temperature of 100° C. (212° F.) devitalizes not only the mature forms, but the spores as well. The methods of sterilization of instruments, dressings, ligatures, etc., are fully discussed under Abdominal Section (*q. v.*). See also Disinfection, Milk (Sterilized).

STERNUM, INJURIES.—Fracture of the sternum is exceedingly rare, except when there exists injury to other bones connected with it. The fracture may be transverse, oblique, or longitudinal. Such injury with dislocation (most usual at the junction of the manubrium with the gladiolus), is often complicated by laceration of the pleura, pericardium, or other injury to the lung. Attempts at reduction are most difficult, although it has been accomplished by manipulation in a few cases. The prognosis in uncomplicated fracture or dislocation of the sternum is favorable. In complicated cases the mortality is high.

Treatment.—When overriding exists, reduction may be obtained by bending back the body over a firm pillow, and then ordering deep respiration; or reduction may be affected under ether. When corrected, the deformity tends to recur, and the bones often unite in faulty position, with no disastrous sequels. Fragments should not be cut down upon or hooked up unless complications are present. After reduction, adhesive strips may be placed laterally, extending down from the axillary line and running vertically from well above the seat of fracture to the ensiform cartilage. An anterior figure-of-eight bandage may envelop the breast. A circular bandage of the chest, a posterior figure-of-eight, holding back the shoulders, may suffice. A large compress held by adhesive plaster and a broad tight roller may be employed. The erect or semierect position in bed favors easy respiration, and antagonizes the tendency to displacement. When the ensiform cartilage is bent in so as to cause great pain or to injure the stomach, it should be excised.

STERNUTATORIES.—See Errhines.

STERTOR.—The noisy breathing of a person in a state of coma. There exists a paralytic condition of the muscles of the lips, cheeks, tongue, fauces, and soft palate. The latter becomes a flaccid curtain moving to-and-fro with respiration—a similar movement occurring in the cheeks and lips. The tongue falls toward the pharynx, mucus collects in the mouth, and, becoming mixed with air, appears frothy at the mouth. As a result of these conditions, there is a snorting noise.

STETHOSCOPE.—An instrument for ascertaining the condition of the organs of circulation and respiration by their sounds. It consists of a hollow tube, one end being placed over the locality to be examined, the other at the ear of the examiner. A binaural form of the instrument consists of a Y-shaped tube—the flexible branches being applied each to an ear of the listener. By this means not only are all extraneous sounds shut out, but an intensified sound is conveyed to the ear. The Phonendoscope (*q. v.*) is a recent modification. See also Chest (Examination).

STILLINGIA (Queen's-root).—The root of *S. sylvatica*, or "queen's-delight." Its active principle is not known. It is expectorant, diuretic, and sialagog, with reputed alterative properties; in larger doses, emetic and cathartic. It is used with sarsaparilla as an antisyphilitic in the tertiary stage. It is valuable with quinin in intermittent fever. Dose of the powdered root, 10 grains to 1 dram; of the fluidextract, 10 minims to 1 dram.

STIMULANTS.—A term which is used in various senses when applied to medicinal agents. Alcoholic preparations, which are true narcotics, are commonly termed "stimulants," and the same expression is employed to designate any agent which excites even briefly the organic action of any part of the system. All excessive stimulation reacts into depression, and most of the agents which stimulates the nerve centers at first will soon depress and finally paralyze them. In many cases

the action is one of progressive stimulation primarily and progressive paralysis afterward, affecting the centers in the inverse order of their development, the highest or latest developed centers being affected first, the lowest or oldest ones last. These laws are well exemplified in the action of Alcohol (*q. v.*) upon the nervous system. *Diffusible Stimulants* are those which have a prompt but transient effect on the general system, such as alcohol, ammonia, camphor. *Spinal Stimulants* exalt the functions of the cord, as strychnin, picrotoxin, ergot, atropin, phosphorus. *Cardiac Stimulants* increase the action of the heart, as alcohol, adrenalin, strychnin, atropin, and morphin in small doses; also squill, convallaria, cimicifuga and digitalis, which slow but strengthen the cardiac action. *Respiratory Stimulants* directly stimulate the respiratory center, as ammonia, strychnin, apomorphin, belladonna. *Vascular Stimulants*, as alcohol, chloroform, ether (all three in very small quantities), adrenalin, ammonia, strychnin, digitalis, and squill, acting on the vasomotor center; and the nitrites, belladonna, electricity, volatile oils, acting as local dilators of the vascular system. *Cerebral Stimulants*, as alcohol, opium, belladonna, caffein, cocain, cannabis, chloroform, ether, tobacco. *Renal Stimulants*, as the diuretic group. *Stomachic Stimulants*, as the aromatics, volatile oils, vegetable bitters, mineral acids, nux vomica, mustard, capsicum. *Hepatic Stimulants*, as nitromuriatic and nitric acids, and the cholagog purgatives podophyllum, jalap, leptandra, euonymin, iridin. *Intestinal Stimulants*, as mercurials, elaterium, colocynth, jalap, scammony, podophyllum, which effect the glandular apparatus—and belladonna, physostigma, nux vomica, rhubarb, senna, aloes, frangula, cascara, which chiefly affect the muscular fibers and the intestinal nerves. *Cutaneous Stimulants*, as the diaphoretic group, and the rubefacients, mustard, capsicum, turpentine, ammonia. *Local Stimulants* increase common sensibility to the extent of producing pain, chiefly by direct action upon the end-organs of the sensory nerves in the skin, though some act probably by stimulating the local circulation, as in inflammation. The principal members of this sub-division are: heat, cold, faradism, alcohol, ether, chloroform, phenol, cresote, ammonia, mineral acids, volatile oils, acrid essential oils, metallic salts, veratrin (at first), cantharis (at first).

STINGS.—See Bites and Stings.

STOKES-ADAMS SYNDROME.—See Heart Block.

STOMACH, CANCER. Varieties.—(1) Hard cancer (scirrhus); (2) colloid cancer; (3) soft cancer (medullary); (4) epithelioma.

Etiology.—(1) Heredity, (2) adult life, (3) male sex, and (4) ulcer of the stomach are the most common etiologic factors.

Pathology.—Cancer of the stomach is generally a primary affection, and next to cancer of the uterus is the most frequent seat of this disease. It is generally situated at the lesser curvature and pyloric end of the stomach. The medullary variety is very prone to undergo ulceration. In many cases cancer of this organ may be secondary to the disease elsewhere.

Symptoms and Clinical Course.—There are no characteristic symptoms in the early stages. Later it presents the following: Constant and localized pain; dyspeptic manifestations; constipation; rapid emaciation; cachexia; moderate anemia and leukocytosis; hematemesis, causing vomiting of a "coffee-ground" material long after eating; absence of free hydrochloric acid in the gastric contents one hour after a test-breakfast; and the presence of a tumor in the epigastrium.

Diagnosis.—(See also Gastritis (Chronic)).

Prognosis.—The disease is inevitably fatal. The duration is from 1 to 3 years.

Prophylaxis.—Since chronic ulceration has been found to be one of the most frequent causes of cancer of the stomach, early excision of gastric ulcers is advisable.

Treatment is merely palliative. If the stomach is intolerant of food, resort must be had to rectal alimentation, and the best that can be hoped for is to prolong life, which can only be one of suffering.

Any formula for rectal alimentation may be used. See Stomach (Ulcer).

Peptonized milk may also be given. It may be made as follows: Extract of pancreas (5 grains), sodium bicarbonate (15 grains), and a cupful of water; to this add a pint of milk. Heat for 10 minutes at a temperature of 100° F.

℞. Pepsin, ʒ j
Dilute hydrochloric acid, ʒ jss
Syrup, ʒ iij
Water, add enough to make, ʒ ij.
Teaspoonful after meals.

℞. Strychnin sulphate, gr. ss
Solution of iron and ammonium acetate, ʒ vj.
Two teaspoonfuls after meals.

For the pain, morphin (1/4 grain) may be given hypodermically. For the indigestion and similar symptoms, see Gastritis (Chronic).

The operative treatment is discussed under Stomach (Surgery).

STOMACH, CATARRH.—See Gastritis.

STOMACH, DILATATION.—A permanent increase in the capacity of the stomach, due to atony or pyloric obstruction.

Synonyms.—Gastrectasia; gastric atony; myasthenia.

Etiology.—(1) Overeating; (2) beer drinking; (3) rapid fermentation of gastric contents; (4) certain diseases—heart-disease, tumors (cancer) of pylorus, typhoid fever, tuberculosis, tabes dorsalis; (5) it may be secondary to chronic gastritis.

Pathology.—The muscular coats of the stomach are much thinner than normal, and the mucous membrane is in a state of atrophy. There are evidences of hyperplasia of connective tissue of the muscular coat in certain areas. The capacity of the stomach may be equal to 6 pints of fluid.

Cancer of the Stomach.	Tumor of the Liver.	Tumor of the Spleen.	Cancer of the Pancreas.	Tumor of the Colon.
1. Tumor nearly always present in region of pylorus (epigastric region).	1. Tumor usually in right hypochondriac region.	1. Gastric cancers seldom present in area of spleen. History of malaria or symptoms of leukemia.	1. Tumor in region of epigastrium.	1. Tumor in umbilical region.
2. Tumor hard, uneven, and tender.	2. Tumor hard, uneven, or nodular and tender.	2. Tumor hard, usually smooth.	2. Tumor hard, nodular, and tender.	2. Tumor may be hard or soft.
3. Tumor slightly movable.	3. Usually movable. If carcinoma, immovable.	3. Tumor immovable....	3. Tumor immovable...	3. Tumor movable.
4. Dulness on percussion.	4. Increased area of dulness in right hypochondriac region.	4. Increased area of dulness in left hypochondriac region.	4. Increased area of dulness when stomach is collapsed.	4. Increased area of dulness, and separable from the stomach.

Symptoms and Clinical Course.—There is a sense of fulness in the epigastrium, which may be visibly distended; eructation of gas, copious vomiting of liquid material, containing small particles of food and having a very sour odor, are also prominent signs. The appetite is lost, the tongue is coated, the bowels are constipated, and the urine is high colored and scanty. Emaciation and anemia may be quite marked.

Physical Signs.—Inspection may detect the outline of the organ, which distends the abdominal walls. In cases of complete obstruction of the pylorus the peristaltic wave can be traced.

Palpation confirms inspection.

Percussion.—The patient is placed in a standing position; percussion should be made from the lower border of the ribs in the midsternal line downward. A tympanitic note will be detected over the upper area of the stomach, and dulness over the base of the organ on account of the fluid contents gravitating to this position as the patient stands erect. Immediately below this dulness tympany again begins, due to the position of the bowel. If the patient assumes a horizontal position, the contents of the stomach gravitate posteriorly, and tympany will exist where dulness was previously found.

Should the area of the stomach be shown to be below the navel, the organ is considered to be in a state of dilatation. If it is desired to confirm the diagnosis, the organ may be dilated artificially: give tartaric acid (1 dram) dissolved in water (2 ounces), and subsequently sodium bicarbonate (1 1/2 drams) in the same quantity of water. Malignant disease must first be excluded.

Diagnosis depends upon the symptoms and physical signs.

Prognosis.—If due to malignant growth, the prognosis is unfavorable. If due to simple atony, relief may be obtained.

Treatment.—The first indication is removal of the cause if possible. The patient must accustom himself to smaller quantities of food at each meal. A quart of liquid may be allowed in the 24 hours.

Constipation must be treated on general principles: first by correcting the diet, then by giving salines—Epsom salt (2 drams) or Rochelle salt (2 drams)—before breakfast. Fluidextract of cascara (1/2 dram) with an equal quantity of glycerin may be given at bedtime. Lavage of the stomach may be practised every 2 days. See Lavage.

℞. Strychnin sulphate, gr. 1/4
Dilute hydrochloric acid, } each, ʒ j
Pepsin, }
Syrup, ʒ iij
Water, add enough to make, ʒ iij.

Two teaspoonfuls after meals.

℞. Creosote, ʒ j
Compound tincture of cardamom, add enough to make ʒ iij.

Teaspoonful half-hour after meals.

STOMACH, EXAMINATION.—The patient shuld be in the recumbent posture in a strong light.

Inspection detects the outline in very thin persons, and sometimes the peristaltic wave and the presence of tumors.

Palpation.—The hand should be placed flat upon the abdomen, the fingers making gradual pressure, at the same time having a rotatory movement. By this method are detected epigastric pulsation, as in cardiac disease, anemia, aneurysm of aorta, the shape and position of epigastric tumors, and localized pain.

Percussion yields a tympanitic note by which may be detected the correct outline. The upper and right lateral boundary extends along the lower border of the right lobe of the liver; the left lateral boundary to the inner border of the spleen. The stomach has no fixed position, as it is very movable. To determine the lower boundary, percussion should begin in the region of the umbilicus, gradually going upward until an impaired resonance is elicited.

The stomach may be *increased in size* by (1) gaseous distention, (2) large quantity of liquid or food, or (3) tumors.

The stomach is *displaced downward* in (1) emphysema, (2) left pleural adhesion, (3) enlargement of the liver or spleen, (4) tight lacing, or (5) deep inspiration.

The stomach is *displaced upward* in (1) tympanites, (2) ascites, (3) tumors, or (4) during the latter months of pregnancy.

The correct outline of the stomach may be obtained by making separate solutions of sodium

bicarbonate (1 1/2 drams) and tartaric acid (1 dram), each in half a glass of water. The tartaric acid solution should be given first, followed immediately by the sodium bicarbonate. Malignant disease should always be excluded before causing rapid dilatation of the stomach.

Auscultation detects (1) the normal deglutition murmur, and (2) obstruction at the cardiac orifice of the stomach.

1. To obtain the normal deglutition murmur, place the stethoscope over the esophagus and just below the xiphoid cartilage, and allow the patient to drink a small quantity of water. The first murmur in health occurs immediately, and is hissing or spurting in character. Within from 5 to 7 seconds the second sound is heard; it is due to the escape of the water from the esophagus into the cardiac end of the stomach, and has a gurgling, sprinkling, or splashing sound.

2. When there is obstruction at the cardiac orifice of the stomach, the second is delayed in some instances for over a minute. See STOMACH-CONTENTS.

STOMACH, INJURIES. Rupture.—Traumatism seldom causes a laceration except when the stomach is overdistended with liquid or semi-liquid material. It may be severely injured through contusion of the abdominal wall, in which case the rent is found near the pyloric orifice. Laceration of the mucous membrane has been found resulting from lavage of the stomach. In the case of incomplete tears there are hematemesis and severe localized pain, resembling gastric ulcer in its gnawing character, together with symptoms of shock. If the wound of the organ is large, and there is a great extravasation of the stomach-contents, a general peritonitis is produced. If, on the contrary, the wound is small, there is a tendency to form adhesions whereby the inflammatory area will be isolated from the general peritoneal cavity.

Treatment.—Whenever the stomach is perforated, the indication is to explore the parts after abdominal section, and remove all infection that may have taken place in the peritoneal cavity by the extravasation of the intestinal contents. The wound in the stomach is then sewed by means of Lembert sutures, and is closed according to the general rules of antiseptic surgery.

Foreign Bodies.—These generally consist of such substances as have been swallowed accidentally, or of concretion from the constant ingestion of such substances as hair and wool, which finally agglutinate into a mass. The only treatment for such a condition is to open the organ (gastrotomy) and remove the mass; if, however, the foreign body is of small dimensions, such as a coin, it may safely be allowed to pass onward. See STOMACH (Surgery).

Hernia of the Stomach.—The stomach has been rarely found in inguinal hernias and still less frequently in femoral hernias. The diagnosis is not usually made until operation, and fatal results are common. Herniotomy is indicated in such cases, and the stomach should be dealt with by simple reposition or resection of a portion of its wall if damaged beyond the possibility of repair. The stomach may also prolapse in a diaphragmatic hernia.

STOMACH, NEUROSES.—See GASTRIC NEUROSES.

STOMACH, SURGERY.—Gastrolysis, or loosening the stomach from adhesions, has been found necessary in a number of cases in which extensive adhesions have given rise to severe pain and decided disturbance of digestion.

Such adhesions arise most frequently as a result of gastric ulcer, but they may be caused by general peritonitis or inflammatory conditions in neighboring organs, such as the liver, gall-bladder, colon, pancreas, spleen, or abdominal wall. The condition is difficult of diagnosis, as there are no distinctive symptoms, and it is seldom that the cause of the disorder has been determined before operation. The adhesions may be very broad or they may be band-like, in which case there is often danger of constriction of the bowel. Operation by celiotomy and excision of the bands or loosening the adhesions is usually followed by perfect relief. In some cases of very extensive adhesions producing stenosis of the pylorus or partial hour-glass contraction, gastroplasty, resection, or partial gastrectomy may be necessary.

Gastrotomy for the removal of foreign bodies is indicated in cases in which the nature of the foreign body is such that it either cannot pass or can only pass with great risk, or if urgent symptoms arise. More or less sharp or jagged bodies, such as pins, small knife-blades, and bits of glass, have often been well tolerated by the stomach; but in cases accompanied by serious pain and discomfort operation is imperative. Any body the size of which permits it to pass the cardia will usually pass the pylorus, but this is not true of long bodies. Aggregations of small bodies, such as masses of hair, fish-bones, or pebbles, sometimes require removal. In case severe and continued pain or distress is present, with or without nausea, vomiting, and hemorrhage, operation is demanded.

Diagnosis.—Usually the history of the case leaves no doubt as to the diagnosis, and very often the object may be felt through the abdominal wall. In children, insane persons, etc., in whom there is doubt as to the condition, the use of the X-ray will often furnish valuable information.

Gastrotomy for the relief of stricture of the esophagus may be necessary in cases in which it is impossible or undesirable to dilate by means of a bougie passed by the mouth. This is often the case if the stricture is located low down in the esophagus, particularly in cases in which the esophagus becomes dilated or pouched above the stricture. Immediate dilatation by bougies or the fingers may be practiced or the stricture may be divided by Lange's specially constructed knife-blades or by Abbé's bow-string method. In such cases the stomach is immediately closed. If, however, a large portion of the esophagus is constricted and repeated dilatation is required, a temporary gastric fistula may be established,

which will either close spontaneously, or may be closed at a subsequent operation.

Abbé's Bow-string Method.—A string is passed into the esophagus through the mouth, or, better, through an opening into the esophagus in the neck; then it is passed into the stomach and out through the gastric incision: the stricture is made tense by a bougie, and the string, sawed back and forth, will only divide the tense stricture and not the relaxed portion of the esophagus.

Exploratory gastrotomy has been performed in a number of cases in which no positive diagnosis could be reached by any other means; discovery has thus far followed in every case, and in most cases pathologic conditions have been found and successfully treated. The slight danger from the operation and the facility which it offers for correct diagnosis in cases of hemorrhage arising from erosions or small ulcers, symptoms due to incipient carcinoma, polypi of the mucous membrane, and other obscure conditions, makes the operation thoroughly justifiable.

Exploratory operations are strongly indicated "in cases of rapidly developing cachexia and emaciation with the symptoms of chronic gastritis and absence of HCl. Tentative treatment should not be prolonged over three weeks. It is not nearly so serious a fault to have caused the opening of a stomach and found nothing operable, as to permit a case to continue and find out at the autopsy only that it was a circumscribed carcinoma, the removal of which might have prolonged life for years." (Hemmeter.)

The Operation of Gastrotomy.—Before anesthetizing the patient for operation, it is desirable to wash out the stomach, and 8 or 10 ounces of some innocuous fluid may be left to aid in finding the stomach. The distention of the stomach by large quantities of gas, as has been suggested by some surgeons, is not without its danger of infecting the peritoneum, particularly if the stomach-wall is ulcerated, nearly perforated by a foreign body, or rendered friable by disease. If stricture of the esophagus is present, this lavage is, of course, impossible. The incision may be made parallel to the left costal margin, or, if the foreign body is large, in the median line. Before opening the stomach, it should be brought out of the abdominal cavity, if possible, and carefully examined to make certain that the stomach and not the transverse colon is being dealt with; the colon is recognized by its longitudinal muscular bands. It is then walled off with iodoform gauze to avoid contamination of the peritoneum. Stay loops may be passed through the serous and muscular coats to aid in holding the organ. The line of incision in the stomach-wall is perhaps best made parallel to the course of the vessels—that is, transversely to the curvatures—but it will depend much upon the object of the operation; after this is attained the opening is closed by Lembert's or Halsted's mattress sutures, and the abdominal wound is sutured without drainage.

Gastrostomy is the establishment by operation of a fistula through the abdominal and gastric walls, for the purpose of introducing nourishment.

Indications.—The reason for the operation exists in some insuperable obstruction in the digestive tract above the stomach, which prevents the introduction of food: to prevent death by starvation. Perhaps the most common source of obstruction is malignant disease of the esophagus or cardia; other causes are: Syphilitic stricture, diverticulum of the esophagus, congenital closure, cicatricial contraction, chemic or traumatic destruction of the walls of the esophagus, obstruction by the pressure of growths outside the esophagus, and malignant disease of the pharynx and mouth.

Epithelioma is the most common variety of malignant growth affecting the esophagus, and it occurs more frequently in males after middle life. **Fibrous stricture** is usually a sequence of ulceration caused by swallowing very hot water or caustics, or, in at least two recorded cases, as a sequel of typhoid fever. It may be due to constant traumatic irritation or injury, as sword swallowing. Benign tumors outside the esophagus, taking their origin in its walls, are rarely a cause of obstruction; this is also true of growths in the neck or thorax, such as aneurysms of the aorta or innominate artery, tumors of the larynx, etc.

Diagnosis of Esophageal Obstruction.—The most important subjective symptom is difficulty in swallowing, which gradually increases until there is absolute inability to swallow first solid food and later food of any sort. Pain at the part affected radiating to the stomach and mouth is frequent. There may be tenderness on pressure. Food is regurgitated, in some cases mixed with mucus, pus, and blood. There is digestive disturbance, and loss of strength and weight. Objective signs are obtained by passing the esophageal bougie and by auscultation. The bougie should be soft and flexible and must be passed with great care, as deaths have been reported from the rupture of aneurysms, perforation of the pleura and of the esophagus itself, even by skilled surgeons. Considerable familiarity with the sounds of deglutition in normal and diseased conditions is necessary for satisfactory diagnosis by this means.

The operation of gastrostomy has been performed by various methods, the object aimed for in most of them being the avoidance of leakage of the gastric contents and subsequent excoriation of the skin, which followed the earlier operations in which the stomach was fixed to the abdominal wall and opened directly.

The operation which was devised independently by **Ssabanejew and Frank** avoids leakage and the necessity for wearing a tube, and is generally to be preferred. According to this method an incision is made along the left costal border, and the stomach is drawn out into a cone above 1 1/2 inches (3.9 cm.) long. A second incision is made an inch (2.5 cm.) above the costal border; the skin between the two incisions is undermined; the apex of the cone of the stomach, which has already been fixed by suture at the first incision, is drawn out through the second incision, passing under the bridge of

the ensiform cartilage. The cut is about 4 inches long and may be enlarged by a transverse section of the rectus.

The small intestine is exposed by pulling the omentum upward and to the left. The jejunum is then to be found; the loop of gut is emptied and clamps are applied.

On the lowest possible point of the anterior wall of the stomach a spot is selected for the stomach opening. This portion of stomach and the loop of jejunum are pulled out of the belly and the cavity protected with gauze pads. An anastomosis is made between the stomach and the jejunum, using either sutures or the Murphy button. The method of making the anastomosis is identical with that of enteroenterostomy (lateral anastomosis).

The field of operation is cleansed, all instruments which have touched the mucosa are put aside. The line of union is inspected, and if necessary, reinforced with a few Lembert sutures. If the point of union causes the intestine to kink sharply, this may be remedied by a few stitches uniting to the stomach a little more of the afferent or efferent portions of gut or of both. The wound is closed.

The after treatment is very important. As soon as the patient has recovered from the anesthetic he should be placed in the semierect position, as this facilitates the passage of fluid through the anastomotic opening and also tends to prevent pulmonary congestion. In treating these patients Mayo begins to give them one ounce of hot water by mouth at the end of sixteen, eighteen or twenty hours. If it is well borne, the quantity is rapidly increased. At the end of 36 hours he allows liquid food.

Pylorectomy.—By this term is understood the removal not only of the pylorus, but with it as much of the duodenum and stomach as is diseased.

Indications.—The operation is performed almost entirely for carcinoma of the pylorus, although it has been practised in a number of cases for ulcer and cicatricial stenosis of this region. Whether the operation is undertaken or not depends upon the extent of the growth; the amount of adhesions to other organs, and the extent of involvement of glands. In the present state of medical knowledge it is impossible to determine absolutely the existence of carcinoma in its incipiency; but if operation is to be more than palliative, it must be undertaken early. Considering the harmlessness and simplicity of exploratory celiotomy and the fatal consequences of delay, it seems justifiable that, in cases of obstinate gastric disturbances that do not yield to medical means, exploratory operation should be undertaken even in the absence of a palpable tumor. Factors that are of aid in the diagnosis are the existence of dilatation of the stomach, cachexia, an excess of lactic acid, hematemesis, the presence of the Oppler bacillus, absence of free hydrochloric acid, age past 40, and a diminished amount of hemoglobin and number of red blood-corpuscles.

The Operation.—The preparation is the same as for gastroenterostomy. Various methods have been employed. Billroth resected the tumor, and as the opening in the stomach is so much greater than that in the duodenum, the stomach wound was partially closed by suture until it reached a size sufficient for end to end anastomosis with the duodenum. The anastomosis is best made lower than the upper end or middle of the gastric opening, to facilitate emptying the contents of the stomach. Kocher closes both the stomach and duodenum and makes a posterior end to side anastomosis by insertion of the duodenum in the posterior wall of the stomach, with or without Murphy's button. Czerny first performs posterior gastroenterostomy with Murphy's button, and then, after resection of the tumor, closes the stomach and duodenum. Forceps may be used to good advantage.

The average mortality of the operation as now done by skilful surgeons is probably from 20 to 25 percent. Some have reported series of cases with a considerably lower death rate than this, Mayo for instance, having done 100 operations with a mortality of 14 percent and Kocher 58 with a mortality of 15 percent.

Pyloroplasty is the term applied to operative enlargement of a stenosed pylorus. It has fallen into disfavor with the majority of surgeons, although a few still practise it. Mayo states that it failed to give relief in 30 percent of his cases and that another operation had to be resorted to.

The Heineke-Mikulicz operation was devised and performed independently by the surgeons whose names it bears in 1886–87. A longitudinal incision is made at the seat of constriction, the incision is then stretched at its middle at a right angle to the incision, so as to dilate the strictured pyloric opening, and the margins of the opening are sutured in this new position.

Gastroplication or Gastrorrhaphy.—The former is the preferable term. It is used to designate the operation of making a fold in the stomach-wall and suturing it.

Indication.—The operation has been performed chiefly in the treatment of dilatation of the stomach, although its use has been suggested in threatened perforating ulcer. In case the dilatation is due to malignant pyloric stenosis, pylorectomy or gastroenterostomy is the preferable operation.

The Operation.—After opening the abdomen the greater curvature of the stomach is lifted up to the lesser curvature, thus folding the anterior wall on itself, and the fold is held in place by two rows of sutures. A similar result has been attained by certain operators by the use of purse-string sutures.

The permanent results of the operation are not yet definitely determined, for as yet sufficient time has not elapsed to form judgment. Sixteen operations have been reported with but one death. The almost unanimous conclusion of those who have performed the operation is in its favor.

Gastropexy is the name applied to the operation of suturing the stomach to the anterior abdominal

wall. The operation has been performed for the relief of gastroptosis or sagging of the stomach, which is with difficulty distinguished from dilatation. The condition present is usually one of general visceral ptosis, hence the operation is commonly futile (Binnie).

Gastroplasty, Gastroanastomosis, and Gastrogastrostomy are performed for hour-glass stomach. In gastroplasty a longitudinal incision is made in the constricted portion between the two pouches of hour-glass stomach; the incision is stretched at a right angle, and sutured as in the Heineke-Mikulicz operation of pyloroplasty. The operation has been performed successfully in 7 cases. In gastrogastrostomy an opening is made in each of the two gastric pouches, and a free communication is established between them by anastomosis of the two openings. The operation has been performed in 5 cases with 1 death. Gastroanastomosis has also been successfully performed by Watson, as follows: The pouches were folded over on the constricted portion between the two as a hinge; the anterior wall of the stomach was incised, to give access to the double septum between the pouches; an opening was made in this double septum and sutured, and the incision in the anterior stomach-wall was closed. This method would be impossible if there were adhesions fixing either pouch.

The three operations seem equally successful, and the one selected would depend upon the mechanic conditions of each case. Hour-glass stomach may be congenital, but usually does not develop until adult life. The most common cause is adhesions following gastric ulcer. It is with great difficulty that a differential diagnosis can be made between this condition and obstruction due to pyloric stenosis. If severe disturbances of digestion arise, as is often the case, one of these operations would be indicated.

Surgical Treatment of Gastric Ulcer.—See STOMACH (Ulcer).

Gastrectomy.—The operation may be either partial or complete. In partial gastrectomy, only a portion of the stomach-wall is removed pylorectomy is an example of partial gastrectomy. This operation is indicated in cases of tumors of the stomach and in certain perforating or perforated gastric ulcers. Complete gastrectomy is the removal of the entire stomach. It has been believed possible to distinguish between the epithelial layers of the mucous membrane of the esophagus and of the stomach, but recent investigations seem to indicate that no well-marked boundary-line exists, so it is difficult to say absolutely when the entire organ is removed. Sufficiently extensive operations to deserve the name of total gastrectomy have been performed in 10 cases, with 4 recoveries from the operation. Two of these patients have since died from recurrence of the growth.

Indications.—The operation may perhaps be considered indicated in case of extensive malignant growths of the stomach which have not caused metastasis or become extensively adherent to neighboring organs, but the operation should certainly be performed only in the rarest and most unusually favorable cases, by surgeons of exceptional skill and wide experience in abdominal surgery.

STOMACH, ULCER. Synonyms.—Peptic ulcer; simple or round ulcer; gastric ulcer.

Etiology.—(1) Traumatism; (2) hemorrhagic infiltrations; (3) hyperacidity; (4) anemia; (5) heart-disease; (6) nephritis; (7) chronic catarrh. Both gastric and duodenal ulcers result from the same causes.

Pathology.—Generally, the ulcerative spot is round in contour and is situated on the posterior wall of the lesser curvature of the stomach. The edges are usually clean-cut, and from above downward are cone-shaped, with the base resting on the peritoneal coat of the organ. In some instances a perforation occurs, leaving a "punched-out" appearance. The duodenal ulcer is usually situated at the upper portion of the bowel. In many cases there is a series of ulcers scattered over the mucous membrane of the stomach.

Symptoms and Clinical Course.—There are localized pain, vomiting, hematemesis, gradual loss of flesh and strength, dyspepsia, grave anemia, and excessive secretion of hydrochloric acid. The hemoglobin may be reduced to 50 per-cent and the red cells are proportionately decreased. The leukocytes in some cases are decreased; other cases show leukocytosis.

The pain is very characteristic, being always localized and made worse by pressure or ingestion of food. It is of a burning, sharp, or acute character.

Hematemesis is possibly the most marked objective symptom of the disease. It may come on either while taking violent exercise or during the period of rest, and has occurred during the night hours. Hematemesis occurs in about 50 percent of the cases of gastric ulcer.

Complications.—(1) Perforation, giving rise to peritonitis; (2) death from hemorrhage, perforation, or exhaustion; (3) cicatricial contraction, causing obstruction.

Diagnosis.—See GASTRITIS (Chronic).

Prognosis is guardedly favorable.

Treatment.—For the first few weeks after the ulcer has been detected absolute rest in bed should be enjoined, and only a liquid diet allowed. In most cases, perhaps, it is best to give the food by the rectum for the first few days, continuing as long as the digestive powers maintain the strength of the patient.

Rectal Alimentation.—Before giving a nutritive enema the bowels should always be irrigated with a quart of lukewarm water, or normal saline solution, given as a high enema. Peptonized milk is the best nutrient (Tyson).

Boas recommends the following nutritive enema; 8 ounces of milk; the yolks of 2 eggs; 1 dram of sodium chlorid; 1 ounce of claret wine; and a tablespoonful of aleuronat flour. These ingredients to be thoroughly beaten together, subsequently warmed for a few minutes at a temperature of 99° F., and then slowly injected by means of a fountain syringe.

Ewald recommends the following: From 3 to 5 eggs are beaten up with 5 ounces of a 15 percent solution of glucose, to which a small amount of starch-water has been added. Also this: Boil flour (1/2 dram) in half a cupful of a 20 percent solution of glucose and add a wine-glassful of claret. To this are afterward added 2 or 3 eggs, well beaten in a tablespoonful of water.

Later in the treatment milk may be given by the mouth, together with a small amount of soup made from beans or potatoes. No solid food should be given for at least 3 weeks from the time the disease is diagnosed, and then only the lightest articles of diet.

Hematemesis.—Absolute rest must be enjoined, the patient not being allowed to sit up to take food or medicine or to defecate or urinate. If possible neither solids nor liquids should be given by the mouth for at least 2 days. To assuage thirst, the lips and tongue may be sponged off with ice-water containing a very small amount of glycerin.

An ice-bag or cloths dipped in ice-water or the ice-coil may be placed over the affected area. Pieces of ice may be swallowed. Copious enemata of hot water are advocated by Tripier. If the hemorrhage is severe, ergotol (20 minims) may be given hypodermically, together with morphin (1/4 grain). At the present time, however, preference is given to adrenalin chlorid in repeated doses of 10 drops of the 1 to 1000 solution, given in 1 dram of water.

Two weeks after the hemorrhage has occurred, Fox recommends the best treatment, a glass of laxative mineral water daily, with a light diet, and hot applications to the epigastrium. Nitrate of silver (1/4 grain) may be taken in a glass of water before meals.

Bismuth subnitrate in doses of 90 to 120 grains daily has proved most efficient in promoting healing of the ulcer. Local applications may relieve the pain; morphin should be avoided if possible.

The Lenhartz Treatment.—The patient is put to bed for 3 to 4 weeks and for the first 2 weeks is given a diet rich in albumen. Ice-cold food is given slowly by the mouth in small amounts at short intervals, beginning with 2 drams of egg and 4 drams of milk every hour for the first day, the intervals being 1 hour from 7 A. M. to 9 P. M. for the first 10 days. Lembert has suggested feeding the mixture of egg and milk, instead of each singly every hour, and adding sugar after the third day. For the effects of hemorrhage, enteroclysis is practised, and iron and arsenic are given for the anemia.

Surgical treatment may be indicated in non-perforating or in perforating gastric ulcers. The more remote effects of gastric ulcer have been discussed and their treatment has been considered under gastrolysis, gastroenterostomy, pyloroplasty, resection of the stomach, and the operations for hour-glass contraction of the stomach. See STOMACH (Surgery). Acute perforating ulcer indicates operation in case of dangerous and repeated hemorrhage, extremely severe pain, and intractable vomiting and indigestion; or when there is a suspicion of malignant degeneration. In such cases the ulcer may either be excised and the gastric wall sutured, or gastroenterostomy or pyloroplasty may be performed to put the ulcer at rest. Gastroenterostomy has been combined with excision in certain cases, with advantage.

Perforated Gastric Ulcer.—Usually, perforation occurs very suddenly, without any apparent cause, although violent exertion or traumatism has sometimes been the immediate cause. There is intense pain, generally localized in the left hypochondrium; there may be nausea and vomiting, perhaps vomiting of blood; soon after this symptoms of peritonitis set in; the abdomen becomes distended, tympanitic, and tender; and liver dullness is obliterated. The other constitutional symptoms develop as the peritonitis progresses.

Treatment.—All food should be withheld and preparations should be made for immediate operation. The incision may be made in the median line above the umbilicus or to the left of the median line. When the diagnosis is absolutely certain, the incision may be made with advantage parallel to the border of the ribs, as a large proportion of gastric ulcers perforate near the cardia and lesser curvature. A careful search should be made, first of the anterior wall of the stomach, beginning near the cardia, taking next the pylorus, and, finally, the posterior wall, the positions named being given in order of the relative frequency of perforation. The edges of the ulcer are inverted and the stomach-wall is sutured by one or two rows of Halsted or Lembert sutures. Great care should be taken that the entire ulcer is inverted, and careful search should be made for a second perforation or for a threatened perforation. Needless fatalities have resulted from the neglect of both of these precautions. If it is impossible to invert the edges of the ulcer, they may be brought into contact by suture, as if a cutaneous wound were being dealt with; and in case of possible insecure suture, the application of an omental graft would be an additional safeguard. If neither of these procedures is possible, the abdominal cavity may be walled off by iodoform gauze and a tube may be introduced down to the ulcer. The fistula that will result usually closes spontaneously or it may be closed later by a plastic operation. Great care should be taken in cleansing the peritoneal cavity. It should be thoroughly flushed with warm sterile salt solution and any suspicious spots wiped clean; if necessary, counteropenings may be made, and it is usually desirable to drain, not only at the seat of operation, but also from the pelvis. Success depends mainly upon early diagnosis and operation; patients operated upon within 12 hours from the time of perforation have excellent prospects for recovery, the mortality being only about 16 percent since 1896. Other features of importance are the amount of food contained in the stomach at the time of perforation, the condition of the patient, and the skill of the operator. A few years ago the mortality in a series of cases carefully collated was

about 53 percent. Moynihan has recently estimated it to be from 35 to 40 percent.

STOMACH-CONTENTS, EXAMINATION.—For purposes of examination, the contents of the stomach should be obtained through the stomach-tube, as vomited contents contain so much buccal and esophageal mucus that the examination is rendered difficult and imperfect. See LAVAGE. The gastric contents are examined as to color, amount, odor, consistency, individual food elements present and their state of disintegration and solution; also as to the presence of mucus, blood, pus, fragments of mucous membrane, or foreign bodies. This macroscopic investigation is followed by chemic analysis and microscopic examination.

Test-meals.—The contents are usually examined after a test-meal. One of the following test-meals is usually employed:

1. Ewald-Boas test-breakfast consists of 1 or 2 rolls and a cup of water. The examination is made 1 hour after eating.

2. Leube-Riegel test-dinner consists of soup, meat, potato and roll. Examination is made 3 or 4 hours afterward.

3. A meal consisting of 1 or 2 broiled finely chopped beef-balls, 1 or 2 ordinary slices of dry stale bread, and a cup of water (hot or cold). This is eaten at 9 o'clock in the morning, and the stomach is examined at 12 o'clock noon. No breakfast is allowed before 9 o'clock in the morning.

If possible, the stomach-contents are obtained undiluted, a feat quite readily accomplished by the Ewald expression method, which consists of voluntary contraction of the patient's diaphragm and abdominal muscles, thereby compressing the stomach and forcing a portion of the contents upward through the tube. Usually from 40 to 100 c.c. are thus obtained, and then filtered, and examined for hydrochloric acid. Before filtration, however, the contents may be tested for free acid by Congo paper, which changes from red to blue.

The chief tests for free hydrochloric acid are Günzburg's, Boas', and Toepfer's.

Günzburg's reagent is composed of phloroglucin (2 gm.), vanillin (1 gm.), and absolute alcohol (30 c.c.); it is unnecessary to use absolute alcohol, as ordinary pure alcohol will do as well. This solution is changed by the light, and should be kept in a colored-glass bottle. A porcelain capsule is overlaid with gastric filtrate, and 3 or 4 drops of the reagent added; the capsule is agitated to insure thorough mixture, and evaporated to dryness slowly over a Bunsen burner or an alcohol lamp. In the presence of free hydrochloric acid a beautiful rose-red color appears.

Boas' reagent consists of resorcin (5 gm.), white sugar (3 gm.), and alcohol (100 c.c.), and gives, with free HCl, a bright-red color, the test being conducted in the same manner as with the phloroglucin vanillin solution.

Toepfer's reagent is a 0.5 percent alcoholic solution of dimethylamidoazobenzol. It must be kept in a colored bottle. In the presence of free HCl it strikes a bright cherry-red without the use of heat. To 5 c.c. of the gastric filtrate add 1 or 2 drops of the reagent, and the whole turns red. This is a delicate, convenient, and valuable test, and is quickly made. It reacts to large (unusual) amounts of lactic or other organic acid, but in ordinary work this objection has no force. Friedenwald thinks highly of the test; Einhorn considers it somewhat unreliable; Hemmeter gives it front rank; and by others it is valued greatly.

Not only is Toepfer's reagent useful in the qualitative detection of free HCl, but also its quantitative estimation. Thus 10 c.c. of the gastric filtrate reddened by the addition of the reagent are treated by a decinormal sodium hydrate solution from a buret until the red gives place to a yellow color, and the number of cubic centimeters of soda solution required to neutralize the free HCl is taken as the multiplier of 0.00365. For example, 3 c.c. of soda solution are used and $0.00365 \times 3 = 0.1095$ percent.

For the determination of the amount of free HCl, organic acids, and acid salts, a 1 percent aqueous solution of alizarin may be used. To 10 c.c. of the gastric filtrate add 1 or 2 drops of the alizarin solution, and neutralize with decinormal sodium hydrate solution; a violet color results.

It is important to know the **total acidity** of the gastric contents, which is obtained as follows: To 10 c.c. of the gastric filtrate add 1 drop of the 1 percent alcoholic solution of phenolphthalein, and neutralize with decinormal sodium hydrate solution added slowly from a buret; a cherry-red color results. The number of cubic centimeters of sodium hydrate solution required to neutralize 10 c.c. of gastric filtrate is expressed as if 100 c.c. of the filtrate were used. The normal total acidity after a test-breakfast is from 40 to 65 percent—*i. e.*, 4 to 6.5 c.c. of soda solution are required to neutralize 10 c.c. of the gastric filtrate.

Lactic Acid.—For the detection of lactic acid Uffelmann's test is commonly used: Ten c.c. of a 4 percent solution of carbolic acid are diluted with 20 c.c. of distilled water, and 1 drop of ferric chlorid solution is added, which gives rise to an amethyst-blue color. The gastric filtrate is added, and if lactic acid is present, a canary-yellow color is produced. Alcohol, phosphoric acid, and glucose also give the reaction.

Butyric Acid.—Fatty acids may usually be detected by the odor. As they are volatile, the vapor arising from a test-tube in which the gastric filtrate is boiling reddens blue litmus paper held at the mouth of the tube.

Acetic acid may be detected by its odor, but it is better to extract with ether, evaporate, make an aqueous solution of the residue, neutralize with soda solution, and add a weak ferric chlorid solution, which gives a dark red color if acetic acid is present.

The Digestion of Proteids.—The hydrochloric acid of the gastric juice combines with albuminoids to form first syntonin or acid albumin. Pepsin hydrochloric acid digestion then results in the formation of proto- and heteroalbumose.

Following this change deuteroalbumoses are formed, and, finally, peptones. These albumoses are grouped under the name of propeptone, and though by elaborate tests they may be separated and differentiated, it suffices that propeptone is precipitated by adding an equal part of a saturated solution of sodium chlorid and acidulating with acetic acid; it dissolves on heating, and precipitates again on cooling. Peptone yields a purplish-red color upon the addition of Fehling's solution to the filtrate, as also does propeptone.

Rennet Ferment.—Add about 4 drops of the filtrate to 5 c.c. of fresh milk, and place in warm water (100° F.). In 15 minutes coagulation should take place. In case the milk is not curdled in half an hour, add 2 or 3 drops of a 1 percent solution of calcium chlorid, and if coagulation takes place, it indicates the presence of rennet zymogen.

Starch Digestion.—The action of saliva upon starchy foods is continued in the stomach to the formation of erythrodextrin, achroodextrin, and maltose. Tested with Lugol's solution, erythrodextrin strikes a reddish-brown color, while achroodextrin and maltose give no color change.

The microscopic examination of the gastric contents is important. In cases of hyperchlorhydria unchanged starch granules are often present in large numbers; while in cases of deficient gastric secretion undigested muscle-fibers are more numerous than under normal conditions. With benign pyloric stenosis, gastrectasia, and food stagnation, sarcinæ and yeast-cells are often found. They may be stained with methyl-blue, which also stains the so-called "Faden" bacillus —the Oppler-Boas bacillus—found with carcinomatous pyloric stenosis, and so significant of the disease. This is a very long, delicate, thread-like bacillus. Sarcinæ and yeast-cells are also found in the stagnating contents of carcinoma ventriculi, but not so frequently as in benign stenosis.

Pus-cells are rarely found. Red blood-corpuscles may be present. Mucus, epithelium, and mucus-corpuscles are commonly seen, especially in gastric catarrh. Many bacteria are present, among which may be a number that give rise to the formation of lactic acid. Small fragments of mucous membrane are sometimes found in the washings from the stomach, and they have been especially studied by Boas, Einhorn, and others. They have been found in cases of gastric erosion. They should be hardened, stained, and mounted, as atrophy of the glands or mucoid or cancerous degeneration may thus be discovered.

STOMATITIS, APHTHOUS (Herpetic Stomatitis; Vesicular Stomatitis).—This form of stomatitis is more common than the simple catarrhal form. It is characterized by a hyperemia of the mucous membrane of the mouth, and by the formation upon it of small, yellowish-white vesicles of a herpetic character. Children from 6 to 18 months of age are the most commonly affected.

Etiology.—The direct cause is uncleanliness of the mouth, improper and poorly prepared food, and dentition. The predisposing causes are malnutrition, unhygienic surroundings, digestive disturbances, and the tubercular diathesis.

Symptoms.—Quite characteristic symptoms are noticed in this affection. The child is dull, fretful, and feverish, does not wish to be disturbed, and refuses nourishment. The mouth is hot and painful, and the saliva, running over the chin and neck, causes these parts to be irritated. On inspecting the mouth, small vesicles are found under the tongue, on the gums, or upon the inner side of the lips. The vesicle soon disappears, but a small shallow ulcer remains for 4 or 5 days. These herpetic spots may be discrete or diffuse, covering more or less of the mucous membrane.

Treatment.—This affection is evidently self-limited. Recovery without treatment, as a rule, would probably take place in the course of a week or 10 days. As recommended in catarrhal stomatitis, however, in all cases the diet should be carefully regulated, the bowels gently acted upon with a laxative, the hygienic conditions, if faulty, improved, and the mouth and the nursing-bottle kept clean. In any form of stomatitis the following is an excellent mouth-wash:

℞. Salicylate of sodium, ʒ ij
Water, ʒ j.
Apply 5 or 6 times a day.

If the ulcers heal slowly, they should be touched with a stick of nitrate of silver.

STOMATITIS, CATARRHAL.—A simple catarrhal inflammation of a portion or of the entire surface of the mouth. It occurs most commonly during the period of first dentition.

The causes are uncleanliness of the mouth and of the nursing-bottle, etc., the ingestion of irritating or overheated food, and the eruption of the teeth. It may be secondary to gastrointestinal disturbances or to the exanthems.

Symptoms.—The mouth is red and is at first dry and hot; later, there is an increased salivary flow, which becomes acid and excoriates the skin around the mouth as it is dribbled. The tongue is coated, and the child is restless, feverish, and thirsty; the appetite is diminished, and the bowels usually are constipated.

Sucking causes pain, which is shown by the fact that the child drops the nipple with a cry as soon as its hunger is partly satisfied. The course of this form of stomatitis is usually acute, an attack lasting about a week.

Treatment.—Attention to the proper hygiene of the mouth will usually prevent it from becoming sore. The nursing-bottle and nipple should be kept scrupulously clean; the fingers should not be introduced into the child's mouth before being thoroughly cleansed; and, before and after feeding, the infant's mouth should be washed with plain boiled water or with borax and water on a clean, soft cloth. Careful regulation of the diet, a mild laxative, such as small doses of calomel (1/12 grain every 2 hours) or calcined magnesia (10 or 20 grains); and a mild alkaline mouth-wash,

such as the following, will usually be sufficient to cure the condition:

℞. Borax, ʒ j
Glycerin, ʒ ij
Rose-water, ʒ ij.

Use every 1 or 2 hours with a swab, gently washing the mouth. (Older children will be able to wash their mouths without the swab.)

STOMATITIS, GANGRENOUS (Noma; Cancrum Oris).—A rare affection, consisting of a gangrenous destruction of the tissues of the cheek, and possibly of the adjoining structures as well.

Etiology.—It is supposed to be microbic in origin. The most frequent predisposing causes are the exanthems or any disease which leaves the child weak and debilitated. In nearly all cases it is seen in those who are subjected to the worst possible hygienic and sanitary surroundings.

Symptoms.—There will be noticed at first an inflamed spot on the inside of one cheek near the corner of the mouth. This spot is at first hard, but soon ulcerates, and the cheek becomes swollen and edematous. From the first the breath has a gangrenous odor, and later the fetor becomes intense.

The gangrenous process spreads rapidly, perforating the cheek, and death will be caused by septic pneumonia or by a general systemic poisoning. Many cases die as early as the first 3 or 4 days, while others linger 2 or 3 weeks: recovery is extremely rare.

Treatment.—Strict cleanliness of the mouth in children whom debilitating diseases render liable to this affection is of prophylactic importance. When the gangrenous condition has commenced, however, the only treatment that offers any hope is free excision of the affected areas.

STOMATITIS, PARASITIC (Thrush).—An affection of the mouth characterized by a catarrhal condition and by the presence on the mucous membrane of white, flake-like patches. It occurs usually in young infants, and is caused by a vegetable parasite (one of the mold fungi) variously known as oidium albicans or saccharomyces albicans.

Etiology.—Uncleanliness of the mouth, giving rise to acid fermentation, is the principal indirect cause. It may be transmitted from one child to another by the nursing-bottle, spoons, etc. Dirty nipples and long nursing-tubes offer a fertile soil for the propagation and growth of the parasites.

Symptoms.—The fungus appears on the inside of the lips, on the gums, tongue and hard and soft palates, and may be limited to a small area of these parts or may extend to the pharynx or esophagus. It is white or gray in color, and has the physical appearance of curdled milk, for which, upon superficial examination, the spots might be mistaken; it will be found, however, that they are adherent to the mucous membrane.

The general symptoms are those of catarrhal stomatitis, by which it is accompanied. Microscopic examination of the deposits will make the diagnosis certain, if any doubt exists.

Treatment.—Absolute cleanliness of the child's mouth, and of the feeding apparatus and everything that may be brought in contact with it, is essential.

The diet must be appropriate and carefully regulated and prepared, and the general hygienic conditions must be made as good as possible, as this is essentially a filth disease. The mouth should be carefully washed every 1 or 2 hours when the child is awake, and before and after each feeding. The cloths that have been used to wash the mouth should be burned, and care should be taken to keep all articles that may have been in the mouth away from other children, as thrush may be conveyed from one to another.

The following formula is an efficient mouth-wash for this condition:

℞. Listerine, ʒ j
Dobell's solution, ʒ ij.

Dilute with an equal quantity of water and wash the mouth frequently.

STOMATITIS, ULCERATIVE.—This form of stomatitis consists of an inflammation and ulceration of the mucous membrane of the gums principally, though the tongue and cheeks may also be affected. It may occur at any time after dentition commences, but is most common between the ages of 3 and 10 years.

Etiology.—Ulcerative stomatitis is a prominent symptom of infantile scorbutus; it is also seen following the acute infectious diseases, and it is caused by salivation from the administration of mercury. Unhygienic conditions, malnutrition, etc., are common predisposing causes.

Symptoms.—Constitutional symptoms, such as slight fever, restlessness, anorexia, and thirst are usually present. The edge of the gums over the teeth—usually the lower incisors—is first seen to be reddened and swollen. The pain and salivation are more marked than in aphthous stomatitis, and the saliva is acrid, irritating, and of an offensive odor. The mucous membrane soon becomes purplish in color, spongy, and congested, and hemorrhages from it occur on the slightest pressure. The tongue is coated, the breath foul, the appetite lost, and the child rapidly becomes weak and emaciated. Under favorable conditions and proper treatment the affection usually disappears in 1 or 2 weeks. When caused by a cachectic condition or by constitutional disorders, such as scorbutus, the course will be governed by these conditions. In protracted cases the ulcerations may become gangrenous, and necrosis of the jaw may ensue.

Treatment.—The sanitary surroundings should, if faulty, be improved, and fresh air and sunlight are essential. Nourishing liquid diet should be given, and cool drinks to satisfy the thirst. If there is any constitutional disease that is the possible cause of the stomatitis, it should be properly treated.

Chlorate of potassium is a specific in this form of stomatitis. It should be given internally (as it is eliminated by the salivary glands) and as a mouth-wash. A child under 1 year of age may safely

be given from 10 to 20 grains in the course of 24 hours, and it is best given in small doses, frequently repeated. A convenient method of administering this remedy is to dissolve 1 dram in half a glass of water, giving from 1/2 to 2 teaspoonfuls, according to the child's age, every 1 or 2 hours. The mouth should be frequently washed with the same solution or with a solution of borax or salicylate of sodium. A teaspoonful of dioxid of hydrogen to the ounce of water also makes an effective wash.

STONE.—See Bladder (Stone), Gall-bladder (Diseases), Kidney (Stone).

STOOL.—See Feces.

STOVAIN. — Benzoylethyldimethylaminopropanol hydrochlorid. It is more stable than cocain, and is less than one-half as toxic as cocain, though equally powerful as an anesthetic, and has the great advantage of being a vasodilator, cocain being a vasoconstrictor. As a substitute for the latter it is used with great satisfaction for local and spinal anesthesia. Locally it may be used in the eye in 4 percent solution and applied to other mucous membranes, in 5 to 10 percent solution. For hypodermic injections for local anesthesia it can be used in 0.75 to 1 percent solution. For spinal injection, 1/2 to 5/8 of a grain is used (Badcock) in the spinal fluid, the alkalinity of which necessitates the addition of sodium chlorid in the proportion of 5 percent. See Intraspinal Anesthesia.

STRABISMUS.—See Eye-muscles.

STRAMONIUM (Thorn-apple).—The dried leaves of *Datura stramonium*, the well-known Jamestown or jimson-weed. It contains the alkaloids *atropin* and *hyoscyamin*, also some *hyoscin*, and a volatile oil containing daturic acid. *Daturin* is the name of the mixed alkaloids. Dose, 1/2 to 3 grains. See Belladonna. It has the general properties of belladonna, but is more powerful. Stramonium has held a high position as a local remedy in spasms of the glottis and in asthma. The smoke from the burning leaves may be inhaled. A convenient means of using it is to draw the fumes into the lungs through a pipe filled either with the pure leaves or with a mixture of the same with tobacco. The impression is ordinarily combined with that of nitrate of potassium. The effect should be carefully watched, since the poisonous properties of the drug may easily be induced. The smoke from about a half ounce of the leaves may be inhaled at a single sitting. The number of sittings is determined by the attendant circumstances. A sensation of heat in the lung, of fulness about the head, or of nausea is an indication that a maximum has been reached.

Preparations.—**S., Ext.** Dose, 1/8 to 1/2 grain. **S. Flext.** Dose, 1/2 to 3 minims. **S., Tinct.,** 10 percent strong. Dose, 5 to 15 minims. **S., Ung.,** contains of the extract 10, water 5, benzoinated lard 85 parts. **Daturin** is the alkaloid. Dose, 1/200 to 1/80 grain.

STRANGULATION.—See Asphyxia, Hernia, Intestinal Obstruction, Neck (Injuries).

STRANGURY.—Painful, scanty urination. It is a most prominent feature of poisoning by turpentine or cantharides, being induced even by the action of a blister. In various inflammatory conditions and morbid growths of the bladder and prostate gland it is also present, and is a constant symptom of acute posterior urethritis.

Treatment.—As a rule, hot baths and morphin are the most efficacious remedies. Free saline purging and the administration of belladonna are recommended. Barley-water, effervescing waters, milk, and other bland drinks are to be freely taken when the attack exists. Thirst may be slaked by iced drinks.

If there is overdistention of the bladder, catheterization may be necessary. See Urine (Retention).

STREPTOCOCCUS.—See Serum Therapy and Vaccine Therapy; Suppuration.

STREPTOCOCCUS INFECTIONS.—Denys (1896) succeeded in obtaining a streptococcus serum, and explained the mechanism of its action. He showed that it contained bacteriotropins (opsonins), and promoted phagocytosis when tested by animal experiment or in a test-tube. Marmorek maintains that all streptococci produce the same toxin, and that the serum of animals immunized against one form of streptococcus is effective against the toxins of all varieties. Other observers generally disagree with him in regard to these contentions, and are endeavoring to produce a serum which will be as polyvalent as possible, by immunizing with many species of streptococci. It is generally conceded that this serum is harmless, and that in cases of pure streptococcus infection it will destroy the organisms and control the symptoms caused by their toxin, unless used too late for any remedy to be effective. Some authorities consider it neither bactericidal nor antitoxic in its action.

Antistreptococcus serum has been employed successfully in erysipelas, puerperal fever and several forms of septicemia and pyemia due to streptococcus infection. Marmorek treated 411 cases of erysipelas with his serum, and reported a mortality of only 3 1/2 percent. He used it also in 16 cases of puerperal fever, of which seven, due to streptococcus infection, recovered; one, due to bacterium coli, died; and among eight of mixed infection with streptococcus, bacterium coli and staphylococcus, five died. Williams reported 14 cases of severe puerperal septicemia treated with this serum, and 2 deaths. Reports of 70 cases so treated by various physicians show only 2 deaths; among them being 29 of erysipelas, 15 of puerperal septicemia, 11 of infected wounds, and smaller numbers of septic cellulitis, cerebrospinal meningitis, scarlet fever, septic measles, pyemia, and acute gangrene. Packard and Wilson found records of 117 cases treated with antistreptococcus serum during 1901–2, of which 114 showed either a marked temporary improvement or a prompt recovery. These cases included puerperal septicemia, erysipelas, tuberculosis with pyogenic infection, general pyemia, local streptococcus infections, and a few cases of simple and pernicious anemia which seemed to be decidedly improved by injections of this serum. A combination serum, obtained from animals im-

munized by injections of both diphtheria toxins and streptococcus cultures, is used in advanced cases of diphtheria with double infection.

The treatment of articular rheumatism by antistreptococcus serum has been advocated by many clinicians, especially by Menzer, who showed that the action of this serum is bacteriotropic (opsonic), and claimed that it effects a cure or improvement even in cases which have become chronic. Other observers state that its true field includes the subacute and chronic cases without the stationary formation of new tissue. It has proved effective in endocarditis and in severe tonsillitis.

A streptococcic vaccine (strepto-bacterin) has given very satisfactory results in the same class of cases as the serum, also as a preventive and curative treatment in scarlet fever. Whether the serum or the vaccine is the most valuable therapeutic agent has not yet been definitely established (Potter).

STRICTURE.—See Esophagus(Stricture), Rectum (Stricture), Urethra (Stricture), etc.

STRIDOR.—A peculiar, harsh, vibrating sound arising from some obstruction in the throat or in the larger respiratory tubes. It is most commonly due to compression of the trachea by some extraneous growth, or to spasm or paralysis of the vocal bands.

STROKE.—See Brain (Hemorrhage), Heatstroke.

STRONTIUM.—This metal is represented in medicine by its salts, the bromid, iodid, salicylate (see Bromin, Iodin, Salicylic Acid) and the lactate. They are believed to be much less irritating to the stomach and less prone to cause eruptions than the sodium and potassium salts, though at the same time they are less powerful than the latter. Elimination, too, is more rapid and more complete.

The lactate in doses of 5 to 30 grains has been successfully employed in diabetes and in albuminuria. It diminishes the amount of albumin in Bright's disease, in the parenchymatous nephritis of rheumatic and scrofulous subjects, and in the albuminuria of pregnancy; for which purpose it should be given in full doses (gr. xxx) thrice daily. It is contraindicated when there is scanty urine or symptoms of uremia.

STROPHANTHUS.—The ripe seed deprived of its long awn, of *Strophanthus Kombé*, an African climbing plant from which the natives extract a toxic preparation known as the Kombé arrow-poison. It contains a crystalline glucosid, named *strophanthin*, the active principle, which is an agent of great energy, the frog being killed by a solution of 1 part in 10,000,000. Dose of strophanthus, 1/2 to 2 grains. In medicinal properties it closely resembles digitalis, producing loss of reflex sensibility and of voluntary motion, but not causing contraction of the arteries to the same degree. Strophanthus is undoubtedly a valuable cardiac stimulant, from the rapidity and permanence of its action, as well as from its noninterference with the caliber of the peripheral vessels. It promptly relieves cardiac dyspnea, often modifies the pulse-rate in less than an hour, while the influence of a single dose upon the circulation persists for a long time. It may replace digitalis in the treatment of chronic nephritis and valvular lesions of the heart, when it is important that the work of the heart should not be increased by any additional resistance in the arterial system. It has been reported as useful in the treatment of dyspnea, orthopnea, dropsy, and uremia, also in mitral insufficiency, with great anasarca and dyspnea; in palpitation, exaggerated cardiac action, and in weak heart, and for exophthalmos, with tumultuous action of the heart; also in pulmonary edema, due to valvular lesions or to pneumonia. It is useful in endocarditis, also in atheroma of the arteries; in reflex palpitation of neurasthenia, hysteria, and chlorosis, and for rigors due to catheterization or operations on the urethra. Dose of the tincture, 5 to 10 minims; of strophanthin, 1/300 to 1/100 grain.

STRUMA.—See Scrofula.

STRYCHNIN.—$C_{21}H_{22}N_2O_2$. A poisonous alkaloid in the fruit of *Strychnos nux vomica* and found in St. Ignatius' bean. It crystallizes in four-sided prisms, melting at 284° C., and possessing an extremely bitter taste. See Nux Vomica.

STUMP.—See Amputation.

STUTTERING.—See Speech Defects.

STYE (Hordeolum).—A furuncular or phlegmonous inflammation near the hair follicles or margin of the lid. Eye-strain is a common cause.

Symptoms.—It begins with a pricking pain, soon followed by swelling of the affected lid. A tender, hard spot is easily located by palpation, and may be inspected by raising the lid away from the eyeball, when a yellowish point will be seen.

Treatment.—If pus is seen, it should be released; and, as a rule, the symptoms will usually immediately subside. The pointing of the stye is hastened by the application of hot compresses for 15 minutes every 2 hours. To prevent recurrence, cleanliness and disinfection with a lukewarm bichlorid solution (1:5000) are demanded. A 10 percent sulphur ointment may be used. Recurrence of styes is suggestive of refractive error or of constitutional disorder, and the ametropia should be corrected and the general health improved.

STYPTICIN.—The hydrochlorid of cotarnin, a base produced by the oxidation of narcotin. It has been used with good results as a styptic and sedative in a number of cases of uterine disease, the dose being from 1 to 5 grains by mouth or hypodermically, four or five times a day.

STYPTICS.—See Hemostatics and Styptics.

STYRACOL.—Guaiacol cinnamate. Styracol is an intestinal antiseptic and is claimed to combine the antituberculous actions of guaiacol and cinnamic acid. It is said to liberate in the intestinal canal a larger proportion of its guaiacol (up to 85 percent) than other synthetic preparations of that substance. Dose, 15 grains.

STYRAX (Storax).—A balsam obtained from the wood and inner bark of *Liquidambar orientalis*, or oriental sweet-gum. It contains a volatile oil (styrol), a crystalline solid (styracin), several resins, and cinnamic acid. It is a stimulant

expectorant, an antiseptic, and disinfectant, acting like benzoin and tolu, and is used in bronchial affections and in catarrh of the urinary passages. Externally, it is an antiseptic and parasiticide. It is a constituent of Friar's balsam. Dose, 5 to 20 grains.

SUBARACHNOID INJECTION.—See INTRASPINAL ANESTHESIA.

SUBINVOLUTION.—Failure or delay on the part of the uterus to return to its normal condition after labor. See INVOLUTION.

SUBLAMIN.—A combination of mercuric sulphate and ethylene diamin, containing 43 percent of mercury. It is insoluble in alcohol, but freely soluble in water, and is used in 1:500, or 1:1000 solution for disinfecting hands and instruments.

SUBLIMATE.—See MERCURY.

SUBMERSION.—See DROWNING.

SUBUNGUAL EXOSTOSIS.—See NAILS (Diseases).

SUCCUSSION.—The shaking of the individual from side to side for the purpose of determining the presence of fluid in a cavity or hollow organ of the body. **The succussion sound** or **splash** is the peculiar splashing sound heard in hydropneumothorax or pyopneumothorax when the patient's chest is slightly shaken. It is due to the combined presence of air and fluid in a closed cavity. It was first described by Hippocrates, and hence is also known as the "Hippocratic sound." The sound may also be obtained in the presence of a dilated stomach partly filled with fluid. See CHEST (Examination).

SUDAMEN.—See SWEAT GLANDS.

SUDDEN DEATH.—See DEATH (Sudden).

SUDORIFIC.—See DIAPHORETICS.

SUFFOCATION.—See ASPHYXIA.

SUGAR.—See DIABETES, URINE (Examination).

SULPHOCARBOLATE.—The old name for phenolsulphonate. A salt of phenolsulphonic acid (sulphocarbolic acid). See PHENOLSULPHONATE.

SULPHONAL.—Sulphonmethane. Acetone diethysulphone. It is soluble in 100 parts of water at 16° C., in 20 parts at 100° C., and readily soluble in alcohol; it crystallizes in colorless leaflets or plates that melt at 126° C., and is odorless and tasteless.

Therapeutics.— As a hypnotic sulphonal acts admirably in many instances, if administered in hot fluids and about 2 hours before its action is required; but its efficacy decreases with use, and it is of no value whatever against insomnia due to pain. The average hypnotic dose is about 20 grains for a woman and 30 grains for a man. The dose is to be administered only once daily, and should be discontinued at the first sign of toxic action. In no case should its administration be continued over any great length of time. In cases of insomnia due to neuralgia and nervous excitement, the dose of sulphonal may be advantageously combined with a small dose of morphin, in proportion to suit individual cases, the mixture forming a safe and efficient hypnotic. An excellent hypnotic combination is made by mixing together 10 or 15 grains each of sulphonal and trional, to be taken in some hot liquid at bed-time. The trional producing early sleep and the sulphonal effects being manifested later, the patient will usually obtain a more prolonged result from the small dose of each agent administered together than from a larger dose of either alone. See TRIONAL.

Poisoning.—The prolonged use of sulphonal may give rise to such minor toxic effects as noises in the ears, headache, vertigo, weakness, and incapacity for mental or physical exertion. The patient may next pass into a condition of drowsiness or stupor and even death, or he may suffer from difficulty of speech; ptosis, edema of the eyelids, and cyanosis may occur. The stopping of the drug in subjects of sulphonism is followed by vertigo, motor disturbances, general weakness, digestive disturbances, etc., a condition resembling that in morphinism when the morphin is suddenly cut off (Lepine). In one reported case a dose of 20 grains nightly for 15 months was accompanied by complete cessation of menstruation (Potter). It has produced persistent skin eruptions in some cases and severe functional disturbances in others. The chief characteristics of chronic poisoning by this drug are as follows: Disturbances of digestion, shown by vomiting and diarrhea or constipation; disturbances of the nervous system, as ataxia and feebleness of the limbs, ptosis, and ascending paralysis; also ischuria and oliguria, sometimes albuminuria, or the presence of hematoporphyrin (Karst). Recovery follows rapidly if the entire alimentary tract is thoroughly purged; and as long as this is kept free, and the kidneys act efficiently and normally, the drug may be considered harmless (Fuerst). In order to secure elimination and to guard against cumulative action and consequent toxicity, its administration should be interrupted from time to time. Anorexia, vomiting or pains in the stomach may be regarded as indications for immediate discontinuance (Karst).

SULPHUR (Brimstone).—S = 32; quantivalence II, IV, VI. Sulphur is official in three forms:

Sulphur Sublimatum, *Sublimed Sulphur,* prepared from crude sulphur by sublimation and condensation. It is a fine citron-yellow powder, of faintly acid taste and acid reaction, insoluble in water or alcohol. Ignited it burns with a blue flame, forming sulphurous acid gas, and leaving no residue or only a trace. Dose, 10 grains to 2 drams.

Sulphur Lotum, *Washed Sulphur,* prepared by digesting sublimed sulphur with dilute water of ammonia, thoroughly washing with water and passing through a sieve. Solubility and dose same as for sulphur precipitatum.

Sulphur Precipitatum, *Precipitated Sulphur, Lac Sulphuris, Milk of Sulphur,* prepared by boiling sublimed sulphur with slaked lime and water. It is a very fine, yellowish-white, amorphous powder, odorless and almost tasteless, insoluble in water or alcohol, but completely soluble in carbon disulphid or in a boiling solution of soda. By heat it is completely volatilized. Dose, 10 grains to 2 drams.

Sulphur is chiefly used as a laxative when pultaceous rather than liquid stools are required,

as in hemorrhoids and anal fissure, also in constipation. Scabies has long been treated by its local and internal use, but sulphur alone does not kill the itch insect. The older sulphur ointments were made with sublimed sulphur, and probably contained a considerable amount of sulphurous acid, on which their parasiticide property depended. The later ointments, made with purified sulphur, all contain an alkaline ingredient and develop sulphids, which are powerful insect poisons. Sulphur fumigations are practically applications of volatile sulphurous acid, while most of the sulphur baths and sulphurous mineral waters are solutions of sulphuretted hydrogen or of the alkaline sulphids. They are of value in lead poisoning to favor the elimination of that metal, in chronic constipation, chronic rheumatism and sciatica and many skin diseases, especially chronic psoriasis, eczema, pityriasis and prurigo. The ointment is used in scabies.

Preparations.—**S. Dioxid,** SO_2, a colorless gas of irritating odor, formed by the combustion of sulphur; and in the presence of moisture acting as a powerful bleaching and disinfecting agent. As an insecticide it is unexcelled. See DISINFECTION. **S. Iodidum,** I_2S_2, used as an ointment, 30 grains to 1 ounce. **S. Ung.,** washed sulphur 15, benzoinated lard 85 parts.

SULPHURIC ACID.—H_2SO_4. Oil of vitriol, a heavy, oily, corrosive acid, consisting of not less than 92.5 percent sulphuric anhydrid and 7.5 percent water. Its uses and actions are the same as those of most other mineral acids, particularly hydrochloric acid. In lead-poisoning it forms an insoluble sulphate. It is used as a remote astringent in diarrhea, hemorrhoids, hemorrhages, night-sweats, and in mucous discharges. It does not increase the acidity of the urine. In **poisoning** by sulphuric acid water is to be avoided. Alkalies—such as sodium carbonate or bicarbonate, magnesia, chalk, soap, whiting, and wall plaster—are antidotes. Albumin, flour, milk, starch, and olive oil will protect the mucous membranes. Of antagonists, opium, ammonia (intravenously), and alcohol may be given to combat the depression of the vital powers.

Preparations.—**Acid, Sulph. Aromatic.,** contains 20 percent (by weight) acid, diluted with alcohol and flavored with cinnamon and ginger. Dose, 5 to 15 minims, well diluted. **Acid., Sulph. Dilut.,** contains 10 percent strong acid to 90 of water. Dose, 5 to 40 minims, well diluted.

SULPHUROUS ACID.—H_2SO_3. A colorless acid containing about 6 percent sulphurous anhydrid in 94 percent water. The gas, SO_2, is a very valuable disinfectant. The acid is used as a spray or lotion in diphtheria and stomatitis, and as a wash for indolent and syphilitic ulcers. The various hyposulphites are mainly valuable in that they decompose and give off sulphur dioxid. Dose, 5 minims to 1 dram. See MAGNESIUM, POTASSIUM, and SODIUM.

SUMBUL.—The dried rhizome and root of an undetermined plant. It contains *angelic* and *valeric acids*, also a volatile oil, balsamic resins, and a bitter principle. Dose, 10 to 60 grains.

Sumbul is an efficient nerve tonic, having qualities closely resembling musk and valerian. It is used by the Russian physicians in very many morbid conditions and seems to be a favorite remedy in that country for almost any disease. It is probably of some value in hysteria and other nervous derangements of delicate females, and may be used as a substitute for musk in typhoid conditions and fevers, asthma, delirium tremens and perhaps in epilepsy.

Extractum S. Dose, 1 to 10 grains. **Fluidextractum S.** Dose, 10 to 60 minims.

SUMMER COMPLAINT.—See CHOLERA INFANTUM, CHOLERA MORBUS.

SUNBURN.—The superficial local effects of exposure to the sun's rays. In slight cases little or no treatment is required. Powdered starch, zinc oxid, bismuth or boric acid, or mere sprinkling with elder-flower water or rose-water may suffice. A solution of ammonium acetate may be pleasant. Severe cases require lead lotion, with morphin or cocain. Subacetate of lead with glycerin and elder-flower water or rose-water makes a good application. Preventive treatment consists in protecting exposed parts from the sun's rays. Sunshades, veils, and masks are useful but inconvenient. The greased paints used by actors may be employed in sea-bathing. Pigments mixed with glycerin of starch are better than those compounded with grease. For the freckles following sunburn, lotions of mercuric chlorid or boric acid—especially when made with almond water in emulsion by the use of glycerin—or the juice of cucumber may have a beneficial effect. See FRECKLES.

SUNSTROKE.—See HEAT-STROKE.

SUPERIMPREGNATION.—Two varieties of superimpregnation are described: (1) Superfecundation and (2) superfetation.

Superfecundation is the fecundation of two or more ovules at or near the same period of time. It occurs in one variety of twin pregnancy.

Superfetation is the production of conception while an embryo already exists in the uterus. Some remarkable cases have been reported that would seem to prove the possibility of its occurrence. That it can occur after a long interval is doubtful, however, since there is no proof of ovulation during pregnancy.

SUPERINVOLUTION.—An exaggeration or abnormal prolongation of that process by which the uterus regains its normal condition after labor. See INVOLUTION.

SUPPOSITORY.—A solid, medicated compound, designed to be introduced into the rectum, urethra, or vagina. Its consistency is such that, while retaining its shape at ordinary temperatures, it readily melts at the temperature of the body. The basis of most suppositories is oil of theobroma. For urethral suppositories a mixture of gelatin and glycerin is used. It is generally molded into a conic shape, but is sometimes cylindric or spheric. According to the directions in the U. S. P.: *Rectal suppositories* should be cone-shaped or spindle-shaped, and when made from oil of theobroma should weigh about 2 grams.

Urethral Suppositories (*Bougies*) should be pen-

cil-shaped, pointed at one extremity, and either 7 cm. in length, weighing about 2 grams, or 14 cm. in length weighing about 4 grams, when made with glycerinated gelatin. If prepared with oil of theobroma, they should weigh about one-half the above quantities.

Vaginal Suppositories should be globular or oviform in shape and weigh about 10 grams if made with glycerinated gelatin, and about 4 grams if made with oil of theobroma.

There is one official suppository, the glycerin suppository, containing glycerin, monohydrated sodium carbonate, stearic acid, and water.

Anodyne suppository:

℞.	Extract of opium,	gr. j
	Extract of belladonna leaves,	gr. ss
	Extract of hyoscyamus,	gr. ij.
	Cacao-butter, a sufficient quantity to make 6 suppositories.	

Use one in the rectum morning and night.

SUPPRESSION OF URINE.—See URINE (Suppression).

SUPPURATION.—By this term is meant the production of pus. While it is true that experimentally (as by the hypodermic injection of nitrate of silver, calomel, turpentine, abrin and ricin) suppuration can be produced without the presence of pyogenic bacteria, yet it may be laid down as a broad general principal that where there is pus there also are found the bacteria or the poisons that produce it.

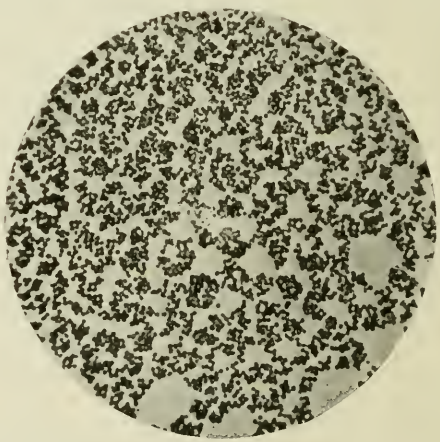
Pus from an acute abscess in an otherwise healthy person is a thick, creamy, opaque, yellowish-white, slightly alkaline fluid, with a faint odor, salty taste, and a specific gravity of about 1030. If a drop is examined under the microscope, it is found to consist of a fluid (the liquor puris) and corpuscles (pus-cells). Some of these corpuscles are globular, slightly granular, and measure 1/2400 inch in diameter, while some contain two or three nuclei, which are made more evident on the addition of acetic acid to clear up the granular matter. Among them may be seen other corpuscles, indistinguishable from leukocytes, and exhibiting, when examined on a warm stage, ameboid movements. The latter are living leukocytes and tissue cells; the former, leukocytes and proliferated tissue cells that have undergone death and degeneration. The proportion of dead to living pus-cells varies with the duration of the inflammation. The liquor puris consists of water, albumin, and salts, of which chlorid of sodium is the chief. It coagulates on boiling. Though probably derived in chief part from the exudation of the serum through the vessels, it differs from serum in that it does not coagulate spontaneously. In acute abscesses the pus contains granular material, derived from the rapid degeneration of the tissues, and various species of microorganisms, usually cocci. If allowed to stand or decompose in an imperfectly drained abscess cavity, the pus will be found, moreover, teeming with the bacteria of putrefaction.

Varieties of Pus.—*Normal, healthy* (formerly called *laudable*) pus is best illustrated by that which is found in staphylococcic infections; it tends to remain localized, and the tissues from which it comes quickly recover after thorough drainage has been established. It is a greenish-white, creamy fluid, without odor, alkaline in reaction, and of a specific gravity of 1030. *Sanious* pus is mixed with blood, and is sometimes seen in caries and carcinoma. *Malignant or ichorous* pus is watery, acid, and very irritating to the tissues. *Blue* pus is due to the bacillus pyocyaneus, *orange* pus to hematoidin crystals the result of degeneration of red blood corpuscles, and *stinking* pus to the bacteria of putrefaction or the bacillus coli communis. *Concrete or fibrinous* pus contains flakes of lymph; *serous* pus, a large quantity of serum; and *muco-pus*, mucus. *Gas producing* pus is due to the bacteria of putrefaction, bacillus of malignant edema, bacillus aerogenes capsulatus, bacillus coli communis, or to communication with one of the air-containing viscera.

Tuberculous, scrofulous, caseous, or curdy pus, found in tuberculous processes, and *gummy* pus, the result of a degenerating gumma, are not, strictly speaking, pus.

The microorganisms that are most active in this process are the staphylococcus, the streptococcus, the gonococcus, and the bacillus pyocyaneus.

The Staphylococcus Pyogenes.—The varieties are staphylococcus pyogenes aureus, staphylococcus pyogenes citreus, and staphylococcus pyogenes albus. The staphylococcus pyogenes



STAPHYLOCOCCUS PYOGENES AUREUS, PURE CULTURE. × 1000.—(*Williams.*)

aureus is the one most commonly found in all cases of localized suppuration. The arrangement of the growth is in the shape of a bunch of grapes; hence the name "staphylococcus." These varieties of the staphylococcus grow upon artificial culture media, and from their chromogenic properties in this respect produce various colors: "aureus," orange or golden color; "citreus," lemon color; "albus," white color. The different forms are not motile and are without spores.

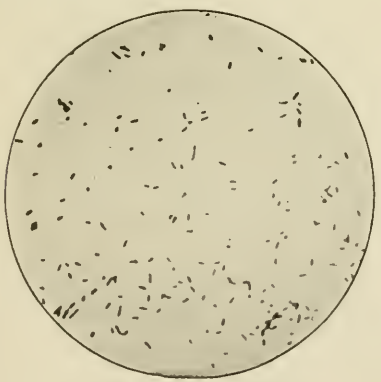
They stain with the ordinary watery or alcoholic solutions of anilin dyes and by Gram's method.

Streptococcus Pyogenes.—In this variety of pyogenic cocci the arrangement of the organism in its growth is in the shape of chains; hence the name "streptococcus." While in the case of the staphylococcus the tendency is to produce a local-

STREPTOCOCCUS PYOGENES, FROM A PURE CULTURE. × 1000.—(*Williams.*)

ized abscess, the streptococcus produces a suppurative process having a tendency to spread throughout the tissues. It is supposed to be one of the causes of erysipelas. The microorganism is not motile, and does not contain spores. It grows upon artificial culture media and stains with ordinary watery or alcoholic solutions of anilin dyes and by Gram's method.

The streptococcus erysipelatis is described under ERYSIPELAS (*q. v.*).



BACILLUS PYOCYANEUS.—(*Kolle and Wassermann.*)

The gonococcus was discovered by Neisser, in 1879, and is the cause of gonorrhea. These small hemispheric microorganisms are not motile, like other forms of cocci, and have no flagella and no spores. For many years attempts to cultivate this variety of bacteria upon artificial culture media proved futile, but after very painstaking effort it has been grown upon a mixture of human blood-serum and agar-agar. In the gonorrheal pus the microorganism is nearly always found in pairs within the epithelial cells. It stains best with rather weak, watery solutions of anilin dyes, but not by Gram's method. See GONORRHEA.

The bacillus pyocyaneus is a short, delicate bacillus of small size, frequently united in chains of 4 or 6. It has round ends, is actively motile has one terminal flagellum, does not form spores, and is almost purely aerobic. It stains well with ordinary solutions, but does not retain the color by Gram's method. It is found in pus of a peculiar bluish or greenish color.

Method of Staining for Staphylococci, Streptococci, and Gonococci.—Upon a perfectly clean cover-glass place a drop of the pus to be examined, and upon this place a similar cover-glass. Separate them horizontally, and dry in the air. With a pair of forceps grasp one edge of the cover-glass and pass through the flame of an alcohol lamp or Bunsen burner 3 times, each time allowing the specimen to occupy about 3 seconds in its passage through the flame. Upon this specimen then pour, by means of a pipet, a saturated aqueous or alcoholic solution in the case of streptococcus or staphylococcus pyogenes, but a weak, watery solution in case of gonococci of one of the anilin dyes, preferably methylene-blue, and allow it to remain for from 1/2 to 2 minutes; then rinse in water and mount in Canada balsam.

Gram's Method of Staining Bacteria.—Fix the specimen on a cover-glass. Instead of using the ordinary anilin dyes in alcoholic or watery solution, the following is used. It should always be freshly prepared (Ehrlich's solution):

Pure anilin,	4 gm.
Saturated alcoholic solution of gentian-violet,	11 gm.
Water,	100 c.c.

Grasp the prepared specimen with a pair of forceps, and pour upon it a few drops of the above solution and warm over the flame for from 2 to 5 minutes, constantly adding the solution. Remove and place in:

Iodin crystals,	1 gm.
Potassium iodid,	2 gm.
Water,	300 c.c.

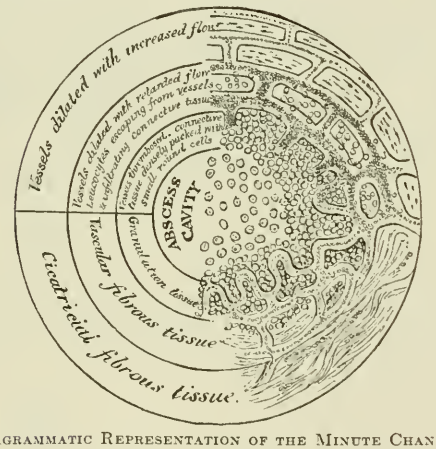
Allow the specimen to remain in this solution for from 2 to 5 minutes, wash in 95 percent alcohol, and counter-stain with eosin or Bismarck brown.

Circumscribed Suppuration or Abscess.—An abscess is "a circumscribed cavity of new formation containing pus." According to location, abscesses are named *dorsal, iliac, mammary, ischiorectal, perityphlitic, retropharyngeal, urethral*, etc. Abscesses are also known as superficial, deep-seated, acute or phlegmonous, chronic, common, specific, and residual.

An acute abscess is one that runs its course rapidly, and is always accompanied by well-marked inflammatory symptoms. It is, from its great frequency, one of the most important of surgical diseases. When an inflamed part becomes

more heated and more swollen; when the skin assumes a dusky hue, and becomes glossy and shiny; when the pain, which has been of a dull, heavy nature, becomes persistent, steady, and throbbing, and when the skin over the swelling is edematous, then there can be no doubt that an abscess has formed.

Pathology.—In the formation of an abscess the first phenomena are those of inflammation, which have been described; when the production of embryonic tissue has been reached, if it stops at that point, resolution is established and recovery ensues; but should the new "cellular infiltrate" be invaded by any microorganism of suppuration, and a suitable soil for its nidus and growth be found, their excreta, known as ptomains, peptonize the fibrin and change the embryonic tissue to a liquid, which is pus. The changes here described begin in the lymph spaces, so that an abscess never has its commencement at a single focus; the accumulation of liquid and of cells causes the lymph spaces to be greatly distended; the fibrous tissues separating these spaces are widely pressed asunder, causing their supply of blood to be cut off, sloughing being the result; moreover, the living pus-cells find in these fibers a source of nourishment, and they are thus destroyed; hence the lymph spaces become converted into a single cavity, and an abscess is formed.



Diagrammatic Representation of the Minute Changes in the Formation and Healing of an Abscess.

The upper half shows abscess enlarging; the lower half abscess healing.—(*Walsham.*)

From the periphery to the center of an abscess all stages of inflammation are presented, from the first, which is the stage of congestion, to the last, which is the period of the formation of pus. Between these two conditions there is a middle point, when the inflammatory process has reached only the formation of embryonic tissue; and hence it is that the cavity of an abscess is always circumscribed by a tissue of new formation. Not only does an abscess extend in various directions, but all abscesses tend to empty themselves at the point of least resistance; they approach the surface, where they spontaneously evacuate themselves, their tendency being toward the skin. The abscess discharges itself by a small opening, which is due to the death of a limited portion of the skin. The contents of an acute or phlegmonous abscess are pus, micrococci, and some shreds of dead tissue. In some cases the abscesses contain air, when the contents are extremely fetid.

Phlegmonous abscess occurs in all periods of life and in all classes of persons; it varies in size, and is frequently found in subcutaneous connective tissue, in the muscular tissue, around the lymphatic glands, and around the bones. Its most common sites in the viscera are the liver and the brain.

Chronic Abscess.—The effect of the bacillus of tuberculosis on tissue is to produce a chronic inflammation, which results in the production of granulation tissue; this is the so-called pyogenic membrane of old authors, and acts as a protective wall to the surrounding tissue. The degenerative changes that take place are caused by local anemia and by the chemic action of the ptomains of the tubercle bacilli; they consist of caseation and liquefaction of the cheesy material. This purulent material has hitherto been looked upon as pus; it is now known to be tissue that has undersgone metamorphosis. Pus is never present in a tubercular process unless the microorganism of suppuration is present, when there will be a mixed or double infection.

If the bacillus meets with a double resistance from the surrounding tissue, it exhausts the nutritive material in the granulations and dies; or it remains in a latent condition; the granulation is converted into a cicatricial tissue, and the local lesion is cured. This is designated spontaneous cure. The liquid may also be absorbed, when a similar favorable termination is possible. If the cavity is opened under antiseptic precautions, cure is accelerated; if, however, secondary infection with pus microbes takes place, the patient is in danger of septic infection as well as of local and general dissemination of the tubercular process.

Treatment of Abscess.—The chief indications are to remove the pus with as little injury to the tissues as possible, to insure sufficient drainage, and to maintain the parts in an aseptic condition. When it is evident that suppuration must ensue, it should be promoted by moist warmth in the form of a large boric acid poultice sprinkled wih opium or hot poppy fomentations. As soon as fluctuation is detected, the abscesses should be opened by making a free incision in the most dependent part or where it is pointing, of course taking care to avoid blood-vessels or other important structures in the neighborhood. The pus should generally be allowed to flow out of its own accord. To insure thorough drainage, and to prevent any tension from reaccumulation, the opening should be free and a drainage-tube should be inserted. If the abscess is large, a counteropening may be necessary, or the abscess cavity may degenerate into a sinus. If the drainage is efficient, no harm will ensue if a poultice—the favorite treatment of the older surgeons—is applied; but if the abscess is deep and the aperture small, and there is thus danger of the pus being retained and undergoing

decomposition, antiseptic dressings or boric acid fomentations should be used, as under these circumstances the retained discharge will probably be under some degree of tension, and the granulation walls of the abscess hence inefficient to prevent absorption. Although it is a rule in surgery to open an abscess as soon as fluctuation clearly shows that pus has formed, there are some instances in which this is especially imperative. Thus, an abscess should be opened at once when it is situated in the perineum, in the abdominal or thoracic walls, in the sheath of a tendon, under a deep fascia or the peritoneum, in the orbit, near a joint, and in the neck if attended by dyspnea; when obstructing some passage; when caused by the infiltration of urine, feces, etc., and when a spontaneous opening would produce deformity.

Hilton's method, as it is called, of opening an abscess is very useful when the abscess is situated deeply and among important structures, as at the root of the neck or in the axilla. It consists of making an incision through the skin and fascia and then working gently in the direction of the pus with a director. As soon as pus presents, a pair of dressing forceps are slid along the groove of the director into the abscess cavity, the director is removed, and the blades of the forceps are separated so as to stretch the opening and make a free exit for the pus.

The complications of acute abscess are: (1) Hemorrhage from the involvement of a large vessel; (2) the implication of some important part, as the peritoneal cavity, the interior of a joint, etc.; (3) degeneration into a sinus or fistula; (4) blood-poisoning (sapremia, pyemia).

The chronic abscess must not be allowed to open itself spontaneously. This precaution is to be particularly borne in mind when the glands of the neck are affected. Open the abscess in the most dependent portions, using a straight, sharp bistoury for the purpose; press out the accumulated material; scrape out the abscess thoroughly; wash it with an antiseptic solution of bichlorid of mercury, then bring the opening together by means of a suture; insert a drainage-tube and place iodoform gauze upon the outside. Before opening an abscess of large size, and after ether has been administered, give 1/6 grain of morphin, hypodermically, and also administer 1/6 grain of opium every 8 hours. The effect of opium is to prevent capillary hemorrhage after the removal of pressure.

Constitutional Treatment.—When the suppuration is profuse, tonics—such as iron, quinin, and strychnin—together with good, nutritious diet, milk-punch, etc., and change of air, must be insisted upon.

To repair waste from suppuration:

℞. Syrup of iron, quinin, and strychnin, ℥ vj.
A teaspoonful in water thrice daily.

℞. Syrup of hypophosphites, ℥ vj.
A dessertspoonful thrice daily.

The injection of bacterial vaccines although at one time recommended, has not proved of so much value in the treatment of abscess as it has in superficial infections such as furuncles. In fact it is probably worthless, and at most is uncertain and unsatisfactory. If employed at all it should be used only as a supplement to surgical and general medicinal measures. See Serum Therapy and Vaccine Therapy.

See Brain (Inflammation), Hectic Fever, Liver (Abscess), Psoas Abscess, Spine (Caries), Sepsis etc.

Diffuse suppuration may occur either in the substance of tissues or organs, or on the surface of the skin or of the mucous or serous membranes. An example of the former is cellular erysipelas. Examples of the latter are seen in gonorrhea, bronchitis, and peritonitis. These affections are all discussed under their separate headings.

SUPRARENAL DISEASE (Addison's Disease; Adrenal Disease).—A well-marked, constitutional disease, exhibiting itself locally as a chronic inflammation of the suprarenal capsules, but in its essence consisting of a peculiar anemic condition, always tending toward death; and which is characterized by intense development of pigment in the cells of the rete malpighii and in the epithelium of the mucous membrane of the mouth.

The etiology is obscure. Tubercle, scrofula, and syphilis have each been given as the cause.

Pathologic Anatomy.—A low form of inflammation, terminating in degeneration of the suprarenal capsule. The blood is deficient in fibrin and red corpuscles, with a slight increase of the white corpuscles. Fatty degeneration of the heart and vessels has been observed in some cases. The most striking change during life—the abnormal pigmentation—is due to the deposition of granular pigment in the cells of the rete malpighii, in the papillary portion of the cutis, and even in the connective-tissue corpuscles. No change occurs in the proper structure of the skin. Similar pigment deposits occur in the mucous membrane of the mouth, especially along the edges of the teeth. The disease of the suprarenal capsules excites an irritation of the vasomotor system—the trophic system—that leads to the pigmentation.

Symptoms.—The onset of the disease is insidious, with a feeling of extreme languor, muscular fatigue, asthenia, indigestion, anorexia, dyspnea, cardiac palpitation, vertigo, melancholia, and excessive drowsiness. The surface is first pale, then changes to a hue like that seen in melancholia, changing to icteroid, finally resembling the color of a mulatto, and then to a lusterless bronze. These changes also occur on the mucous membrane of the lips, tongue, gums, and mouth.

Prognosis.—The disease is incurable. The duration is 1 or 2 years.

Treatment is symptomatic, and is of little use. Arsenic and cod-liver oil give the best results. Iron and other tonics are useful, especially a combination of the chlorid of iron, glycerin, and chloroform. Phosphorus has seemed to exert a beneficial influence. Adrenal extract has been employed in a few cases, with some benefit while used.

℞. Tincture of iron chlorid, Spirit of chloroform, } each, ℥ j
Glycerin, ℥ vj.
A dessertspoonful in water thrice daily.

SUPRARENAL EXTRACT (Adrenal Extract).—The selected dried and powdered suprarenal capsules of oxen and sheep. One part of this powder represents 5 parts of the fresh organ. Systemically, its effects are principally on the circulatory and nervous systems. It is a remarkable astringent, and is much used in operations upon the eye, ear, nose, and throat in the treatment of local congestions, inflammations and hemorrhages, especially of the eye, ear, nose and throat. When applied to any mucous surface, it produces more or less profound ischemia, depending on the strength of the solution and the manner and time of application. Locally applied, it is never followed by any constitutional manifestations. The bloodless condition of the mucosa is unmistakably due to the local action of the extract on the vasoconstrictors of the capillaries, constricting them and inducing bleaching of the surface. No injurious effects to the tissue follow the continuous application, nor is there any danger of contracting a habit, as the action of the adrenal extract is purely local on mucous surfaces, no absorption taking place sufficient to produce any evidence of constitutional effects. The pupil, accommodation, and intraocular tension are in no way affected. It has absolutely no action on the skin, nor does it possess any anesthetic properties wherever applied. Its action is wholly but strongly astringent; hence its efficacy in preventing hemorrhage during an operative procedure on mucous membranes. The depletion is complete. Maurange first recommended it for the prevention of hemorrhage in eye operations. Its local effects are enhanced by a preceding application of cocain or antipyrin solution. When applied locally for either therapeutic or operative purposes, it should always be preceded by a 5 percent solution of cocain, so as to secure the combined anesthetic and enhanced effects of the cocain and extract. The adrenal capsule has of itself no anesthetic properties, being purely astringent, and then only when applied to the mucous surfaces. The astringent action begins in from 30 to 40 seconds, and lasts from 1/2 of an hour to 3 hours, after which interval the mucous membrane returns to its normal condition. The solution of the capsule is not at all irritating, but rather imparts a cooling sensation to the conjunctiva.

A preparation made by placing 5 grains of desiccated suprarenals in 1 dram of cold, saturated boric acid solution and allowing the mixture to stand 10 minutes before filtering, applied locally, relieves congested mucous membrane, and prevents hemorrhage, thus enhancing and prolonging cocain anesthesia. Its full effect is noticed in a few seconds, and lasts from 1 to 2 hours. The extract is not antiseptic nor anesthetic, and no tolerance is established by its use. Fresh solutions should be prepared for each operation. Powdered desiccated suprarenal capsules of the sheep, 1 grain representing 8 grains of the fresh substance, in ounce bottles, are for sale.

Internally, suprarenal extract has been given with great benefit in shock and hay-fever. It has been used in Addison's disease, pernicious anemia, diabetes insipidus, diabetes mellitus, cyclic albuminuria, and heart disease, in doses of from 3 to 5 grains, 2 or 3 times daily. This extract has given good results in nasal, pulmonary and gastric hemorrhage, acute and chronic bronchitis, bronchial asthma, congestion and edema of the lungs, edema of the glottis and diabetes insipidus. It will be found useful in chronic muscular affections, especially those involving loss of tone or degenerative changes, and will probably be found valuable in all conditions in which the vasomotor tone is impaired. Being a powerful but temporary stimulant of the heart it may be used cautiously in cardiac weakness, in failure of the heart from any cause and in valvular diseases of that organ.

By local application the angiostenotic properties of suprenal extract have been successfully utilized in the treatment of local congestions, inflammations and hemorrhages, especially those of the eye, ear, nose and throat. It is an excellent hemostatic for hemorrhage following operations on the nose, and is used as an application to inflamed tissues prior to their being anesthetized by cocain, also to the mucous membrane of the turbinated bodies in ulceration or hypertrophy thereof.

Suprarenaden is a preparation made from the suprarenal capsules, used in Addison's disease, menopause, neurasthenia, and diabetes insipidus. Dose, 15 to 23 grains daily. See Adrenalin.

SUSPENDED ANIMATION.—See Asphyxia; Syncope.

SUSPENSION.—A mode of treatment of certain diseases, especially tabes dorsalis, in which the patient is so placed that the whole weight of the body hangs upon the neck, the head being supported at the chin and the occiput. The stretching of the spinal cord sometimes removes the morbid process in a manner at present not well understood. See Spine (Diseases).

SUTURE.—A stitch used in closing the edges of a wound. Suture material may be of silk, silkworm-gut, catgut, or other animal material, and of metal. See Ligature.

The Interrupted Suture.—The needle, carrying a single ligature, is passed through the skin on one side of the wound from without inward, and is then inserted from within outward at the corresponding point on the opposite side of the wound. The ends of the ligature are drawn together and tied tightly in a double knot. The ligature is then cut and another suture introduced at an interval of 1/2 of an inch, and so on.

Lembert's interrupted suture is recommended in wounds of the intestines. The stitches should be 3/8 of an inch from the margin of the wound, the middle suture being first introduced; the distance between the sutures should not exceed 1/4 inch. When the requisite sutures have been applied, the

Sutures for Immediate Gastrostomy.

ends are to be tied, and cut off close to the knot. The bowel is then returned to the abdominal cavity and a glass drainage-tube inserted.

The Twisted or Harelip Suture.—Having placed the edges of the wound accurately in contact, a sufficient number of needles are passed through the edges of the wound. When the necessary number of needles have been introduced and the parts have been accurately adjusted, the middle of the long ligature is twisted around the uppermost needle in the form of a figure ∞. Then the two ends of the ligature are brought down and twisted around the other needles successively, when they are secured by a knot. After insertion the points of the needles must be cut off with pliers. The upper pin must be removed at the end of the second day, and the lower pin at the end of the third day.

The Glover's Continuous Suture.—This suture is employed in wounds of the intestines and abdomen. It is applicable to cases of injury of great extent when there is tendency to the escape of fecal matter in the intervals between stitches. It is merely the ordinary stitch employed for sewing materials together; it is made by simply passing the needles diagonally from one side of the wound to the other.

The figures on the next two pages illustrate the principal sutures.

SWALLOWING, DIFFICULT.—See Dysphagia.

SWEAT-GLANDS, DISEASES.

Hyperhidrosis (Excessive Sweating)

A functional disorder of the sweat-glands characterized by an excessive secretion of sweat. The affection may be general or local.

Symptoms.—The hands, when affected, are cold and clammy. In severe cases the sweat drops from the palms, incapacitating the patient from all manual work. The feet, when affected, become tender, so that walking produces pain. The soles are reddened and the epidermis is macerated.

Etiology.—General hyperhidrosis results from faulty innervation. It may, however, be physiologic, as during violent muscular exertion. The local forms are probably due to some disturbance of the vasomotor apparatus.

Treatment.—In general hyperhidrosis constitutional remedies are to be employed—belladonna or atropin, ergot, nux vomica, mineral acids, quinin, etc. Crocker speaks highly of sulphur, given in 1-dram doses twice daily, for both general and local sweating. For the local forms the remedies are, for the greater part, to be applied to the affected regions. Upon the palms this condition is much more refractory to treatment than upon the soles. The following prescription will be found of great value in the treatment of sweating feet:

℞. Salicylic acid, gr. xx
Boric acid, ʒ j
Lanolin, Petrolatum, each, ʒ ss.

To be rubbed in well at bedtime.

The feet should not be washed more than once a week. It is well also to place boric acid in the stockings. Hebra's plan was to wrap up the feet in diachylon ointment, and continue the treatment for a fortnight. Crocker recommends the use of belladonna ointment. All of these remedies will be found more efficient in sweating feet than in sweating hands. To check sweating of the axillæ apply, for a few hours, a sponge soaked in very hot water. Faradization and galvanization are sometimes of value in hyperhidrosis.

Bromidrosis (Osmidrosis)

A functional disorder of the sweat-glands, characterized by sweat secretion of an offensive odor. The condition may be symptomatic, as in uremia, rheumatism, etc. There is usually an excessive sweating, although the amount may be normal. The odor is often so unpleasant as to unfit the sufferer for society. The etiology is obscure. It usually occurs upon the feet of young persons. The sweat is not offensive when secreted, but soon becomes so from the action of microorganisms. The treatment is practically that of hyperhidrosis.

Anhidrosis

A disorder of the sweat-glands characterized by diminution or suppression of sweat.

It may be symptomatic, as in diabetes, fevers, etc. It may also be due to faulty innervation. There may be but slight diminution of sweat secretion or total absence. In congenital cases no treatment is of avail. In acquired cases one may employ massage, electricity, vapor and alkaline baths, etc.

Chromidrosis

A disorder of the sweat-glands characterized by colored sweat. There are two forms—idiopathic and accidental (color due to certain substances taken into the system). The color in the idiopathic form is usually black or sepia. The orbital region is usually affected.

Accidental Forms.—Green sweat is found frequently in copper workers. Red sweat, which occurs often in the axillæ, is due to the action of the bacterium prodigiosum, and is often associated with leptothrix.

The treatment is based upon broad general principles.

Uridrosis

A condition characterized by the excretion through the sweat-glands of constituents of the urine in considerable quantity. The sweat normally contains small quantities of urea. In suppression of the urine, as in Bright's disease, cholera, etc., urinary products are eliminated through the sweat-glands. There is a urinous odor to the skin, and sometimes a deposition of salts on the skin.

Hematidrosis (Bloody Sweat)

A condition characterized by hemorrhage from the sweat-pores.

The affection is very rare. It occurs in young hysteric women. It has been observed on the face, ears, umbilicus, hands and feet.

Sudamen (Miliaria Crystallina)

An eruption characterized by the formation of numerous superficial, pinhead-sized, transparent vesicles, occurring during the course of febrile diseases. The vesicles are non-inflammatory. They have been aptly described as resembling "dewdrops." They are most abundant upon the trunk and neck, and disappear in the course of a few days. The vesicles are due to a collection of sweat in the upper layers of the epidermis, as a result of obstruction of the sweat-ducts. The affection undergoes spontaneous involution.

Miliaria (Prickly Heat)

A mild inflammatory affection, caused by obstruction of the sweat-ducts, characterized by the occurrence of small papules and vesicles at their mouths.

Symptoms.—The affection comes on suddenly, after profuse perspiration. The lesions are discrete, never tending to coalesce. Itching is usually present. The trunk is the seat of predilection. In children it is likely to be complicated by furunculosis.

Pathology.—Obstruction of sweat-ducts, with surrounding inflammation.

Treatment.—Prophylactic. Children should be lightly clad in thin woolens and kept out of the heat. Constipation should be avoided. Sedative lotions and dusting-powders constitute the local treatment. The following is a useful combination:

℞.	Phenol,	♏ xxx
	Boric acid,	ʒ j
	Zinc oxid,	ʒ jss
	Glycerin,	ʒ ij
	Alcohol,	ʒ ij
	Water, add enough to make,	ʒ vj.

Sop on the skin as indicated.

Or a dusting-powder may be used:

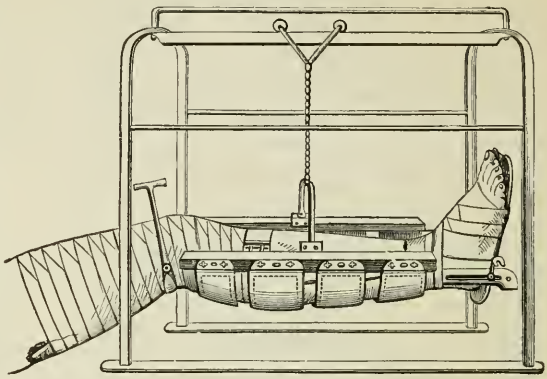
℞.	Magnesium carbonate, Boric acid, Powdered starch,	each, ʒ ij.

An excellent method is to sop on a saturated solution of boric acid, and follow this with a dusting-powder. When the entire body is involved, bran, starch, or alkaline baths may be employed with good results.

SWEATING SICKNESS.—See Miliary Fever.

SWEET OIL.—See Olive Oil.

SWING.—An apparatus consisting of a cradle that moves on wheels along a horizontal bar on an iron framework; it is used in the treatment of fractures of the lower extremities.



Salter's Swing.

SWOONING.—See Syncope.

SYCOSIS.—Chronic inflammatory disease of the hair follicles, usually of the bearded region, characterized by papules, pustules, and tubercles perforated by hairs.

Symptoms.—The disease commences by the formation of discrete pinhead-sized to pea-sized papules or pustules at the sites of hair follicles. The pustules are flat or acuminated, and contain a yellowish fluid; they show no disposition to rupture, but dry into crusts. The surrounding skin is reddened, sometimes swollen and infiltrated, and is the seat of a variable amount of itching, burning, and pain. The pustules are discrete, but may be closely aggregated. A hair perforates the center of each lesion. In the beginning the hair is firmly attached; but as suppuration becomes free, it is more easily extracted. At times tubercles are present. The eruption comes out in crops, the disease lasting for months, or even for years. The affection is confined to hairy regions, particularly the beard and mustache.

Etiology.—The disease obviously occurs only in adult males. It is due to invasion of the follicles by microorganisms, chiefly the staphylococci aureus, citreus, and albus. Nasal discharge may produce a sycosis of the upper lip.

Pathology.—The pathologic process consists of a folliculitis and perifolliculitis, due to pyogenic cocci. The inflammation is at first perifollicular, the follicle only becoming secondarily invaded by serum and pus.

Diagnosis.—Sycosis vulgaris may be confounded with tinea sycosis and pustular eczema. The differential diagnosis is appended:

Sycosis.	Tinea Sycosis.
1. A typical case shows small discrete papules or pustules pierced by hairs.	1. A typical case shows large, lumpy, or nodular tumefactions.

Sycosis.	Tinea Sycosis.
2. Hairs firmly attached until free suppuration occurs. Roots often swollen with pus.	2. Hairs broken and easily extracted. Roots usually dry.
3. Course slow. Little change from week to week.	3. Course rapid. Marked changes from week to week.
4. Mustache frequently affected.	4. Mustache practically never affected.
5. Absence of fungus in hairs.	5. Trichophyton fungus in hairs.

Sycosis.	Eczema Pustulosum.
1. Lesions strictly follicular, pierced by hairs.	1. Lesions likely to be interfollicular as well.
2. Eruption limited to bearded region.	2. Tends to spread upon nonhairy regions.
3. Absence of oozing.	3. Oozing marked.
4. Itching slight.	4. Itching more severe.

Prognosis.—Very few cases are incurable. The disease, however, is often refractory to treatment, and lasts months or years. Recurrences are common.

Treatment.—Internal remedies, such as iron, arsenic, cod-liver oil, etc., are at times indicated by the general condition of the patient.

External treatment, however, is far more important. An essential step in the local treatment is the systematic shaving or clipping of the hairs. The beard should be closely clipped with scissors, or, better still, shaved every 2 or 3 days. When suppuration is free, daily depilation should be practised.

When the inflammatory signs are marked, soothing lotions—such as lotio nigra or saturated solution of boric acid, or ointment of cold cream, oxid of zinc ointment, etc.—may be employed. Most cases, however, require more stimulating applications.

As in most follicular inflammations, sulphur is of great value here. It is best employed in salve form, although lotions may also be used:

℞. Precipitated sulphur, gr. xxx to ʒ j
Petrolatum, ʒ j.

A mercurial ointment often acts efficiently:

℞. Ammoniated mercury, gr. xv to xxx
Petrolatum, ʒ j.

The following formula is highly spoken of:

℞. Ichthyol, ʒ j to ij
Petrolatum, ʒ j.

A lotion of bichlorid of mercury, 1/4 to 1 grain to the ounce, sopped on frequently, is often followed by good results.

Ichthyol is of value especially when introduced by cataphoresis, a 10 percent solution at the cathode. Pyoktanin introduced in the same way is also advocated. Sodium sulphite in solution with glycerin and water applied locally is recommended. Copper sulphate as a lotion combined with zinc sulphate is highly praised. The X-rays have proved efficacious.

SYMPATHETIC OPHTHALMIA.—An inflammation of the ciliary body, iris, or choroid, or a combined inflammation of any or all of these in one eye, due to injury in the other eye.

Cause.—The usual cause is an injury to the ciliary body, or incarceration of the ciliary body and iris in a scleral wound. A foreign body in one eye, causing cyclitis, is often followed by sympathetic inflammation in its fellow. The manner in which sympathetic inflammation is produced is not clearly understood. Mackenzie supposed that sympathetic inflammation passed from the retina of the injured eye through the chiasm, to the retina of the other eye. Deutschmann suggested that germs travel along the optic sheath through the chiasm into the sheath of the opposite nerve, and thence into the eye. Bacteriologic infection of the sympathetically affected eye can rarely be proved. A more recent theory is that the path of irritation is from the first eye through the ciliary nerve to the ciliary ganglion; through the sympathetic root of the latter to the carotid plexus of the same side; then through the circle of Willis to the carotid plexus of the other side; and then in a centrifugal direction to the ciliary ganglion and the ciliary nerves of the second side. The time of outbreak of the secondary attack varies from 4 to 8 weeks after the original lesion, but cases have been reported from 2 weeks to 40 years afterward.

Symptoms and Diagnosis.—The premonitory symptoms are those of **sympathetic irritation**—asthenopia, photophobia, lacrimation, reduced accommodation, cloudy vision, and a mild pericorneal injection. The aqueous may be moderately opaque and the disc slightly reddened. As the stage of true **sympathetic inflammation** ensues, signs of inflammation corresponding to exacerbations of inflammation in the exciting eye are noticed. The ciliary region becomes extremely tender; cyclitis, iritis, or some form of keratitis becomes visible. The pain and cloudiness increase, and the visual acuity steadily diminishes. Synechiæ may form, and the intraocular tension becomes at first increased, and afterward diminished, as atrophy begins. It is the rule, after varying improvement and relapse, to find an adherent iris, cataractous lens, or atrophied globe from deficiency in vitreous, causing retinal prolapses and incurable blindness, despite all treatment. However, it is possible to retain some indistinct vision in favorable cases; but the process is always prone to relapse, and the inevitable result follows.

Treatment is preventive, and must interrupt the nervous connection between the eye first involved and the one showing signs of sympathetic inflammation. It has been suggested that this be accomplished by cutting the ciliary nerves. Several different methods have been proposed, one of which is to cut completely through the optic nerve, expose the posterior pole of the eyeball, and cut the ciliary nerves entering at this location. Evisceration has also been proposed. The only certain method of prevention and cure is **enucleation of the eye first affected.** This is so important a

subject that the concise rules laid down by Fick are given here as a guide:

1. If the first eye is blind, painful, and sensitive to pressure, enucleation is to be advised; it is to be urged if the patient lives a distance from a surgeon, and thus may be in danger of overlooking the beginning of sympathetic inflammation. If the patient will not consent to the operation, he should be told to seek aid at the first sign of visual disturbance or of inflammation in the other eye.

2. If the first eye has a foreign body in it, and is painful and sensitive to pressure, enucleation should be urged, even if the eye sees; it is to be supposed, of course, that the foreign body cannot be removed independently.

3. If the sympathetic inflammation, or even irritation, appears in the second eye, the first must be enucleated at once. If the first eye is not blind, but still retains a certain visual acuity, and is to some extent quiet, both patient and surgeon will hesitate at such radical proceedings. There is, however, no general rule for such a case. The visual acuity of the first eye must be carefully compared with the degree of irritation in the second; the more there remains to rescue in the second eye, the greater price can be paid by the first.

If the sympathetic inflammation is fully developed, enucleation proves of little value, and the pain must be lessened by cocain, atropin, warm compresses, and bandages, and the patient must be confined to bed. Mercurial inunctions and subconjunctival sublimate injections have been advised; iodids and mercurials may be given orally; but despite all treatment, the eye is generally lost.

SYMPHYSEOTOMY.—The subcutaneous separation of the symphysis pubis for the purpose of enlarging the pelvic diameters. The maximum degree of separation of the pubic bones is 7 cm. if injury to the sacroiliac joints is to be avoided. By this amount of separation there is gained in the true conjugate diameter 1.5 cm.; in the oblique diameter, 3.5 cm.; and in the transverse diameter, 3 cm. By this means safe delivery is secured, which under ordinary circumstances would be impossible.

Indications.—The operation is indicated in certain degrees of contracted pelvis. Unless the child is below the average size, it should not be attempted if the true conjugate measures less than 7 cm. Ordinarily, it would not be necessary with a conjugate above 8 cm. A rigid, nondilatable cervix would contraindicate the operation, as would also a narrow, contracted vagina. Marked varicose condition of the veins about the symphysis and vulva might give rise to dangerous hemorrhage.

Technic.—The steps of the operation are as follows:

1. The patient is thoroughly prepared for the operation, anesthetized, and placed in the lithotomy position.

2. A metallic catheter is passed into the urethra and pressed downward and to the right, so that injury to this structure may be avoided.

3. An incision, about 2 inches in length, is made in the median line just above the symphysis.

4. The incision is carried down through the fascia and the attachments of the recti muscles, separated sufficiently to permit the introduction of the index-finger along the posterior surface of the symphysis.

5. Using the left index-finger as a guide, the Galbiati knife is hooked under the symphysis, inclined a little to the left, and by a sawing or rocking movement the joint is divided from below upward and from within outward. If the joint does not separate, the knife should be reintroduced and the subpubic ligament divided.

6. To prevent too great a separation of the joint, the trochanters should be supported by assistants. Hemorrhage is usually profuse, but can be controlled by plugging the wound with gauze.

7. The catheter is now removed, and the child is delivered with forceps if engagement has occurred; by version, if it has not.

8. The wound is now united with a few interrupted sutures of silkworm-gut, and a firm pelvic binder is applied.

The patient remains in bed for 4 or 5 weeks. To secure union of the joint, she should remain upon her back with the limbs closely approximated. This position is best secured by a specially arranged trough-shaped bed, or hammock, or by the use of sand-bags extending from the axilla to the ankle.

Prognosis.—The maternal mortality of symphyseotomy at the present day is about 10 percent. On account of the close approximation of the limbs it is difficult to keep the parts perfectly free from the discharges. This, and the fact that the wound is so close to the genitalia, favor the development of sepsis after the operation. There may be some difficulty in walking, but this soon disappears. The rapid extraction of the child also favors injury to the soft parts. The infantile mortality is about 20 percent.

SYNCOPE.—A swooning or fainting. A partial or complete temporary suspension of the functions of respiration and circulation.

Causes.—Syncope may be due to a condition which interferes with the action of the heart, either intrinsically, through the nervous system, through the blood, or through more than one of these channels.

When intrinsic, cardiac complications, especially fatty degeneration, may be causative. Compression of the heart from diseased conditions or by tight articles of dress, excessive natural or artificial heat, or certain drugs or poisons may be provocative of syncope. The most common nervous cause is uncontrolled emotion, such as fear, joy, or grief. The reflexes are also sources of provocation, from the effects of irritant or intestinal poisons, worms, scybala, etc. Of the causes connected with the blood, that of hemorrhage is the most common, while chronic anemia and chlorosis are often accompanied by it.

Fainting also occurs from hunger and starvation, railway shocks, grief, painful lesions, and cerebral concussion. Fainting from overheated air is partly due to the direct effect of heat upon the circulation, partly to interference with respiration, and partly to the effect on the heart of carbonic acid and other excrementory products.

The duration of the several stages of shock varies from a few seconds to hours.

Prognosis.—The most common termination is recovery, but death may occur.

Fatal syncope has occurred at the height of an attack of diphtheria and in chronic valvular heart-disease, while there is a tendency to syncope in myocardial disease. Death by syncope may follow hemorrhage or may be due to thrombosis or embolism of the pulmonary artery or to pneumothorax. Sudden and fatal syncope from serofibrinous effusion in acute pleurisy may be induced by such slight exertion as getting out of bed.

Diagnosis.—Syncope must be differentiated from apoplexy, from concussion of the brain, from shock, and from poisoning of many kinds, including poisoning by gases and by alcoholic liquors. The character of the pulse will distinguish between those conditions which have their origin in the brain and those from poisoning (unless due to poisoning by heart depressants). Hysteric faints, not cardiac, are readily diagnosed by the pulse, which is of good volume and force in these cases. Shock usually produces a degree of syncope. See SHOCK, COMA.

Treatment.—Two indications are to be met: (1) The removal of the cause of the faintness, and (2) the restoration of the action of the heart. The patient should be placed flat on the back, and all neck or chest constriction, from clothing or otherwise, removed. The atmosphere should be as pure as can be obtained by throwing open windows, doors, etc., or by removal to the open air. Any causative hemorrhage must be checked, and any other cause must be removed. Cardiac stimulants are to be employed. Alcohol, as brandy, whisky, or strong wine, may be given, and ammonia or smelling salts should be inhaled. Cold water may be dashed over the face. Amyl nitrite is very efficacious in anemic subjects. Atropin hypodermically, 1/100 to 1/60 of a grain, is a valuable remedy. The oil of cinnamon is a powerful stimulant. Tincture of nux vomica in 5-minim doses is of benefit in extreme cases of cardiac syncope approaching heart failure. The compound tincture of lavender is stimulating and effective. Galvanization to the pneumogastric nerve, if practicable, is recommended, but still better is the electric brush swept over the abdomen and chest. ARTIFICIAL RESPIRATION (*q. v.*) is not to be neglected. Most cases will revive spontaneously.

SYNDACTYLISM.—See WEBBED FINGERS.

SYNOVITIS.—See JOINTS (Diseases), JOINTS (Injuries).

SYPHILIS. Synonyms.—Lues venerea; morbus gallicus; pox; "bad disorder." Fr., *Vérole.* Ital., *Sifilide.* Ger., *Lustseuche; Krankheiten der Französen.* Span., *Sifilis.* Swed., *Radezyge.*

Definition.—Syphilis is a general infectious disorder, transmitted from one individual to another both by contact and inheritance, chronic in course, and displaying a more or less determinate sequence involving one or several of the organs of the body. It is classed with the infective granulomata, and it is due to the toxic effect of the invasion of the bodily tissues by a morbific germ.

Etiology.—The spirochæta pallida or treponema pallidum of Schaudinn is in all probability the cause. This work of Schaudinn has been confirmed by Metchnikoff and other observers. Schaudinn considers that the spirochæta pallida (treponema pallidum) belongs to the protozoa rather than to the bacteria and therefore must not be classed with the spirilla. It is found in the primary and secondary lesions of acquired syphilis and in the organs of a

The Spirochæta refringens is the larger and more darkly stained organism, while the lightly stained and more delicate parasite is the Spirochæta pallida (*Treponema pallidum*). From a chancre stained with Wright's blood stain.—(*Hirsch—by Rosenberger.*)

congenitally syphilitic child, and has been demonstrated in the blood stream. For its inoculation a raw surface or abrasion is required. The infection is usually transmitted through the secretions of the primary or secondary lesions, but sometimes through the blood of the syphilitic patient. It is probable that the tertiary lesions are also capable of conferring the disease. Normal secretions unless contaminated with secretions of the lesions are not infectious. The disease may be transmitted, however, by the spermatozoa or ova of syphilitic patients.

Though the majority of cases of acquired syphilis result from sexual intercourse, the infection may be conveyed by drinking utensils, infected hands, lips, or by handling infected patients. The syphilitic child may infect the wet-nurse. Rarely the disease has been a quired by vaccination.

The Spirochæta Pallida.—This organism does not readily take up anilin dyes. A reliable stain for it is the Giemsa stain, freshly prepared: 12 c.c. of eosin solution (25 c.c. of 1 percent eosin solution in 500 c.c. of water); 3 c.c. of a 1 to 1000 aqueous solution of azur I; 3 c.c. of a 0.8 to 1000 aqueous solution azur II. One drop of this solution added to 1 c.c. of water is used as the stain, the specimen being kept in the stain for 18 hours.

The Wassermann Reaction.—The *serum diagnosis of syphilis* depends upon certain principles. If the washed red corpuscles of the sheep (antigen) are added to heated serum of a rabbit, previously immunized with washed red corpuscles of the sheep (amboceptor), and fresh guinea-pig

serum (complement) thus forming the "hemolytic series," hemolysis occurs. Bordet and Gengou showed that when emulsions of bacteria are mixed with inactivated serum and complement, hemolysis does not take place by reason of the anchorage of complement to the bacteria which prevents union of the red cell and complement through the ambocepter. This phenomenon has been applied by Wassermann to the diagnosis of syphilis. As in the immunization of the rabbit, so in syphilis, amboceptors are formed. When the blood serum of the monkey, made inactive or immune by previous syphilitic infection, was added to human syphilitic serum, no hemolysis occurred, showing that the monkey serum must have contained antibodies.

Method.—To the syphilitic antigen (extract of syphilitic organs) are added (1) the complement (fresh guinea-pig serum). (2) the suspected serum heated, (3) the amboceptor (heat-inactivated rabbit's serum), (4) the washed red corpuscles of the sheep, and the mixture is subjected to the action of incubator temperature. No hemolysis occurs by reason of the complement having been absorbed in the hemolytic series, the antigen and the serum tested being homologous. Such reaction is called positive.

The Noguchi Modification.—Recently Noguchi has modified this reaction by using human instead of sheep corpuscles in the hemolytic series. He has also introduced test papers saturated with antigen, complement and amboceptor. His method is as follows: An antigen paper is applied to a definite quantity of the suspected human serum and fresh guinea-pig serum is added. After being subjected to incubator temperature, it receives the addition of the hemolytic amboceptor paper and a definite quantity of washed human blood corpuscles. See Luetin Reaction.

Chancre (Initial Lesion, or Sclerosis).—A chancre is a modification of the sound or pathologically altered skin or mucous membrane occurring after syphilitic infection, and displayed after an incubation period, characterized by a circumscribed sclerosis and accompanied by an enlargement and induration of neighboring glands. The sole constant characteristics are: (1) An incubation period preceding its appearance—averaging between 10 and 30 days, ordinarily betwen 21 and 26 days, called the period of first incubation; (2) a sclerosis of the base of the lesion; (3) primary adenopathy, an enlargement and induration of the glands in nearest anatomic relation to the chancre. Every such initial lesion means a syphilis, mild or severe, actually present. Chancres may be represented at one time or another by every recognized lesion of the cutaneous surface, including the superficial erosion, the oftenest ignored and yet the commonest of chancre symptoms; the papule, the common result of inoculation of the skin as distinguished from that of the mucous surface; an ulcer, the result of local irritation, which may be shallow or deep. Mixed chancre exhibits at the outset all the features of the chancroid, but later becomes specifically indurated at the base, and is followed by a general syphilis. Another mixed variety is the chancre of syphilitic origin later infected with microorganisms. Persons infected with syphilis have usually but one attack in a lifetime, and most, if not all, of the so-called chancres of the syphilitic are without question gummatous. The initial lesion may occur upon any portion of the body surface, the genital region being most often involved merely because of the frequency of transmission during the sexual act. Extragenital chancres are not a rare occurrence. The lesions are seldom multiple; most often they are single, differing from the soft chancre, which spreads from one point to another on account of the autoinoculability of its discharge.

The induration of the initial lesion is one of its constant features. This may precede or follow the evolution of the chancre, or it may first be observed at the moment of detection of the sore itself; but sooner or later it wholly disappears. From the number or appearance of the lesions no prognosis can be made as to the severity or mildness of the ensuing disease. Chancres may or may not persist until the evolution of the systemic disease. They seldom leave scars, on account on their indisposition to undergo ulceration.

Diagnosis.—*The chancroid* is usually a pustular lesion, is never indurated, is usually multiple; the adenopathy is usually represented by a single bubo; and the secretion is indefinitely auto-inoculable.

Herpes progenitalis lasts but a few days, is essentially vesicular, and the cause may often be determined without great difficulty in systemic derangement.

Balanitis is always short-lived, and yields readily to treatment; produces itching and burning; there is no induration or glandular complication and no ulceration.

Venereal warts are never indurated, rarely ulcerate, survive for long periods of time, and show no adenopathy.

Epithelioma occurs commonly after middle life, is of long duration, inactive, and noninflammatory.

Molluscum epitheliale is never ulcerated, indurated, inflammatory, or the seat of evidence of any acute process; and cheesy masses can be expressed from the orifice of the sebaceous gland involved.

Lichen planus presents lesions always papular, never indurated or ulcerated, or accompanied by glandular enlargement; and it is usually multiple.

Treatment.—Strict observance of cleanliness, in order to avoid any irritation of the sore, must be observed. Cleansing with warm water and hot borated solutions, followed by bland dusting-powder and the avoidance of salves and unguents, are the principal points to be observed. Mercury should be administered by the mouth when the diagnosis is satisfactorily established, but not before. The adenopathy ordinarily requires no treatment, unless painful, when frequent ablution with hot water is the best and most grateful method of treatment, followed, when needed, by a weak mercurial salve well rubbed into the overlying skin.

Division of constitutional syphilis into primary, secondary, and tertiary stages is now abandoned

or largely modified, there being ordinarily no such definite demarcation in its manifestations. The majority of syphilitic histories may be traced within the four following divisions:

1. Benignant syphilis with mild and transitory symptoms. In these cases a slight efflorescence upon the abdominal surface, a few days of malaise, and the disease is at an end, irrespective of any treatment whatever. This is rare.

2. Benignant syphilis with relapsing or persistent superficial symptoms. This occurs in a large number of all cases occurring in the white race. Typical chancres are followed by superficial lesions without the production of any permanent results of the process. Patients of this large class, as a rule, entirely fail to exhibit symptoms of the type described as "tertiary."

3. Malignant syphilis with relapsing or persistent profound symptoms. The malignancy of these cases is declared in the deterioration of the tone of the system, in the production of cachexia, in the production of gummata, which resolve under appropriate treatment; or, when degeneration occurs, the repair is either good, or the damage resulting is so slight as not to interfere with bodily health. In this class the best results of treatment are exhibited.

4. Malignant syphilis with relapsing or profound lesions that are ultimately destructive. Here the disintegrating and ulcerating gumma destroys whatever tissue is attacked, and at times pushes its destructive forces to a fatal result. Syphilis, however, often mutilates, but rarely kills. In the majority of malignant cases the rapidity of progress of the malady is conspicuous.

The determining influences that result in these divergences are of the highest importance. First, a soil rendered favorable by other diseases or by malnutrition; second, neglect of early and proper treatment. The implantation of the germ of syphilis upon a system contaminated with tuberculosis, struma, and such cognate disorders as rickets is much rarer than is generally supposed.

The Evolution of Syphilis Subsequent to the Chancre.—The signs of a gradual intoxication are progressively apparent. The skin assumes a peculiar hue; there are often rheumatic pains, headache, backache, lassitude, neuralgia, and in some cases jaundice. The number of the red blood-corpuscles decreases and the leukocytes increase. Thermal variation may be absent or may be either slight or pronounced. Fever is more often observed in the cachectic and weak than in the strong. The lymphatic system exhibits characteristic changes; the glands become enlarged, soft, and voluminous, as distinguished from the densely indurated buboes accompanying the chancre. At a given moment this may be the sole appreciable symptom. They are usually painless and have no tendency to degenerate. Resolution is by the ordinary absorptive process. Syphilitic cachexia may occur either early or late, may be produced solely by the disease, and may be relieved greatly by properly directed medication, and may also be induced or aggravated by the injudicious employment of mercury.

Syphilis of the Skin.—A study of the syphiloderms is a study of the changes impressed by the infective process upon the simple manifestations of all skin-diseases. The early cutaneous symptoms are usually symmetric, but as the disease progresses, they exhibit a greater tendency to assymmetry. Although the terms "copper-colored" and "raw-ham tint" have been employed to designate the special hues of the syphilitic exanthem, there is displayed no color which may not at times be recognized in nonsyphilitic subjects; but the color with the other picture presented is usually highly suggestive. Multiformity is a characteristic of syphilis shared by but few other maladies. The arrangement of the syphiloderms in groups having the outline of a circle, either complete or in segments, is also highly distinctive. Itching and pain are ordinarily absent, but in some lesions, particularly in condylomata, the itching may be severe. Situation modifies the espression of the local manifestations. Pustules are often seen upon the scalp and on the face; papules, over the neck and brow; secreting lesions, around the mucus-outlets of the body. Papules are usually ham-colored, and have a tendency to scale at the apex. Tubercles are generally grouped, and tend to ulcerate and to crust. The crusts are usually bulky. Scales are commonly thin, and of a dirty whitish hue. Ulcers have a soft base, undermined edges, and a sloughing floor with purulent or hemorrhagic secretion. Pustular lesions are usually, if not always, due to secondary infection with pyogenic microbes. Scars, when recent, are generally pigmented; but when old, are of a dead white shade, with flaky, wrinkling surface.

Classification of the Syphiloderms.—

1. Macular
   - (*a*) Pigmentary.
   - (*b*) Erythematous.
   - (*c*) Purpuric.
2. Papular
   - dry
     - (*a*) Miliary.
     - (*b*) Lenticular.
   - moist
     - (*a*) Mucous patches.
     - (*b*) Condylomata.
3. Pustular
   - (*a*) Miliary.
   - (*b*) Lenticular.
4. Tubercular.
5. Gummatous.

1. **Macular Syphiloderms.**—The pigmentary variety occurs as a distinct network of macules, the pigment being gradually diminished, commencing in the center of each deposit, until at last it is wholly removed. This condition is most common in the earlier stages of the malady, and frequently in the uncleanly and negligent. The normal quantity of coloring-matter may remain after involution, or a true vitiliginous atrophy of the pigment may follow. The erythematous syphiloderm is the most common, the most benign, the earliest, and the most classic of the skin symptoms of the disease. It may be limited to the regions covered by the clothing, and it is for the most part unaccompanied by any subjective sensation. It usually appears between the sixth and seventh week, and is of a dull shade of yellowish-red, fading

under pressure. As a rule, the eruption fades under treatment in a week or 10 days. The circinate arrangement may be conspicuous. Purpuric lesions are most commonly seen in the inherited form of the disease, though they are not rare in adults. It must be remembered that iodid of potassium is capable of producing purpura of the skin. When due directly to the disease, and not to the drug, it is a somewhat grave symptom.

2. **Papules.**—Papules are among the most common of the syphiloderms. They vary largely, according to the site of each lesion. Upon the exposed surface of the skin they are usually dry and squamous; upon apposed surfaces they enlarge, flatten, and secrete; upon mucous surfaces they form a mucous patch. Dry papules may be miliary, or from pinhead-sized to bean-sized or larger. When resolution occurs, the papule flattens to the level of the skin, leaving a pigmented macule, which is apt to be exceedingly rebellious to treatment and slow to disappear. When developing upon the palms and the soles, papules have a characteristic aspect and career, and will not readily be confounded with other disorders. The papule in this situation produces a circumscribed thickening of the skin, which scales in the epidermal portions, and in extreme cases induces an ulceration in the region of each papular thickening. Papules sometimes linger for years as almost the sole symptom of the disease. The moist papule upon the mucous membrane becomes the **mucous patch**, which is pathologically identical with the moist papule of the skin. Moist papules occur on the skin in regions where the conditions are similar to those of mucous membranes with respect to heat, moisture, and the apposition of surfaces. On the mucous membranes they are moist, secrete a thin mucus, are offensive, and their secretion is highly contagious. Occasionally they develop into large vegetating masses; at other times they ulcerate. Condylomata are hyperplastic, moist papules, and are either flat or pointed. The flat condyloma is seen only in syphilitic subjects, and is a distinct symptom of the disease. Condylomata are found most frequently about the anus, and are usually the seat of a tormenting pruritus. The pointed wart is seen not only in syphilis, but in other venereal diseases as well. Condylomata are often compared in appearance to a cockscomb.

3. **Pustular Syphiloderm.**—Under this title are included all fluid-containing lesions of the skin—vesicles, pustules, and bullæ. When they appear, some accident has intervened to divert the career of the papule into singular channels—such as medicaments, pus microbes, neglect, filth, or parasites. They are extremely rare in properly treated patients. The lesions may be miliary, pinhead-sized to bean-sized, or confluent. They have frequently been mistaken for the lesions of smallpox, which they greatly resemble. The cicatrices left from the smaller lesions are rarely conspicuous; but from the larger and confluent sores the scars may be indelible. In the confluent variety there is distinct circular grouping of the pustules, and an ulcerating ring forms. There may be but few such lesions forming a single group. When repair ensues, the crusts fall, the ulcers granulate, and cicatrization concludes the history.

From *varicella* and *variola* this manifestation of the disease may be distinguished by the fever, by the activity of the lesion, by the umbilication and multiplicity of the sores; from *acne*, by the region invaded, the latter being usually limited to the face and upper trunk.

4. **Tubercular Syphiloderm.**—The tubercle is with difficulty distinguished from a gumma; clinically and pathologically there is little difference between the two lesions. Tubercles, ordinarily more superficial, are more apt to resolve, develop at an earlier period, are more numerous, and are more commonly grouped. Tubercles ordinarily occur after a lapse of from 2 to 10 years. They are firm nodules, copper-tinted, ordinarily arranged in portions of circles. They may be dry or atrophic, resolving beneath an unbroken epidermis, leaving a pigmented macule that fades and leaves an indented scar. They may be ulcerative, the upper portion of the small tumor being destroyed, involving either the small circumscribed area or producing broad, palm-sized, and larger destruction of tissue.

5. **Gummatous Syphiloderm.**—Gummata of the skin are at first uncolored elevations; later they become livid, as the integument becomes thinned to a point where bursting of the contents occurs through its envelope. They are usually late lesions, occurring from 2 to 5 years after the chancre, but may develop within a few months. They are most common on the leg; also common on the shoulders and back. The bones of the part invaded frequently suffer, causing extensive mutilation, especially about the face. Not the least conspicuous among the distinctive features of these severe ravages of syphilis is the extraordinary extent to which, when properly treated, repair ensues—a distinction of the highest value in respect to diagnosis.

Serpiginous and vegetating syphiloderms are conditions due to peculiar forms assumed by lesions previously mentioned, and are not special cutaneous expressions of the disease.

Syphilitic Affections of the Hair.—Syphilitic alopecia may be due to the action of the disease either upon the nutrition of the hair or directly upon the scalp. The most common form, however, produces no structural change in the integument. The loss of hair may be partial or general, affecting at times only the hair of the scalp; at other times, that of the entire body. As a rule, bare patches in areas from fingernail-size to palm-size occur upon the scalp. The lack of symmetry is noticeable; the hairs of one eyebrow for example disappearing while the other eyebrow remains intact. When the integument undergoes structural changes, the hair follicle itself is frequently destroyed, preventing a return of the hair; whereas in the simpler form already mentioned, the loss is not without remedy.

Syphilitic Affections of the Nail.—Syphilitic onychia and paronychia are not infrequent, and may coexist. There may be superficial exfoliations, fissures, or ulcers; the nail fold, the nail

groove, or the matrix may be the seat of deep and ill-defined infiltration. The course is commonly indolent; at times, exceedingly painful. The odor is highly offensive and the secretions are contagious. The nail may be lost entirely or partially, and the new-formed nail may be correspondingly misshapen. This complication is often a portent of a grave syphilis, and is likely to occur in middle-aged patients with weakened constitutions. When the change is confined to the nail itself, there may be either atrophy, and a characteristic worm-eaten appearance, or hypertrophy with perceptible thickening.

Syphilis of the Mouth and the Tongue.—These lesions correspond strictly to those already studied as of occurrence in the skin, modified simply by peculiarities of site and by such habits as using tobacco, holding pipes, cigars, and toothpicks in the mouth, and by the drinking of hot or highly spiced liquids and the use of salted foods. Carious teeth pressing upon the tongue and cheeks are also frequently productive of such lesions. The macular syphiloderm produces an area of vivid or dusky redness, which may result in erosion or ulceration, but which disappears under proper treatment. The papular syphiloderm is here represented by the **mucous patch** of varying size, slightly raised above the general level. These patches are usually painful, and are succeeded by superficial erosion and ulceration, particularly at the angles of adjacent surfaces, such as the outer angles of the lips, where both the mucous and cutaneous surfaces may be involved. Gummata occur in the tongue, usually single, breaking down rapidly into ragged ulcers. Usually, these lesions are present in persons who are large users of tobacco, especially in chewers. In severe cases the results may be equaled only by the extensive ravages of cancer in the same region, but the repair wrought by skillful treatment is extraordinarily happy in results.

Syphilis of the Nasal Passages.—In this tract chancres are rare. The lesions present are mucous patches and gummata. The destruction is often extensive, the hard and soft palates being perforated or destroyed or passages being obliterated by cicatricial occlusion. The disease may thus extend to the meninges of the brain. Mucous patches and gummata also occur in the pharynx, producing grave destructive results when the bone is invaded. In the larynx typically developed mucous patches are rarely seen, but erosions and superficial ulcers may be discovered over the epiglottis, the vocal cords, and other parts on laryngoscopic examination. Later, gummatous changes may produce more serious accidents. The resulting ulcers leave cicatrices which may prove harmless or may draw together the walls of the larynx or fasten the epiglottis to the tongue or to the pharyngeal wall. The chief symptoms recognized without laryngoscopic examination are the hoarse voice, cough, dyspnea, and symptoms due to imperfect aeration of the blood, varying from the mildest to the severest distress. In the great majority of cases the prognosis is favorable, restoration of the voice being secured even after well-nigh complete aphonia for months or years. In the trachea and bronchi syphilitic lesions resemble those upon the structures immediately above. The more deeply syphilitic lesions spread toward the lungs, however, the greater is the gravity.

Syphilis of the Bones.—Most of the changes in bone are due to gummatous deposits, either in the periosteum, between it and the osseous tissue, within the bone substance, or in the medulla. The lesions are commonly multiple, forming tumors varying greatly in size, which are exceedingly painful, especially at night. In fact, the nocturnal exacerbations are considered diagnostic, and are due to the warmth engendered by the bedclothing, which increases the tension between the tense periosteum and the unyielding mass of the osseous tissue. The course may be either complete involution or degeneration by softening, the tumor breaking at the center, leaving an ulcer with exposed bone at the base.

Syphilis of the Joints.—Synovitis and arthritis may involve one or more joints. The articulations are tender, painful, and hot, motion is limited, and there are generally pyrexial symptoms. Termination may be by resolution, by ankylosis, or by destruction of the joints. The knee and the sternoclavicular and scapuloclavicular joints are chiefly involved.

The tendons and tendinous sheaths may be involved in gummatous processes; the aponeuroses may also be involved. In the muscles gummatous infiltration may involve the muscle bundles, producing pain, sometimes permanent contracture, or atrophy; the latter condition may also result from involvement of the nerves supplying the muscle. Syphilitic pericarditis is rare. Gummata have been found postmortem in the septa and substance of the heart. Fibrous myocarditis of syphilis is due to invasion of the coronary arteries. Aneurysm of the heart has been recognized as directly due to syphilis, and also to the indirect results of its cachexia. The blood-vessels may be affected by a fatty metamorphosis, resulting in the formation of aneurysmal pouches; or the endothelium of the vessels may be thickened, producing an endarteritis obliterans. Gummatous periarteritis has also been observed in both the circumscribed and diffuse forms.

Considerable difficulty in discriminating between gumma and tubercle of the lungs has obscured the characteristic features of syphilitic disease. The latter, however, is found in the posterior and lower lobes of the lung oftener than in its apex; and on section the lung closely resembles the condition seen in simple pneumonia, its substance being firm and grayish or reddish. The absence of leukocytes is conspicuous. The absence of tubercle bacilli is, of course, of the greatest value in establishing a diagnosis.

Syphilis of the intestinal canal is rarely encountered save in the anorectal pouch, where gummatous deposits are found. Gummata are sometimes found in the liver of the subjects of syphilis, near the capsule or deeply set. The effect is frequently like that occurring in cirrhosis. It is rare that symptoms pointing unmistakably to hepatic

involvement are displayed during life. Syphilis of the spleen and pancreas is exceedingly rare. When these organs are involved, gummatous deposits of varying size are found.

In the anal region chancres are often mistaken for piles. The early lesions are usually flat papules, in consequence of heat and moisture becoming condylomata and mucous patches, which are rapidly developed. Syphilitic ulcers of this region are circular in outline, and have undermined walls and pultaceous floors, contrasting with the sharply cut, irregularly outlined walls and deep floors of tuberculous invasion.

Syphilitic stricture of the rectum, whether resulting from a proctitis leading to the specific complication, or from gummatous changes in the lower segment of the rectum, is more common in women than in men, and constitutes one of the most formidable of the complications of the disease. The lumen of the gut is interfered with in various grades, from those due to bands, bridles, or constricting rings around the organ to the severe grades in which the rectum is converted into a tortuous channel, interrupted by knobs and bridles and almost completely occluded. Relief is difficult in the absence of surgical interference, which may require division of the strictured portions of the gut by the aid of the electrocautery (often eventually valueless), by the production of an artificial anus in the groin, or by complete excision of the entire neoplasm. By the use of bougies relief may be secured for a time, internal treatment proper to the malady being at the same time instituted.

Gummata of the rectum may be single, multiple, or diffuse, occurring frequently in an annular form, producing the large majority of all rectal strictures.

Syphilis of the Genitourinary Organs.—Gummata developing in the corpora cavernosa are represented by nodules or, very rarely, by annular bands. Deep deposits in the urethra, as well as in the prostate gland and seminal vesicles, are quite rare. The epididymis and cord are occasionally invaded. The globus major and, more rarely, the globus minor become indurated, inelastic, and at times somewhat tender. Syphilitic orchitis is a frequent complication of late syphilis, the change occurring frequently without the knowledge of the patient. The gummatous infiltration may be circumscribed or diffuse, or there may be dense induration, suggesting the firmness of a marble. The size of the glands may be unaltered, or they may be either enlarged or shriveled. In other cases degeneration and bursting of the gumma result. Gummatous lesions of the vulva are not uncommon, while the vagina is rarely invaded. The cervix and os uteri may be the seat of either primary or consecutive lesions, which must be carefully differentiated from epitheliomata, polypi, and chancroids. The bladder is rarely involved. An acute nephritis due to syphilis may occur within a few months after infection, but recovery usually follows vigorous treatment. In late lesions lardaceous degeneration is characteristic. When both organs are involved, the prognosis is grave; but good recovery ensues frequently when but one organ is affected.

Syphilis of the Nervous System.—Changes in the nervous system due to syphilis may result from the effects of the disease upon the osseous system, upon the meningeal coverings of the nerves, upon the nerve-cells and fibers, or upon the vessels furnishing nutriment to the nerves. A fatal issue in syphilis can more often be ascribed to the nervous than to any other system. Gummatous deposit in the cortical portion of the brain is perhaps the most common involvement. An obliterating endarteritis may cause thrombosis and subsequent occlusion, or small aneurysms with subsequent rupture and cerebral hemorrhage. The symptoms are headache, with nocturnal exacerbation, possibly aggravated by pressure over certain points. The capriciousness and multiformity of the surface symptoms, however, are striking. Monoplegic or hemiplegic attacks indicate affection of the larger ganglia. Lesions of the crus, of the pons, and of the medulla are indicated by symptoms similar to those produced by other lesions of the same areas. Syphilis of the cord may produce bilateral spastic paralysis of the lower extremities, exaggeration of tendon-reflexes, contractures of muscles, rectum and bladder symptoms, and, in some cases, severe pains in the lower limbs. Syphilis is, without question, a precedent fact in a large majority of all cases of tabes and paralytic dementia.

Syphilis of the Eye.—Any of the ocular appendages—the eyelids, the lacrimal gland, the canaliculi, the sac, and the nasal duct—may be involved in any one of the early or late manifestations of syphilis. Syphilitic iritis is the most common of all luetic affections of the eye. The subjective symptoms are photophobia, lacrimation, deep-seated pain, and imperfect vision. There are noticed change of color, irregularity of the pupillary opening, sluggishness of the iris, and deep ciliary injection. The prognosis is good. Syphilitic choroiditis is next in frequency. The symptoms are clouding of the vitreous humor by specks on the membranes, diminution of ocular tension, pain, and amaurosis. Pure retinitis without choroiditis is rare. The fundus is misty, the papilla is obscured, and the disc is encircled by a grayish retina. Exudation and hemorrhages may occur. The optic nerve may be affected either within or without the cranial cavity. Bilateral choked disc indicates an intracranial lesion. When but one eye is involved, the disturbance may be wholly within the orbit. Atrophy of the optic nerve may result. Syphilis of the ocular muscles is due not to a specific myositis, but to intracranial lesion. Implication of the bony walls of the orbit, causing pressure upon the nerve, may produce exophthalmos and violent neuralgia. Abscesses may form and burst, leaving fistulous tracts to carious bone.

Syphilis of the Ear.—The external ear may be the seat of any of the cutaneous lesions of systemic syphilis. The membrana tympani is rarely attacked. Most syphilitic affections of the middle ear result directly from disorders of the nasal pharynx and eustachian tube.

Hereditary Syphilis.—Syphilis may be transmitted from progenitor to offspring as a strictly inherited disease. **Colles' law** points conclusively

to the fact that syphilis of the child means syphilis of the mother, whether or not the mother betrays other symptoms of the disease. It cannot always be determined whether such women have been infected with syphilis directly, from their husbands, or indirectly, from the syphilitic contents of the uterus. If, however, the mother is without syphilis, the child commonly escapes. The period of pregnancy beyond which the mother cannot transmit her disease to her unborn child is not fixed. After the sixth month, the child probably escapes. The question whether inherited syphilis can be transmitted to the third generation can, for the immense majority of all cases, be answered in the negative. The question respecting acquisition of syphilis later in life by the subject of inherited disease is to be answered in the same manner. A few cases have undoubtedly occurred in which the victim was not certainly protected from a second attack. See LUETIN REACTION.

Syphilis of the Placenta.—In some cases of undoubted syphilis of the offspring the placenta has been found wholly free from morbid symptoms, while in other cases the villi are represented by gummatous masses, and the vessels of the cord have been more or less obliterated. It is a matter of importance to note that the liquor amnii of the woman bearing a syphilitic fetus is capable of communicating the disease to the accoucheur.

Symptoms of Hereditary Syphilis.—A series of pregnancies resulting in abortions, first at an earlier and later at a more advanced stage of gestation; these succeeded by one or more miscarriages, and the latter by the birth of a mature child surviving but a few hours, furnishes a typical history of syphilis of the mother. Eventually, a child may be born apparently healthy at birth, but before the fourth month may develop symptoms of inherited disease. The mortality in these cases is between 60 and 90 percent. About seven-eighths of diseased infants exhibit symptoms of the inherited malady before the termination of the third month. Children showing symptoms of the disease at or about the age of puberty have, in all probability, really betrayed evidences of syphilis in infancy that were overlooked.

The cutaneous lesions in a fetus aborted as the result of syphilis are maceration of the skin and bullæ filled with ill-conditioned serum. A viable child may be born with a specific exanthem more or less generally evolved. An infant under the average weight, weazened, yellow-tinted, snuffling, with an aged appearance, with blisters on the fingers and toes, a circlet of papules about the mouth or anus, with a feeble cry and obvious weakness, enables the practitioner to make a diagnosis at a glance. In these infants the syphiloderm may be macular, papular, or tuberculous. The nails, hair, glands, bones, and genital organs may be affected. The saber-blade deformity of the tibia is characteristic. The teeth, as described by Hutchinson, are characteristically notched, particularly the central upper incisors. (See TEETH IN DIAGNOSIS). The pharynx, larynx, trachea, and bronchi may be the seat of changes that may destroy the perichondrium or cartilages. The liver may be the seat of miliary or of larger sized and diffused gummata. The spleen is frequently enlarged. The kidneys may present evidences of lardaceous degeneration. The nervous system may suffer in any portion, resulting in mental states varying from feeble-mindedness to complete idiocy. With the exception of retinitis and optic neuritis, the eye and ear are subject to most of the disorders of the acquired disease.

Treatment of Syphilis.—Attention to the general health far outweighs in importance the question of drugs. An ample supply of nutritious and digestible food; alcoholic beverages in wise discretion, according to the judgment of the practitioner; daily sponging with salt water—cold, if the patient is vigorous—with rubbing with coarse towels afterward, are important aids to a favorable issue. The use of tobacco invites mucous patches in the mouth, as does any other irritation, such as the use of chewing-gum, constantly holding toothpicks in the mouth, and the presence of carious teeth. Diversion of the mind, outdoor living, care of weak eyes, of hernia, or of hemorrhoids, all have distinct value. Delay in instituting systemic treatment until the fullest recognition of the disease has been established in no way jeopardizes the future of the patient or his amenability to the later management of his malady. In fact, an early and frank efflorescence is an augury for good in an otherwise healthy subject. The length of time during which treatment should be kept up varies according to the health before infection, the management during treatment, the virulence of the infection, and the surroundings of the patient. Most patients practically recover after from 2 1/2 to 3 years.

Mercury holds the most important place among drugs esteemed efficient both for the relief of the symptoms and for the radical cure of the disease. Its preparations, in the order of their value, are the protiodid, the bichlorid, the biniodid, the tannate, blue pill, calomel, and the gray powder. It is well to begin with an average dose of the metallic salt, to be increased according to indications. The patient should gain in weight, and should digest his food with appetite and profit. The protiodid may be given in doses of from 1/10 to 1/3 grain after each meal, combined with Vallet's mass or the citrate of iron and quinin. Whenever such a course seems desirable, any one of the other preparations of the metal may be substituted for the protiodid; for instance, the bichlorid 1/60 to 1/12 grain; the biniodid, 1/50 to 1/16 of a grain; the tannate, 1/2 to 1 grain; bluepill, 1/4 to 1 grain; calomel, 1/10 to 1/4 grain; and the gray powder, from 1 to 5 grains. It is believed that, when all progresses satisfactorily, the patient who secures complete immunity from symptoms of his disease in the first half year does better when no remedy is administered save mercury. Other things being equal, he who has secured complete relief from syphilis without using the iodid of potassium has usually had either a mild or an exceedingly tractable form of the disease.

Iron is administered with decided advantage to the great majority of all patients affected with

syphilis, and should be used whenever not contraindicated. The iron and quinin citrate, from 3 to 8 grains before meals, or the muriated tincture of iron in combination with corrosive sublimate (of the latter, 1/60 to 1/30 grain after meals), may be used.

Inunction of mercury has the excellent recommendation of sparing the stomach, and is also of advantage in grave cases or in cases of emergency; also when there are persistent lesions refusing to yield to internal medication. The ointment, in 50 percent strength, combined with lanolin or vaselin, should be rubbed in until it has practically disappeared. Often it is desirable to give a course of 20 inunctions, after which the rubbing may be suspended while other treatment is pursued, the inunctions being renewed until the entire number advised is completed. New areas of inunction should be selected on successive days in order to avoid dermatitis. Such a dermatitis is, however, rarely serious. When it really seems to demand treatment, a simple dusting-powder or Lassar's paste usually suffices.

The mercurial vapor bath is both efficient and speedy, and in an emergency is capable of producing very rapid effects. Calomel or cinnabar, or the two in combination, may be selected. It is best given before bedtime, and should last for about half an hour. If debility is induced by the steaming, tonics, and even a generous glass of wine with the dinner, should be administered.

Hypodermic injections are employed more frequently than formerly. Rapidity of effect, the sparing of the digestive tract, simplicity, and cleanliness are contrasted with its danger, its liability to produce abscesses at the site of injection, cardiac and pulmonary symptoms after injection within a vein, considerable pain, exhaustion, and possible sudden death. If, nevertheless, the hypodermic treatment is selected, strict surgical cleanliness and asepsis are extremely important. Corrosive sublimate is usually employed, dissolved in a few minims of water suspended in olive oil or emulsified, and in the strength of from 1/12 to 1/10 grain. The method has not as yet shown results that warrant its adoption as a routine treatment, its disadvantages rendering its general adoption improbable. The well-known toxic effects of mercury—including salivation, dyspepsia, anemia, and symptoms simulating those of muscular rheumatism—must be carefully watched, for many symptoms popularly accredited to mercury are really due to the syphilis, and are wrongly imputed to the metal.

Intramuscular injections have come into prominence in the last few years, the gluteal region being the preferable site. Of the soluble salts, the benzoate and the binodid of mercury are most frequently used; of the insoluble the salicylate, calomel and gray oil.

Intravenous injections of soluble salts have proved valuable in the hands of some clinicians. See Intravenous Injection.

Arsenic has recently been advocated, alone or alternately with mercury. Of the three forms which have recently come into favor atoxyl, soamin, and arsacetin (*q. v.*), the first has been found to produce optic atrophy. The second, soamin, too has been reported to be dangerous. Arsacetin, the most stable and least toxic is probably the preferable drug. See Arylarsonates.

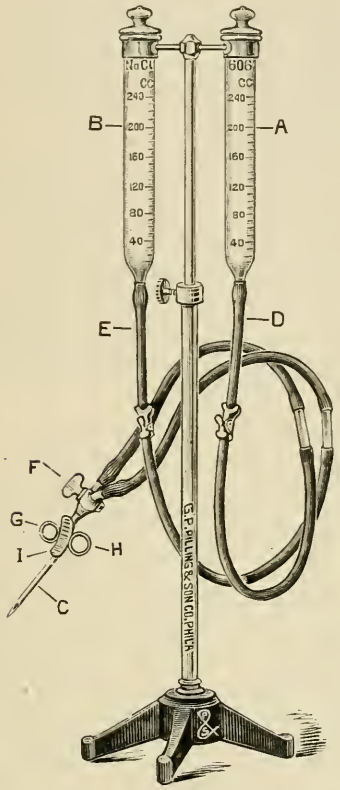
Salvarsan ("606").—The latest addition to specific therapy is Ehrlich's synthetic arsenic compound, arsenobenzol (dioxydiamidoarsenobenzol dihydrochlorid) called "606," as it was the 606th preparation tried. A single injection of a proper dose is reported to be as destructive to the spirochæta pallida as quinin is to the plasmodium malariæ. Within a day or two one injection of the drug will kill all the spirochetes in superficial lesions such as mucous patches or primary lesions.

The dose of "606" at present is from 0.45 to 0.6 gram injected subcutaneously below the scapula. "606" is an unstable yellow powder put up in vacuum tubes to prevent its rapid oxidization in the air. In order to make the injection painless—the acid solution resulting from the addition of water producing much pain—the drug is injected in the form of an alkaline salt (Alt) or, preferably, of a neutral base (Wechselmann's method). The neutral base is obtained by dissolving the dose to be given in 1 to 2 c.c. of sodium hydrate solution and then adding acetic acid, drop by drop. To the fine yellow precipitate—the base—that forms is added 1 to 2 c.c. sterile distilled water and then 1/10 normal sodium hydrate or 1 percent acetic acid, as required, until the reaction is exactly neutral to litmus. Ehrlich warns against the use of the drug in advanced disease of the heart or blood-vessels or in ocular disease involving the optic nerve. Attempts are being made to reduce to a minimum the toxicity of the drug. The latest improvement—Ehrlich's "hyperideal" is claimed to be but one-third as toxic as the original. While there is not complete unanimity on the byeffects of the drug, all the clinicians who have been testing it agree that it is not toxic to the human adult in doses of five to eight grains, and that it is a remarkable specific for syphilis.

Intravenous injection is now being used; it is claimed that this method is painless, more powerful in its effects upon the *Spirochæta pallida*, allows of more accurate dosage, and is not followed by so many bad after-effects.

Boehm's method of giving salvarsan intravenously is described by Hirsch as follows: "Two graduated glass containers of 250 c.c. capacity are used. Into one is poured 150 to 200 c.c. of sterile salvarsan solution. The other is filled with a like volume of sterile saline solution (made with sterile distilled water and chemically pure sodium chlorid). The saline solution is allowed to flow out of the needle so as to expel all air from the tube. The stop-cock is now reversed, allowing the salvarsan solution to flow out of the needle, thereby expeling all air from its tubing. The stop-cock is now reversed to its former position, until the saline solution is running in a slow even stream from the needle. The desired site of puncture is selected on the arm or at the elbow, and the needle is gently pushed or thrust through the skin into the vein. Meanwhile the saline solution is continu-

ously running from it. The needle is held at about an angle of 10 to 15 degrees to the skin surface, depending on the prominence and caliber of the vein. Care must be exercised not to push the needle through both walls of the vein. This can be avoided by not introducing too long a surface of the needle into the tissues.



The patient's arm having been carefully cleansed, a ligature in the form of an ordinary soft rubber catheter or tubing is tied around the middle of the arm, above the selected site of puncture, and the patient is requested to tighten the fist so as to make the superficial veins more prominent. Some prefer to expose the vein in all cases.

As soon as the needle has entered the vein, the rubber ligature is released by an assistant, the stop-cock of the needle is reversed, and the salvarsan solution flows through the needle into the vein. Hence there is no danger of any salvarsan solution getting into the subcutaneous tissues. The intravenous injection must be given slowly, not less than ten minutes being spent in the process; and the solution must be quite warm when poured into the container so as to allow for its cooling when flowing into the apparatus; when it enters the vein, the solution should be about the temperature of the blood. An ideal intravenous injection is painless."

Iodin and its compounds stand next after mercury in value. The following are conditions in which it is wise to employ them: First, in attempts to resolve gummatous lesions; second, when the patient is intolerant of mercury, or when he cannot be made to gain in weight and appetite during youth; third, when the patient is being subjected to the action of mercury by external use; fourth, as an alternate medication to mercury. Iodin is the one remedy earliest and most often resorted to by the ignorant, and it is the one which is last used, and then most effectively, by the expert. The dosage depends almost wholly on the emergency presented. Ordinarily, it may be administered in 5-, 10-, or 20-grain doses; but as high as 600 grains, and even more, of the iodid of potassium have been given in 24 hours with favorable results. It should be stopped or reduced upon the occurrence of any symptoms of iodism, constipation, or bladder trouble, or as soon as the immediate effect in view is secured. As a rule, the toxic effects of the drug speedily disappear when the exhibition of the remedy is suspended.

"Mixed Treatment."—This term designates a method by which mercury and a salt of iodin are administered at the same time in a single dose. A 6-ounce mixture containing from 1 to 3 grains of the biniodid and from 1/2 to 2 ounces of the potassium iodid may be advantageously given in teaspoonful doses after meals. One of the bitter tinctures may be added to produce a tonic effect. The corrosive sublimate may be substituted in equal amount for the biniodid.

The treatment of syphilitic lesions as they are presented in the several organs of the body:

Syphilis of the skin yields to systematic treatment, but at times local treatment is of value. The erythematous and papular syphiloderms may be sponged with warm boric solution and anointed with an unguent having vaselin or cold cream for a basis, with from 5 to 20 grains of calomel or white precipitate to the ounce; or the following may be used:

℞.	Mercuric chlorid,	gr. iv
	Alcohol, Tincture of benzoin, Tincture of tolu, Glycerin, each,	ʒ j
	Rose-water, enough to make	℥ iv.

For the papular and scaling lesions nothing is better than mercurial ointment in full or reduced strength. Condylomata should be washed with deodorizing solutions of chlorinated soda or boric acid, after which they are to be dusted with equal parts of calomel and starch or with boric acid. Pustular lesions, especially over the face, require careful attention. Washing with hot boric solution, followed by touching with a solution of corrosive sublimate, 1 or 2 grains to the ounce of benzoin, should be followed by dusting with calomel, europhen, or boric acid.

Early syphilitic alopecia should be treated by shampooing with tincture of green soap 3 or 4 times a week, followed by an unguent of white precipitate or calomel, 5 grains to the ounce of vaselin, or 1 dram of precipitated sulphur and 1 grain of cinnabar to the ounce.

Mucous patches should be touched daily with a silver nitrate solution, or with the solid stick. This should be done by the physician. For individual use, a lotion or gargle may be employed, such as 1 dram of potassium chlorate and 1/2 ounce each of honey and tincture of myrrh to 6 ounces of distilled water, diluted as required. When the palate is involved, medication should be prompt, both internal and local, and should be pushed to the largest tolerated doses.

In cases of **ozena** a vapor from the following solution should be snuffed through the nostrils:

℞.	Phenol,	ʒ j
	Tincture of iodin,	ʒ iv
	Ammonia water,	ʒ ij
	Cologne water,	ʒ iv.

Pharyngeal lesions may be treated with medicated sprays, caustics, the galvanocautery, or the knife.

The nails, when involved, should be bathed in warm borated water, followed by a weak mercurial salve or dusting-powder.

Syphilis of the bones and periosteum calls, in general, for the iodid of potassium internally, with mercurial unguents or plaster over accessible nodes or tumors. Any sequestrum should be removed when completely separated.

In all cases of **visceral syphilis** there is urgent need of systematic tonics, together with antisyphilitic treatment.

Lesions of the rectum and anus call for the iodids in large doses.

Strictures should be dilated by rubber bougies; and when the result of such treatment is only temporary, surgical interference is indicated.

When the epididymis or body of the **testicle** is involved, the iodid internally and abstention from sexual intercourse usually give good results.

Lesions of the nervous system require the largest tolerated doses of the iodids, with inunctions of mercury at the same time. Tonics, a highly nutritious diet, and daily sponging with hot water are valuable.

For treatment of the **eye and ear,** the reader is referred to the special articles on diseases of these organs. See Ear (Diseases), Iritis, Retinitis, etc.

The special treatment of the **syphilitic pregnant woman** is by mercurial inunctions, together with the mixed treatment. When the syphilitic infant is at the breast, the treatment of the mother is not to be neglected. Only upon very strong evidence should direct treatment of a **syphilitic infant** be begun, since even after the birth of intensely syphilitic fetuses and a series of abortions there are brought into the world children who never exhibit signs of the disease even when both parents have been infected. The child should always be nourished by its mother, and should never be allowed to take the breast of a healthy wet-nurse. When symptoms are unmistakably present, the child may be given calomel, 1/20 to 1/2 grain 3 times a day, together with tonics; or the protoiodid in doses of 1/10 to 1/4 grain; or corrosive sublimate, $\frac{1}{100}$ to $\frac{1}{50}$ grain. Iodid of potassium may be given cautiously, from 1/4 to 5 grains. Mercurial inunctions may be used in the earliest period of life. The ointment should be combined with 2 or more parts of pure white vaselin, and increasing quantities should be used until 20 to 30 grains are rubbed in daily.

The acquired syphilis of infancy is chiefly remarkable for its display of moist and secreting lesions and for its failure to relapse in cycles when the disease is duly recognized and properly cared for. But in unrecognized or neglected acquired syphilis of infancy the results may be as mutilating and as disfiguring as in the worst phases of acquired disease of later years.

SYRINGOMYELIA.—The morbid condition caused by the presence of an adventitious cavity in the spinal cord or by dilatation of the central canal.

Pathologic Anatomy.—The cavities are formed partly by defective closure of the central spinal canal and partly by the breaking down of the residual embryonal tissue. The cavity of a syringomyelia is usually in the posterior part of the cord, extending toward the posterior cornua. It may prevail throughout the entire extent of the cord, but in most cases involves only the cervical or dorsal regions or more limited areas.

The essential symptoms are loss of sensibility, chiefly to pain and to temperature; and, to a less degree, loss of simple tactile sense; also muscular atrophy, the latter progressive in development. The sensory symptoms are the earlier and the more constant. There may not only be a loss of thermal sense, but it may be reversed, in that heat is felt as cold, and vice versa. So, also, subjective sensations are felt, including heat and cold, or in their absence pain, which may be neuralgic in character. The involvement of all forms of sensibility probably takes place when the posterointernal columns are extensively involved. The muscular atrophy is the result of injury to the motor cells of the anterior cornua in the compression to which they are subjected in the dilatation. There is also muscular weakness, involving the trunk muscles, from which lateral curvature sometimes results.

The reflexes may or may not be increased, and myotatic irritability may in rare cases be lost, while tremor of the limbs has been noted in some cases. Trophic symptoms are not rare in the parts affected by sensory loss. The skin may be glossy and thin, or thick and horny, while there may be eczema, herpes, bullæ, even ulceration and gangrene. The nails may become fissured and drop off. Vasomotor disturbances are more common, including coldness, lividity, or redness with swelling and heat. There may be sweating, or its absence, brittleness of bone, and joint changes like those of tabes.

The area of the cranial nerves may be invaded when there is involvement of the medulla and pons. The phenomena include paralysis of one vocal cord and of the tongue and face, difficulty in swallowing and in breathing, and embarrassed heart action. The eyes may be disordered; the pupils unequal, and smaller on the side where greatest severity of symptoms exists, but the other special senses escape, and the sphincters are unaffected.

Diagnosis.—This is based upon the sensory symptoms, and of these, thermoanesthesia and analgesia, rather than tactile sensibility, together with muscular atrophy succeeding after some interval. Cervical pachymeningitis runs a more rapid course; the anesthesia includes all varieties of sensation, and corresponds more nearly in its distribution to that of the muscular atrophy; pain is more conspicuous, and the reaction of degeneration is commonly present in the wasting muscles. The symptoms of syringomyelia are sometimes simulated by the anesthesia and wasting of anesthetic leprosy; but in the latter disease the trophic changes are more marked, the phalanges often drop off, while the sensory symptoms include all varieties of sensation.

Progressive muscular atrophy differs in the absence of altered sensation. A spinal tumor in the same situation as a syringomyelia furnishes almost identical symptoms, and may have an identical origin if it starts from the neuroglia; but the symptoms are more rapid in their development (Tyson).

Prognosis.—This is ultimately fatal, although the course is slow, extending over a period of from 15 to 20 years. Toward the end the course is more rapid, death resulting from exhaustion or from interference with the functions of the medulla.

Treatment.—This consists of measures to combat such symptoms as cystitis, bed-sores, etc., and general tonic and alterative measures.

SYRINGOMYELOCELE.—See Spina Bifida.

SYRUPS.—Concentrated solutions of sugar in water or in aqueous liquids. They sometimes contain acetic acid, and occasionally alcohol; and are termed *simple*, *medicated*, or *flavored*, according as they are simple solutions of sugar in water alone, or contain soluble medicinal substances or flavoring ingredients. The sugar used should be very dry, and its official description corresponds with the granulated sugar of commerce. The permanence of these preparations depends chiefly on their possessing the proper relative proportions of sugar and water. They are prepared either by solution with heat, by agitation without heat, by adding a medicated liquid to simple syrup, by digestion or maceration, or by cold percolation. They are best preserved by being poured while hot into pint bottles, which should be corked securely while full, and the tops dipped into melted sealing-wax. Fermented syrups are useless for dispensing purposes. There are 29 official syrups.

T

TABACUM.—See Tobacco.

TABES DORSALIS.—See Locomotor Ataxia.

TABES MESENTERICA (Tuberculosis of the Peritoneum).—See Peritonitis; Scrofula; Tuberculosis.

TACHYCARDIA.—Abnormal paroxysmal or persistent rapidity of cardiac action. The pulse may attain a speed of 200 a minute. It is a comparatively rare affection, due to paralysis of the inhibitory nerve of the heart or to stimulation of the cardiac accelerator nerves. See Heart-disease (Functional). See Heart Examination, Pulse.

TAKA-DIASTASE.—See Diastase.

TALIPES (Club-foot).—Talipes is the technical name for club-foot, whether congential or acquired. Congenital talipes presents varieties not so numerous and less complicated than the acquired form, which develops after the second year of life. The features of congenital talipes are so pronounced that one can differentiate this from the acquired form. Acquired talipes is easily recognized, and is marked by a loss of power in certain groups of muscles, although it must be admitted that a moderate grade of talipes, resulting from slight paralysis in early life, may assume the characteristics of a congenital form in later life. Such cases, however, are exceptional. The different varieties, then, are: (1) Talipes equinus; (2) talipes varus; (3) talipes calcaneus; (4) talipes valgus; (5) talipes cavus; (6) talipes planus.

Talipes Equinus. Talipes Calcaneus. Talipes Cavus- or Arcuatus. Talipes Varus. Talipes Equino-varus. Talipes Calcaneo varus.

1. **Talipes equinus** may be described as extension of the foot, with spasm or shortening of the tendo Achillis, and usually with a loss of power in the anterior tibial group. The patient stands on the tips of the toes, on the distal ends of the metatarsals with the toes hyperextended, on the ball of the foot with the heel slightly raised or on the heel and ball of the foot, but is unable to dorsiflex the foot beyond a right angle It will thus be seen that there are four grades of equinus. Equinus is more frequently combined with varus, but it may be associated with valgus and cavus. Congenitally, it is more frequently associated with varus, and, as an acquired deformity, with valgus. It is also associated with cavus. The terms, then, would be talipes equinovarus, talipes equinovalgus, talipes equinocavus.

2. **Talipes varus** is an inversion of the foot, associated with rotation at the midtarsal joint. The degree of the deformity is determined by the amount of manual correction possible and there are recognized: first, easily corrected and maintained; second, corrected and maintained with difficulty; and third, incorrigible by the hands. Anatomically, the tissues on the inner side of the ankle and foot are shortened, and certain tendons, such as the anterior tibial and the flexor brevis pollicis, are displaced toward the inner and posterior aspect of the limb, while the structures on the outer side are lengthened and the tendons likewise are more or less displaced. Bones, ligaments, muscles, and fascia all participate in these changes. Varus is associated with equinus, usually as a congenital deformity; less frequently as an acquired deformity. Occasionally it occurs with cavus; very seldom with calcaneus.

3. **Talipes calcaneus** is, as a rule, an acquired deformity; exceptionally, it is congenital. The deformity is characterized by elongation of the tendo Achillis and of the muscles associated therewith, by shortening of the anterior tibial group of muscles, and by slight flexion of the toes. The os calcis becomes very prominent, and the patient literally walks on the heel. This bone lies vertically in place of horizontally, in the severer forms and is continuous with the vertical axis of the leg. Calcaneus is associated with valgus, frequently with varus, and not infrequently with cavus.

Talipes Valgus. Talipes Calcaneo-valgus. Talipes Equino-valgus.

4. **Valgus** is usually acquired, rarely congenital, and is a deformity of the foot in which eversion is a prominent feature. The outer border of the foot is raised, the foot is everted, the patient stands on the inner border of the foot, and, as in the other varieties of talipes, presents the different degrees. In an extreme form the patient would bear the weight on the internal malleolus. Valgus is the opposite of varus, and is combined with equinus and calcaneus: never with cavus.

5. **Cavus** is an exaggeration of the normal transverse arch of the foot, and is the result of bony subluxation at the midtarsal joint and of contraction of the plantar fascia. The typical cavus of third degree is seen in the foot of a Chinese lady.

6. **Planus** is the opposite of cavus and is a relaxation of the ligamentous, fascial and tendinous structures in the arch and sole of the foot. The arch sags and there is a flat-foot. It may be relaxed or rigid and is due to many different causes, among which are obesity, occupation, ill-fitting shoes, right-angled equinus, and weakened tissues in the foot.

Etiology of Talipes.—The appearance of talipes equinovarus, dependent upon slight paralysis many years previously and not influenced by treatment, is so much like the congenital deformity that the points of distinction are well-nigh obliterated; hence the popularity of the theory that a congenital club-foot results from an intrauterine paralysis. The theory advanced many years ago by Essericht, of Copenhagen, is that the feet of the fetus occupy various positions during the course of intrauterine life, in order that the joint surfaces, the muscles, and especially the ligaments may be developed in accordance with the future usefulness of the feet; that when anything centric or excentric prevents the feet from assuming these positions at the proper time, or holds them in any given position beyond the limit of time during which they should normally occupy such a position, talipes results. The variety of congenital talipes will depend upon the date of its production; the severity will be in direct ratio to the mechanic obstruction at work.

The etiology of acquired talipes is less difficult, the more common form being the result of anterior poliomyelitis, although it must not be inferred that talipes is the necessary result of the paralysis; it is, rather, an accidental result.

Of themselves, few cord-diseases produce talipes; but the resulting muscular contractions induce the deformity. The bilateral equinus in cases of compression myelitis is well known; yet the deformity rarely receives treatment. In cerebral hemorrhage in infancy the gastrocnemius is often the seat of a contraction that, by its long persistence, ends in contracture of the tendo Achillis.

Ostitis of the ankle occasionally includes an equinus, a varus, or an equinovarus. Rachitis may be mentioned, as one of the causes, but in reality, when deformity occurs, it is believed to be due to weak ankle or "spurious valgus." Cicatrices from lacerated wounds of the ankle may be mentioned as another cause.

Spastic paralysis has for one of its manifestations an equinovarus or an equinus, usually first noticed when the child begins to walk. There also exists a marked inward rotation of the limbs, and the deformity is readily recognized, being bilateral, symmetric, and easy of correction by manual force.

Many of the milder forms of talipes can be attributed to sprains of the ankle. However slight the deformity, the pain and annoyance caused by use are often greater than when the deformity is more marked, and to this mild grade of the deformity Schaffer has given the name of "nondeforming club-foot." Rheumatism may be mentioned as an occasional cause of talipes valgus; indeed, it is not an uncommon cause of what is known as spasmodic pes planus.

The symptoms and signs of talipes and of its varieties may be gathered from the foregoing, and little need be said beyond the description already given. There are really very few symptoms that belong to talipes. The signs are those of deformity, and are noted either as the patient stands or walks. Occasionally, in very young children, when the deformity is congenital, standing and walking are not necessary to bring out the signs.

Diagnosis.—The recognition of the various forms of talipes is easy, and particularly is this so of the deformity in the second and third degrees. It is only in the first degree that confusion may sometimes arise. Many infants in arms present certain evanescent deformities of the feet that are regarded as club-foot. A child, for instance, when it begins to stand, bears the weight on the toes and balls of the feet a good deal; the heels are raised, and deformity apparently exists. In especially stout children, in whom the gastrocnemius is flaccid, and in whom the tendo Achillis is easily stretched, a calcaneus can be produced, and often is produced. When the tendo Achillis is distinctly short, or when the anterior tibials are short and there is a history of paralysis, a talipes equinus or a talipes calcaneus may easily be diagnosed. Deformity must also be differentiated from weak ankles—a very common condition in rachitic subjects or in children who are very stout.

Prognosis.—Talipes is a deformity that can easily be corrected at almost any stage; in a young child the prognosis is exceedingly difficult. It may be said that under efficient treatment, long continued, the prognosis is good: that is, a useful foot—one free from deformity—with functions fully restored.

Treatment.—The treatment of talipes is both mechanic and operative. The two must not be regarded as separate and distinct, but as supplementing each other. The most efficient treatment is a combination of the two.

Mechanic.—The particulars underlying mechanic treatment are, first, an appliance that will hold the heel and the front of the foot in position; and, second, a lever that will correct. This lever must extend up the calf or to the thigh, sometimes to the pelvis.

The principal types of club-foot shoe are:

1. **The Knight club-foot shoe,** which is a modification of the old Scarpa shoe. This consists of a

foot-plate the shape of the sole of the foot, made of metal—steel preferably—covered by leather; a heel-cup of steel, consisting of uprights passing from a point just below one malleolus to the other; and leather, thin saddle skirting, shaped to a model of a heel, riveted to these steel uprights. An instep strap is also required, and this may be continuous with the heel-cup. The upright consists of a spring of steel passing from the outer side of the heel-cup and terminating at a calf band that is secured in place by a leather band. Half of the band is of steel. Where the spring is attached at the ankle there is a stop-joint, which holds the foot at a right angle with the leg and allows dorsiflexion, but no extension. In many instances there are double uprights in place of single ones. In adjusting this club-foot shoe the foot-plate is first secured to the plate by means of the instep strap and a bandage around the toe; then the spring is pulled back so that the calf band will grasp the calf. In making use of it, one must change frequently—at least twice a day—manipulate the foot at the same time, and guard against excoriations.

2. **The Taylor club-foot shoe** is practically the same as the Knight shoe in principle, except that the spring is on the inner side of the leg, and in place of a small calf band there is a lacing attached to a plate that passes along the inner side of the leg.

3. **The Schaffer club-foot shoe** is intended for traction on the tendo Achillis and on the plantar fascia.

The operative procedures are: Division of tendons and fascia; subcutaneous division of ligaments, either subcutaneously or by open method; open section, after Phelps; removal of the head and neck of the astragalus; osteotomy through the neck of the astragalus; cuneiform osteotomy through the os calcis, practised by Bradford; removal of the astragalus, known as astragalectomy; and supramalleolar osteotomy. All these are cutting operations, but the one most frequently resorted to is correction by manual force, frequently supplemented by the Thomas wrench—practically a tarsoclasis.

The order of operation should be as follows: (1) Division of the tendo Achillis and plantar fascia, supplemented by manual force for overcorrection; (2) division of the tendons, supplemented by subcutaneous division of the deltoid ligament, and, in addition, manual force and the Thomas wrench; (3) the open division of all obstructing soft tissue on inner side of foot (Phelps); (4) removal of head and neck of astragalus; (5) cuneiform osteotomy (Davies-Colley); (6) supramalleolar osteotomy.

The details of these various operations are simple, and few instruments are required.

Tenotomy, fasciotomy, syndesmotomy, and myotomy are performed with a small tenotome not any longer than a fascia knife. The subcutaneous tenotomy is better than the open method, because the operation is simplified, and need never be followed by sepsis. There is no special instruction needed for the site of operation. The most prominent portion of tendon, fascia, ligament, and muscle invite, so to speak, the insertion of the tenotome either directly down upon it or underneath it.

For the **open method of Phelps** the usual preparations for an aseptic operation are necessary. The foot and leg are rendered as nearly bloodless as possible by an Esmarch bandage, and then an incision is made through the skin, beginning at a point about 1 inch anterior to the internal malleolus and extending across the inner margin of the sole rather obliquely for a distance of about 1 1/2 inches. While eversion is made with one hand the section is continued to greater depths, until all tissues that offer resistance are divided. With foot thus in overcorrection rubber tissue is stretched over the gaping wound, and a sterile dressing applied over this and around the foot and ankle. The plaster-of-Paris may be applied before or after removal of the Esmarch bandage. The hemorrhage is seldom an annoying feature, and the blood becomes organized, filling in the gap with new tissue.

The operations of **astragalotomy** and **astragalectomy** are made through an incision over the head of the astragalus, prolonged sufficiently to admit of removal of the head and neck after section with osteotome, or of the entire bone after section of the ligaments holding it in place. The wound is sewed up with or without drainage, as the operator may prefer.

The cuneiform osteotomy of Davies-Colley is made through an incision over the cuboid and fifth metatarsal on the dorsal aspect. The wedge includes usually the cuboid and a portion of the distal end of the os calcis or the proximal end of the metatarsal. The smaller portion of the wedge encroaches on the middle and external cuneiform bones and the astragalus.

The section of the tibia and fibula above the malleoli is made subcutaneously by an osteotome, and the point selected is about 2 inches above the malleoli. Manual force supplements the section, and the foot is put up in eversion.

All of these operative procedures are of little avail if the deformity is not overcorrected at once, and if the good position secured is not maintained by a dressing that does not yield. Plaster-of-Paris is to be preferred. One should not be content with a single plaster-of-Paris dressing, but should renew this once a fortnight, getting the foot into better position at every dressing.

After a few weeks in plaster the foot should be fitted with one of the club-foot shoes described and over this a shoe should be worn. The anatomy of the talipes foot must never be lost sight of, and the apparatus should be worn until normality is reestablished.

The mechanic treatment of flat-foot includes the construction of a boot or a shoe so that the inner border of the foot will be raised and the weight of the body thrown nearer to the normal vertical axis of the leg with the foot.

This may be accomplished in two ways: (1) By building the boot on a last with a high arch—known as a Spanish last—and inserting an insole the inner border of which shall be from 1/8 to 3/8 inch thicker than the outer border, especially at the

heel and the ball of the shoe. (2) Fill in the shank with leather along the inner side the same height as the heel, and make the inner border of the sole and this elongated heel from 1/8 to 3/8 inch thicker than the outer border (Thomas). The effect of this is to remove the natural spring of the shank of the shoe and to throw the weight of the body over toward the middle and outer side of the foot. In the more severe forms of pes planus, associated with much bony deformity and spasm, correction of the deformity by manual force, under an anesthetic, and retention in plaster-of-Paris for two weeks will render the foot amenable to a steel shank worn within the shoe. The shank that gives most relief is known as the Whitman spring. The best fit is secured over an iron model taken from a cast of the foot in the corrected position.

Cutting operations involving removal of bone are seldom called for, in view of the relief afforded by the milder operative procedures.

In many cases it is advisable, and even necessary, to correct the deformity by manual force, under an anesthetic, and then allow the foot to remain in plaster-of-Paris some weeks before applying a sole-plate. The thorough and persistent use of exercise after the correction of the deformity is essential to the ultimate cure of the case and recovery may be aided by strapping with adhesive plaster to prevent external rotation of the os calcis and assist in supporting the arch.

When flat-foot is of congenital origin, it is sometimes necessary to refresh the astragaloscaphoid articulation, and to nail the bones together in a corrected position. In general, however, the operative treatment of flat-foot is rarely necesssary.

TAMPON.—Tampons are used principally for the purpose of applying pressure—as in uterine displacements and in vaginal and uterine hemorrhages—and for depleting in pelvic and uterine inflammatory conditions. When depletion is desired, the tampon should be made of fine lamb's wool saturated with glycerin, or 10 percent solution of ichthyol in glycerin. The well-known hygroscopic action of the glycerin acts most favorably in cases of chronic congestion from laceration of the cervix, subinvolution, and pelvic inflammation. Tampons used for this purpose are removed at the end of 24 hours, after which a hot vaginal douche is given. They may be introduced at intervals of from 2 to 5 days.

As a means of effecting continued pressure, tampons are occasionally useful in backward displacements of the uterus complicated by slight adhesions. Lamb's wool should here be used, and the tampon should be placed well back of the cervix in the posterior vaginal vault. It should be renewed daily.

For the purpose of controlling vaginal and uterine hemorrhages nothing is superior to the tampon. The tampon in these cases should be of iodoform or sterile gauze. It is removed usually at the end of 48 hours.

TANNALBIN.—A light brown powder recommended as an excellent intestinal astringent in chronic and subacute intestinal catarrh. Dose for adults, 1/2 to 1 1/2 drams; for children, 5 to 15 grains. Tannalbin is a compound of tannin and albumin, and may be prepared as follows: To 10 parts of a 10 percent solution of albumin 6.5 parts of a 10 percent solution of tannin are added; the precipitate formed is collected on a strainer, washed, pressed, and dried at 30° C. The resulting mass is then triturated and forced through a fine sieve, and finally spread out in thin layers and dried for 6 hours at 120° C. This compound is only decomposed by the alkaline secretions of the intestines.

TANNIC ACID (Tannin).—Tannic acid is a glucosid obtained from many vegetable astringents. The official tannic acid of the U. S. P. and B. P. is made from galls, and is distinguished from that occurring in leaves, barks, etc., by the name of gallotannic acid, while the others take the name of the source from which they are derived, as quercitannic acid, from oak bark. Tannic acid is solid, uncrystallizable, white or slightly yellowish, inodorous, without bitterness, very soluble in water, less soluble in alcohol and ether, especially when anhydrous, insoluble in the fixed and volatile oils. It is also very soluble in glycerin, and almost insoluble in absolute ether, chloroform, benzol, and benzine. It is incompatible with alkaloids, gelatin, albumin, and solutions of tartrate of antimony and potassium, and with ferric salts, with which it forms a black precipitate (the old-fashioned ink). It does not react with the salts of the ferrous oxid. If it is rubbed with the chlorate of potassium, the mixture explodes with great violence; hence these drugs should never be ordered in powder together, and if they are prescribed in the same solution, they should be dissolved separately. From tannic acid is prepared styptic collodion (containing 20 percent of tannic acid in the diluted collodion), troches of tannic acid (containing each 1 grain of tannin), and the ointment of tannic acid (containing 10 percent). See QUERCUS.

The effect of tannic acid resembles more closely that of alum than that of any other mineral astringent. It is more irritating, however, than the agent last named. This effect can be reduced in a measure by combination with borax and a small proportion of phenol. A paste prepared by mixing tannic acid two-thirds and gallic acid one-third is thought by some practitioners to be superior as a hemostatic power to one in which only tannic acid enters. It enters in combination with gun-cotton and ether, and in this form is known as styptic collodion.

A combination of the effects of tannic acid and carbolic acid is obtained as follows; to a half pint of water add 1 dram of tannic acid and 2 grains of phenol; filter thoroughly, with care. Glycerite of tannic acid is useful in the proportions of glycerin 5 parts and tannic acid 1 part. A tannated cotton is prepared by steeping absorbent cotton in a solution of tannic acid.

Tannic acid is of special value on mucous membranes and on abraded or superficially ulcerated skin surfaces. It is noted that many of its indications are found in localities where sound integu-

ment joins a mucous- or ichor-yielding lesion, as at the nostril, anus, or vulva, and at the margins of ulcers, fissures, etc.

TANNIGEN.—An acetic ester of tannic acid. Dose, 3 to 8 grains, up to 2 drams daily. A yellowish-gray powder used in chronic diarrhea as an intestinal astringent.

TANNISMUTH.—Bismuth bitannate. It is claimed to be efficient in chronic intestinal catarrh. Dose, 5 to 10 grains.

TANNOFORM.—A compound of tannic acid and formaldehyd. It is a powerful intestinal antiseptic and astringent. Dose, 4 to 8 grains. It is used locally in 10 percent ointment or dusting-powder with 2 or 4 parts of starch.

TANNOPIN (Tannon).—A condensation product of tannin with hexamethylenamin. It has the same action as its two components, into which it is gradually decomposed in the intestines. It is recommended in intestinal catarrh, in tuberculous enteritis, and other intestinal disorders. Dose, 15 grams.

TAPE-WORMS.—See Worms (Tape).

TAPOTEMENT.—See Massage.

TAR.—See Pitch.

TARAXACUM (Dandelion).—The root of *T. officinale*. Its properties are due to a bitter extractive principle; it is tonic, diuretic, and also aperient. It is of reputed use in dyspepsia. Dose, 1 to 8 drams. **T., Ext.** Dose, 5 to 30 grains. **T., Flext.** Dose, 1 to 8 drams.

TARTAR (Argol).—A hard mineral deposited on the inside of wine-casks as a whitish or reddish crystalline crust, the impure supertartrate of potassium. **Tartar** is also the name applied to a hard incrustation on the teeth, consisting of mineral and organic matter. **T., Cream of,** purified argol or acid potassium tartrate. **T., Emetic,** the tartrate of antimony and potassium. See Antimony.

TARTARIC ACID.—$H_2C_4H_4O_6$. A dibasic, organic acid, chiefly employed in refrigerant drinks and in baking-powders; 20 grains neutralize 27 of potassium bicarbonate, 22 of sodium bicarbonate, and 15 1/2 of ammonium carbonate. Dose, 5 to 20 grains. It is widely distributed in the vegetable world, and occurs principally in the juice of the grape, from which it deposits, after fermentation, in the form of acid potassium tartrate (argol). It results on oxidizing saccharic acid and milk-sugar with HNO_3. It crystallizes in large monoclinic prisms, which dissolve readily in water and in alcohol, but not in ether. It melts at 167°–170° F. Its salts are the tartrates. See Antimony, Potassium, Tartar.

TASTE, DISORDERS.—Taste is the sense by which savors are perceived and discriminated. The glossopharyngeal nerve and the lingual branch of the fifth pair are the nerves mainly connected with this sense, of which the tongue is the chief organ. The lips, the insides of the cheeks, the palate, and the pharynx also receive impressions from sapid substances.

The chief sensations of taste are called sweet, sour, salt, bitter, and metallic. Flavor usually blends with the gustatory sense, but it is due to the sensation of smell reaching the olfactory mucous membrane through the posterior nares. If the posterior nares are closed, so that no air passes up through them, the sense of flavor is lost and only that of taste remains. It is necessary, therefore, to distinguish between the senses of smell and taste, and, as well, to determine how far sensations that are in themselves normal are responsible for alternation of the appreciation of the sense of taste: *i. e.*, how far the sense of taste is increased or diminished in its enjoyment of or disgust at some article, the sensation itself being normal.

Taste may be impaired or lost from a variety of causes: (1) from morbid conditions of the mucous membrane of the tongue and palate, as in chronic gastritis or rhinitis; (2) from lesions of the nerves concerned in the conduction of sensory impression; (3) from certain cerebral conditions.

The first variety of causes is most common, and impairs, rather than destroys, the sense of taste. The parts of the mouth capable of receiving taste impressions are the tongue, the palate, and the palatine arches. A dry tongue or a thick coating dulls the sense of taste.

The fifth nerve is the one usually concerned in disorders of taste. It is more likely that this nerve is concerned in taste impressions of the posterior portions of the tongue and soft palate than the glossopharyngeal nerve.

In caries of the middle ear loss of taste for both the back and front of the tongue usually is noted. In general hemianesthesia and in hysteria loss of taste on one or both sides of the tongue and mouth is likely. Gustatory hyperesthesia occurs in myxedema and in mental and epileptic disorders, and is sometimes of central origin.

Tests.—Various substances may be placed on the protruded tongue, the eyes being closed. The quantity of the substance should be small, and taste should be perceived before the tongue is withdrawn into the mouth. The following are used: for bitter, quinin; for sweet, honey; for sour, vinegar; for salt, common table salt; and for metal, a feeble electric current.

Treatment.—This depends upon the etiology. Mercury or podophyllin as purgatives are to be used for a cankery taste unconnected with alcoholism, or half a glassful of pure, cold water may be taken half an hour before breakfast. Gray powder, 1/3 grain given 3 or 4 times daily, will usually remove from the mouth the disagreeable taste due to dyspepsia, in chronic disease, or in early convalescence. Electricity may add to the function of taste when its loss or perversion is due to nerve-disease.

TATTOOING.—The operation of marking the skin permanently by the introduction of foreign substances, such as carbon, India ink, and vermilion. It is a common practice among sailors, the color being introduced into the true skin by pricking it with needles.

Tattooing as a therapeutic measure, to restore the natural colors in parts which are pigmented, is occasionally resorted to. For white, use baryta white; and for other colors, the earth colors (ochers —yellow, brown, red). To assist these, cinnabar

and ultramarine may be used. Mix the colors on a glass plate and impregnate the needles. Electrolysis, followed by tattooing, is useful in cases of vascular nævi.

Tattooing of the cornea is an operation to diminish the unpleasant appearance of leukoma of the cornea by tattooing the same so as to simulate the appearance of the normal pupil and iris.

To Remove Tattoo Marks.—The method recommended by Variot is as follows:

The skin is first covered with a concentrated solution of tannin, and retattooed with this in the parts to be cleared. Then an ordinary nitrate of silver crayon is rubbed over these parts, which become black by formation of tannate of silver in the superficial layer of the derma. Tannin powder is sprinkled on the surface several times a day for some days, to dry it. A dark crust forms, which loses color in 3 or 4 days, and in 2 weeks or so comes away, leaving a reddish scar, free of tattoo marks, and, in a few months, is scarcely noticeable. It is well to do the work in patches about the size of a silver dollar at a time. The person can thus go on with his usual occupation.

TAXIS.—A reduction of a prolapsed structure, as a hernia or a prolapsed uterus, by methodic manipulation without instruments. See HERNIA.

TEA (Thea).—The leaves of *Camellia theifera*, a Chinese evergreen shrub. Tea contains an alkaloid (thein) and tannic acid, boheic acid, gallic acid, gluten, coloring-matter, etc. A decoction of the leaves is a popular astringent, restorative beverage, producing an exhilarating effect upon the nervous system. Used to excess, it powerfully affects the stability of the motor and vasomotor nerves, the action of the heart, and the digestive function, producing flatulent dyspepsia, tremulousness of the limbs, pallor of the surface, irregular cardiac action and feeble impulse, hallucinations, nightmare, anorexia, headache, nausea and vomiting, obstinate neuralgia, especially of the supraorbital and occipital nerves; also constipation and a pain in the left side are not infrequent. The condition of chronic tea-poisoning is termed *theinism or theism*, and is very often seen among women of the lower class in cities, who do not indulge in alcoholic beverages, but freely accept the dominion of the "cup that cheers" and worse than inebriates. Tea contains much more tannin than coffee, and that used as a beverage by the poorer classes is little more than a decoction of tannin, and a fruitful source of dyspepsia and other forms of gastric disorder. The properties of tea are due to thein, $C_8H_{10}N_4O_2$, a substance identical with caffein and a mild cerebral stimulant.

TEETH, ACHING.—See TOOTHACHE.

TEETH, EXTRACTION.—When extracting any tooth carry the beaks of the instrument employed up under the free margin of the gums and alveolar process until you can close the forceps upon the middle third of the tooth, thus reducing in a large measure the possibility of breaking the crown off and leaving the root. The above accident frequently results when one endeavors to extract by only grasping the tooth at its neck.

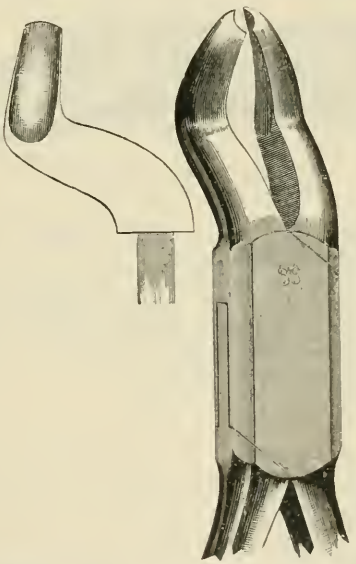
Position of Operator and Patient for the Extraction of Teeth.—Have the patient seated in a solid chair, and his head tipped slightly back, on about a level with the operator's chest, who now takes his position on the right side, and passes left arm around the patient's head and places his fingers between the lips in such a position as will best expose the teeth to be extracted and protect those not to be removed.

This position is maintained when removing all the superior and inferior teeth from right lateral to left third molar with but slight shifting of palm and fingers to best support the face or mandible, and protect the lips from injury. Some operators will find it advisable to lower the patient and have his head carried slightly forward when extracting these inferior teeth.

Take position to right and facing patient when removing all superior and inferior teeth from right cuspid to third molar. Protect lips and sustain face and body of mandible with palm and fingers of left hand.

Order of Eruption of Permanent Teeth.—See DENTITION.

Forceps to be Employed in the Extraction of the Permanent Teeth.—Upper and lower incisors,



No. 10 FOR SUPERIOR THIRD MOLARS.

cuspids (canine), bicuspids and all roots can be removed by Dr. M. H. Cryer's universal forceps No. 150 and 151, manufactured by S. S. W. Co.

For superior first and second molars, employ S. S. White's No. 88, right and left.

For superior third molars S. S. White's No. 10.

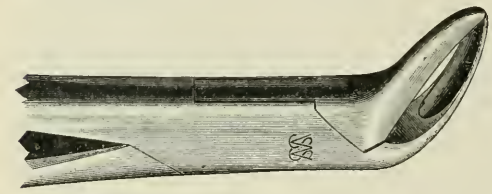
For inferior first, second, and third molars employ S. S. White's forceps No. 47.

Detailed Description of the Application of the Forces to be Employed in the Extraction of all Permanent Teeth. *Superior incisors.*—First a slight rotary motion, and then carry the tooth bodily in a labial direction with slight traction.

Superior cuspids (canines).—Carry the tooth in

a labiolingual motion with positive careful traction.

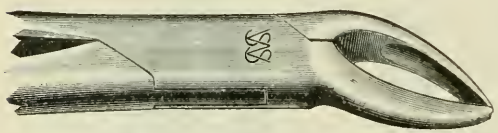
Superior first bicuspids.—Apply force cautiously in buccolingual direction, and positively no rotary motion employed for fear of fracture of the frail root ends.



No. 151 Cryer's Universal Lower Incisor, Cuspid Bicuspid, and Root Forceps.

Superior second bicuspid.—A slight buccal and rotary motion with gradual traction.

Superior first and second molars.—Positive downward and slight buccal movement until the lingual root is gradually loosened, then careful traction without rotation.

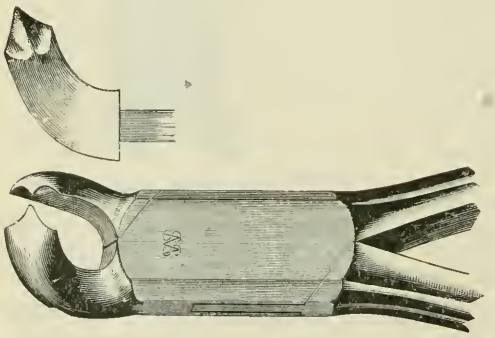


No. 150 Cryer's Universal Upper Incisor, Cuspid, Bicuspid, and Root Forceps.

Superior third molars are easily extracted by the creation of traction buccally.

Inferior incisors are removed by the application of labio-lingual motion. Great danger of root fracture with application of slightest rotary force.

Inferior cuspids.—First a labiolingual force then a gradual rotary traction.

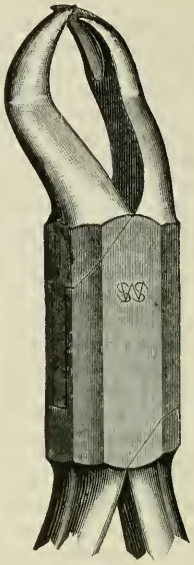


No. 47 For Inferior First, Second and Third Molars.

Inferior first and second bicuspids.—A buccolingual force, then slight rotary motion.

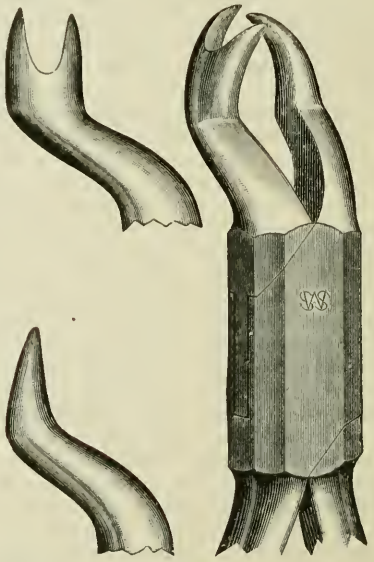
Inferior first and second molars.—A buccolingual and traction force without any rotary motion.

Inferior third molars.—The most difficult one of the molars to extract; and the direction of the force to be applied should be slightly toward the cheek with positive traction that is directed a little backward.



No. 88 R. For Superior First and Second Molars.

To properly grasp some partially erupted inferior third molars, the bony alveolar process and soft tissues on buccal and lingual sides must be cut away before the beaks of the forceps can be properly placed.



No. 88 L. For Superior First and Second Molars.

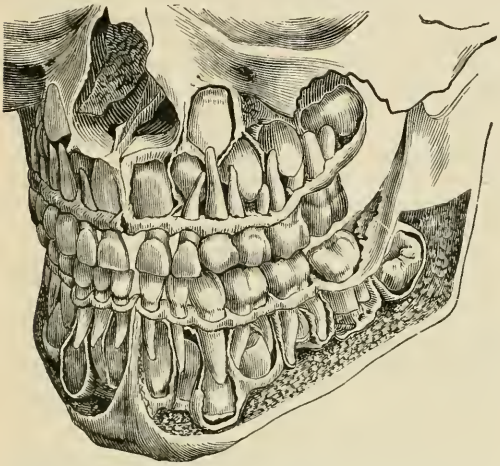
Order of Eruption of Deciduous Teeth.—See Dentition.

Deciduous teeth should be retained their full

term, for the known beneficial influence their presence has upon the normal development of the jaws and face.

When extracting the deciduous teeth, take same position as outlined as appropriate for the extraction of the permanent ones. Forceps No. 250 and 251 as designed by H. M. Cryer will be the only ones needed for the removal of all the deciduous teeth.

Great care should be exercised when extracting deciduous teeth that the beaks of the forceps are not carried to a depth that might engage the oncoming teeth.



Illustrates the Jaws of a Child between six and seven years of age, showing the relations of the two sets of teeth. (*Harris.*)

Treatment of Post-operative Hemorrhage Following the Extraction of Teeth.—To determine what socket is the seat of hemorrhage where a number of teeth have been extracted at one time, have the patient rinse out his mouth with a sterile solution, then immediately applying a previously prepared solid roll of cotton, about the size of the index finger over a number of the openings from which the teeth have been extracted, holding said pack under pressure from one to three minutes. Then remove and the deepest blood stain will be found above the socket where the excessive hemorrhage has been occurring. By this procedure you have the location and number of openings needing interference.

For controlling this hemorrhage, employ a pellet of cotton that will comfortably fill the opening to be packed. Saturate this with alcohol and then thoroughly incorporate it with powdered tannic acid (tannic acid causes the most insoluble clot to form in the presence of saliva).

Now with curved dressing forceps force the medicated cotton pellet to the bottom of the socket and hold it in position until it has become well saturated with blood, and ceases to have a tendency to leave its position.

Remove the pack in 24 to 48 hours and do not replace unless for the purpose of controlling a secondary hemorrhage.

In some pronounced cases the extracted tooth after proper sterilization has been replaced to control the hemorrhage. One precaution that should always be observed is that an operator should never dismiss a patient after the extraction of a tooth until all pulsating hemorrhage has ceased.

A Few Brief Statements in Reference to the General Question of Extraction of Teeth.—The use of an elevator for the extraction of any lower tooth should be condemned on the grounds that in their employment the mandible may be, and frequently has been, fractured.

Care must be exercised in maintaining a positive grasp upon the extracted tooth until it is well out of the mouth, to prevent its slipping from the forceps into the patient's throat.

When teeth are to be extracted from both arches, remove lower ones first, thus maintaining this field more free from blood.

Cocain above a 1 percent solution should not be employed as a local anesthetic for the extraction of teeth.

Injections should not be made into an abscess area, but may be made about it.

Chloroform is the most dangerous general anesthetic that can be administered for the extraction of teeth, and nitrous oxid should always have the preference; when prolonged anesthesia is demanded and continuous nitrous oxid anesthesia cannot be maintained, ether should be employed *and not chloroform.*

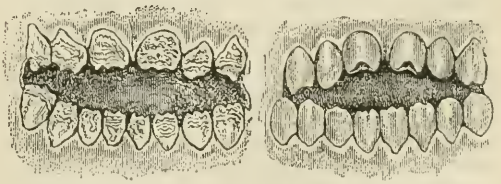
The superior and inferior second deciduous molars and cuspids (canines) should never be extracted before the child has reached the age when the permanent ones will soon be erupting, otherwise a positive irregularity of the permanent teeth will result.

No permanent or deciduous tooth should be extracted if it can be made comfortable and useful.

Teeth may be extracted during any stage of the formation of a dental alveolar abscess without danger to the patient.

Never extract a patient's tooth without first informing him that you are about to do so; otherwise you betray your patient's confidence.

TEETH IN DIAGNOSIS.—In hereditary syphilis the permanent teeth, especially the upper incisors,



Mercurial Teeth. (*Hutchinson.*) Syphilitic Teeth. (*Hutchinson.*)

are notched in a most peculiar manner. The cutting-edge, instead of being straight, with 2 or 3 small serrations, is concave from side to side; the whole tooth is dwarfed, and, especially at the sides, is somewhat beveled off from above downward, so that it has a peg-shaped

appearance. This change, which was first described by Hutchinson, is characteristic; it very rarely, if ever, occurs under any other circumstances, and it is caused by, and is proportionate to, the stomatitis of infancy. If this is severe at the time the dental papillæ are developing, they are so much reduced in size and so altered in shape that it is almost impossible to recognize them as teeth. Mercurial teeth and malformed teeth after certain infantile exanthems, in which the enamel is defective transversely and is marked by horizontal darkened grooves and pits, are totally different, but it is not uncommon to find the two associated. In exceptional cases in which the stomatitis has been late or prolonged, a similar change is visible in the lateral ones as well; but it is only the median teeth of the upper jaw that are definite and characteristic.

TEETHING.—See DENTITION.

TEMPERAMENT.—A term vaguely applied to the predominance of one group or order of constitutional functions over others in an individual. The various divisions of temperament were based on the former doctrine of the four humors of the body—blood, lymph, bile, and atrabilious or black bile, the predominance of any one resulting respectively in a sanguine, lymphatic, bilious, or melancholic temperament. Although the doctrine of the temperaments has long since lost its significance, it is generally admitted that an individual may have a predisposition to types of mental action not improperly classed as nervous, phlegmatic, lymphatic, etc.

Bilious temperament is that marked by a predominance of bile, persons of this type having sallow complexions, dark hair, sluggish circulations. They have great firmness and endurance.

Lymphatic temperament is that characterized by fair complexion, light hair, flabby muscles, slight force of character, and slightly developed passions.

Nervous temperament is that characterized by great activity and sensitiveness of the nervous system.

Sanguineous temperament is that characterized by fair or ruddy complexion, rapid pulse, a hopeful disposition, and strong passions.

TEMPERATURE.—Observations on the temperature of the body are valuable for diagnosis, because the temperature is easily altered when normal action of the nervous system is disturbed or in consequence of disease, or when toxic or infectious substances have been introduced into the body from without; because changes in the blood temperature occur to herald the onset of disease before even its presence is discernible or before even the slightest indisposition is present; because the courses of many diseases are accompanied by corresponding alterations of temperature, and because, in the numeric expression of the variations, and the complex conditions of disease, the thermometer will detect earlier and judge more correctly the conditions of the patient's body than any other means.

The temperature in health in the mouth of an adult is about 98.4° F. In the vagina and rectum it is 0.3° F. to 0.6° F. higher. In health there may be a difference of 20° F. between the temperature of exposed parts of the skin and the interior. Throughout the day the temperature varies. It is lowest between 2 and 6 A. M., gradually rising until its highest points are reached between 5 and 8 P. M. This rise is usually slower in the middle of the day, the afternoon hours showing a more rapid elevation. These facts are of fundamental importance, since they affect the judgment of health and disease. Race and sex have no influence upon the range of temperature. Age does influence the range of daily temperature. In an infant just born the temperature is slightly higher. In the first weeks of life a higher temperature is maintained. The temperature is very easily influenced in children. In old age also the temperature is higher than in adult life, and a greater mobility of temperature is observed. Pregnancy has no appreciable influence on temperature, although parturition increases the temperature slightly. As a rule, the constancy of the bodily temperature in health is such that general conditions of life, occupation, etc., show but little influence over it.

Local changes in temperature are brought about by local influences or by disease of a part. In a paralyzed limb the temperature may be lower or higher than in the other limb. In hemiplegia the paralyzed side is frequently higher in temperature. Neuralgia sometimes gives an increased temperature in the part affected, and hysteria is liable to show a variety of temperature changes.

In taking a temperature it is necessary:

1. That no local influence, such as unusual exposure or the passage of cold air or of hot or cold fluids, shall affect the temperature of the part selected.
2. That the bulb of the thermometer should be in most complete contact with surrounding parts, the column of mercury not being exposed.
3. That ample time should be allowed for the mercury throughout the tube to attain an even temperature.
4. That the thermometer should be read with the eye vertically over the point of the index.
5. That the observation be cautiously repeated if the result is unexpected, and with a reliable instrument. See THERMOMETER.

Depression of temperature is observed in hemorrhage, starvation, wasting from chronic diseases, and diseases of the brain and spinal cord. In brain-disease, with the symptoms of melancholia, lowering of the general temperature and extreme coldness of the surface occur. In the collapse of typhoid fever, in acute peritonitis, and in poisoning by various substances, temperature is lowered. In cholera the axillary temperature may be 89.6° F., while the general temperature may reach 104° F. In alcoholic intoxication general temperature may be greatly lowered, particularly when the patient has been exposed to cold and wet. In chronic diseases of the respiratory tract, in chronic heart- or kidney-disease, and in chronic nephritis the temperature is somewhat lowered.

Elevation of Temperature.—External cold after fatigue by exercise, in addition to the cooling of the

body from respiration, may be followed by a rigor, with rapid rise of temperature. No disease developing, the proper balance will soon be restored. The temperature may rise from such disturbance of the heat-regulating functions as the passage of a gall-stone or of a stone through the urethra. An injury may derange the nervous system and its heat regulation, causing the temperature to rise. Temperatures of from 110° to 111° F. have been observed after injuries to the spinal cord (cervical portion). In tetanus temperature as high as 112.5° F. has been observed. In sunstroke or heat-stroke a similar point has been reached. There is sometimes a rise of temperature just previous to death.

Hyperpyrexia has followed convalescence from acute rheumatism; and excessive rise in temperature has caused death in hysteria, although a high temperature to which the pulse and respiration do not correspond is suspicious.

In convalescence trifling external influences may cause a rise in temperature.

Significance of Abnormal Temperatures.—**Temperature is below normal** at 97° F. (36.2° C.)

Subnormal temperature is 97°–98° F. (36.2°–36.7° C.).

Normal temperature is 98.0°–99.5° F. (36.7°–37.5° C.).

Temperatures Above Normal.—*Subfebrile*, 99.5°–100.5° F. (37.5°–38.5° C.). *Moderate febrile*, 100.5°–102° F. (38.05°–38.88° C.), for the morning; 102.2°–103° F. (39°–39.44° C.), for the evening. *Febrile temperature of high degree*, 102.5° F. (39.2° C.) and more in the morning; 105°–106° F. (40.6°–41.1° C.) in the evening. *Hyperpyrexia*, 105.8°–107.5° F. (41°–42° C.).

A temperature below 93° F. (33.88° C.) or above 108° F. (42.22° C.) is almost always fatal. As a single observation this is of value, and in a general way such observations are of value for diagnosis. When other symptoms exist, the knowledge of an altered temperature will alter the aspect of the case. Fatigue, and its effect on temperature, should, of course, be eliminated in a single observation of temperature. Systematic series of observations are of greater value. In types of pyrexia this method will indicate the mode of rising, whereby some disease may be distinguished. Thus, in pneumonia the temperature rises rapidly and continuously to about 104° F. (40° C.); in typhoid fever a gradual rise in each succeeding day of about 2° F. occurs, going down again each morning about 1° F., the maximum of about 105° F. being attained on the fifth day. At the height of a disease the temperature fluctuates about 103° F. (39.5° C.), the range varying in different diseases.

Considerable remissions or intermissions may be observed in the decline of acute diseases, while in certain other chronic affections—such as syphilitic affections, tuberculous affections, in pernicious anemia or leukemia—the remissions become more marked as exhaustion of the patient increases. The intermittent type of pyrexia is shown in malarial diseases, chronic tubercular disease of the lungs, and pyemia.

Crisis in the decline of a fever occurs when the temperature falls rapidly to or below the normal in from 12 to 26 hours, even in 6 to 8 hours. Lysis is the gradual decline of elevated temperature by a daily fluctuation. The former may be accompanied by collapse or acute delirium, neither of which is of unfavorable prognosis, and from which conditions patients rally well. Irregularity in temperature in a disease which usually runs a definite course indicates some complication. External causes easily influence temperature in convalescence. See Chill, Cold, Fever, Heat-stroke.

TENDERNESS.—The condition of abnormal sensitiveness to touch; soreness. It usually implies pain in varying degrees and of different kinds, elicited by pressure or by percussion, as distinguished from subjective sensation felt spontaneously by the patient. It is a symptom of great importance, and merits close attention. It is often present when no complaint exists, while it is by no means an accompaniment of spontaneous pain. Its very absence is of consequence. Examinations made to elucidate it require gentleness and discretion, and often an especial knowledge of anatomy and physiology.

Tenderness in inflammation, especially when superficial, is of value in diagnosis. In neuralgic pain there is, on the whole, freedom from tenderness. Pressure, indeed, often relieves it. So, when associated with a particular nerve, pressure may differentiate between inflammatory trouble and a merely functional disorder. Actual neuritis gives rise to tenderness. Pressure will relieve muscular rheumatism when not of inflammatory type. Malignant growths are usually accompanied by pain and tenderness, while those of benign character are free from such symptoms. Destructive changes may be heralded by tenderness, as in diseases of the joints, in pressure from aneurysm or other tumor when there is, at the same time, spontaneous pain. Limited and obvious pain may indicate the presence of a foreign body. Localized tenderness on percussion is an important symptom in cerebral tumor. Tenderness is of value in diagnosis when there is no complaint by the patient, as in limited, obscure diseases of the abdomen, such as cancer, ulceration, or suppuration. It may also lead to undetected suppuration elsewhere. In children manifestations of pain during examinations will indicate the locality of morbid processes, and may lead to useful information. General tenderness is a striking symptom of rickets.

Acute erythema, erysipelas, peritonitis, gout, and spinal irritation are some of the affections in which tenderness is present. Other conditions are corns, bunions, chilblains, neuroma, superficial and multiple neuritis, stumps after amputation, boils, whitlows, felons, etc., and many affections of the eye and of the matrix of the nails.

Treatment.—As a rule, treatment of the disease with which tenderness is associated will relieve the tenderness itself. All pressure is to be avoided, as from clothing and bedclothes. Cradles to lift off the coverings may be used. Hot and cold applications, anodynes, and allied agents may be applied locally.

TENESMUS.—Rectal or vesical pain, with spasmodic contraction of the sphincter ani or sphincter vesicæ. The painful desire to empty the bowels or bladder without the evacuation of feces or urine.

Rectal tenesmus is a marked feature of dysentery. It may also be associated with other local diseases of the lower part of the rectum and anus, such as piles, fistula, or malignant diseases. Cystitis and pressure upon the bladder are causes of vesical tenesmus.

Treatment.—Local causes must be removed or cured, when practicable. Moist applications of heat and cold, or small enemata containing laudanum, or suppositories with morphin, extract of belladonna, or cocain hydrochlorid will often relieve the condition. See CYSTITIS, DYSENTERY, etc.

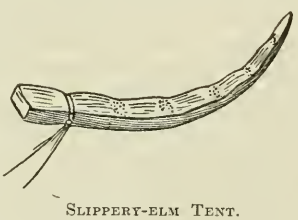
TENIA.—A genus of parasitic worms of the class cestoda (tape-worms). They form ribbon-like stocks, composed chiefly of a row of consecutive segments progressively increasing in size posteriorly (*proglottides*), and arising by strobilation from the knob-like head (*scolex*) which is provided with organs of adhesion. Over 200 species are recognized, having for their hosts very widely separated animals, with correspondingly wide geographic distribution. See WORMS (Tape-).

TENIAFUGE.—See ANTHELMINTICS.

TENNIS LEG.—This consists of rupture of the plantaris, and may occur during climbing, jumping, boxing, tennis, and similar exercises. There is a sharp pain in the calf like the sting of a whip (*coup de fouet*), tenderness, swelling, and, after a day or two, ecchymosis along the posterior surface of the leg; identical symptoms are produced by the rupture of a deep varix. The *treatment* is rest of the leg for one week, ichthyol, and a firm bandage. Later the patient may walk, but should not rise on the toes for several weeks (Stewart).

TENSION.—See EYE (Examination).

TENT.—An instrument made of compressed sponge, laminaria, slippery elm, tupelo, or other material that increases in volume by the absorption of water; it is used chiefly for dilating the cervix of the uterus. When lodged in the uterus, laminaria slowly expands the cervical canal, which in this way usually becomes accessible to the finger for diagnostic purposes. The value of the agent in the main relates to the management of some of the consequences of abortion, or the postpartum retention of the products of conception. It is largely employed by some practitioners in facilitating the application of local remedies to the endometrium. The use of the tent is always accompanied by risk, and it should not be employed without extreme caution. It must not be introduced into the uterus when there is any evidence of pelvic inflammation.



SLIPPERY-ELM TENT.

TEREBENE. $C_{10}H_{16}$.—A hydrocarbon obtained by the oxidation of oil of turpentine by means of sulphuric acid. It is soluble in alcohol and is recommended for winter cough as an expectorant, and for inhalation in bronchitis. Dose, 5 to 15 minims on sugar or suspended in water.

TEREBINTHINA.—See TURPENTINE.

TERPENE.—One of a number of hydrocarbons analogous to turpentine oil. They have the formula $C_{10}H_{16}$, or $(C_5H_8)_n$, and are contained in the volatile or ethereal oils obtained in the distillation of various plants (chiefly *Coniferæ* and *Citrus* species). The terpenes that have been thus isolated are very numerous.

TERPIN HYDRATE. $C_{10}H_{18}(OH)_2.H_2O$.—Obtained by distilling oil of turpentine with an alkali. Useful in bronchial and pulmonary diseases to loosen and facilitate the expectoration of mucus. Dose, 1 to 5 grains.

TERPINOL.—An oily substance formed by boiling terpin and terpin hydrate with aqueous mineral acids. It is a thick liquid, with a peculiar odor, boiling at 215–218° C. Its uses are similar to those of terpin. Dose, 2 to 5 grains.

TESTICLE, ABNORMALITIES. Absence.—Complete absence of the testicle is sometimes seen, and such a subject presents the ordinary appearance of a eunuch. A well-developed seminal vesicle and vas deferens have been found with no trace of testicle, and vice versa.

Supernumerary testicles have been described, but they are usually found to be fatty or fibrous tumors of the cord, old epiploceles, or encysted hydroceles.

Malposition.—The abdomen, inguinal canals, or the perineum may be the retaining place of the testicle, or it may lodge in the subcutaneous tissue of the upper thigh or be in the inner and upper part of the thigh; or it may be so rotated in the scrotum that the epididymis is in front; or it may be there completely inverted. When there is malposition in the scrotum, it must have been caused by some abnormality in the development of the cord. The consequences of retention in the abdomen are arrest of development, sometimes fatty, fibrous or malignant degeneration, or, if otherwise normal, failure to secrete a fertilizing fluid.

Retention in the Inguinal Canal.—Retention in the inguinal canal is often accompanied by inguinal hernia, and when inflamed at puberty, causes great pain from the distention of surrounding parts. In such cases peritonitis may cause the swelling to simulate a hernia. The testicle retained in the inguinal canal may be mistaken for a strangulated bubonocele or for a bubo. Retraction may be differentiated from retention by comparison with the state of development of the corresponding slde of the scrotum. A perineal or femoral position of the gland is not necessarily attended by any bad result.

When the gland in the inguinal canal is attended by inconvenience, it may be placed in the scrotum by operation. Extirpation may be necessary if, from shortenss of the cord, this is impossible.

Trusses are not to be recommended for infants, even when malposition is complicated by inguinal hernia, as the hernia frequently subsides, and the truss will then interfere with descent of the testicle. When it has passed through the crural ring, the malposition cannot be remedied. If in the perineum or thigh, the testicle may be placed in the infantile scrotum by operation. Malpositions in the scrotum are important only from the standpoint of operations, as for hydrocele, etc. Arrest of development sometimes occurs even after the testicle has passed into the scrotum, but with no serious consequences.

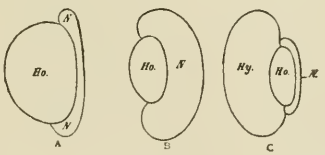
Atrophy.—Rupture or ligation of the spermatic artery, and occasionally acute orchitis (especially that variety which is associated with mumps), are the chief causes, the testicle shrinking to a small nodule. Rupture or ligation of the vas deferens, chronic epididymitis, the pressure of ill-fitting trusses, and abuse may be followed by the same effect; but the wasting is seldom so extreme. Whether it is ever a result of varicocele is doubtful, though this is so often associated with a soft and flabby condition of the gland.

Hypertrophy is said to occur as compensation in cases of unilateral retention.

TESTICLE, HERNIA.—This condition is also known as "benign fungus of the testis," and may be superficial or deep. It is recognized as a fungus protrusion from the scrotum, the size of a pea, or even of a small egg, red or yellowish-red in color. In the deep form the tunica albuginea has been perforated, and seminal tubules form the greater part of the mass. It may occur after any form of suppurative orchitis.

Treatment.—Well-adjusted pressure and applications of silver nitrate or mercuric oxid may suffice. Freeing the margins of adhesions and suturing the over-stretched skin is usually very successful. If due to specific cause, antisyphilitic treatment is indicated.

TESTICLE, INFLAMMATION (Orchitis; Epididymitis).—Acute inflammation of the testicle is generally spoken of as orchitis or as epididymitis, according as the body or the epididymis is primarily or chiefly affected.



Diagrammatic sections of (A) Orchitis, (B) Epididymitis, and (C) Hydrocele of the Tunica Vaginalis. *Ho*, Testis; *N*, Epididymis.—(*Tillmanns.*)

Etiology.—Gonorrhea is the most frequent cause; but injury of the testicle, or irritation of the prostatic urethra, as from the tying-in of a catheter, or from the impaction of a calculus or fragment of a calculus, are not uncommon causes. Orchitis sometimes occurs during an attack of mumps, and is then said to be due to metastasis. It has also been attributed to the use of strong injections for the cure of gonorrhea. In what manner inflammation of the testicle is induced by the irritation of the urethra is disputed. It is variously taught, however, that it is due to (1) inflammation spreading along the vas; (2) reflex irritation; and (3) metastasis.

Symptoms.—In a well-marked case there is intense pain in the testicle, with a dragging or aching pain in the groin and along the course of the cord. The testicle is swollen, and is exquisitely tender to the touch; the cord is slightly thickened; and the skin of the scrotum is edematous and of a dusky red color. When the inflammation is in the epididymis, the pain and swelling will be chiefly confined to the lower and back part of the testicle—the region of the epididymis—and fluid will often be detected in the tunica vaginalis. If the inflammation of the testicle occurs during an attack of gonorrhea, the discharge generally ceases or diminishes when the inflammation is at its height. The local signs are often accompanied by sharp febrile disturbance, elevated temperature, furred tongue, nausea, or even vomiting, and constipation.

Treatment.—When the attack is acute, rest in bed, with the testicle supported on a pillow, is desirable. Cooling lotions, such as lead water and laudanum and a weak alcoholic solution of ammonium chlorid are time honored applications. Hot moist compresses sometimes afford relief when cooling lotions fail. Recently hot saturated solution of Epsom salt has been highly recommended. Another much esteemed application is 25 percent guaiacol in olive oil or glycerin, painted over the affected half of the scrotum once or twice daily. Internally, a brisk purge should be given at the onset, followed by saline laxatives and small doses of antimony. If the pain is very severe, opium may be given. Urethral treatment must be stopped.

If the effusion into the tunica vaginalis is extensive, a few punctures may be made with a fine tenotomy knife, or an ordinary trocar and cannula may be introduced; and if the veins of the scrotum are distended, they may be pricked and encouraged to bleed, or leeches may be placed over the inguinal canal; but, although it is largely practised by some surgeons, and apparently with impunity, puncture of the testis itself is not advisable.

After the acute stage has subsided a properly fitting suspensory bandage should be worn. Martin's epididymitis bag is the most satisfactory American appliance.

After the skin has been lightly anointed with vaselin, the suspensory bandage is lined with cotton and so adjusted as to raise the scrotum toward the abdomen. The degree of pressure can be regulated from time to time according to the amount of swelling and tenderness of the organ.

An effort should always be made to secure resolution of the nodules which persist after the acute inflammation has entirely subsided. For this purpose the application of compound iodin ointment or oleate of mercury is useful, the latter applied very sparingly so as not to produce great irritation of the integument. Iodin internally has been thought by some to favor reso-

lution. Given in the form of syrup of hydriodic acid it will rarely, if ever, cause gastric irritation.

Traumatic orchitis may be treated in the same way. When due to metastasis, warm fomentations are better from the first; and if there is much infiltration of the scrotum, so that the condition of the circulation is doubtful, or if the patient is old and feeble, cold should not be used, for fear of gangrene.

Chronic Inflammation.—This may begin as such or may be the relic of an acute attack. When confined to the body of the testis, it is nearly always due to syphilis; gout and malaria are exceptional causes. If the epididymis only is concerned, it is probably tubercular or urethral, and in the latter case it may be either the remains of an acute attack or chronic from the first. Syphilis occasionally affects the epididymis only (in the early secondary period), and not infrequently both epididymis and testis.

Symptoms.—The testicle appears enlarged, smooth, laterally compressed, egg-shaped, hard, heavy, and painful on pressure; the testicular sensation is not lost; the vas is but slightly thickened; the skin is nonadherent, and the epididymis (except when the disease is limited to that part) is not distinguishable from the body of the organ. In chronic epididymitis an indurated, painful, and tender lump is felt in the situation of the globus minor or major.

Treatment.—Mercury or potassium iodid should be given internally, and the enlarged organ may be strapped. Mercurial inunctions are also of value.

Tubercular disease of the testicle, also known as strumous orchitis, or strumous sarcocele, is variously believed to depend upon the presence of the tubercle bacillus, or upon a chronic inflammation in a strumous subject; and to begin either as a tubercular affection in the intertubular connective tissue or as a catarrhal inflammation in the interior of the tubules.

Pathology.—Opportunities for examining the testicle in the early stages of the disease are not common, and there is uncertainty as to the origin and exact nature of the inflammation.

Symptoms.—The disease usually begins very insidiously. The epididymis, especially the head, and, later, the body of the testicle are found enlarged. The testicle is usually but slightly tender to the touch, and the testicular sensation is not lost; a hydrocele may be present or part of the tunica vaginalis may be obliterated. Subsequently, the cord, especially the vas, becomes thickened and the skin adherent; while still later the skin may give way and a fungus, composed of the infiltrated tubules, may protrude or a discharging sinus may be produced. When the testicle becomes adherent to the skin, soreness and pain will develop as the initial manifestations of the long-existing disorder. The seminal vesicles or prostate may now be felt enlarged on examining by the rectum, and bladder or urinary disorders may set in; while symptoms of tubercle in the lung, larynx, or other organs may supervene, and the patient may succumb to tubercular disease. At other times no constitutional signs manifest themselves, and the patient may completely recover.

Diagnosis.—From syphilitic orchitis it may generally be distinguished by the enlargement of the epididymis, thickening of the cord, adhesion of the skin, enlargement of the seminal vesicles and concomitant signs of tubercle elsewhere.

Treatment.—In the early stages, before the vas or seminal vesicles have become involved, some surgeons advise castration or resection of the epididymis for the purpose of preventing, if possible, general dissemination of the disease; and when both testicles are affected, even the removal of both. Others, however, rely on constitutional, hygienic and climatic treatment, and only advise the removal of the testicle should it become destroyed by the disease. If the seminal vesicles are found affected in the early stages, or if signs of tubercle are discovered in other parts, the testicle should, of course, on no account be excised.

The *constitutional treatment* is that of tuberculosis.

The *local treatment* consists in suspension of the organ, avoidance of horseback riding or other violent exercise, and recumbency during an exacerbation of the inflammation. Should the tubercle soften and suppuration occur, the abscess must be opened and the wound dressed with iodoform or other antiseptic. If intractable sinuses remain, they should be scraped with a Volkmann's spoon. If a fungus forms, it will frequently recede under rest in bed, cleanliness, and the application of a stimulating ointment or of iodoform. Should the testicle become completely disorganized, it had better be excised.

Syphilitic Inflammation.—Subacute epididymitis may occur in the early secondary stage, a painful irregular swelling making its appearance at the back of the testicle, involving the cord to a slight extent. It never possesses the severity of urethral epididymitis; the skin may be reddened, but is not edematous; and, like the other secondary symptoms with which it occurs, it subsides rapidly under mercury.

True orchitis appears later, either during the intermediate period (when both glands are involved), or with the tertiary symptoms, when one gland is often attacked long before the other. As a rule, it does not affect the epididymis or the cord, and is very chronic in its progress; but often, in neglected cases, after the first testicle has been enlarged for some time, the second suddenly becomes actually inflamed, the skin grows hot and red, the tunica vaginalis distended, the epididymis affected as much as the testis, and the pain so severe that the patient is compelled to apply for relief.

Symptoms.—The character of the swelling depends upon the distribution of the syphilitic exudation and upon the changes it undergoes. In some cases, especially the earlier ones, there is uniform enlargement of the whole gland, so that it remains ovoid, smooth, and even, and merely becomes heavy and intensely hard; in others the surface is nodular and uneven in con-

sistence, dense indurated patches alternating with others that are soft and elastic. The exudation, in other words, may be uniformly distributed throughout the whole of the fibrous tissue of the gland, or it may be aggregated either into one central gumma or into numerous scattered gummata of various sizes; and, according to the success of the treatment, it may be completely absorbed, merely leaving a slight depression, or may become organized into cicatricial bands, or may break down and undergo caseation and liquefaction. Occasionally, this ends in suppuration and hernia testis; more frequently, partial absorption takes place, and a hard, irregular mass is left, sometimes in the middle, sometimes at one side of the testis, composed of a caseous or even calcareous center, surrounded by an immense thickness of cicatricial tissue—a so-called chronic abscess.

The size to which a testicle may attain under these conditions is enormous; usually, when large, it is painless and is devoid of testicular sensation. Heat, redness, thickening of the cord, edema of the skin, and effusion into the tunica vaginalis are signs of acute inflammation, and are only present when the testicle is first attacked or when a fresh gumma suddenly develops. Cases of this kind have lasted for 10 years, with occasional subacute attacks compelling the patient to apply for relief, until at length the testicles were enormously enlarged, irregular in shape, hard, painless, and absolutely devoid of sensation.

The diagnosis of syphilitic orchitis is rarely difficult; the only form that resembles it is that occurring in gout. The chief features are the essentially chronic character of the affection (varied from time to time by more acute attacks); the smooth, hard, heavy character of the swelling; the disappearance of the epididymis, which in many instances is so flattened out that it cannot be felt (occasionally, it is enlarged); the absence of pain (during the greater part of the time) and of testicular sensation; and the fact that both testes are involved, though usually not to an equal degree. .

Treatment.—In epididymitis and recent orchitis mercury may be given freely, with a view to causing speedy absorption; later, especially if the disease has relapsed, more benefit is derived from small doses of bichlorid of mercury, continued with occasional interruptions. Iodid of potassium always causes a rapid diminution in size, but absorption of the syphilitic exudation is rarely complete; it progresses up to a certain point, continues as the dose is increased, and then comes to a standstill, leaving a dense mass, over which nothing appears to have any influence. The acute symptoms, however, are quickly relieved by it. Occasionally, other remedies are of service: mercury, for example, rubbed into the skin on the inner side of the thigh (it cannot be applied to the scrotum), strapping, or the removal of hydrocele fluid. If suppuration occurs, the abscess must be opened; and at length, if the testis becomes useless and is a constant source of pain and suffering, castration may be advisable.

TESTICLE, PAIN.—Pain and retraction of the testicle are of frequent occurrence in disease of the kidneys and in affections involving branches of the lumbar plexus; further, after obliteration of the vas, sexual intercourse, or even sexual excitement, may be attended by severe pain and swelling of the gland; in addition to this, however, in certain persons the testicles are liable to attacks of intense neuralgia, coming on at regular intervals or excited by the most trivial irritant. Usually, one only is affected, but both may be; the gland may be apparently well nourished, or it may be small and flabby; it may be exceedingly irritable, resenting the slightest touch, or there may be nothing noteworthy about it. In many cases there is a history of injury, but it seldom stands cross-examination. Gout, malaria, anemia, and other constitutional ailments are sometimes present. Neuralgia of the testicle may occur in the most continent; and though in many there is a history of abuse, it is difficult to connect one condition directly with the other. Sexual hypochondriasis may be associated with it, and often the family history is decidedly neurotic.

Treatment is very unsatisfactory. Any local or constitutional cause that can be detected must, of course, receive thorough consideration; a suspensory must be worn; lead or some other cooling lotion should be applied; and the thoughts and ideas directed into other channels. Cupping over the loins, massage of the back, and the free (local) use of anodynes may be tried as well. If there is a large varicocele, operation may give relief, but castration is useless.

TESTICLE, REMOVAL.—See CASTRATION.

TESTICLE, TUMORS. Hematocele.—See HEMATOCELE.

Hydrocele.—See HYDROCELE.

Dermoid and hydatid cysts are occasionally met with. The former may be recognized by their congenital origin, though often they do not attain much prominence until late in life, and their uneven consistence; but no certain diagnosis can be made without puncture.

Cystic adenoma is more common. Like parotid glandular tumor, it is peculiar to the organ from which it springs, and only admits of a somewhat vague comparison with other growths. It consists of cysts of all sizes, lined with cubic or flattened epithelium, filled with a clear brownish or greenish fluid, and developed from the seminiferous tubules, the epithelium of which has either lost or has never acquired its distinctive characters. A variable amount of fibrous tissue exists between them, sometimes undergoing myxomatous degeneration, and occasionally mixed with cartilage. Intracystic growths may occur as well. Tumors of this kind may occur at any age, but they are rarely noticed before puberty. Growth is slow and painless, the patient suffering no inconvenience other than that due to the weight. The vas is never affected, and secondary deposits do not occur, the cases in which this is said to have taken place having really been sarcomata, with an accidental development of cysts.

Fibroma and enchondroma of the testis are met

with in young adult life, but they are both very rare. The chief clinical feature is the slow growth of a hard and heavy painless mass. The surface is usually smooth, but it may be nodular, suggesting the presence of cysts. Growths of this kind do not extend along the cord, invade other organs, or recur; but removal is always advisable. There is no means of distinguishing one from the other but by a section.

Carcinoma of the testis is nearly always encephaloid, though a few cases of scirrhus have been described. It is stated to be most common between 20 and 40 years of age. The beginning is usually very insidious; the testis is enlarged, smooth, ovoid, and at first fairly firm; the cord is not thickened, nor are its components matted together, but it is fuller than the other, and the veins over the scrotum are distended. There is little or no pain or tenderness, and testicular sensation is soon lost. In a very few weeks there is a rapid increase in size; the tumor is softer, the surface uneven, the cord distinctly thickened, the shape becomes globular and the epididymis flattened out at the back. If left, it becomes so soft that it almost seems to contain fluid; the skin becomes adherent, the veins are more distended, the thickening extends higher up the cord, and, perhaps, if the patient is thin, an ill-defined sense of resistance can be made out by deep pressure at the back of the abdomen. The skin of the scrotum soon gives way, allowing a bleeding mass to protrude, the glands of the groin enlarge, secondary deposits make their appearance in other organs, and the patient sinks rapidly from exhaustion.

Sarcoma of the testicle presents greater variety of appearance and character. It may be round-celled or spindle-celled, and the latter especially may become more or less converted into cartilage (without, however, losing one atom of its malignant sarcomatous character); sometimes there are only nodules here and there, sometimes branching outgrowths—due, perhaps, to the spreading of the disease inside the lymphatics—and occasionally so much that the original sarcomatous growth is hard to find. In addition both of these forms may be associated with cysts, due either to softening and hemorrhages or to distention of the seminiferous tubules, with proliferation of the epithelium lining them, and occasionally intracystic growths, so that they may present a close resemblance to some of the forms of cystic adenoma. Sarcoma may occur at any age, even before birth, though it is most common under 10 years and between 30 and 40. The round-celled variety, unless the patient is a child, or unless both testicles are attacked at once, cannot be distinguished from encephaloid carcinoma; the progress is as rapid, and the glands of the lumbar and other regions are involved as soon; if possible, it is even more fatal. The other variety is much less uniform in rate of growth and consistence; it may, for example, be formed almost wholly of cartilage or of fibrous tissue; cysts are less common, and it does not appear to fungate so readily; but the ultimate results—the infiltration of the glands with growth of the same histologic character as the primary one, and the secondary deposits in the lungs and other organs—are equally certain.

Teratomata.—These are congenital tumors containing embryonal tissue elements from the three blastodermic layers. Dermoid cysts also belong to this class. Many of these tumors are exceedingly malignant, especially those which contain tissue resembling chorioepithelium.

Treatment.—Sarcoma, carcinoma, and the teratomata should be removed as soon as the diagnosis is made. The usual operation of castration is inadequate for the removal of malignant tumors of the testicle. Although it is impossible to reach the lymphatics which drain the testicle at their termination, they should nevertheless be divided as high up as possible.

Following the method of Cumston and Rolfe an incision is made parallel to, and about three quarters of an inch above, Poupart's ligament, the inguinal canal laid open, the cord freed and lifted out. The iliac fossa is then entered by an opening made through the posterior wall of the canal. The vas is followed downward into the pelvis as far as possible, cut, and the stump touched with pure carbolic acid. The spermatic vessels are then traced upward as far as possible, ligated in two places and divided between the ligatures. The cord is separated from its coverings from above downward to a point below the external ring. The testicle may be pushed up and removed with the cord unless it is very large, when a longitudinal incision down the scrotum is required for its removal. The prognosis is very unfavorable, but in all probability this is due in some measure to delay; there is evidence to show that if castration is performed in time, recurrence may not take place for many years. Even if the skin is involved and the cord thickened, the operation is advisable in order to save the patient from the formation of fungus, if only there is reasonable prospect of securing immediate union of the wound.

Diagnosis of Tumors of the Testes. *Age.*—A tumor that appears in infancy is probably hydrocele; sarcoma and syphilitic and tubercular orchitis occur, but are very rare in comparison.

Etiology.—A definite history of accident deserves consideration, though it may merely have drawn attention to an already existing, but unsuspected, enlargement. Sarcoma as well as hematocele may follow injury.

Rapidity of Growth.—Hematocele is an affair of minutes, or, at most, of hours; malignant disease, of a few weeks. Acute orchitis presents no difficulty in diagnosis; chronic inflammation, on the other hand, if only one side is involved, if there is no evidence of constitutional complaint, and if there are but little heat or pain and no redness, can often be diagnosed only by the results of treatment. Syphilitic orchitis, for example, may, so far as a single examination is concerned, be indistinguishable from incipient malignant disease.

Duration.—If the tumor has lasted more than 6 months without the doubt in diagnosis clearing up, it is not malignant.

Consistence, whether solid or fluid. Hydrocele

and hematocele are the only fluid tumors at all common, but there are many sources of fallacy. A hydrocele may conceal an enlargement of the testes (hydrosarcocele). Old hydroceles and hematocle may have walls of such thickneess as to appear solid, and rapidly growing malignant tumors may be as soft and elastic as if they contained fluid.

Translucency.—This distinguishes at once thin-walled hydroceles.

Number.—Hydrocele and sarcoma may occur on both sides, but when both testes are affected, the tumor is nearly always of inflammatory origin.

Shape.—If the tumor retains the shape of the testis, it is probably either chronic inflammation or incipient, malignant disease. Sarcoma and carcinoma (when more advanced), hematocele and encysted hydrocele, are all spheric; other tumors are very irregular.

Pain and Sensitiveness.—Hematocele may be very painful at first; the others—except acute inflammation—are rarely attended by pain. In chronic orchitis, malignant disease, and hematocele testicular sensation soon disappears.

The Condition of the Cord.—In chronic orchitis, hydrocele, and hematocele, the cord is not affected. In acute inflammation and incipient malignant disease it feels full because of the increased amount of blood. In acute epididymitis and advanced sarcoma and carcinoma it is thickened and all its component structures are welded together. The vas itself is enlarged in tubercular epididymitis. The skin is not adherent unless there is acute inflammation or advanced malignant disease (Moullin).

The following table, from Keyes and Stewart, shows the main points in the diagnosis of chronic diseases of the testicle:

	Simple Chronic Epididymitis.	Tuberculosis.	Syphilis.	Tumor.
History	Gonorrhea, stricture, or hypertrophy of prostate.	Tuberculosis, family or personal.	Syphilis inherited or acquired.	Perhaps trauma.
Frequency	Uncommon	Frequent	Frequent	Rare.
Size	Small between attacks.	Does not reach any great size.	Does not reach any great size.	May reach any size.
Tenderness	Yes	Yes	No	No.
Shape	Between attacks testis normal, epididymis nodular.	Epididymis nodular. Testis not involved unless acute or ancient.	Testis evenly enlarged, slightly nodular, "clam shell" epididymis.	Testis greatly enlarged, no characteristic involvement of epididymis.
Cord	May be slightly thickened.	Enlarged and nodular.	Free	Free.
Seminal vesicles	Usually distended	Tuberculous	Uninfluenced	Uninfluenced.
Prostate	Posterior urethra inflamed.	Congested or tuberculous.	Uninfluenced	Uninfluenced.
Urine	Cloudy	Cloudy, may contain bacilli.	Clear	Clear.
Hydrocele	Unusual	Often	Nearly always	Unusual.
Onset	Usually acute	Usually chronic	Chronic	Chronic.
Age	Adult life	Not often after 30	Middle life	Any age.
Origin	Epididymis	Epididymis	Testicle	Testicle.
Course	Recurring acute attacks.	Chronic	Very chronic	Usually rapid.
Suppuration	Unusual	Common	Rare	None, but fungus common in later stages.
Atrophy of testis	Rare, potency unimpaired.	Rare, potency somewhat impaired.	Common, potency somewhat impaired.	Never, potency unimpaired.
Opposite testicle	Often involved simultaneously.	Usually involved subsequently.	Free	Free.

TESTICULAR EXTRACT (Orchitic Extract.)—This substance has been recommended as a general tonic for the aged, for subjects of impotence, or for a debilitated nervous system. It has been used in general adynamia, anemia, atonic gastro-intestinal affections, scurvy, malaria, epilepsy, cancer, nymphomania, perverted sexual habits, impotence, neurasthenia, hysteria, melancholia, diabetes, tuberculosis, hemiplegia, paralysis agitans, and locomotor ataxia.

It is prepared in the following manner: The testicles of bulls, enveloped in their membranes, are washed in a 10 percent solution of sublimate, and again with sterilized water, are each divided into 5 or 6 parts, placed in aseptic glycerin (a pint to the pound of testicle), and allowed to macerate therein for 24 hours. An equal quantity of a 5 percent solution of common salt in boiled water is then added, and the mixture is filtered and sterilized by being subjected to a pressure of 30 atmospheres of carbonic acid gas. The dose is from 10 to 20 minims hypodermically, once daily or every other day, with strict aseptic precautions as to the syringe used and the site of injection; the latter should be washed with a 1:1000 sublimate solution or with a 2 percent solution of carbolic acid. The extract seems to have little or no effect when given by the mouth, but is efficient when administered by the rectum.

TESTIMONY, MEDICAL.—See EXPERT TESTIMONY.

TESTS.—See URINE (Examination), BLOOD (Examination), SPUTUM, STOMACH-CONTENTS, BACTERIOLOGY, PATHOLOGIC TECHNIC, VISION (Tests), HEARING (Tests), etc.

TETANUS (Lock-jaw; Trismus).—An infectious disease, marked by tonic spasms of the voluntary muscles, with distinct exacerbations. The contractions may be confined to the muscles of the lower jaw (trismus) or to certain other groups of muscles, or they may involve the muscles of the whole body. Tetanu smay occur at any age. It

BACILLUS OF TETANUS, SHOWING SPORES.—(*Fränkel and Pfeiffer.*)

is often epidemic among children. Males suffer oftener than females by about 4 to 1.

Etiology.—Tetanus is caused by a specific bacillus—the tetanus bacillus, first discovered by Nicolaier, and first obtained in pure culture by Kitasato. It is present in surface soil and dust. This explains the fact that wounds which have been infected by dust or earth are so often followed by tetanus.

This bacillus is long, slender, and swollen at one end in the shape of a "drumstick," in which a spore develops. The germ is generally isolated or in pairs, and is motile, but has no flagella. The bacillus of tetanus is anerobic. It is exceedingly resistant to the action of heat and to that of carbolic acid solution. It grows upon artificial culture mediums, such as gelatin, bouillon, and with gelatin containing glucose.

Men, horses, mice, rabbits, and guinea-pigs are all susceptible; birds and dogs are less so, while the frog is immune. It is said, however, that if the body temperature of the frog is increased it becomes susceptible. The bacillus of tetanus stains well with all the ordinary aqueous solutions of anilin dyes and by Gram's method.

Symptoms.—At first the patient finds stiffness in the movement of the jaw; he experiences uneasiness in swallowing, and soon perceives that he has difficulty in separating his teeth for the admission of food. He begins, now, to feel pain behind the sternum, and this pain extends from the pit of the stomach toward the vertebral column. The muscles of the back and those of the back of the neck begin to be affected by spasms; then those of the abdomen, afterward those of the limbs, and lastely those of the face. The muscles become more and more rigid as the case proceeds. In the extreme period of the disorder all the muscles of voluntary motion are affected; among others, those of the face; the forehead and nose are drawn up; the eyes are distorted, fixed, and motionless; the cheeks are retracted, and the features undergo an extraordinary change. The spasms become universal, and a violent convulsion puts an end to the misery of the patient.

Profuse sweating usually occurs during a paroxysm. The temperature in some cases is normal throughout; in others there is marked pyrexia from the outset, the temperature reaching 105° or 106° F. before death, and being 109° or 110° F., and even higher, soon after death. When death occurs, it is usually due to exhaustion, inanition; spasm of the diaphragm, or the muscles of respiration; spasm of larynx, with asphyxia; arrest of heart action from spasm or paralysis.

Diagnosis.—The symptoms are so characteristic, with the addition of a history of a wound, that an error seems hardly probable.

Tetany.—The spasms chiefly affect the extremities, the muscles being free in the interval and trismus a late or very rare condition.

Strychnin poisoning often closely resembles tetanus, but there is no beginning trismus and there is more rapid development of the symptoms. No history.

Hydrophobia does not have trismus; but respiratory spasm occurs, excited by attempts at swallowing, with increasing mental symptoms.

Prognosis.—In the acute form the prognosis is very grave; in the chronic form it is favorable.

Treatment.—The indications are to keep up the strength of the patient until the disease ceases; to remove, as far as practicable, all conditions believed to have the power of creating the tetanic state; and to employ any sedative or special

treatment from which it may be hoped to derive advantage. Perfect quiet is absolutely essential; the room should be darkened, and the patient kept, as nearly as may be, in perfect repose; remedies should be administered as gently as possible; everything harsh or violent should be avoided. If nourishment cannot be swallowed, it should be administered through the anus; it should be as plentiful as the nature of the case will admit; the supply of brandy and wine should be abundant. Quinin and iron should be freely administered; opium and morphin have, in many cases, been serviceable; chloral hydrate, chloroform, Indian hemp, and tobacco have all been tried in turn, and sometimes with success. Hydrobromid of hyoscin has recently been highly recommended in the treatment of convulsions. Large doses of bromid of potassium and chloral are also used. Should suffocation be threatened from spasm of the glottis, inhalations of nitrite of amyl should be resorted to: the usual quantity administered is from 5 to 10 minims. From a physiologic standpoint, calabar bean is the drug that deserves the most attention, as it is antagonistic to the tetanic spasms caused by strychnin. It has, however, not proved to be a specific for tetanus. Extract of physostigma, 1/8 grain, may be given every hour until complete contraction of the pupil occurs, and this must be followed by stimulants to counteract the resulting depression.

Intraspinal injections of magnesium sulphate suggested by Meltzer have been used with success in some cases. The danger of respiratory paralysis is combated by the administration of oxygen and artificial respiration long continued if necessary.

Specific Treatment.—This consists in the use of the antitetanic serum along with the other treatment. The dose is 10 to 20 c.c. of fresh serum, every 4 to 12 hours according to the severity of the symptoms. Results have not been better because generally the treatment is begun too late. In any suspected case the serum should be administered at the earliest possible moment after the infliction of the wound. As tetanus antitoxin is harmless it should be used as a prophylactic measure, a dose of at least 5000 units being given. The subarachnoid injections of magnesium sulphate should be used in connection with the injections of tetanus antitoxin.

TETANUS ANTITOXIN.—The toxin of tetanus is a toxalbumin of extraordinary potency, and is perhaps the most virulent poison known. Whereas the fatal dose of strychnin for a man weighing 70 kilos is from 30 to 100 milligrammes (gr. ss–jss), that of the tetanus toxin is estimated at 0.23 milligramme (gr. 1/320). In laboratory experiments the disease is prevented and cured by its antitoxin with almost absolute certainty, but the conditions are in every respect different from those which obtain in cases of accidental infection, the amount of toxin present in the animal being known, and the antitoxin being administered at the same time with the toxin or very soon afterward. The disease is clinically unrecognizable until the nervous system has been sufficiently damaged to produce symptoms of nerve lesions, and the toxin is firmly united with the proteins of the central nervous tissue before symptoms develop, until which a diagnosis is impossible. The case is usually far advanced when professional assistance is first sought, and is therefore not so amenable to treatment as diseases which manifest their symptoms by progressive stages.

The study of tetanus statistics shows that its mortality prior to the use of antitoxin was from 70 to 90 percent, in the acute form 80 to 90 percent, and in the chronic type about 40 percent. The available statistics of cases treated by antitoxin give the general mortality under this treatment as between 40 and 50 percent, the reduction being chiefly manifested in the subacute and chronic cases, acute tetanus showing a mortality of 70 to 80 percent.

On account of the natural difficulties in treating this disease by antitoxin at the late period when the symptoms are manifested, and from the fact that the serum is powerfully immunizing and harmless, the tendency is to adopt a prophylactic method in all cases, giving a full immunizing dose as soon as possible after the infliction of a wound received under circumstances which indicate a possible tetanus infection. For this purpose not less than 1500 antitoxic units should be administered. Along with this treatment the usual preventive measure should be employed, including excision of the part or the actual cautery if the wound is recent. The actual cautery, or the application of a strong solution of corrosive sublimate with tartaric acid, or the injection of phenol solutions, are the most effectual methods of combating the tetanus germs in the wound. For curative purposes the serum should be injected as soon as possible, the quantity being determined according to its stated strength, the gravity of the symptoms, the patient's age and the time since infection. The serum must be fresh to be effective, and as a curative agent should be given so as to reach the nerve centers as quickly as possible, therefore 5000 units are given intraspinally, or 10,000 units intravenously, and repeated as indicated.

TETANUS, INFANTILE.—Tetanus occurring in infants, as in adults, is an acute infectious disease due to a certain bacillus (Nicolaier's bacillus) which has its habitat in the soil. The germ of tetanus usually gains access to the body of the infant through the umbilical wound. Tetanus is rare except when dirt and filth prevail, but these alone are not sufficient to produce the disease.

Symptoms.—These usually begin on the fifth or sixth day or at the time of the separation of the cord. The first symptom may not appear before the tenth or twelfth day, but seldom later, and the first thing noticed is a difficulty in nursing, due to the rigidity of the jaws. The muscles of the jaws and face are hard and firm. Soon a slight stiffening of the body occurs, the child remaining rigid for a short time, but relaxing during the intervals. These paroxysms soon increase in extent and frequency; the whole body becomes rigid and stiff; the arms are extended, the thumbs turned in, and the hands clenched. The thighs

and legs are extended and no motion is possible at the hip or knee. The jaws may become firmly closed, and food cannot be taken. The pulse is rapid and weak, the temperature is more or less elevated (101° to 104° F.). The duration of fatal cases is very short (24 to 48 hours); but when recovery takes place, which is rare, the disease continues from 1 to 3 weeks, and the child usually suffers from malnutrition for some time longer.

Treatment.—The preventive treatment consists in obstetric cleanliness and in especial care, in districts where tetanus is epidemic, that the cord is kept in a perfectly aseptic condition. Tetanus antitoxin should be given as soon as the slightest suspicion of the disease exists. The child should be kept in a very quiet, darkened room. During severe paroxysms inhalations of chloroform should be given until the patient is quiet. When the mouth cannot be opened, it may be necessary to introduce a wedge, so that nourishment can be taken.

When unable to swallow, food should be introduced through a stomach-tube, which, when it cannot be passed through the mouth, may be inserted through the nose. Chloral hydrate should be given, and often large doses will be necessary. Beginning with 1 grain every hour, this may be increased, if the effects are not marked. The chloral should be well diluted in water, and may be given by the mouth or rectum. Extract of physostigma in 1/10-grain doses should be given hypodermically 3 times a day, or more frequently if necessary.

TETANY.—Tetany is a form of tonic muscular spasm, affecting most commonly the muscles of the extremities, especially those of the hands and feet. It may occur at any age, but is most frequent during infancy.

Etiology.—Tetany rarely occurs as a primary disease, but when occurring in infants, it is, in a majority of cases, associated with rickets, although in some cases it occurs with marasmus, chronic diseases of the intestinal tract, or some of the acute infectious diseases. The principal exciting cause is some irritation of the gastro-intestinal tract, as acute diarrhea, worms, prolapse of the rectum, or intussusception. In some cases teething may be the exciting cause. It has been known to recur among school-girls as an epidemic, in this respect resembling chorea.

Symptoms.—The attacks consist of cramps of the muscles of the extremities. There is no loss of consciousness and, as a rule, no spasm of the facial muscles, but the face wears an expression of pain when the cramps come on, and the infant screams when it is touched. The legs and arms are flexed and rigid, and the hands and fingers are tightly flexed. The feet may assume various positions of flexion, such as that of talipes equinus or equinovarus. The duration of the disease varies from a few minutes to hours or days. There is no loss of consciousness and no fever with the spasms. Laryngismus stridulus is quite often associated with tetany, as are also general convulsions. Tetany of itself is seldom fatal, but the prognosis of any case must depend upon the original disease that tetany may complicate.

Diagnosis.—The diagnostic features of the disease are bilateral spasms without loss of consciousness, the spasm in infants being usually limited to the hands and feet.

Tetanus is to be distinguished from tetany by the fact that the former is a very rare disease, except in the new-born, etc., and that the attack begins with trismus, which does not occur in tetany. From **meningitis** tetany is distinguished by the fever and cerebral symptoms.

Treatment.—When tetany is due directly to some digestive disturbance, as is usually the case, this should receive attention. A dose of castor oil (1 to 4 teaspoonfuls) should be given to clear out the intestinal tract, or, for the same purpose, calomel, 1/6 grain every 2 hours.

If worms are suspected, the following should be given:

℞. Calomel, gr. j
Sodium bicarbonate,
Milk-sugar, } each, gr. vj.
Powdered santonin,
Make 12 powders, giving 1 every 2 hours, until 3 are taken, and repeat every other day.

For the attack a hot bath is very effective, and sodium or potassium bromid, in 5- to 15-grain doses, should be given until the child is quiet, but continuing the bromid in small doses as long as any nervous symptoms remain.

Following the attack, the child's general nutrition should receive careful attention.

TETRONAL. — Diethylsulphondiethylmethane. A disulphone of the ethyl and methyl groups, harmless in ordinary doses, and having marked hypnotic properties. Dose, 10 to 30 grains.

TETTER.—See ECZEMA.

THALLIN.—A synthetic chemic product and a derivative of coal-tar. It is a powerful antipyretic, but its effects are not so lasting as those of antipyrin. It is likely to produce collapse. Dose of thallin or its sulphate, about 5 grains.

THEA. THEIN.—See CAFFEIN, TEA.

THEOBROMA.—A genus of plants of tropical America. *T. cacao* is the cacao plant, or chocolate tree. See CACAO-BUTTER. **T., Ceratum** ("red-lip salve"), cacao-butter, white wax, of each, 35; oil of almond, 30; oil of rose, to flavor, and carmin, to color, a sufficient quantity of each. **T., Oleum,** butter of cacao. The fixed oil of the seed of the chocolate tree, *T. cacao.* It consists mainly of stearin, with a little olein, and is demulcent, not becoming rancid. It is used in making suppositories.

THEOBROMIN.—$C_7H_8N_4O_2$. An alkaloid occurring in the seeds of *Theobroma cacao* (1.5 percent), obtained from the pressed cacao mass by mixing with slaked lime and exhausting with 8 percent boiling alcohol. It is a white, crystalline powder, slightly soluble in water, alcohol, and ether. Theobromin is a homolog of caffein, differing in containing one CH_2 group less; it unites readily with alkalies, forming soluble salts. See DIURETIN. Because of its insolubility, theo-

bromin is unsuitable for use, but is employed in the form of a double salt. In physiologic action it resembles caffein, being, however, free from any irritating action on the nerve-centers. See CAFFEIN.

Theobromin Salicylate.—$C_7H_8N_4O_2.CO_2.C_6H_4OH$. This occurs in small, white needles having an acid reaction and an agreeable bitter taste, and being slightly soluble in water. It is recommended as a substitute for diuretin in the same doses. The advantages claimed over the latter are that it is perfectly stable, and is not altered by air, moisture, or carbonic acid. See DIURETIN.

Theobromin Sodium Formate (Thephorin).—A powerful diuretic said to be free from irritant effects on the stomach. Dose, 7 1/2 grains.

Theobromin Sodium Iodid (Iodotheobromin).—A white powder, soluble in water, decomposed by hot water. Used to increase arterial pressure; also as a diuretic. Dose, 8 grains.

THEOCIN.—The trade name for synthetic theophyllin (dimethylxanthin), an organic base isomeric with theobromin. It is a white crystalline powder. Like theobromin it differs from caffein in having but little effect on the central nervous system.

Theocin has not so great a stimulant action on the heart as caffeine, but is a much more powerful diuretic than either caffein or theobromin. The diuretic effect, however, is not prolonged and its administration is, therefore, advantageously followed by one of the theobromin derivatives having a weaker, but more persistent, action. It occasionally produces gastric disturbances, and renal irritation has also been reported. In doses of 3 to 5 grains in warm tea, it is recommended in cardiac affections, nephritis, dropsy, etc.

The double salt, *acet-theocin-sodium*, being more soluble, is said to be more readily absorbed and better tolerated than theocin.

THERMODIN.—Phenacetin-urethane. An analgesic, antipyretic and antiseptic. It is said to be effective in typhoid fever and other febrile conditions, influenza, pneumonia, tuberculosis. It is claimed to produce no unpleasant by-effects. Dose, as an antipyretic, 5 to 10 grains, as an analgesic, 15 to 20 grains.

THERMOMETER.—An instrument for measuring the intensity of heat, consisting of a reservoir of mercury (or of alcohol) expanding into a vacuous capillary tube, the intensity being measured by the length of the column of mercury.

Varieties.—**Centigrade** (or **Celsius**), one in which the freezing-point is at 0° and the boiling-point at 100°. **Fahrenheit**, one in which the interval between freezing and boiling is divided into 180 equal parts, each called a degree, the zero-point being 32 degrees or divisions below the freezing of water. The freezing point is 32°, and the boiling point 212°. **Reaumur**, one in which the freezing-point is 0°, and the boiling-point 80°.

Comparison of Thermometers.—To convert the registration of one thermometer into that of another, the following formulas are useful:

Let F = number of degrees Fahrenheit.
Let C = number of degrees Centigrade.
Let R = number of degrees Reaumur.

Then:

$$C° = \frac{5}{9}(F° - 32) \qquad C° = \frac{5}{4}R°$$

$$F° = \frac{9}{5}C° + 32 \qquad F° = \frac{9}{4}R° + 32$$

$$R° = \frac{4}{5}C° \qquad R° = \frac{4}{9}(F° - 32)$$

The following is a comparative table:

FAHR.	CENT.	REAU.	FAHR.	CENT.	REAU.	FAHR.	CENT.	REAU.
212	100	80	122	50	40	32	0	0

The clinical thermometer is a small, maximum, self-registering, mercurial thermometer, used in obtaining the temperature of the body. In its usual form the range of scale is about 15° F., and graduation is carried to one-fifth of a degree. The bulb is of extremely small diameter and fine bore, in which the mercury is rendered visible by a lens-fronted stem. The best clinical thermometers register in 30 seconds, but to secure sufficient accuracy it is generally desirable to allow 5 minutes to elapse before removing the thermometer from the mouth or axilla. Especially in obscure cases is this desirable.

The axilla is the locality most suitable for ther-

mometric observation. The mouth, the rectum, or even the vagina may be utilized. When inserted in the mouth, the thermometer should be placed under the tongue, and the lips should be tightly closed. Great care is to be exercised that the instrument does not slip too far into the rectum when rectal temperature is taken. The thermometer should be introduced 2 inches deep, or above the internal sphincter, the patient lying on the side, the thermometer being kept *in situ* by one hand, letting the other rest on the hip of the patient to arrest any turning movement which might be made. To remove the instrument, it may be gently pushed forward a little to bring the bulb in contact with a fresh part of the mucous membrane, a part that has not been cooled by the thermometer. A practical caution is that the thermometer should not be introduced into a mass of feces which may fill the rectum. The inguinal fold or the fold of skin between the thumb and second metacarpus may be used for special, but not for general, clinical purposes. The clinical thermometer should be washed after usage. See TEMPERATURE.

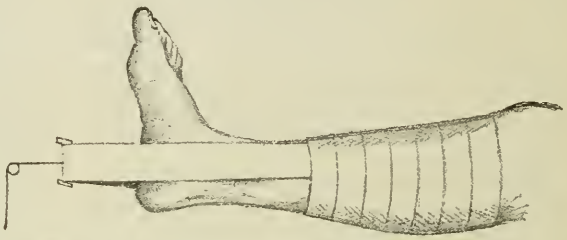
THIGENOL.—The trade name of a solution of sodium sulphite in a synthetic sulphuretted oil containing 10 percent of sulphur in organic combination. It occurs as a dark-brown, syrupy fluid, soluble in distilled water, alcohol, or glycerin. It is odorless and almost tasteless, and is used locally in eczema, seborrhea, acne rosacea, and other skin diseases. Dose, 3 to 10 grains.

THIGH, AMPUTATIONS.—In amputations through the shaft of the femur the mixed method (an anterior skin flap with a shorter posterior one by transfixion) answers so well that any other is seldom needed. Care must be taken not to slit or prick the artery as it is passing out of Hunter's canal, and in arranging the dressings it must be remembered that, owing to the rotation of the thigh, the flaps very soon assume a lateral position.

Amputation through the condyles may be performed according to either Carden's or Stokes' method. The section of the bone in the former runs through the base of the condyles, and the anterior flap passes across the limb midway between the apex of the patella and the tubercle of the tibia; in the latter the bone is divided above the condyles (supracondyloid), and the anterior flap reaches down to the tubercle, the increased length being required by the patella, the sawed surface of which is removed, so that it may face and become adherent to the cancellous tissue of the femur. They are both far superior to amputation through the thigh, owing to their enabling the pressure to be borne (in part, at least) on the face of the stump and their preserving the insertion of the adductor, and, in Stokes', the insertion of the extensor muscles. Gritti's amputation is similar to Stokes', but the bone is divided 1/2 inch lower, and the patella does not fit so well. In Carden's operation there is no posterior flap; in Stokes' the posterior flap is nearly as long as the anterior, and is cut either by dissection or transfixion, according to the bulk of the limb. See AMPUTATION.

THIGH, FRACTURES.—**Fracture at the upper end of the femur** is a frequent injury, and is of great practical importance. The neck of the femur is situated in large part within the joint capsule; hence, pure intracapsular fracture may occur. Fracture nearer the base of the neck may be entirely extracapsular, but, as a rule, the line of such a fracture is oblique to the long axis of the neck, and the fracture is partly extracapsular and partly intracapsular, or "mixed."

This fracture results generally from a fall upon the hip: (1) upon the trochanter, the fracture resulting generally being at the base of the neck (extracapsular), impaction not infrequently occurring into the trochanter; (2) upon the extended knee or leg, such fracture generally being intracapsular. Extensive rotatory movements may likewise cause fracture, through tension and traction of the iliofemoral ligament (fracture by traction). These fractures occur frequently in old persons—most frequently in old women. This is due to the fragility of the bones in advanced age, which is especially pronounced at the upper end of the femur. The bones become fragile earlier in women than in men; and, together with the sharper angle that the neck forms with the shaft in women, this fragility explains the more frequent occurrence of this fracture in women than in men.



MODE OF APPLYING STIRRUP FOR WEIGHT-EXTENSION.

Impaction of the thin portion of the neck into the head (intracapsular fracture) or of the neck into the trochanter (extracapsular fracture) is likely to result if the force producing the fracture acts in the direction of the long axis of the neck. Such impaction prevents the occurrence of several of the physical signs of fracture (abnormal mobility, crepitation); and when it occurs, no effort should be made to disengage the fragments. Clinically, such impacted fractures resemble incomplete fracture of the neck of the femur.

The symptoms of fracture of the neck of the femur are sometimes very obscure, a positive diagnosis often being impossible. Fracture is probable when a person of advanced age is unable to walk after receiving a fall, and when the injured leg is rotated outward and is more or less shortened. In forward luxation of the femur the leg is fixed *elastically* in outward rotation, while in fracture of the neck the rotation can be readily overcome, but the limb immediately drops back outward on being released. In incomplete or

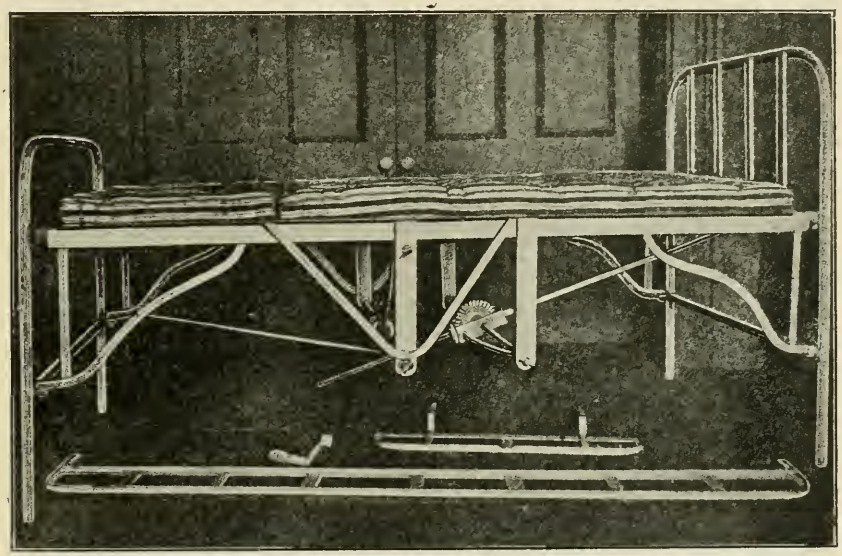
impacted fracture this outward rotation is less marked.

The higher position of the trochanter, determined by the comparative relationship to Nélaton's line, is a matter of great importance. If there is shortening of the injured side, measuring from the anterior superior spine of the ilium to the knee, and if the distance from the tip of the trochanter to the knee is the same on both sides, manifestly the seat of the shortening must be in the neck of the femur.

It may happen that no fracture is sustained at the time of the fall, only a severe contusion, which, however, markedly interferes with the nutrition of the head of the femur and of the contiguous portion of the neck; the result of this may be a complete breaking down of the bone structure, and the appearance of a fracture secondarily. This occurrence is rare, but does undoubtedly take place. Movements of the injured thigh, are usually possible in all directions, are painful, and elicit crepitation when the fragments are loose and remain in contact. In rotating the thigh the shaft of the femur turns about its long axis in extracapsular fracture, while in intracapsular it turns about a radius equal in length to the intact portion of the neck of the femur. The X-rays should be employed in all these cases and will remove all possible doubt as to the character and extent of the injury.

Treatment.—These patients are generally old, and therefore treatment is complicated by the necessity of preserving and improving general health and nutrition, and of guarding against the occurrence of an asthenic hypostatic pneumonia, which may easily prove fatal. Frequent change of position is indicated—sitting up, turning from side to side, deep breathing, and, finally, early walking with the aid of ambulatory splints. This last is most readily accomplished by means of a spica of plaster of Paris; the sole of the shoe on the sound side is raised, and then a pair of crutches permit locomotion without disturbing the injured hip. In intracapsular fracture the fragment composed of the head is so poorly nourished that bony union is exceptional, fibrous union the rule. In extracapsular fracture callus-formation is likely to be abundant, and so bony union is the rule.

In impacted fracture, or in loose fracture without tendency to displacement and outward rotation, the indicated and necessary rest is readily attained by means of sand-bags placed along the inner and outer sides of the limb. Comfort or necessity may demand the addition of a Buck's extension apparatus (adhesive-plaster straps, weight, and pulley). In the ordinary loose fracture, with displacement, reposition must first be carefully effected; then a Buck's extension apparatus applied, the foot preferably being held fast and controlled by means of a sliding foot-rest to which the foot is made fast, thus preventing the tendency to outward rotation. A weight of from 10 to 15 pounds ordinarily serves to maintain the fragments in good position. This weight and pulley method is especially admirable in that it permits mobility of the limb and the assumption of a semirecumbent attitude, without injury or pain.

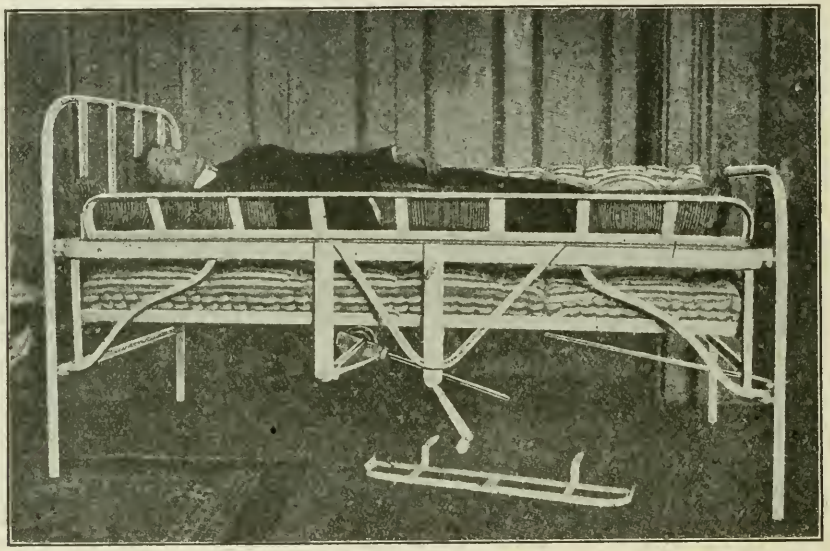


Bed Used in Fracture of the Thigh.—(*Bullitt.*)

Plaster-of-Paris and hip splints of leather are applicable only when the patient is able to leave the bed, intermittingly at least. The majority of these patients are old and feeble, so a brilliant final result is seldom to be expected; most of them do very well if they learn to walk again with a limp and a cane after the expiration of 6, 8, or more weeks.

The serious difficulty in the treatment of these cases is the maintenance of rest of the injured

hip in good position, at the same time providing for frequent shifting of the patient's position, combating the hypostatic tendency. The hip must, therefore, frequently be sacrificed to the patient's life. The accompanying illustrations show a bed designed by Bullitt for meeting this very difficulty. The bed is so arranged that the whole bed plane can be tipped from side to side, and the head can be raised to an almost upright position without any movement on the part of the patient. The utility of this contrivance in the handling of such cases is obvious, and practical use has demonstrated its great value. The working and uses of the bed are illustrated by the cuts made from photographs. The first cut shows the bed for use as an ordinary bed. The second cut shows the bed plane tilted laterally, thereby shifting the weight from the back to the side. Small, firm, hair pillows are packed in



The Bed Tilted Laterally.

between the patient and the side bar, and so the patient does not move or slip while the change in position is being effected. The third cut shows the bed-frame tilted lengthwise; this position is especially designed for the treatment of fractures of the thigh and hip in old persons. The foot of the sound side is supported by two small and firm hair pillows inserted between it and the foot-board, so permitting the foot of the injured side to swing free. Elevation can be accomplished to almost an upright position, though such a degree of elevation would probably seldom be employed.

The great trochanter is rarely separated as a result of direct force. When separation occurs, it is recognizable through the displacement, the fragment being felt behind and above the glutei muscles, with a wide diastasis between it and the femur. The muscular traction makes it difficult to hold the fragment in place by dressings. In case of failure, it only remains to fix the fragment in place directly by means of suture or nails. In any event, the thigh should be kept in abduction.

Fractures of the diaphysis of the femur in its middle third, or just above the middle, are frequent. Some are due to torsional force, but the greater number to bending by direct force (run-over accidents). In this locality displacement is generally considerable in the adult; in children the relatively thick periosteum remaining intact usually prevents marked displacement. The fracture line is generally oblique, and longitudinal traction of the powerful thigh-muscles easily effects displacement, which is sometimes extreme. Abnormal mobility is readily demonstrated; likewise crepitation. If crepitation cannot be demonstrated, especially after reposition, it is presumable that soft parts are interposed between the fragments; correct and bony union cannot be expected unless the fragments are brought into good apposition.

A typical displacement accompanies fractures above the middle of the shaft. The upper fragment is carried into flexion by the iliopsoas muscle, and into abduction by the glutei muscles; at the same time the lower fragment is drawn upward and inward by the hamstrings and the adductors. This projection of the upper fragment forward and outward is to be carefully borne in mind when effecting reposition and fixation; otherwise the deformity will be found persisting after the consolidation of the fracture.

Treatment.—In the treatment of fractures of the diaphysis permanent extension, by means of adhesive-plaster straps, weight and pulley (Buck's extension apparatus), is of the very greatest usefulness, and tends to greatly simplify treatment. The adhesive-plaster straps are to have broad surfaces, and should be capable of supporting a weight of from 20 to 25 pounds, which is necessary to overcome the upward muscular trac-

tion. Pillows and sand-bags sometimes suffice to support and further control the position of the limb; usually, however, it will be found best to support the fragments by means of short splints padded and securely bound to the thigh over the extension apparatus. The addition of a sliding footboard is sometimes necessary properly to control the rotatory tendency of the lower leg. In fracture with a short upper fragment the displacement already referred to (forward and outward) is difficult to combat. Here the double inclined plane of Agnew is of good service, together with an extension apparatus acting on the thigh from the knee upward and making traction in the direction of the displacement of the upper fragment forward and outward. Perhaps the best support of all is by means of molded leather splints in combination with Buck's extension apparatus. The splint is cut from saddle skirting leather and is made of a shape to extend from the knee well over the hip and to cover the anterior and outer aspects of the limb. The leather is immersed in hot water (hot as the hand can bear), and is then molded to the part, being held in place for a few minutes by means of a roller bandage. It is then removed and dried before the fire for a short time, when it will retain its shape. The extension apparatus is now applied, reposition is effected, and the leather splint is securely bound to the limb. It is necessary from time to time to measure the two thighs from the anterior superior spine to the patella, guarding in this way against the occurrence of any excessive shortening.

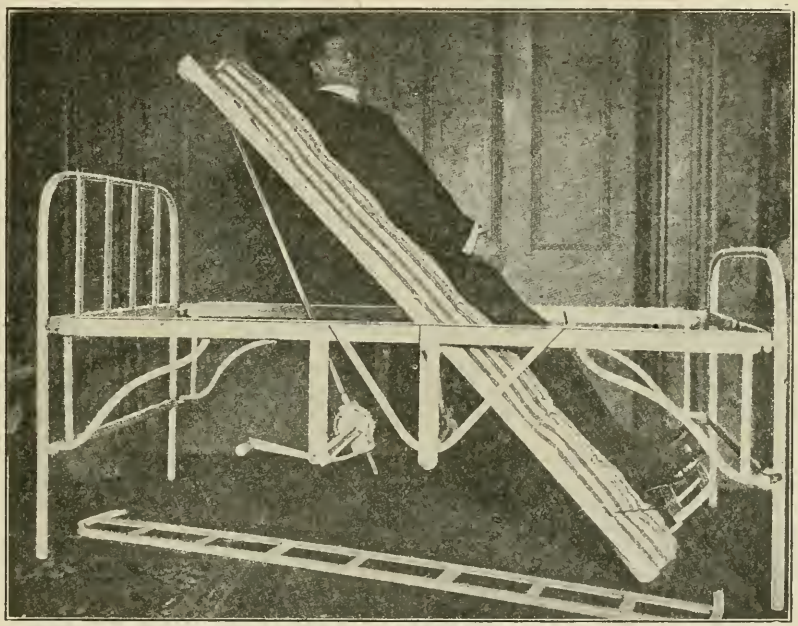
Ordinarily, at the end of 4 weeks consolidation is far enough advanced to change the dressing to one of plaster of Paris, which permits locomotion and is worn for 4 weeks more.

Bryant's Vertical Extension for Fracture of Femur in Children.

In children the method of **vertical suspension** of the whole limb (or better, of both limbs) is a most excellent one. Vertical suspension is also applicable in adults when it is found otherwise impossible to preserve the proper position of the fragments.

In new-born children almost the only possible way to fix the thigh is in the position of the fetus *in utero*, with the thigh flexed against the abdomen and held there by means of adhesive-plaster straps. This dressing permits the ready handling and cleansing of the child.

Every fracture of the thigh is likely to be attended by greater or less permanent shortening of the limb.



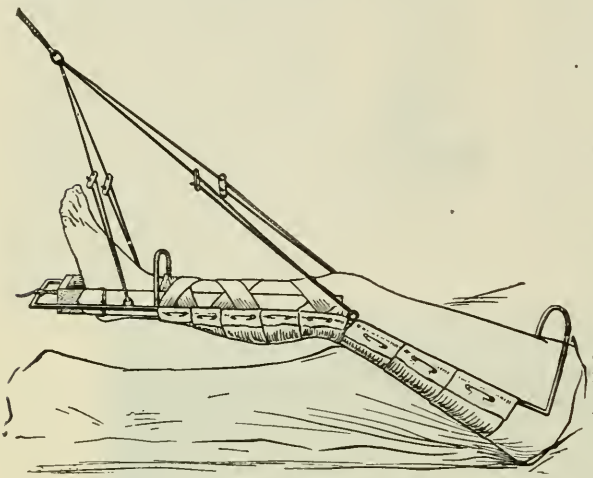
The Bed Tilted Lengthwise.

Compound fractures, which require frequent change of dressings, are very conveniently treated by means of the suspending splint of Hodgen.

Fractures at the lower end of the femur are rarer than those of the shaft and neck, and result from direct violence.

In supracondylar transverse fracture the lower fragment is drawn downward in flexion by the calf-muscles, while the traction of the thigh-muscles tends to increase the overriding of the fragments and the marked displacement. In epiphyseal separation similar displacement occurs, although slighter in degree, because the periosteal covering remains intact, in part, at least. The

knee-joint may be involved, and certainly is if the lower fragment becomes split longitudinally—T-fracture. The vessels and the sciatic nerve are in danger of injury from the sharp edges of the displaced lower fragment. Abnormal mobility and crepitation readily determine the nature of the injury. After requisition it is manifest that the mechanically correct position is one of flexion, more or less acute, whereby the tendency of the lower fragment to recurrent displacement is best overcome. This may be accomplished by a posterior angular splint or by the double inclined plane. Sometimes permanent extension is suitable, together with gentle pressure from behind against the lower fragment. After 4 or 5 weeks passive motion should be instituted, and further treatment, as for articular fracture elsewhere, should be given.



Hodgen's Suspension Splint.—(*Moullin.*)

Fracture of one condyle is necessarily intra-articular, and is recognizable by the to-and-fro movements at the knee, by crepitation and by the localized pain. Hemorrhage into the joint may be profuse, and if so, the blood should be evacuated by aspiration. An extension dressing with a posterior splint is best, or a double inclined plane may be used. Care must be taken to counteract any varus or valgus tendency that may become manifest.

THIOCOL.—The potassium salt of guaiacol sulphonic acid. It contains about 60 percent of guaiacol, and is in the form of a fine, white powder, which has a taste at first bitter, then sweetish. It is used in diarrhea, pneumonia, and all forms of tuberculosis. As advantages over other remedies may be mentioned: Entire freedom from odor, great solubility in water, ready absorption, and freedom from irritant action on the mucous membranes. It is claimed that these properties make it applicable for the most sensitive patients. Dose is from 7 to 30 grains, up to 1 1/2 drams or even 4 drams daily. Daily doses of from 150 to 225 grains may be continued for a considerable time without disadvantage, which is of the greatest importance in the creosote treatment. It causes no nausea or diarrhea.

THIOL.—Prepared by the sulphuration of certain nonsaturated hydrocarbons, and is a product very similar to ichthyol. It occurs in both dry and liquid form, the former, *Thiolum siccum*, as dark-brown lamellæ or powder, of bituminous odor and bitter, astringent taste; soluble in water and in chloroform, sparingly in alcohol, insoluble in ether and in benzin. The liquid form, *Thiolum liquidum*, is a dark-colored, syrupy fluid, miscible in all proportions with water. Dose, internally, 5 to 30 grains.

The dry form is used as a dusting powder in erysipelas, eczema, erythema, intertrigo, impetigo pemphigus, periphlebitis, subcutaneous, hemorrhages, and syphilitic ulcers. It is an efficient application in pelvic exudations and endometritis. Thiol causes neither pain, burning, nor other symptoms of irritation, nor any bleeding from eroded surfaces.

Glycerinated thiol is a remedy for chilblains, consisting of equal parts of liquid thiol and glycerin.

THIOSINAMIN.—Allyl-sulpho-carbamid. It is prepared by heating together oil of mustard 3, alcohol 3, and ammonia 6. It occurs as colorless crystals, which are very soluble in alcohol and in ether, and moderately so in water. The addition of antipyrin in one-half the quantity renders it soluble in water to the extent of 15 percent (Michel). It produces a local reaction when injected for lupus, or where sclerotic tissue is present, which it softens and permits of its absorption. It is used for the removal of scars, corneal opacities, and keloid; also for lupus, fibrous deposits in joints, stenosis of the esophagus, and for deafness due to thickening of the drum or fixation of the aural bones. Dose, 1/2 to 1 grain, thrice daily by mouth; or 10 to 20 minims of a 10 percent solution in absolute alcohol, hypodermically every third day. The ethyl-iodid of thiosinamin is said to be of service in arteriosclerosis, asthma, emphysema, scrofula and syphilis, given internally in doses of 2 grains several times a day.

THIRST.—The state manifested by a desire for drink. It is marked by dryness of the mouth and fauces, together with constriction of the pharynx and esophagus.

Although referred to the back of the throat, thirst is not a purely local feeling, since it cannot be allayed until fluid reaches the stomach and is absorbed. In febrile disorders, after hemorrhage or operation, in cholera and diarrhea, in diabetes mellitus, and in acute and chronic gastritis thirst is usually present. It forms a useful diagnostic sign between chronic gastritis and mere atonic dyspepsia.

Remedies that allay thirst and impart coolness, such as the vegetable and mineral acids, ice, water, if cold, effervescing drinks, fruit-juices, and many diaphoretics are called refrigerants. Acid drinks allay thirst by promoting the secretion of alkaline

saliva, but when excessively used, they will derange the stomach. Cracked ice, sucked, is very grateful, and allays thirst in fever. Fruit-juices, or those made into drinks, must be used in moderation: excess will do harm. Bitters, in drinks with acids, most effectually slake the thirst. A weak infusion of orange-peel acidulated with hydrochloric acid makes an efficient thirst-queller in fever patients. Tepid drinks are useful in the thirst of diabetes.

THOMSEN'S DISEASE.—See MYOTONIA CONGENITA.

THORACIC DUCT, AFFECTIONS. Diseases.—Narrowing may result from inflammation of the coats or blocking of the lumen by pressure of an aneurysm, tumor, or contracting cicatrices, or from cancerous or tubercular material. Complete obliteration need not cause death or even marked symptoms, since the veins seem to act vicariously. Aneurysm of the duct and dilatation and calcification of the walls have also taken place. A primary growth in the duct has not been recorded.

Injuries.—The thoracic duct has occasionally been torn or wounded. In such cases a discharge of a spontaneously coagulating fluid, milky during digestion, has taken place. In one instance the fluid escaped into the pleural cavity, which had to be tapped repeatedly. A diagnosis of injury to this duct is impossible save by evidence of this chylous fluid escaping or being tapped from the pleural cavity. The prognosis is of the utmost gravity, as death is the general rule, in weeks rather than months, and from marasmus. In one case the opening in the duct was said to have healed under a plug. In another case a clamp was made use of, and packing of the cavity around this with gauze resulted in recovery. See CHEST (Injuries).

THORACOPLASTY.—See PLEURISY (Treatment).

THORAX.—See CHEST.

THREAD-WORMS.—See WORMS.

THROAT.—See ESOPHAGUS, LARYNX, NECK, PHARYNX.

THRUSH.—See STOMATITIS (Parasitic).

THUMB.—See HAND AND FINGERS.

THYME.—A plant of the genus *Thymus*.

Oil of Thyme is a stimulant and antiseptic oil containing thymol; chiefly used topically in veterinary practice.

THYMOL.—$C_{10}H_{13}HO$. A phenol with active antiseptic and anesthetic properties. It exists in oil of thyme and other vegetable oils. It occurs in large, colorless plates, melting at 44° C. and boiling at 230° C. It has a thyme-like odor, and is slightly soluble in water but readily soluble in alcohol. Thymol is chiefly employed as a gargle, spray or inhalation in laryngitis and diphtheria; as an ointment in ringworm, eczema and psoriasis, and as an injection in ozena. A solution of 1 part in 1000 is the strength usually prescribed. Internally it has been used with success in diphtheria, typhoid fever and other intestinal affections, diabetes, phthisis and vesical catarrh. Its fragrant odor renders it a very agreeable antiseptic application for ulcerated conditions of the mouth and fauces, but makes it very attractive to flies, which fact together with its high price will prevent it becoming a favorite in hospital practice. A solution, used as a mouth-wash, is very efficient in removing the odor of tobacco from the breath. Thymol is almost specific against the intestinal parasite ankylostomum duodenale (*uncinaria Americana*) for which it is given in three or four doses of 10 to 30 grains, well triturated, in capsules; care being taken that no alcoholic drink is ingested afterward, in order to avoid the absorption of thymol and consequent poisoning thereby. Dose, 1/2 to 3 grains. **T. Inhalation,** thymol, 20 grains; alcohol, 3 drams; magnesium carbonate, 10 grains; water; add enough to make 3 ounces; add a teaspoonful to a pint of water at 150° F. for each inhalation. **T. Iodid,** See ARISTOL. **T. Solution,** for spraying, 1 : 1000. **T., Ung.,** contains 5 to 30 grains to 1 ounce. **Volkmann's Thymol Solution,** thymol 1, alcohol 10, glycerin 20; and water 100. It is used as a spray and antiseptic lotion; it does not produce eczema, as do phenol lotions.

THYMUS GLAND.—See STATUS LYMPHATICUS, NECK (Injuries).

THYMUS GLAND EXTRACT.—An animal extract whose mode of preparation and dose are similar to those of thyroid extract. It has been serviceable in exophthalmos with anemia and debility, in leukemia, chlorosis, idiopathic and pernicious anemia, and in the so-called "status thymicus."

THYRESOL.—The methyl ether of santalol. It is similar to sandal wood oil in its properties but is said not to produce gastric or renal irritation. It is recommended in the treatment of gonorrhea, etc. Dose, 8 grains in milk or in gelatin capsules.

THYROID EXTRACT.—See THYROID TREATMENT.

THYROID GLAND, DISEASES.—Colloid degeneration, affecting the contents of the sacs and attended with atrophy of the cellular lining, is of so common occurrence as almost to be considered normal. Nothing is known with regard to its function beyond the general fact that the activity of growth and nutrition of all parts of the body (including the brain) are intimately connected with its integrity. In women it frequently enlarges and becomes tender—at puberty, during the menstrual period, and during pregnancy. Cretinism is, in all probability, due to its imperfect development; removal during childhood causes a similar condition, and, in a large proportion of cases, removal of the whole gland is followed by myxedema, if performed on adults. The temperature falls; the oxygenating capacity of the blood diminishes; leukocytosis sets in; the coagulability is lessened; the skin and subcutaneous tissue undergo a peculiar transformation; nervous symptoms (tremors, paresis, paresthesia, etc.) make their appearance, and, at length, a cretinoid condition, with imbecility and coma, follows. When this does not take place, it is probably owing to the fact that the whole gland

has not been removed, or that accessory thyroids (which are of very common occurrence) have undergone compensative hypertrophy. Sometimes it follows with great rapidity shortly after the operation; sometimes, on the other hand, slowly and gradually. In a few instances the immediate onset, after a period of apparently perfect health, has been brought on by exposure to cold (Moullin).

Inflammation may be acute or chronic, and in resolution or in suppuration and sloughing, according to the cause and the addition or not of pyogenic irritants.

The symptoms, when the attack is acute, are very alarming, often beginning with a rigor and high fever. Owing to the way in which the gland is bound down by the cervical fascia the pain is very severe; the tissues of the neck are hard and rigid, the superficial veins distended, the trachea and esophagus compressed against the spine, and there may be cerebral symptoms caused by the obstruction to the cranial circulation. In most cases resolution sets in after 48 hours, and the acute symptoms begin to subside, but often the improvement is only partial; the diffuse enlargement disappears, but one or more local swellings remain; the skin becomes red and edematous, and at length fluctuation is apparent. Death may occur from pressure upon the trachea, from pus finding its way down into the lungs, or from pyemia or septicemia. In one or two instances the gland has sloughed.

The treatment must be energetic. At the onset aconite or antimony may be given internally in small, frequently repeated doses, until a distinct effect is produced upon the arterial tension. Ice-cold compresses should be placed upon the neck, the superficial veins pricked to relieve the circulation, and leeches applied to the supraclavicular region. Venesection (either from the arm or the external jugular) may be advisable, if the patient is young and the inflammation sthenic. If signs of suppuration make their appearance, the superficial structures must be carefully divided, layer by layer, and a director used for exploration, after Hilton's method. A drainage-tube must be inserted to prevent the opening becoming valvular.

Goiter, or **Derbyshire neck,** is an enlargement of the thyroid gland. It may be due, as is commonly the case, to simple hypertrophy of the normal tissues of the organ (*ordinary goiter*), and may then involve the whole gland or one of the lateral lobes or rarely only the isthmus. In other instances the hypertrophy may fall chiefly on the fibrous tissue, constituting the septa of the gland (*fibrous goiter*). Or along with some amount of simple hypertrophy and increase of fibrous tissue (*adenoma*) one or more of the normal alveolar spaces may become enlarged, forming single or multiple cysts (*cystic goiter*). Such cysts contain, when single, a serous fluid, or when multiple, a colloid or a dark, grumous material sometimes mixed with altered blood; while occasionally, proliferating growths project into their interior from the cyst walls. In other instances again, but more rarely, the hypertrophy is associated with a great increase in the vessels, and a forcible and expansile pulsation is given to the gland (*pulsating goiter*). But the tissues, besides hypertrophy, may undergo secondary changes. Thus, calcification may occur, and the enlarged gland become of stony hardness (*calcified goiter*) in places, or the fluid normally contained in the alveolar cavities may assume a colloid character. Lastly, the enlargement of the thyroid may be due to malignant disease (*malignant goiter*). In certain districts goiter is endemic, especially in the Rhone Valley in Switzerland, and in Derbyshire in England, and is then frequently associated with the condition known as cretinism. It also occurs sporadically; and in some cases again is accompanied by a peculiar jerking beat in the carotids, by anemia, and by a prominence of the eyeballs. See Exophthalmic Goiter.

The symptom common to any form of enlargement of the thyroid is a swelling taking more or less the characteristic shape of the thyroid gland, and *moving with the larynx in deglutition.* In this country the enlargement is generally moderate; but sometimes, and especially in Switzerland, the goiter forms a large mass hanging in front of the neck, and may press upon or even displace the trachea and esophagus. It occurs chiefly in women. In the ordinary variety it is soft, semi-fluctuating, and of uniform consistency; in the cystic one or more fluctuating places may be felt; while in the fibrous it will be firm and hard and more or less lobed or irregular, and when calcification has taken place, of stony hardness. Malignant goiter, which is very rare, may be known by rapid growth, enlarged glands, and the other signs of malignancy.

The cause of endemic goiter is not known. It has been attributed to impure water, water from limestone, and snow water, but without conclusive evidence. It is said to be most prevalent in valleys where, from their direction, the sun does not penetrate, on damp soil, and in damp parts of towns; but, according to Berry, these influences have little or nothing to do with its causation. In sporadic cases heredity, disturbance of the sexual functions, and conditions producing congestion of the head and neck are given as causes.

Treatment.—Sporadic cases of ordinary goiter should be treated by the internal and external application of iodin, and removal from the goitrous district. Thus the syrup of the iodid of iron may be given internally, and an ointment of iodin and iodid of potassium applied externally. The use of biniodid of mercury ointment, followed by exposure to a hot sun, has been attended with much success in India. An ice collar has sometimes been of service.

Cystic goiter may be treated by aspiration, drainage or enucleation. Of these the first is of little avail, except as a temporary expedient in an urgent case, or as a preliminary to other measures. The fluid must be drawn off very slowly, or hemorrhage may occur from the delicate vessels in the

walls of the sac, and fill it even more tensely than it was before.

Drainage and enucleation are more successful. A linear incision is made through the superficial structures, and the capsule of the gland freely exposed. If there is a large single cyst, it can usually be enucleated by careful dissection, clamping and dividing between two ligatures every vessel; solid adenoma may be treated in the same way. If this is impracticable, the cavity may be laid open and the contents cleaned out; but the operator must be prepared for severe hemorrhage. Plugging with iodoform gauze may be necessary if it does not stop at once. It does not appear to be necessary to fasten the edge of the cyst to the skin or the cervical fascia; according to Clutton, if the superficial structures are not disturbed or displaced, there is very little risk of inflammatory infiltration. If a number of small cysts are packed closely together, it is better to excise the part so long as it is not too large, ligating the vessels one by one as they appear, and taking especial care of the recurrent laryngeal nerve.

Operative treatment consists in ligation of the thyroid arteries; division of the isthmus; removal of the isthmus or one lobe; or partial removal of both lobes.

In beginning goiter ligation of the superior thyroid arteries has sometimes arrested the process of morbid growth. Division of the isthmus is a palliative operation for late cases in which the trachea is compressed.

It may be stated as a general rule that every rapidly growing goiter should be removed. Timely recourse to operation will save the patient much trouble. Partial excision of the thyroid is the operation of choice. It is performed as follows: As little anesthetic as possible, and that chloroform or ether by the open method, should be given since dyspnea is liable to occur during the operation. On this account some surgeons employ local anesthesia with cocain. An incision is made over the tumor along the anterior border of the sternomastoid when part only of one lobe is to be removed. If a part of both sides, then a curved incision across the front, so that the scar may be covered by a necklace. Then the sternomastoid is retracted, and the sternohyoid, sternothyroid split, or, along with the omohyoid, cut across, but as far from the line of the cutaneous wound as possible to prevent their adherence to the scar, which would then be puckered in every time the muscles contract. The tumor having been thus exposed, the fascia should be opened carefully so as not to injure the veins lying beneath it. When necessary, the veins are divided between clamp forceps, and later tied. Enucleation should now be begun with the finger, aided by a small sponge held in clamp forceps, bearing in mind that although the common carotid artery is pushed outward, the internal jugular vein usually runs over the tumor, being held more or less in position by the veins opening into it. The pulsation of the artery is therefore no guide to the position of the vein, which may run in front of, or internal to the artery.

The superior thyroid arteries should be sought at the upper and inner part of the tumor and securely tied. Of the lower part of each lateral lobe a piece should be left, at least as large as the end of the thumb. In this way one may avoid injuring the recurrent laryngeal nerve which passes upward among the main divisions of the inferior thyroid artery. When the tumor has plunged behind the sternum, delicate manipulation is needed to isolate it from the pleura and innominate veins. After applying ligatures, the capsule may be drawn together by a purse-string suture, next the divided muscles should be sutured together if possible, and the skin united except for a small drain.

Sarcoma or carcinoma arising in the thyroid gland, if it is to be removed must be diagnosed early. A tumor arising in the thyroid gland, in a patient over forty, especially in a man, and a gumma being excluded, should at once be explored, and removed early, while still within the capsule of the gland.

THYROID GLAND, INJURIES.—See Neck (Injuries).

THYROID TREATMENT.—The treatment of disease by the administration of thyroid gland or substances derived from it.

Preparations.—(1) The fresh gland of the sheep, minced. (2) The thyroid glands of the sheep, freed from fat, and cleansed, dried and powdered (the desiccated thyroid gland of the U. S. P.). (3) Dry thyroid (thyroideum siccum of the British Pharmacopeia). This is prepared be removing the fat and connective tissue from the healthy gland taken from the sheep directly after it is killed. The gland is minced, dried at from 90° to 100° F., and powdered. Fat is removed by washing with petroleum spirit, and the powder dried. (4) Glycerin extract of thyroid (liquor thyroid of the British Pharmacopeia). The fresh, healthy thyroid glands of the sheep are bruised with 34 minims of glycerin and 34 minims of a 0.5 percent solution of phenol for each gland. The mixture is allowed to stand for 24 hours, strained, and sufficient of the phenol solution added to make 100 minims. (5) Iodothyrin. This is obtained by hydrolysis of the colloid matter of the gland with diluted caustic soda, and precipitation of the colloid by acetic acid.

Dosage.—Of the raw gland, from 1/2 to 1 may be used. The dose of the U. S. P. preparation is 4 grains. Three to 10 grains of dry thyroid and from 15 to 60 minims of the glycerin extract may be given twice or thrice daily. Iodothyrin, as found in the shops, is rubbed up with sugar of milk and is administered in 5-grain doses.

Method of Administration.—The transplantation of thyroid glands (*greffe thyroidienne*) as practised by Bettencourt and Serrano has been abandoned. The ingestion of minced, raw, or slightly warmed sheep's thyroids, even when seasoned, so speedily provoke nausea and vomiting that this method is impracticable for prolonged use. The dry powdered gland can be given as such or in capsule, wafer, or tablets by the mouth. The glycerin extract is most frequently employed when given

by the mouth, or when sufficiently diluted, hypodermically. Iodothyrin may be exhibited in substance, in capsule, wafer, or tablet, by the mouth or subcutaneously. The frequency varies from 2 or 3 times daily until the physiologic effects are obtained, then once daily or less frequently as may be necessary to maintain them.

Physiologic Action.—The result of the administration of thyroid is to increase oxidation in the body, the nitrogenous substances being excreted entirely as urea, fats as carbon dioxid by the lungs and as water by the kidneys. Diuresis is a constant effect, and this is greater than can be accounted for by increased oxidation, so that it is evident that the tissues themselves are desiccated. It is probable that the circulating proteids are first destroyed, while the fixed proteids are only attacked after the store of fat is considerably diminished. It is likely, considering the small quantity of thyroid administered, that these effects are brought about through the influence of the nervous system rather than by its direct action upon the tissues themselves. Since glycosuria is often a result of thyroid medication, it is likely that this substance may effect carbohydrate metabolism, so as to diminish the power of the tissues to utilize sugar (Hutchison). Increased rapidity of the heart's action is very constant, and often there are observed irregularity, palpitation, and even weakness; the fall of blood-pressure is probably due to the last-named condition rather than to dilatation of peripheral blood-vessels. As to its effects upon the blood, contradictory results have been observed. Probably small doses exert no influence, while large doses destroy blood-corpuscles. Making use of the colloid material, it may be said that excretion is entirely by the kidneys. This excretion is gradual, and may be continued for several days after its administration is stopped. Whether this material is excreted as such or is broken down in the organism is still an open question.

Some differences are observed in the results of administration of different preparations. The most important are that iodothyrin seems to have no effect upon the heart as to its rate, rhythm, or vigor; and this is true of the intravenous injections of colloid matter. The fall of pressure on administration of the gland or improperly prepared dry extracts is undoubtedly due to contained organic extractions, and it can be definitely stated that absolutely fresh thyroid gland is not poisonous when absorbed by way of the alimentary canal. Iodin is readily detected in the urine of patients who are taking iodothyrin, while it is found with difficulty after administration of thyroid preparations. The explanation doubtless is that normal thyroid stores up iodin and prevents its excretion. Inasmuch as there is no satisfactory method of standardizing thyroid preparations, the dose must, for the present, be determined from the results rather than the physician be guided by the posology as found in the literature.

Precautions in Administration.—Under the term "**thyroidism**" have been described symptoms that may be divided into 2 groups; (1) the alimentary—nausea, colicky pains, and diarrhea; (2) the metabolic—headache, pains and heaviness in the limbs, palpitation, disturbances of cardiac rhythm, and weakness. The first group may be due to products of putrefaction, to which the thyroid is especially liable, particularly if fever, sweating, and collapse are prominent. These can be avoided if the method of d'Arsonval (sterilization in an autoclave by carbon dioxid, under a pressure of 50 atmospheres) is employed. The second group is probably the result of overaction of the substance itself, since idosyncrasy must always be taken into consideration. Symptoms may appear after the use of any preparation, and are the results of increased metabolism. The practical suggestion to be borne in mind is that small and frequent doses—instead of large ones at longer intervals—should be employed. Caution and good sense should be shown in the use of thyroid preparations, and they should always be administered by a physician. The result after thyroidectomy in the practice of surgeons, demonstrates the necessity of strict observance of this rule. As improvement is secured the interval between doses should be lengthened, until constant physiologic effects only are secured.

Therapeutic Applications.—In the treatment of **myxedema** the use of the various preparations of the thyroid gland approaches nearer to specific action than any other in therapeutics, the results of mercury and the iodids in syphilis not even excepted. Inasmuch as in this disease the something that through cessation of function of the thyroid is not supplied to the organism can be furnished by the administration of preparations of this gland, the cure of myxedema becomes an assured fact. This statement is accurate only in the understanding that continued administration is persisted in. The tangible results observed are: (1) Lessening of the physical and intellectual torpor; (2) increased urinary excretion; (3) restoration of body temperature to the normal; (4) reabsorption of the edema of face and limbs. (5) progressive disappearance of difficulty of speech, interference with swallowing and muscular movements; (6) cessation of constipation; (7) diminution of body weight; (8) cessation of trophic disturbances—as, for instance, falling of the hair. In other words, the nutrition is stimulated and the principal functions are regulated.

The treatment may be divided into 2 stages: (1) curative and (2) prophylactic. In the first, daily doses should be persisted in until all symptoms have disappeared. If a preparation free from decomposition products is employed—and none other should be used—the amount given should be that which does not affect the pulse or produce other untoward action. So soon as cure has been obtained, the remedy should be given at intervals of one week or less, in such amount that no symptoms reappear. A fall of temperature or an appearance of slight edema should warn the physician that the dose is too small, the interval too long, or both dose and interval should be changed. If the dry extract is employed, the source of the powder should be known as well as

its strength. Six to 15 grains may represent one thyroid gland, depending upon the manufacturer; tablets are unreliable, since they may not dissolve; capsules are uncertain on account of the varying solubility of the gelatin, and on no account should the powder be previously made into a mass. As a rule, the powder should be used as such, and in about double the dose by mouth as when injected subcutaneously. The glycerin extract is more useful; but of each specimen the dose must be determined clinically, since accurate standardization is, at present, impossible.

Cretinism or Infantile Myxedema.—The same rules apply and the same results are obtained—the dose being somewhat larger than reached by Young's rule and determined by experiment. Here the increase of height is notable, and the development of the intellectual processes is a fairly accurate index of the success of the treatment. In children the difficulties are fewer and the dangers less, for toxic symptoms are but rarely observed.

The treatment of postoperative myxedema (after total extirpation of the thyroid) yields brilliant results when used as a prophylactic. In comparison with the small number of patients observed, the instances of toxic symptoms have been considerable in number. These are entirely unnecessary and would never be seen were the treatment always intrusted to a careful physician. The smallest dose at the longest interval which will keep the patient free from symptoms of the disease should be chosen. Hard and fast rules cannot be formulated; each patient should be studied.

Obesity.—Next to the three conditions just enumerated, obesity affords the best example of therapeutic efficiency. Since the increased nitrogen elimination is due to the breaking down of the circulating proteids and the fixed are not attacked until the store of fat is considerably reduced, the diet should not be much restricted, and nitrogenous matter ought to be well represented. In these cases more than ordinary care must be exercised, because the heart may have undergone fatty changes. Since heredity and habits of life have much to do with obesity, the results of thyroid administration are not always satisfactory. It is claimed that iodothyrin is more efficient in anemic obese persons than in vigorous subjects.

The insanity of myxedema (acute or chronic mania, melancholia, or dementia) is amenable to treatment, because the disease itself can be cured. The insanities from other causes do not present constant results. In the chronic varieties the improvement in nutrition is likely to benefit the mental condition. In acute mania, by increasing tissue metabolism, the danger of exhaustion is heightened. The dangers as to the heart, gastric irritation, and muscular weakness must be borne in mind. Experience only can determine, outside of the exceptions noted, whether a particular patient will be likely to receive benefit.

The results in **exophthalmic goiter** have been various. From the literature as well as from personal experience no final conclusions can be reached. Since, as Gley very properly observes, the majority of the symptons in many patients can be as plausibly explained by the hypothesis of partially deficient thyroid activity as by the hypothesis of augmentation of thyroid function, those who accept the first view are justified in making use of this remedy. Beyond the fact that it may increase the tachycardia and dangerously depress the heart, there is no objection to a trial being made—although good authority holds it to be contraindicated. In goiter the question depends entirely on how far the particular variety of disease has interfered with the proper functionating of the gland. The only constant result has been that the size of the goiter is reduced by its administration.

Skin-diseases.—The rapid and marked changes that occur in the skin of a patient suffering from myxedema while under thyroid treatment suggest its use in various dermatoses. Psoriasis and eczema, particularly the chronic varieties, have received considerable attention. At present, while some successes have been recorded, there is no rule that determines the probability of success, and even the treatment may aggravate the disease. In lupus Bramwell found more encouragement. The cutaneous lesions of malignant syphilis were markedly benefited, in the experience of Menzies, by thyroid medication. Various other conditions have been, with more or less reason, treated by the administration of thyroid preparations. The physician, bearing in mind the physiologic action of these, can determine the probability of success. The influence of the thyroid upon nutrition is available in the treatment of ununited fractures. Allusion must be made to observed facts bearing upon the supplemental secretion of one gland in the deficient action of another. In **akromegaly** it is highly probable the impaired or abolished functions of the pituitary body are taken up by the thyroid gland, and that with the exhaustion of that gland symptoms of myxedema may supervene. To some extent, then, the symptoms of akromegaly may remain in abeyance during the period of exaggerated activity of the thyroid. Further, improvement in some respects has followed the use of thyroid preparations in akromegaly. Whether this supplementary action is reciprocal or not, so far as is known no recorded facts are at hand upon which to base an opinion. Within the boundaries now accurately delineated thyroid preparations have their use, based upon sound physiology and pathology; if their use is improper, the theories in regard to the disease are at fault, and not the facts now well ascertained. See ORGANOTHERAPY; SERUMTHERAPY.

TIBIA.—See LEG.

TIC.—See CONVULSIONS.

TIC DOULOUREUX (Prosopalgia). See NEURALGIA.

TICK.—See BITES AND STINGS.

TICK FEVER.—An obscure tropical disease prevalent in certain districts of Africa transmitted by several varieties of ticks or wood-lice. It is closely similar to, and upon further investigation may be proved identical with relapsing fever

(*q. v.*) due to the spirillum Obermeieri. About a week after the bite the disease is ushered in with prostration, headache, pain in the back and legs, anorexia, vomiting, diarrhea, fever ranging from 101° to 104° F. There may be splenic enlargement. There are several febrile paroxysms of several days' duration occurring about every fortnight.

TIGLIUM.—See Croton Oil.

TINCTURE (Tinctura).—In pharmacy an alcoholic solution of the medicinal principles of a drug, and, excepting the tincture of iodin, of nonvolatile bases. Tinctures are prepared by percolation, maceration, solution or dilution; the menstrua employed being chiefly alcohol, diluted alcohol, and alcohol and water in various proportions. Two ammoniated tinctures are made with aromatic spirit of ammonia, in one acetic acid is an ingredient of the menstruum, and several have glycerin. The official tinctures are now practically in two classes as to strength, 10 percent for the more powerful ones, and 20 percent for the others, with a few exceptions. They number 63, the figures placed after each giving the number of grams to the drug in each 100 c.c. of the tincture: **Tinctura** aconiti 10, **T.** aloes 10, **T.** aloes et myrrhæ 10, **T.** arnicæ 20, **T.** asafetidæ 20, **T.** aurantii amari 20, **T.** aurantii dulcis 50, **T.** belladonnæ foliorum 10, **T.** benzoini 20, **T.** benzoini composita 10, **T.** calendulæ 20, **T.** calumbæ 20, **T.** cannabis indicæ 10, **T.** cantharidis 10, **T.** capsici 10, **T.** cardamomi 10, **T.** cardamomi composita 2 1/2, **T.** cimicifugæ 20, **T.** cinchonæ 20, **T.** cinchonæ composita 10, **T.** cinnamomi 20, **T.** colchici seminis 10, **T.** digitalis 10, **T.** ferri chloridi 13 1/4, **T.** gallæ 20, **T.** gambir composita 50, **T.** gelsemii 10, **T.** gentinæ composita 10, **T.** guaiaci 20, **T.** guaiaci ammoniata 20, **T.** hydrastis 20, **T.** hyoscyami 10, **T.** iodi 7, **T.** ipecacuahnæ et opii 10, **T.** kino 5, **T.** krameriæ 20, **T.** lactucarii 50, **T.** lavandulæ composita 0.8, **T.** limonis corticis 50, **T.** lobeliæ 10, **T.** moschi 5, **T.** myrrhæ 20, **T.** nucis vomicæ 2, **T.** opii 10, **T.** opii camphorata 0.4, **T.** opii deodorati 10, **T.** physostigmatis 10, **T.** pyrethri 20, **T.** quassiæ 20, **T.** quillajæ 20, **T.** rhei 20, **T.** rhei aromatica 20, **T.** sanguinariæ 10, **T.** scillæ 10, **T.** serpentariæ 20, **T.** stramonii 10, **T.** strophanthi 10, **T.** tolutana 20, **T.** valerianæ 20, **T.** valerianæ ammoniata 20, **T.** vanillæ 10, **T.** veratri 10, **T.** zingiberis 20.

For **tinctures of fresh herbs** (*Tincturæ Herbarum Recentium*), the pharmacopeia prescribes a general formula, according to which, when not otherwise directed, they are to be prepared by macerating 50 grams of the fresh herb, bruised or crushed, in 100 c.c. of alcohol, for 14 days, then expressing the liquid and filtering.

TINEA.—See Ringworm.

TINEA VERSICOLOR (Pityriasis Versicolor, Chromophytosis).—A vegetable parasitic disease, due to the microsporon furfur, characterized by furfuraceous, yellowish, macular patches, occurring chiefly upon the trunk.

Symptoms.—The disease begins by the appearance of yellowish macules, from the size of a pin's-head to that of a pea, scattered over the affected region. These, in the course of a few weeks or months, increase in size and coalesce, with the production of large patches. The patches are irregular in shape with sharply defined edges. The color is usually fawn, although it may vary from a pale yellow to a brown; occasionally it has a distinct pinkish tint. The affected area is covered by a fine, furfuraceous, mealy scaling. When this is not apparent, it may be made evident by scratching the surface with the finger-nail.

The eruption is usually confined to the trunk, particularly the chest and interscapular region. The neck, axilla, arm, and in rare cases the face, may also become involved. Itching of a mild character is usually present.

Tinea versicolor pursues a chronic course, lasting, untreated, for months and years. The disease, with rare exceptions, is confined to adults. It is but slightly contagious.

Etiology.—The disease is due to the presence and growth in the skin of the microsporon furfur.

Pathology.—The corneous layer is permeated with a luxuriant growth of mycelium and spores. The mycelium consists of short, jointed, and angular threads, which may be clear or contain spores. The spores are rounded, highly refractive bodies, varying in size from 9/100 to 3/100 of an inch in diameter. In tinea versicolor there is a characteristic tendency of the spores to become aggregated in masses.

Diagnosis.—Tinea versicolor may easily be distinguished from chloasma, vitiligo, and the macular syphiloderm by attention to the character and distribution of the eruption. In doubtful cases the microscope will decide the question.

Prognosis.—The disease responds promptly to treatment. Relapses are not infrequent.

Treatment.—The treatment is rapidly efficient, a few weeks sufficing in most cases to establish a cure.

℞.	Precipitated sulphur,	ʒ j
	Salicylic acid,	gr. xx
	Benzoinated lard,	ʒ j.

Rub in twice a day.

Solutions of hyposulphite of sodium (1 dram to 1 ounce) and bichlorid of mercury (1 to 4 grains to 1 ounce) are easy of application and eminently useful.

It is well to continue the treatment for some time after apparent cure in order to preclude the possibility of relapse.

TINNITUS AURIUM.—The subjective ringing, roaring, or hissing sound heard in the ears in various affections of the tympanum and internal ear, and also after the administration of certain drugs in large doses, notably quinin.

It may be continuous or intermittent, of all characters, and localized in the ear or extending over the cranium. Tinnitus is a frequent symptom of disease of the external, middle, or internal ear. It is usually present when there is undue pressure on the labyrinth. Cerumen on the tympanic membrane, imperfect entrance of air into the tympanum from obstruction of the caliber of the Eustachian tube, or effusion into the tympanic cavity will cause it. It follows blows on the head,

and is a prominent symptom in all nervous affections of the auditory apparatus. An altered condition of the blood-vessels, anemia, cerebral congestion, large doses of quinin, deranged digestion, and diseases of central origin, are causes. It occurs as a prelude to epileptic attacks, syncope, or vertigo, and is not uncommon in the gouty or uric acid diathesis.

Treatment.—Any curable local condition should be treated, and the general health improved. The tinnitus in nervous affections is very intractable. The most useful tonic is strychnin, while quinin exerts a distinctly injurious effect, particularly in large doses. See EAR (Diseases).

TITUBATION.—The staggering gait and incoordination of motion accompanying certain diseases of the spine and cerebellum; also the staggering gait of the drunkard.

TOBACCO (Tabacum).—The dried leaves of *Nicotiana tabacum*, native to America. Its properties are mainly due to an alkaloid, nicotin, $C_{10}H_{14}N_2$, which, next to prussic acid, is the most rapidly fatal poison known. Tobacco is but rarely used in medicine; but it is a powerful depressant, nauseant, emetic, diaphoretic, and antispasmodic; it is also narcotic and sedative, lowering arterial tension. In toxic doses death occurs by paralysis of the respiratory centers. It is used chiefly as an antispasmodic, and is said to be effectual in tetanus. **T. Enema,** 20 grains in 8 ounces of hot water for each enema. **T., Ol.,** obtained by distillation; violently poisonous. **T., Vinum,** 1 ounce to 1 pint. Dose, 5 minims to 1 dram. **Nicotin,** the alkaloid, efficient in tetanus and strychnin poisoning. Dose, 1/20 to 1/10 minim and up to 2 minims in 2 hours. Preparations unof. See LAMBERT TREATMENT for NARCOTIC ADDICTION.

TOE, Amputation.—See FOOT (Amputation).

TOLU.—See BALSAM.

TONGUE, DISEASES.—**Tongue-tie** is due to the tongue being more or less tightly bound down to the floor of the mouth by the shortness of the frenulum. It is likely, when well marked, to interfere with sucking, and later, with distinct speech. It is easily remedied by dividing the frenulum with probe-pointed scissors, care being taken to direct the points downward and backward and merely to notch the free border, lest the ranine artery be wounded—an accident that, in infants, has been attended by severe and, in some cases, fatal hemorrhage. If the division of the frenulum is too free, the tongue may loll backward, pressing the epiglottis over the entrance of the larynx, and produce severe dyspnea or even fatal asphyxia—"swallowing the tongue," as it has been called. On drawing the tongue forward the symptoms will at once cease; but a ligature should be passed through its tip and secured to the cheek, with instructions to again draw the tongue forward with ligature should the symptoms recur.

Macroglossia, or hypertrophy of the tongue, may be congenital or acquired. In either case it is rare.

Causes.—The affection appears to be due to occlusion of the lymphatics at the base of the tongue; at any rate, the lymphatics are found enlarged and distended with lymph, and the connective tissue is increased in amount and infiltrated with lymphoid corpuscles. It appears related, therefore, to elephantiasis—a condition sometimes found coexisting in the neck and other parts of the body.

Symptoms.—The whole tongue is uniformly enlarged, and sometimes so much so that it presses forward the alveolar process of the lower jaw with the incisor teeth, and protrudes from the mouth, hanging as low as the chin. When thus exposed, the mucous membrane becomes cracked, spongy, and bluish-red, and is subject to repeated attacks of subacute glossitis.

The treatment is excision of part of the organ. The removal of a V-shaped piece has been attended by excellent results. It should be done before the teeth and jaw have been deformed by the pressure.

Acute parenchymatous glossitis, or deep inflammation of the tongue, may be due to mercury, fever, iodism, injury, carious teeth, stings of insects, abscesses beneath the jaw; sometimes there is no apparent cause.

Symptoms.—In severe cases the whole tongue is swollen, and protrudes from the mouth, interfering with speech and deglutition, and sometimes threatening suffocation. It frequently ends in abscess. It is often attended with high fever and salivation, and may be quite sudden in its onset.

Treatment.—Should a brisk purge and the milder measures applicable to acute inflammations fail, free longitudinal incisions, which need not be deep, should be made along the dorsum of the tongue, and the swelling will usually subside in a few hours.

Suppuration and abscess sometimes follow an attack of acute glossitis; but the preceding inflammation may be so slight as to be overlooked. The abscess, which then forms a firm, tense, elastic swelling in the substance of the tongue, may be mistaken for a gumma or carcinoma; but the diagnosis is readily made by an exploratory puncture. A free incision is the proper **treatment,** the cavity filling up in a few days.

Chronic superficial glossitis (*leukoplakia buccalis*), also known as psoriasis, or ichthyosis of the tongue, or smokers' patches, is a chronic inflammation of the mucous membrane, and may be induced by syphilis, excessive smoking, some forms of dyspepsia, the abuse of spirits, jagged teeth, etc. It may be found associated with psoriasis. The mercurial treatment of syphilis may be a factor in its etiology. The disease has a marked tendency to become malignant.

Treatment.—All sources of irritation, especially smoking, stimulants, and condiments, should be avoided; antisyphilitic remedies should be given when indicated; gastritis, if present, should be treated; and soothing washes of chlorate of potassium, or sodium bicarbonate (20 grains to the ounce) should be applied. Should any of the leukoplakial patches show signs of ulceration, the whole patch should be excised at once; or should signs of epithelioma already be present, the whole or half of the tongue should be removed.

Simple ulceration may depend on digestive disturbance (*dyspeptic ulcer*) or on irritation, as of a sharp or carious tooth, hot pipe-stem, etc. (*dental or irritable ulcer*). Both varieties are generally superficial, and unattended by the induration and infiltration characteristic of epithelioma. The *dyspeptic ulcer* usually occurs on the dorsum of the tongue near the tip. The ulceration is sometimes extensive and multiple, and is often accompanied by some superficial glossitis at other parts of the tongue. The *dental ulcer* is situated on the side of the tongue, and generally corresponds with a carious or sharp tooth. At first it may be a mere superficial, red abrasion, but if neglected, it becomes a distinct ulcer, irregular in shape, and surrounded by an inflammatory area. The edges are abrupt and a little raised, but not everted; the base is depressed, sloughing, and sometimes phagadenic, but not indurated unless the ulcer has existed some time, when it may become callous. It is always unattended by infiltration.

Treatment.—In the *dyspeptic ulcer* the diet and bowels must be carefully regulated, bismuth or sodium in infusion of calumba given internally, and soothing washes or borax and honey applied locally. Caustics must be avoided. In the *dental ulcer* any offending tooth must be filed, stopped, scraped, or extracted; in short, every source of irritation removed. The ulcer will then heal rapidly, but if neglected, it may become epitheliomatous. On the first appearance of infiltration, therefore, free excision is imperative.

Tubercular ulceration of the tongue is rare, and generally occurs in young adult males, the subjects of phthisis or of general tuberculosis. It usually begins as a small pimple or nodule on the dorsum of the tongue, especially near the tip. This, after a short time, breaks down into round, oval or irregular, painful ulcer. The edges are slightly raised, vertical, inverted, or undermined, sometimes slightly thickened, but never everted or greatly indurated. The base is uneven or nodular, and covered with coarse, pinkish-gray granulations, or with a gray or yellow shredded slough. Sometimes several smaller ulcers appear around the one first formed, and coalesce with it. The ulceration usually progresses in spite of treatment, the patient dying of phthisis or other tubercular affection. The absence of glandular enlargement, of induration, and of signs of syphilis, along with the presence of tubercle elsewhere, and the characters enumerated, should serve to distinguish it from syphilitic and epitheliomatous ulceration.

Treatment has hitherto been of little avail. The ulcer, however, may be soothed by Ferrier's snuff or cocain; or if the constitutional state does not forbid, it may be scraped with a Volkmann's spoon, and dusted with iodoform, cauterized with nitrate of silver, or cut out. The usual constitutional treatment for tubercle should, of course, at the same time be employed.

Syphilitic ulceration may be divided for practical purposes into the superficial and deep, the former commonly occurring in the early, the latter in the later, stages of syphilis.

Treatment.—Large doses of iodid of potassium, combined with quinin, if the constitution is at all broken, and the local application of a cleansing gargle, as chlorate of potassium, will rapidly cause them to heal. The scars left by these ulcers sometimes, though rarely, degenerate into epithelioma. Should any induration, therefore, appear in them, their free removal with the knife should at once be undertaken.

Epitheliomatous ulceration is due to the breaking down of squamous carcinoma. It is described under ulceration instead of among new growths, as, in consequence of the irritation from the teeth and the movements of the tongue, epithelioma in this situation very rapidly ulcerates, even if it does not begin as an ulcer; hence, it is from other ulcers rather than from new growths that it has to be distinguished. It is much more common in men than in women, and seldom occurs under the age of 40. Often it is due to some form of irritation such as that produced by a carious or sharp tooth, or a syphilitic ulcer, or leukoplakia. Occasionally it begins as a wart or pimple in patients in whom no cause for it can be assigned. It is most common on the side of the tongue opposite the molar or bicuspid teeth. The ulcer is irregular, with raised, sinuous, hard, and everted edges, and uneven, excavated, or warty base; while the tissues around are infiltrated and indurated. Its growth is generally rapid, and attended with neuralgic pain and copious salivation. If allowed to take its course, it spreads backward to the pillars of the fauces, downward to the floor of the mouth, and inward to the opposite half of the tongue; while the submaxillary lymphatic glands, and later the lymphatic glands in the neck, become enlarged, and the parts about the angle of the jaw infiltrated and matted together by the disease. Secondary ulcers then form from the breaking down of the glands in the neck, and the patient dies, worn out by pain and irritation, or exhausted by hemorrhage; but, like squamous carcinoma in other parts, it seldom becomes disseminated in distant organs.

Treatment.—Early and free extirpation ought, in every instance, to be undertaken, but even then a recurrence in the glands of the neck is only too frequent. When the disease has attained some magnitude, the propriety of removal becomes a question, and opinions differ as to under what circumstances it ought to be attempted. Its removal is contraindicated: (1) When it has extended so far backward that the finger cannot reach healthy tissue beyond it; (2) when it is firmly and extensively adherent to the jaw; (3) when the tongue is firmly bound down to the floor of the mouth; (4) when the glands not only below the jaw, but deep in the neck, are much implicated; and (5) when the patient is too weak or emaciated from the disease itself, or from disease of other organs, to withstand an operation. Moderate enlargement of the glands, slight adhesion to the jaw, and some infiltration of the floor

of the mouth, do not, it is thought, forbid an operation (especially if the patient is suffering from much pain, and is otherwise in good health), provided the whole of the disease with the enlarged glands can be removed. When the disease is regarded as beyond the reach of extirpation, the pain and salivation may often be relieved by removing not only decayed, but sound, teeth that may be irritating the growth, or by stretching or dividing the gustatory nerve. This, which, however, is sometimes impracticable on account of the extension of the growth, may be done by making a small incision transversely from the last molar tooth through the mucous membrane to the side of the tongue, then passing an aneurysm needle into the wound, and hooking up the nerve, which is here quite superficial. Cocain, or morphin and glycerin, may be painted on the part, while the patient's remaining span of life may be rendered bearable by increasing doses of opium or morphin (Walsham).

Tumors of the Tongue.—*Papillomatous or warty growths* are not uncommon, and may be distinguished from epithelioma, into which they are liable to degenerate as age advances, by the absence of induration about their base. They should be freely removed by the knife or scissors. *Vascular tumors* or *nævi* and *lymphangiomata* are occasionally met with, and may be destroyed by the ligature or knife. *Fibrous, fatty, myxomatous, adenomatous, sarcomatous,* and *carcinomatous tumors* other than the squamous variety, which has already been described under epitheliomatous ulceration, are too rare in the tongue to call for further remark.

Syphilis of the Tongue.—*Primary chancres,* which are very rare in this situation, require no description. *Mucous tubercles* consist, as elsewhere, of heapings up of epithelium over infiltrated and enlarged papillæ, and appear as flattened elevations of a grayish-white color. They are generally present on the palate and fauces at the same time. Mercury internally, and black wash locally, cause them rapidly to disappear. *Superficial glossitis* and the *superficial* and *deep ulcerations* have already been described. *Gumma* occurs as a hard, globular mass in the fibrous tissue of the septum, and also in the substance of the muscles. It may be single or multiple. The mucous membrane covering it is at first natural in appearance, but as the gumma softens, it gives way, and a deep syphilitic ulcer is produced. Iodid of potassium is the remedy.

See Hypoglossal. Nerve.

TONGUE, EXCISION.—Excision with the knife, on account of the profuse hemorrhage that attends it, is only applicable when the anterior portion of the tongue requires removal. The tongue should be well drawn forward, and the diseased portion cut away with one sweep of the knife, and the bleeding vessels tied.

The écraseur is much less used than formerly. The mouth having been widely opened by a gag, two ligatures are passed through the tongue, one on either side of the tip, and the mucous membrane, where it is reflected from the tongue to the jaw, is divided with scissors along with some of the fibers of the geniohyoglossus. The mucous membrane covering the dorsum of the tongue is next divided in the middle line by a bistoury, from the tip as far back as to be well beyond the disease. This allows the tongue to be readily split with the fingers into two halves. The cord of the écraseur is now passed over one-half, and well behind the disease, and, if the whole tongue is to be removed the cord of a second écraseur over the other half. The cord being tightened by screwing up the écraseur, the tongue is cut through. The lingual artery, with the gustatory nerve, is drawn out in the form of a loop by the cord of the écraseur. A ligature should be passed around the artery with an aneurysm needle, and the artery severed in front of the ligature. The anterior part of the tongue will now come away, leaving the ligature on the artery in the stump of the tongue.

Excision with the scissors (Whitehead's method) consists in drawing the tongue well forward by two ligatures through its tip, dividing the frenulum, splitting the tongue as previously described, and then separating the diseased half from its attachments, beginning from below by a series of short snips with blunt-pointed scissors, clamping or tying the lingual artery, if seen, before it is divided, or else immediately after it is cut. The lingual artery lies immediately below the muscle substance about 1/4 inch from the middle line. If the disease involves both sides of the tongue, the opposite half can next be removed in the same way. Should bleeding occur, it can always be arrested temporarily by merely passing the finger into the pharynx and pressing the tongue against the inner surface of the jaw, and then as soon as the mouth has been sponged clear of blood, the bleeding vessel can be seized and tied. Or Lockwood's clamp for compressing the lingual artery may be used during the operation if the surgeon fears severe hemorrhage, the only objection to it being that it is likely to get a little in the operator's way. Some surgeons operate with the patient's head hanging over the end of the table, so that the blood may not run down into the throat. When Hahn's cannula is used, it is often kept in for several days after the operation, for the purpose of excluding septic discharges from the air-passages and so preventing septic pneumonia. The advantages of the scissors over the écraseur are that a cleaner-cut surface is left and consequently that the surgeon can be more certain of having removed the whole of the disease; that less sloughing occurs; and that the operation is more quickly performed. When, however, the tongue is adherent to the floor of the mouth and hence cannot be drawn forward, or the mouth cannot be opened sufficiently wide, or the light is bad, or a reliable assistant is not at hand, removal with the scissors is attended with considerable difficulty, and under these circumstances removal with the écraseur will be found safer (Walsham).

Excision with the galvanocautery is strongly recommended by some surgeons, but is open to the serious objection that it is liable to be followed

by secondary hemorrhage on the separation of the sloughs.

Kocher's Operation.—A preliminary tracheotomy is performed, and an ordinary cannula inserted. Entry of blood is prevented by plugging the pharynx with a sponge soaked in carbolic acid. The incision runs along the anterior border of the sternomastoid from the ear down to nearly the middle of the muscle; from this it turns forward to the hyoid bone and along the anterior border of the diagastric to the symphysis. A flap, containing skin, platysma, and fascia, is reflected upward; the facial artery and vein are tied; the lingual artery is secured on the hyoglossus; and the submaxillary fossa is completely cleared out, beginning from behind. All the cellular tissue is removed, together with the lymphatic glands, and the submaxillary and sublingual glands are removed if they appear involved. The mylohyoid muscle is then separated, the mucous membrane divided, and the tongue drawn through the opening. If the whole thickness is removed, the opposite lingual must be tied as well.

Preliminary Treatment.—Before commencing the operation, the mouth and the nasal cavities are thoroughly washed out with a solution of bichlorid of mercury (1:2000); and after it is finished and the wound adjusted with sutures, the surface of the stump and the pharynx behind it are covered over completely with a sponge soaked with carbolic acid. The dressings are changed twice a day, advantage being taken of the opportunity to pass an esophageal tube and feed the patient; for the rest, nutrient enemata are used. The operation is undoubtedly more extensive than the others, but it is believed that this is amply compensated for by the thoroughness with which the whole of the affected tissue is removed and the way in which the risk of septic inflammation and pulmonary complications is avoided. Kocher himself has been very successful as regards immediate mortality, but the operation does not seem to have been performed by other surgeons to any great extent.

The after-treatment of these cases requires even more than ordinary care. Every endeavor must be used to prevent putrefaction, which, owing to the temperature, moisture, and alkaline reaction, is very prone to follow; the patient's strength must be husbanded and maintained in every way; and precautions taken to prevent food or the discharge from the wound entering the lungs. With this in view, Kocher fills the entire cavity, from the edge of the wound back into the mouth and pharynx, with a sponge soaked in carbolic acid solution, shutting off the nasopharyngeal cavity on the one hand and the larynx and pharynx on the other. The same object may, however, be achieved much more satisfactorily by means of a plan recommended by Barker: The whole wound is carefully cleansed, dried, and dusted with iodoform, and the two ends of the incision sutured. In the middle a piece of rubber tubing is adjusted, is long enough to reach well down into the esophagus; and all the space around carefully packed with antiseptic wool. This can be left untouched for days, the patient being easily fed by means of a funnel as often as it may be required.

TONGUE IN DIAGNOSIS.—The tongue is a general index of disease, whether its condition is a local manifestation of a constitutional disturbance or whether the process is limited. The coated tongue of certain gastric disorders, the reddened tongue of fever, the strawberry tongue of scarlatina, the brown coating and fissuring of the typhoid tongue, the hypertrophic and thickened tongue of myxedema and akromegaly, and the pigmented tongue of suprarenal disease are all characteristic. Herpes febrilis, mucous patches, aphthous stomatitis, and thrush often have their starting-point in this organ.

The elongated and pointed tongue indicates a condition of irritation and determination of blood to the stomach and bowels. The full tongue, broad and thick, is evidence of atony, want of action in the digestive tract. The dry, pinched tongue expresses a want of functional activity in the digestive organs. It is the tongue of acute disease, and is usually associated with dryness. The fissured tongue in chronic disease indicates inflammatory action of the kidneys. The fissured tongue in advanced stages of acute disease is significant of lesions of the kidneys or irritation of the nerve-centers. In many cases there is a defect in the secretion of urine.

Dryness and moisture are important evidences of the condition of the digestive organs. If the tongue is dry, the stomach and intestines are disordered. In acute disease with dryness of the tongue, when it becomes moist, improvement is indicated, and it is nearly always looked upon as a favorable symptom.

The thin, transparent coating of the tongue gives evidence of enfeebled digestion, frequently from intemperate eating and drinking. A tongue coated heavily at the base calls attention to accumulations in the stomach, and suggests the use of an emetic. The broad pallid tongue gives evidence of a want of the alkaline elements of the blood. It may be the basis of the disease, which will fade away as soon as the proper alkali is given, or it may be but a portion, the alkaline salt preparing the way and facilitating the action of other remedies. The deep red tongue, generally dry, indicates an acid.

TONICS.—Medicine or agents that promote nutrition, and give tone to the system. The most typical agents are strychnin, quinin, iron, and the vegetable bitters. Those especially acting on the stomach are arsenic, bismuth, cinchona, hydrastis, and nux vomica; on the spinal cord and general circulation, strychnin; on the heart, digitalis, squill, convallarin, and cimicifuga; on the general nervous system, phosphorus, quinin, and the valerates; on muscular tissue, tannin; on the blood, iron, manganese, cod-liver oil, and other fats.

In administering tonics care is required to see that the tonic is suitable to the case; for in apparent debility and imperfect functional activity, imperfect removal of tissue or other waste is responsible. Not tonics, but cholagogs, purgatives, etc., are then indicated. Tonics are em-

ployed in debility of the whole or part of the body; the character of the medicinal agent depends upon the part affected.

General tonic prescriptions:

℞. Quinin sulphate, gr. xx
Dried iron sulphate, gr. xl
Strychnin sulphate, gr. ss.
Divide into 20 pills. Give 1 pill 3 times a day.

℞. Tincture of iron chlorid, Dilute phosphoric acid, each, ʒ ss
Simple syrup, add enough to make ʒ iij.
A teaspoonful 3 times a day.

℞. Arsenic trioxid, gr. j
Strychnin sulphate, gr. 1/3
Quinin sulphate, ʒ j.
Divide into 20 pills. One pill after each meal.

℞. Iron sulphate, gr. xij
Magnesium sulphate, ʒ vj
Dilute sulphuric acid, ʒ j
Infusion of quassia, ʒ vj.
Tablespoonful in water 3 times a day.

℞. Solution of potassium arsenite, ♏ x
Fluidextract of nux vomica, ♏ xx
Compound tincture of gentian, Tincture of cinchona, Tincture of calumba, Wine of kola, each, ʒ iv.
A tablespoonful after each meal.

℞. Tincture of nux vomica, ʒ ij
Tincture of cinchona enough to make, ʒ iv.
A teaspoonful after each meal.

In atonic dyspepsia:

℞. Dilute nitrohydrochloric acid, ʒ vj
Solution of strychnin, ʒ jss
Tincture of orange, Tincture of calumba, each, ʒ j
Compound infusion of gentian, add enough to make ʒ x.
Tablespoonful in a wineglassful of water 3 times daily, after eating.

Or:

℞. Strychnin sulphate, gr. j
Dilute nitrohydrochloric acid, ʒ j
Compound tincture of gentian, ʒ j
Compound tincture of cardamom, ʒ ij
Solution of pepsin, add enough to make ʒ iv.
A teaspoonful after each meal.

TONSILLITIS (Amygdalitis). Varieties.—(1) acute; (2) chronic; (3) phlegmonous (quinsy, tonsillar abscess).

Etiology.—(1) It most often occurs during youth or adolescence; (2) exposure to the cold and wet; (3) heredity; (4) certain diseases, such as lithemia, rheumatic diathesis; (5) changeable climate.

Pathology.—In the first stage, superficial, of acute tonsillitis the catarrhal inflammatory process is principally confined to the mucous membrane of the tonsil, which is covered with a viscid secretion. The epithelium desquamates rapidly. The organ is enlarged from congestion of the blood-vessels. In the second stage, lacunar or follicular, the epithelium collects in the crypts, and undergoes necrosis, forming small, whitish, offensive, cheesy masses, which obstruct the secretion of the gland. In the last stage, parenchymatous, a phlegmon may form constituting circumtonsillar abscess or quinsy.

Symptoms and Clinical Course. Acute follicular Tonsillitis.—The onset is generally marked by chilliness or a general body ache. The temperature may rise suddenly—often to 104° F.—within the first 24 hours. The region of the affected part is dry, hot, and gives rise to severe pain on swallowing or on opening the mouth. The tonsils are enlarged, and may be felt externally. The surface is usually covered with a thick whitish mucus, often offensive. The tongue is heavily coated; urine high colored, scanty, and contains excess of urates. In the follicular stage the glands are red and swollen, and in the crypts are seen the small, whitish, cheesy plugs, which are the remains of degenerated epithelium. They may often be brushed away in making local applications, leaving small depressions in the glandular substance. In many cases they become detached, and are cast off with the expectoration.

Chronic Tonsillitis.—The lacunæ of the tonsil are filled with debris which impart a fetid odor to the breath. From time to time these cheesy masses are expectorated. The quality of the voice may be altered. There is a more or less constant cough. The tonsils may be slightly or markedly enlarged.

Phlegmonous Tonsillitis (Quinsy).—The affected organ is very painful and greatly distended by the purulent collection, which may be throbbing in character. The jaws are stiff, and the mouth cannot be opened. Often the pain is diffused over the whole angle of the jaw. The jaws may be edematous, and fluctuation may be obtained on palpation of the parts.

Deglutition is painful, and often entirely lost; the voice becomes hoarse, and has a nasal character; saliva is greatly increased. The fever is higher, as a rule, and the suffering more intense than in the other varieties of tonsillitis.

Diagnosis.—

Tonsillitis.	Diphtheria.	Scarlet Fever.
1. History of exposure to cold and wet; rheumatic diathesis, or history of previous attack.	1. History of contagion.	1. History of contagion.

Tonsillitis.	Diphtheria.	Scarlet Fever.
2. Onset sudden; high fever rising rapidly.	2. Onset gradual. Urine quickly showing albumin and casts.	2. Onset sudden; strawberry tongue; scarlet red rash; pulse rapid, out of proportion to temperature; convulsions frequent.
3. Severe pain in region of tonsil on opening the mouth; moderate prostration.	3. General body pain as well as pain in angle of jaws; severe cough or bronchitis may be present; prostration severe.	3. Prostration severe.
4. Absence of membrane in all forms; small cheesy lumps in the crypts of gland in follicular tonsillitis.	4. Grayish-white membrane, and on being pulled off leaves behind a bleeding surface; membrane contains Klebs-Loeffler bacilli.	4. False membrane may be present, but absence of Klebs-Loeffler bacilli.
5. No sequels; symptoms subside quickly.	5. Paralysis of nerves of pharynx or eye common.	5. Tendency to nephritis.

Prognosis is favorable, except in the phlegmonous form, which may involve the deeper tissues, and extend downward behind the carotid sheath, causing death.

Treatment of Acute Follicular Tonsillitis.—In the majority of cases it is well to begin the treatment by the administration of calomel in fractional doses, or saline purgatives. Should there be a rheumatic diathesis, sodium salicylate, or preferably aspirin, 7 grains every 3 or 4 hours, should be given. If temperature is high (102.5° F.), phenacetin, 5 grains every 4 hours, and quinin, 4 grains, may be given from the onset of the symptoms.

℞. Tincture of aconite, ♏ xl
Elixir curacoa, ʒ iij
Solution of potassium citrate, add enough to make ℥ iij.
Tablespoonful every 3 or 4 hours.

Guaiac may be given in the form of the compound tincture, 1 dram with milk every 4 hours, or may be used as a gargle. It may also be administered in the form of a lozenge:

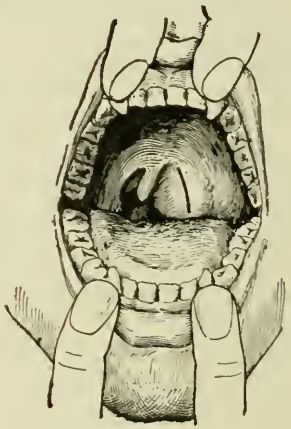
℞. Guaiac, ʒ v
Oil of lemon, ♏ x
Oil of peppermint, ♏ iv
Acacia, ʒ ss
Sugar, ʒ jss.
Confection of rose, add enough to make 30 lozenges.
Allow 1 to dissolve in the mouth every 3 or 4 hours.

Local Treatment.—Small pellets of ice may be allowed to dissolve in the mouth to relieve the inflammation. If the application of cold is disagreeable, hot compresses may be substituted. Occasionally, spraying through the anterior nares with an alkaline solution (see Pharyngitis) will prevent mouth-breathing, and relieve the catarrhal process often present in these parts.

Local applications of nuclein solution (5 percent) twice daily, and also internally in doses of 1 teaspoonful every 4 hours, are valuable. Bicarbonate of sodium or aspirin applied locally may afford marked relief.

Treatment of Chronic Tonsillitis.—If the tonsils are not enlarged the crypts should be emptied by the curette and obliterated by some caustic such as silver nitrate or preferably by the galvanocautery. If the tonsil is enlarged it should be removed with the snare or guillotine. If this is not permitted, daily gargling with antiseptic solutions should be insisted upon and applications of strong tincture of iodin or trichloracetic acid should be made to the crypts. Daily cold bathing especially of the neck, is excellent. It is important to pay attention to the general health in regard to food, exercise, clothing, and tonics.

Treatment of Phlegmonous Tonsillitis.—Hot applications should be applied to the angles of the jaw; at the earliest possible moment, the abscess should be opened with a sharp pointed (but guarded) tenotome, the incision being parallel with the anterior pillar of the fauces, and directed toward the middle line. In all cases the diet should be light and nutritious.



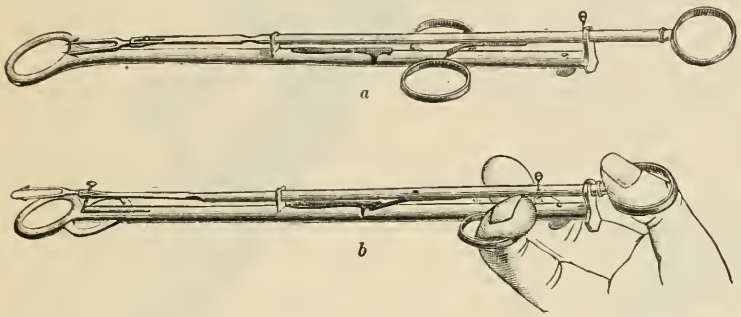
Line of Incision in Quinsy.—(*Veau.*)

TONSILS, HYPERTROPHY.—Chronic enlargement of the tonsils is very common in strumous children, in whom it is frequently associated with adenoid growths in the vault of the pharynx. At times it appears due to oft-repeated attacks of acute tonsillitis.

The symptoms to which it may give rise are a nasal tone of voice; a peculiar vacant expression, acquired by the child constantly breathing with the mouth half open; regurgitation of fluids through the nose; snoring during sleep; distressing dreams, from the imperfect aeration of the blood; and recurring attacks of acute or subacute tonsillitis; deafness from implication of the eustachian tube and middle ear in chronic inflammation, may sometimes be nduced, and even an alteration in the shape of the

chest, and possibly phthisis. The tonsils appear irregularly enlarged, often almost occluding the fauces, but, unless inflamed, are of a natural color, or perhaps slightly paler than natural.

Treatment.—In young children the affection may be cured by persistent painting with the tincture of perchlorid of iron or tincture of iodin, combined with the internal use of cod-liver oil and syrup of the phosphate or the iodid of iron. In older children, or when the tonsils are much enlarged, they should be excised, either with the knife or, better, with the guillotine, and this should be done before the voice has become seriously affected or other disturbance has ensued. The hemorrhage attending the operation, though usually slight, has at times been alarming. Gargling with cold water will generally stop it; but if this fails, ice or astringents, as tannic acid, or pressure with a pencil guarded with lint will nearly always succeed. Should a bleeding vessel be seen, it should be tied or twisted. In exceptional cases the common carotid has had to be tied. Should adenoid growths be present, they should be removed at the same time as the tonsils. See ADENOID VEGETATIONS, PHARYNGITIS, RHINITIS.



TONSILLOTOME.—(*Zuckerkandl.*)

TOOTHACHE.—This is a symptom of caries, periostitis, exostosis, inflamed pulp, or neuralgia, and ultimately the patient should be sent to a dentist. Temporary treatment, however, is often demanded. If there is a cavity, it should be carefully cleansed with warm water and plugged with a pledget of absorbent cotton soaked in creosote, phenol, chloroform, oil of cloves, cocain, or other local anesthetic. A mixture such as the following may be used:

℞. Cocain hydrochlorid, gr. iij
Carbolic acid, ʒ j
Collodion, ʒ j.

A small quantity to be applied to the dried-out cavity upon an absorbent-cotton plug.

Coley states that of all medicinal remedies for toothache none is so successful as sodium salicylate. He believes it is especially useful in those cases when the pain is started by "taking cold." A dose of 15 grains will usually relieve the pain very promptly, and if this is repeated every 4 hours, the inflammation may entirely subside, leaving, of course, a carious tooth to be disposed of according to circumstances. The addition of belladonna is often advantageous Fifteen grains of sodium salicylate with 10 minims of tincture of belladonna, will often procure refreshing sleep instead of a night of agony. It is especially valuable with children, when extraction of teeth is to be avoided, if possible, lest the development of the maxilla should be injured. See DENTAL ANODYNES; DENTITION (Disorders); TEETH, etc.

TORMINA.—Griping pains in the abdomen. See COLIC, DYSENTERY.

TORTICOLLIS (Wry-neck).—An affection due to irregular contraction of the muscles, twisting the head. The sternomastoid is the muscle usually at fault—sometimes the only one—but the others and the cervical fascia often aggravate the evil. It may be primary, caused by disease of the muscle itself (this is usually distinguished as the congenital variety); or secondary, arising from inflammation of some of the structures near the joints, vertebræ, lymphatic glands, etc., or from a disordered condition of the nerve.

Congenital torticollis is rarely noticed until some time after birth. This arises partly from the shortness of an infant's neck, partly from the fact that the deformity itself is not nearly so well marked at this time of life as it is later. Its origin is uncertain. Probably it is due to partial rupture of the muscle at the time of parturition; at least a tender, ovoid mass is not infrequently found, shortly after birth, in the sternal head of the sternomastoid, just where the tendinous and muscular fibers meet; and in several cases wry-neck is known to have been present later in life. The back of the head is drawn down; the chin is directed toward the opposite side, so that the face looks somewhat upward, and the muscle itself stands out like a tense cord, with a hollow in front and behind. The sternal portion is usually the chief offender, and in severe cases the mastoid process may be dragged down so far as to lie immediately over and scarcely an inch from the sternoclavicular articulation. As a result, the cervical vertebræ become twisted and deformed; secondary curves make their appearance in the back; the under side of the face does not grow in proportion to the rest; the line of the eyes becomes oblique; and, if the condition is not remedied before puberty, even the breast fails in its development.

Treatment of Congenital Torticollis.—Unless the patient is treated by position while still an infant, division of the sternomastoid is generally required, followed by a course of systematic exercises in the milder cases, and the use of a supporting brace in the most severe. The sternomastoid is best divided immediately above the clavicle, as here it is furthest removed from the important structures that lie beneath it. A puncture should be made at the inner side of the tendon, a director passed behind

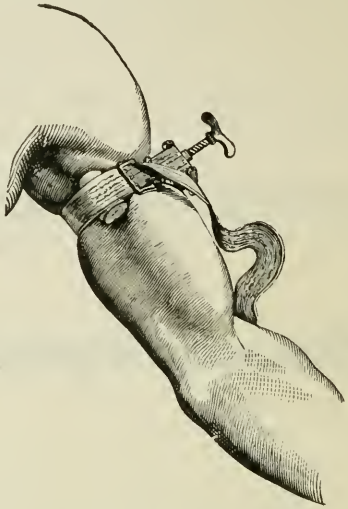
it, and the division made toward the skin with a blunt-pointed tenotome. The tense bands of contracted cervical fascia that now start forward will yield to stretching; it is not safe to divide them. The head should be straightened, and held thus by a bandage and sand-bags. The puncture should be allowed 3 or 4 days to heal before the exercises are begun or the instrument is applied. Some advise the division of the muscle about the middle, believing that this is a more safe procedure; while others again recommend the division of the tendon by open incision, as in this way the danger of puncturing and admitting air into a vein is avoided. If the subcutaneous division, however, is carefully done in the manner here advised, there need be no fear of air entering the veins; sudden death has, however, occurred at the hands of some excellent surgeons, and others have met with alarming symptoms.

Acquired torticollis may be due to rheumatism or exposure to cold, or it may be symptomatic of inflammation of the lymphatic glands, the vertebræ, or other structures of the neck, the muscles (for in this case the splenius and others are in a state of tonic spasm as well) contracting to save the affected part. In many of these cases the diagnosis of the exciting cause is exceedingly difficult, and very great care is required, as cervical caries is by no means uncommon. Tonic torticollis of this character may always be distinguished from the congenital variety by its relaxing completely under an anesthetic, and by the absence of any shortening of the cervical fascia.

Treatment of Acquired Torticollis.—In spasmodic cases conium, Indian hemp, bromid of potassium, etc., may be tried. These failing, the spinal accessory nerve may be stretched just above the spot where it enters the sternomastoid. In very intractable cases a piece of the nerve may be excised, and if the posterior cervical muscles are also involved in the spasm, excision of portions of the posterior division of the first 4 cervical nerves may be simultaneously or subsequently undertaken. Tenotomy of the sternomastoid should in these and in hysteric cases on no account be performed.

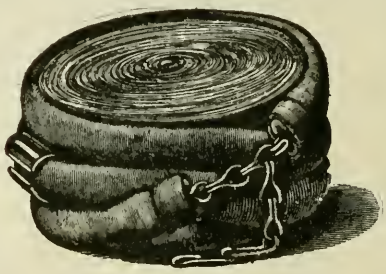
TOUCH.—See SENSATION (Disorders).

TOURNIQUET.—An instrument for controlling the circulation by means of compression. It usually consists of 2 metallic plates united by a thumb-screw and a strap provided with a pad. The strap is fastened about the part, the pad being placed over the artery to be occluded. The screw is placed diametrically opposite the pad, and the strap is tightened by separating the metallic plates of the screw. Dupuytren's tourniquet is one for compressing the abdominal aorta, consisting of a semicircle of metal with a pad at one extremity. Esmarch's tourniquet consists of a stout, elastic-rubber band applied above the proximal turn of an elastic bandage passing around the part to be exsanguinated. It has several disadvantages: It may cause paralysis; it encourages sloughing, especially if used to check primary hemorrhage before amputation; oozing following its removal is often very great; it is intensely painful. It is better to apply an Esmarch bandage first. Petit's tourniquet is used chiefly for the groin and the arm below the axilla. Its pad, or a roller about 1 1/2 inches in thickness, is placed upon the main vessel, the band buckled closely to the limb, and the screw



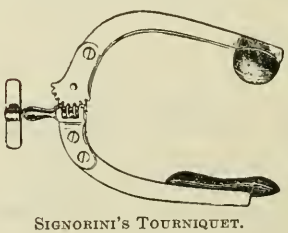
PETIT'S TOURNIQUET.

turned so quickly as to compress the artery as soon as the veins and thus avoid passive congestion. To prevent the skin being dragged, a bandage around the limb is advantageous. Signorini's



ESMARCH BAND.

tourniquet has a pad at each end (one for pressure, the other for resistance), and is operated by a screw and ratchet in the middle so that the arc can be opened or closed at will. It is chiefly for use upon the femoral artery in the groin, the larger pad being placed beneath the tuberosity of the ischium. Lister's tourniquet is of large size, and intended for use on the abdominal aorta. It is to be placed on the patient's right side, so that the vessel does not slip off the fourth lumbar vertebra, is to be screwed up only at the last moment, and then only with enough force to interrupt the circulation.



SIGNORINI'S TOURNIQUET.

In emergency a tourniquet can be devised from a handkerchief tied around a limb and twisted tightly. A stone or block or pad may be placed inside and on the bleeding point.

TOWNS' TREATMENT.—See LAMBERT TREATMENT for NARCOTIC ADDICTION.

TOXALBUMIN.—A proteid substance resembling a ferment rather than a poison. Any of the poisonous albuminoids that are produced or separated from the albumin of the tissues by the agency of bacteria, and entering the circulation constitute the cause of the general symptoms of infectious diseases. Toxalbumins have been obtained from cultures of a number of bacteria—among others from those of diphtheria, typhoid fever, cholera, tetanus, glanders, tuberculosis, anthrax, and pneumonia; likewise, also, from cultures of the staphylococcus pyogenes aureus, and the swine-plague bacillus; from those of certain germs found by Booker in the stools of the summer diarrhea of infants, and from those of two toxicogenic germs isolated by Vaughan from drinking-water. It is possible that poisonous albuminous substances are also produced by animal parasitic organisms. Thus Viron has isolated a toxic proteid from the fluid of hydatid cysts.

TOXEMIA.—See AUTOINTOXICATION, GASTRITIS (Toxic), POISONING.

TOXICOLOGY.—See POISONING.

TOXINS.—See SERUM THERAPY AND VACCINE THERAPY.

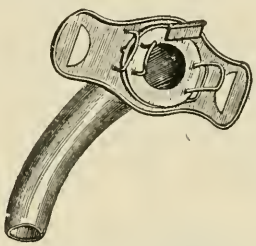
TRACHEA, INJURIES.—See NECK (Injuries).

TRACHELORRHAPHY.—See CERVIX UTERI (Laceration).

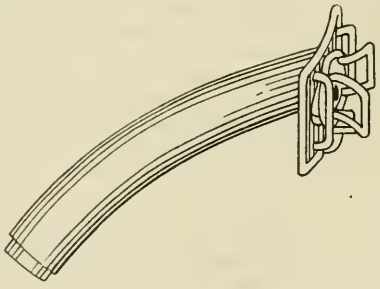
TRACHEOTOMY.—Tracheotomy is frequently required. It may be performed for the relief of obstruction, whether it is temporary (as in croup, diphtheria, edema of the glottis, or muscular spasm) or permanent (as in syphilitic stenosis); for the removal of foreign bodies; to give rest to the larynx in cases of painful ulceration; or as a precaution in operation in order to prevent the entry of blood.

The trachea may be opened either above or below the isthmus of the thyroid; but, unless there is some special indication to the contrary, the former should always be selected. The anterior jugular and inferior thyroid veins are in close relation with the lower part. The innominate artery bifurcates almost on it, and sometimes reaches far up into the neck. The thyroidea ima may cross it. It lies very much further from the surface and is much more easily displaced to one side. In infants, too, the thymus may cause a certain amount of difficulty.

The high operation, the only one that will be described here, may be done either with or without an anesthetic. Chloroform should, as a rule, be given to children, as otherwise their struggles are likely to embarrass the operator. In adults, however, it is not necessary as after the skin incision has been made no pain is felt, and chloroform is liable to increase the dyspnea, if present, to a dangerous extent, and necessitates the operation being rapidly performed; whereas the more deliberately it can be done, the less are the risks attending it. A small pillow having been placed beneath the neck as so to render it prominent, make an incision from the cricoid cartilage, exactly in the middle line, for from 1 1/2 to 2 inches downward, according to the age of the patient, fatness of the neck, etc. Divide the skin and superficial fascia, and, having found the interval between the sternohyoid muscles, continue the incision between them, carefully avoiding any large veins. The isthmus of the thyroid will now be seen in the lower part of the wound as a bluish-red body, and if sufficient room does not exist between it and the cricoid cartilage, draw it down gently with a blunt hook; or if this cannot be done readily, notch it in the middle line or divide it. The drawing downward of the isthmus is greatly facilitated by dividing transversely on the cricoid the layer of fascia, which extends from the cricoid cartilage to the isthmus. By doing this, moreover, the wounding of the veins between the layers of fascia will be avoided. The first 2 or 3 rings of the trachea having now been fully exposed, and all arterial hemorrhage arrested by ligature or pressure forceps, thrust the sharp hook into the trachea immediately below the cricoid cartilage, and, steadying it in this way, divide the first 2 or 3 rings by thrusting in the knife with the back of the blade directed downward and by cutting toward the cricoid. Venous hemorrhage, except from a large vein, which, of course, should be tied or clamped, need not delay the opening of the trachea, as it depends on engorgement of the right side of the heart, and will disappear after 2 or 3 inspirations through the tracheal wound. The wound in the trachea being held open by the tracheal dilator, pass the outer tube, made wedge-shaped by pressing it between the finger and thumb, into the trachea, and then immediately insert the inner cannula, as until this is done air cannot pass freely through the tube. Secure the tube *in situ* by tracheotomy tapes tied behind the neck. When the operation is performed for croup or diphtheria, the tube should not, as a rule be inserted at once, but the wound held open by



TRACHEOTOMY TUBE.



PARKER'S TRACHEOTOMY CANNULA.

the dilator, and any false membrane removed by a feather passed both down into the trachea and up into the larynx, or if this does not succeed, by a Parker's suction-tube apparatus. The bivalve cannula in general use is likely, on account of its shape, to produce ulceration of the anterior wall of the trachea, on which, from its curve, it must necessarily impinge; it has even been known to perforate the wall and to enter the innominate artery. This can be prevented by the improved shaped cannula invented by Parker. Should the breathing cease during the operation, the trachea should still be opened, the obstructing membranes removed, and artificial respiration persevered in for some time.

Dangers and Difficulties of the Operation.—When the operation can be done deliberately, and on a patient with a thin neck, it is attended with no great difficulty; but when, as is frequently the case, it must be undertaken in an emergency, possibly with insufficient light and with no skilled assistant at hand, or on a young child or infant with a fat neck, and must be completed rapidly to prevent death from suffocation, it is perhaps one of the most trying that the surgeon is called upon to perform. The dangers into which the inexperienced and unwary may then fall are the following.

1. *The hyoid bone or the thyroid cartilage* may be mistaken for the cricoid cartilage, and the incision made through the thyrohyoid membrane or into the thyroid cartilage. This mistake could hardly occur except in a fat-necked child, and then only through carelessness in not determining the position of the cricoid cartilage before beginning the operation.

2. *The interval between the sternohyoid muscle may be missed,* and the dissection carried to one or other side of the trachea. The thyroid body and even the carotid artery has in this way been wounded. To avoid such a disaster the head should be held perfectly straight and the incision made accurately in the middle line; one side of the wound should not be retracted more than the other; and the index-finger should be used from time to time to make sure that the dissection is being made over the trachea.

3. *Too short an incision may be made,* and consequently be a source of embarrassment in drawing down the thyroid isthmus, and in defining the trachea before it is opened. The incision should never be less than 1 1/2 inches long, even in a child.

4. *One or more large veins may be wounded,* and the steps of the operation be considerably impeded by hemorrhage. Their walls are very thin; great care, therefore, is necessary to avoid injuring them.

5. *The knife may perforate the posterior wall of the trachea* and enter the esophagus. Caution, therefore, is necessary, and some advise that the knife should be held, while incising the trachea, with the forefinger placed on one side, 1/2 of an inch from its point, so that it cannot penetrate too deeply.

6. *The knife may slip to one side* instead of entering the trachea. This can hardly happen if the trachea is fixed by the sharp hook and drawn well forward into the wound while being perforated.

7. *The innominate vein and even the innominate artery have been wounded* in incising the trachea during the performance of the low operation. The knife, therefore, should be introduced with the back of the blade toward the sternum, and the incision made from below upward.

8. *Blood may enter the trachea,* and if allowed to remain there, will coagulate, and the clots being drawn into the bronchi and acting as plugs may cause suffocation. This danger should be guarded against by tying all bleeding vessels, and thoroughly exposing the trachea before incising it, lest there should be a vessel in front of it. Should only a little blood enter the trachea, it can be coughed up; but if the amount is large, the patient should be turned on his side, and the head depressed, the wound of course being held open by retractors, to allow the blood to run out; or if this does not suffice, an attempt must be made to remove it by suction. When there is a general oozing of blood from the wound, the introduction of the tube will prevent more escaping into the trachea.

9. *The tracheotomy tube may be forced between the fascia and the front wall of the trachea; or one valve of the tube may be passed inside the trachea and the other outside.* To escape these accidents, the incision in the trachea should be free, and its edges well retracted, or one edge may be held up by a sharp hook. To insure both valves entering the trachea, they should be pressed well together; this may be conveniently done by Sankey's forceps.

10. *The tube, when a membrane is present, may be passed between the tracheal wall and the false membrane,* a danger that may be guarded against by removing the membrane before introducing the tube.

11. *The tube has been passed upward into the larynx instead of downward into the trachea.* No excuse and, it is to be feared, no remedy is to be found for such gross ignorance (Walsham).

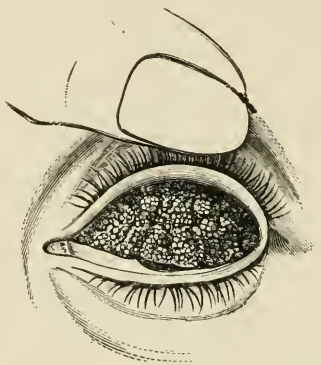
After-treatment.—In the simplest case—chronic laryngeal stenosis, for instance, in which there is no pulmonary complication—all that is needed, provided the tube fits, is something to warm and moisten the air before it enters the lungs, and a dry absorbent dressing around the orifice to diminish the amount of discharge and lessen the risk of bronchopneumonia and cellulitis. The patient should be kept as quiet as possible in a semirecumbent position, and well protected from drafts. A bronchitis kettle may be used, but it is better, for a time, at least, to protect the orifice with a thin, flat sponge, wrung out of hot water, so as to filter the air thoroughly. The wound should be powdered with iodoform, and the flanges of the cannula prevented from pressing upon it by little pads of absorbent wool. The frequency with which the tube requires changing depends upon the amount of irritation it causes; a rubber one can often be introduced on a proper dilator by a second

day. In cases such as these there is very little of that tenacious mucus that is so troublesome in croup or diphtheria. For the first few days the patient should be fed through the rectum; the movements of the trachea in swallowing are very painful (cocain sprayed over the wound prevents this to some extent), and there is great risk of fluid trickling down the larynx and passing by the side of the tube into the lungs. This may happen even after the cannula has been removed, if the larynx has not thoroughly recovered; but usually there is no danger after the wound has healed and the patient has grown accustomed to the change of respiration and learned how to cough. If the rectum becomes irritable or thirst is distressing, an esophageal tube should be used instead. Tracheotomy tubes, if worn permanently, should be frequently changed and carefully inspected from time to time. Their duration of life varies very much, and instances have been known of their breaking and of the end falling down into the bronchi. It is always well to protect the orifice with a suitable respirator.

In diphtheria the after-treatment requires even greater care. The air must be warmed and moistened, and the cot surrounded by screens, but the top should be left open. The tube must be kept clean by means of feathers dipped in a solution of bicarbonate of sodium or potassium, and if there is any membrane discovered floating in the trachea or larynx, it must be cleared away in the same manner. Parker recommends that the solution should be sprayed from time to time over the wound to prevent the viscid mucus collecting and drying around the orifice. The frequency with which the inner cannula requires changing depends upon the success with which this is carried out. At first it may need it almost every hour, but it must be remembered that the process is an exhausting one, and, for a time, very alarming to a child, so that every endeavor must be made to keep the passage free without. Each cannula should have a double set of inner tubes, so that when one is removed and a feather has been passed down the outer to make sure it is clear, the second can be introduced without delay. The outer need only be removed once a day. To clear them they should be placed in a hot solution of soda, and well scrubbed. The time the tube should be retained depends upon the course of the disease; but, in any case, the metal cannula should be replaced as soon as possible by a rubber one (it can usually be done by the third or fourth day), and this should not be worn longer than is absolutely necessary. Before discarding it an attempt must be made to educate the larynx again, and to reduce the amount of air passing through the tube, by using one that is perforated on the convexity or very much shortened. The child, of course, must be watched night and day by some one who can use dilating forceps and replace the cannula at once if there is any real danger.

Prognosis.—Care must be taken to distinguish between the consequences of the operation and those of the disease for which it is performed. Much depends upon the age of the patient; in an infant it is always serious, the structures involved are so small and delicate, and there is such great risk of pulmonary complications, independently of croup or diphtheria. If the lungs are already collapsed and partially consolidated, if the patient is exhausted by prolonged battling against imminent asphyxia, or if he is dying from the diphtheritic poison, the operation can do no good, and tracheotomy must not be blamed for the result, for it may hasten the end. If it is to be of any real service, or if the wound is to be used not merely to relieve a symptom but to attack the disease by removing false membrane and giving the patient pure air—not that which has been befouled by passing over a poisoned surface—it must be performed while there is still a reasonable hope. See LARYNGOTOMY.

TRACHOMA (Granular Lids).—A disease of the conjunctiva, characterized by the unrestricted formation of follicles which, instead of being absorbed as in follicular conjunctivitis, produce permanent granular masses, spreading over the surface of the entire lid, and presenting, in extreme



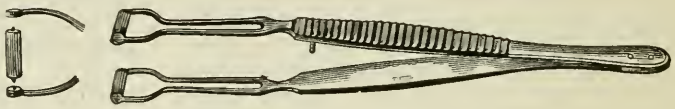
TRACHOMA.

cases, the characteristic appearance of a bunch of grapes of a deep red color. The upper lid is generally first affected. When the follicles are abundant, the conjunctiva is destroyed. Ulceration takes place, and the necrosed membrane is replaced by scar tissue. The disease is chronic, and progresses many years, new nodules forming while others are ulcerating and cicatrizing. The bulbar conjunctiva is not usually involved.

Course.—The disease begins with conjunctivitis, followed by follicular formation and growth of vascular tissue over the cornea, due to friction of the roughened lid, causing keratitis and consequent corneal opacity. The upper third of the cornea is most affected, and there is a distinct line of demarcation between the healthy cornea and the vascular tissue, which never entirely disappears. This condition is called **pannus**, and is fully considered under diseases of the cornea. The second stage of trachoma is ulceration of the follicles. The secretion, until now slight, becomes mucopurulent, and the follicles, instead of being distinct, have a ragged appearance, and are ulcerated. The entire conjunctiva is congested, and the lashes are matted together with the secretion. After

some months the disease passes into the third stage—**cicatrization.** The granulations have now disappeared, there is little secretion, and the conjunctiva is no longer actively inflamed and rough, but is dry and dirty-white, thickened, and rolled into fine folds. This atrophic condition is called **parenchymatous xerosis.** The entire lid is now shorter from above downward, so that the lids when closed gape to a slight degree, and are turned in. The lashes are sparse and irregular, and trichiasis results. Running parallel to the under surface of the upper lid and 2 mm. from it a thick scar is sometimes seen.

The subjective symptoms in the first stage are pain, itching and burning of the lids, lacrimation, photophobia, and asthenopia. Later on there is dimness of vision, which increases in the third stage. There are also the annoying symptoms caused by the inverted lashes.



Knapp's Roller Forceps.

Cause and Distribution.—Poorly nourished and scrofulous persons are most frequently affected. Unhygienic habits and contagion in crowded districts are marked factors in the production of the disease. Trachoma is rare in mountainous regions and increases toward the lowlands. The peculiar susceptibility of some of the Continental emigrants is possibly due to their unsanitary habits, rather than to any inherent racial peculiarity of temperament. According to Burnett and others, negroes are particularly immune from trachoma.

There is unanimity of opinion as to the infectiousness of trachoma, and, although there is an inclination to consider the disease as due to a special organism, the reports of bacteriologic investigation have not been harmonious. The trachoma bodies of Prowazek-Greeff, almost always found in the acute stages of trachoma and absent if the condition is not trachoma, have apparently the best claim to specificity. These bodies or granules are found inside the cells and, when stained by the Giemsa method (on a blue field) resemble tiny red cocci, though they are considered by the investigators to be protozoa. They seem to group themselves near one margin of the cell nucleus.

Prognosis is unfavorable. The disease continues for many years, and there is rarely complete recovery. The dryness of the conjunctiva is very annoying, and by the irritation and exposure of the corneal epithelium, with consequent opacity, vision is affected. Entropion and trichiasis are disagreeable sequels.

Treatment.—The patient should be informed of the infectious nature of the disease, and warned not to wipe his eyes on public towels. To the strumous and poorly nourished, change of environment and constitutional treatment are of great value. The conjunctival sac should be washed several times a day with boric acid or a weak solution (1:8000) of mercuric chlorid. If the symptoms are acute, the temples should be leeched, cold applications instituted and atropin instilled. As the inflammatory symptoms subside, a 50 percent solution of boroglycerid in glycerin should be applied twice daily. It may be alternated with glycerol of tannin or copper sulphate, or alum in pencil form. Prolonged application of silver nitrate leaves distressing scars and discolors the conjunctiva, and is not advised. Those who derive good results from this salt use it with great care, and only after long experience. Boroglycerid is more efficacious and can be given to the patient to drop in the eye at home during the intervals of visits to the physician's office. There is diversity of opinion relative to the value of protargol in this affection. Its use has not been followed by good results. Mercuric chlorid in solution of 1:250 may be brushed over the everted lids. Operations destroying much conjunctiva defeat their own purpose, as the previous destruction of this membrane by the disease is already the cause of many disagreeable complications. In cases in which the granulations are very profuse and have not yet ulcerated, the disastrous sequels may be averted by expression. A favorite method consists of squeezing the granulations with roller forceps, but it is not advised as a routine practice. Tension may be relieved by splitting the external canthus and cutting the canthal ligament. Hyperemic and soft granules must be more carefully handled. Massage with iodoform ointment may be used, and is less painful to the patient, and often gives good results in a very short time. Pannus should be treated by massage, peritomy, or jequirity inoculation. See Cornea (Diseases). Distortion of the lids must be corrected and corneal opacities treated. Constant instillations of glycerin or some bland oil are said to be palliative in xerosis.

TRAGACANTH.—The exudation of several species of *Astragalus*. A natural mixture of gum arabic and bassorin. A demulcent employed mainly as a vehicle for resins and insoluble powders. It is a constituent of 7 of the 9 official troches, and is a better agent than acacia for making emulsions of cod-liver oil. **T., Mucilago,** tragacanth 6, glycerin 18, water to 100 parts. Dose, 1/2 ounce or more.

TRANCE.—A form of catalepsy, characterized by a prolonged condition of abnormal sleep, in which the vital functions are reduced to a minimum, and from which the patients ordinarily cannot be aroused. The breathing is almost imperceptible, and sensation is abolished. The onset and awakening are both very sudden.

Etiology.—Common trance occurs principally among females between 12 and 30 years of age; and the subjects are seldom in perfect health. Various hysteric manifestations are seen, and anemia often exists. Trance has been due to exhausting diseases, as typhoid fever and influenza; to excessive brain-work, or to mechanic obstruction to the circulation of the brain.

Symptoms.—During a trance the subject is usually pale, the limbs are relaxed, the eyelids closed, and the eyeballs directed upward, deviating, and sometimes diverging, from the middle line. The mental functions are in complete abeyance. The pallor of the face is the result of profound depression of the vascular system. The duration of trance may be from a few hours to weeks, months, or even a year. The postmortem examinations of persons who have died in trance throw no light on its nature.

The diagnosis must be made from apoplexy, coma, and death. The presence of life may be determined (1) by the absence of any sign of decomposition, (2) by the normal appearance of the fundus of the eye as seen with the ophthalmoscope; and (3) by the persistence of the electric excitability of the muscles. This excitability disappears 3 hours after death. See COMA.

Treatment.—Food may be given by the nasal tube, or by enema. Warmth should be applied to the extremities, and the development of bedsores prevented. Strong faradization is the most powerful cutaneous excitant. Nerve stimulants, such as ether or valerian, may be given by the bowel. Alcohol must be given with caution and in small quantities. Strong-coffee enemata are often more useful. Recurrence of attacks may be prevented by the improvement of health, physical and moral.

TRANSFUSION.—The operation of the transfusion of blood is not without dangers, and offers no advantages over the infusion of saline solutions either beneath the skin or intravenously. See, therefore, INFUSION. The indications and modus operandi of transfusion are as follows:

The indications for transfusion are certain cases of violent hemorrhage.

Methods.—There are two methods of transfusion —(1) direct transfusion, (2) indirect transfusion.

In the **direct method** blood from an animal is conveyed, by means of a specially devised apparatus, directly from one person or one animal to that of another. According to the **indirect method,** the blood is first withdrawn, and afterward injected into the vein of another.

The direct method is preferable, and is the one generally used. Aveling's apparatus is recommended. The operation as described by Wharton is as follows: The bulb and tube are first placed in a shallow basin containing warm normal saline solution (0.7 percent) and the bulb and tube are filled with this solution to displace any air that they contain. The person supplying the blood places his arm near the arm of the patient, and the operator exposes a prominent vein on the patient's arm at the bend of the elbow, opens it, and inserts into it one of the cannulas filled with saline solution, with the point directed toward the body, and at the same time an assistant introduces the other cannula into a vein at the bend of the elbow of the one who supplies the blood. The cannulas are held in position by assistants, and the tube is quickly connected with them—the stop-cocks being closed before it is taken out of the saline solution to prevent the entrance of air; then upon opening the stop-cocks a direct communication is established between the circulation and the donor. By slowly compressing the bulb (at the same time keeping the tube closed on the side of the donor) the blood is forced into the circulation of the patient. The wounds should be subsequently dressed antiseptically.

Crile's method of arteriovenous anastomosis is described by Da Costa as follows: The vascular system of the donor is united to the vascular system of the recipient, intima being connected to intima. This is accomplished by means of a German silver tube. The vein of the recipient is drawn through the tube, is everted, and is tied into the second groove of the tube.

The end of the tube with the everted vessel over it is passed into the vein of the recipient and fixed temporarily by a ligature. The left arm of each subject is usually employed and the radial artery of the donor is anastomosed to a superficial vein of the recipient. Every small branch over the artery is carefully tied in order to prevent obscuration by blood. The artery is bared for a distance of about 3 cm., tied distally, lightly clamped with a screw clamp proximally, and divided. The vein of the recipient is bared, clamped, and divided, the tube (dipped in sterile olive oil) is inserted into the vein, the cuff of everted vessel is formed over the end, and the artery is pulled over the tube and cuff of vein and held by a ligature tied into the first groove.

Indirect Transfusion of Blood.—According to this method blood is withdrawn from the vein of the donor by venesection, and is received in a clean glass or porcelain vessel, which is placed in water at a temperature of 110° F. It is defibrinated by whipping with a bundle of straws, and is passed through fine linen; it is then injected by means of an ordinary syringe attached to a cannula which has been previously inserted into a vein of the patient. Care should be exercised to prevent air from being introduced with the blood. The apparatus devised by Allen and modified by Hunter is the one most frequently used. See INFUSION.

Autotransfusion.—The driving of the blood from the periphery to the center—the heart and the brain—in order to maintain the circulation, as in bandaging of the limbs in postpartum hemorrhage.

Reciprocal transfusion is the exchange of equal volumes of blood between a patient suffering from a febrile disease and one who is convalescent from that disease, the blood of the latter being supposed to contain an antitoxin.

TRAUMATIC FEVER.—See ASEPTIC FEVER.

TREMOR.—An involuntary trembling or agitation of the body or of some of its parts. Tremors are seen principally in the arms, head, hands, tongue, or facial muscles. They are *coarse* or *fine,* according to the amount of movement involved. They are *passive or static* when they are present during rest; if produced or increased by voluntary movements they are called movement or *intention tremors,* and are suggestive of disseminated sclerosis, lead poisoning and senility. In addition they may be local or general, rapid or slow, regular or irregular.

Etiology.—Tremor is often observed as one of the nervous phenomena of chronic alcoholism and delirium tremens and is generally observed in acute poisoning by lead, mercury, arsenic, and in chronic poisoning by chloral and by opium. It is a symptom of paralysis agitans, invariably present, and appears in association with both paralysis and contracture, and it is found in hysteric subjects. It attacks the aged, chiefly in the arms and head. *Simple tremor* often occurs without assignable cause, sometimes occurring as the result of emotions, such as fright. It is commonly present in debility, *asthenic tremor*, and passes off as strength is regained. In acute disease, such as typhoid fever, tremor indicates a profound toxemia.

Diagnosis.—In order to ascertain whether the tremor be passive or intention, the patient is observed as he performs some voluntary act, such as drinking a glass of water—an intention tremor will be markedly accentuated. Any tremor of the extremities is exaggerated by extension. The tremor in **disseminated sclerosis** is irregular, and the movements are sudden and jerky and much increased by voluntary efforts at restraint. They are absent during rest, but occur upon movement. In **paralysis agitans** the tremor is regular and rhythmic, and, save early in the progress of the disease, occurs during both rest and movement. **Senile tremor** occurs at first only on movement, and during rest almost or entirely ceases. When severe, it may occur both in movement and in rest. It is more influenced by movement than is the tremor of paralysis agitans.

The movements in senile tremor are exceedingly fine, beginning in the hands and often extending to the muscles of the neck, causing slight movement of the head. Alcoholic tremor occurs only during movement, and chiefly affects the tongue, hands, arms, and face. *Toxic tremors* may also be seen in elderly men who are persistent smokers, and they may result from excessive use of tea and coffee, or from drug habituations. There is a peculiar form of tremor observed among smelters and others exposed to the fumes of mercury. It is sudden or gradual in onset, and is usually accompanied by salivation. The arms are first involved, and then the entire muscular system. If allowed to go on, paralysis, mania, and idiocy may result.

The tremor of *exophthalmic goiter* is similar to the toxic temors. It is fine and rapid and is elicited by the extreme extension of the fingers.

Fibrillary twitchings of the facial muscles may be induced by chronic alcoholism, paresis or profound neurasthenia. It occurs in other regions, as well in progressive muscular atrophy. See Blepharospasm.

Closely allied to tremors are choreiform movements. See Chorea.

Treatment.—This will depend upon the causal condition. Little result from treatment can be expected. Nerve tonics and sedatives may be tried in simple and senile tremors.

TRENCH FEET.—See War Surgery.

TRENCH FEVER.—A group of imperfectly classified and ill-understood conditions has been noted in soldiers occupying trenches on the battle line under the designation "trench fever." The onset is quite abrupt, with severe frontal and postorbital headache, followed by rachialgia and pains in the extremities.

The fever rapidly rises to 102°–104° F. and falls rather abruptly to normal about the fourth day. A second rise is frequently noted, so that many of the temperature charts have a saddle back character.

There is no rash and the disease is often diagnosed as influenza, although there are no catarrhal manifestations to justify such diagnosis. The spleen is frequently palpable. The pulse is often slow, thus resembling the group of dengue-like fevers.

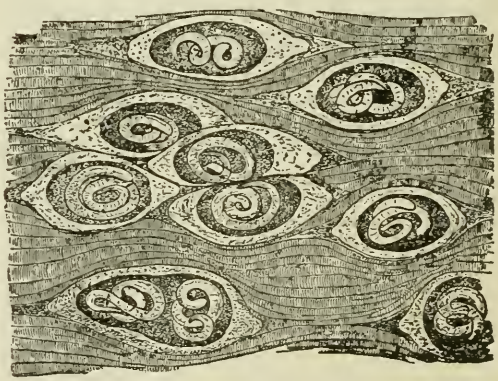
Besides the influenza-like type of trench fever another type has been described as the long period one. In this there are frequent relapses, as many as five or six. The fever rise at such times is very short, only lasting a few hours or a day or so. A characteristic pain noted in trench fever is a cutaneous hyperesthesia over the shins.

Houston and McCloy have thought it possible that the *Enterococcus* is the cause of these fevers. It has been suggested that lice might transmit the disease (Stitt).

TREPHINING.—See Skull (Surgery).

TRICHIASIS.—See Eyelids.

TRICHINIASIS (Trichinosis).—A disease produced by the ingestion of meat, pork, or sausage containing the trichina spiralis. The parasites lie coiled up in capsules between the muscular fibers of the meat. After their entrance into the human body their presence gives rise to nausea, vertigo,



Trichina Spiralis.—(*Ziegler*).

fever, diarrhea, prostration, stiffness and painful swelling of the muscles, edema of the face, and in some cases perspiration, insomnia, delirium, and death from exhaustion or some complication, as pneumonia. The blood always shows an eosinophilia. The stages of the disease are the *intestinal stage*, *migration stage*, and *encapsulation stage.*

The parasite is found in two forms—intestinal trichina, which is sexually mature, and muscle trichina, which is sexually immature.

The intestinal trichina is a small, hair-like worm, the male measuring 1/18 inch, and the female 1/8 of an inch in length; the head is smaller than the rest of the body; the tail of the male has a bilobed

prominence, between the divisions of which the anal opening is placed, and from which a single spiculum can be protruded; the female has a blunt, rounded tail, the reproductive outlet being situated toward the anterior part of the body; the ova are very small, containing embryos that are produced viviparously at the rate of at least 100 each week after the entrance of the female into the intestinal canal.

The muscle trichina develops its sexual apparatus after it has entered the intestinal canal of the host. The viable embryos discharged from the female are in a state of motion, and at once migrate from the intestines to the muscular structure of the individual, and here set up inflammatory action; they becoming surrounded by a capsule or shell in which they are coiled. After a time, in the muscle, the trichina undergoes a further change: lime salts are deposited in and about the capsule and in the parasite itself, and minute specks of lime are seen distributed throughout the muscular structure. The development of the parasite from the period of the impregnation up to the time of sexual maturity is, under favorable conditions, less than 3 weeks. Within 2 days from the ingestion of the infected pork occurs the maturation of the muscle larvæ; in 6 days more the birth of embryos occurs, and in about 2 weeks the migrating progeny have arrived at their habitat, the muscular structure.

The prognosis depends upon the amount of infection in the pork or beef. Mortality is between 20 and 50 percent.

Treatment.—The preventive treatment consists in eating no pork that has not been so prepared as to kill any trichinæ that might exist. If the parasites have been recently taken—within the first 4 or 5 days—emetics and purgatives to remove them from the stomach and intestinal canal are indicated. After thorough action from these, attempts may be made to destroy such of the parasites as have escaped the action of the emetic or purgative. For this purpose glycerin 1 part, water 2 parts, is much in favor; or a trial can be made of carbolic acid and tincture of iodin, as suggested by Bartholow. Quinin has given good results.

After migration has begun, the vital powers should be sustained by nourishing food, stimulants, and tonics, as there are no drugs that have any influence upon the embryos in their migration through the muscles.

TRICHLORACETIC ACID.—A monobasic organic acid ($CCl_3.COOH$) obtained from the oxidation of chloral hydrate with nitric acid. It should be kept in dark well-stoppered bottles in a cool place. While penetrating deeply it does not cause as much pain as many other escharotics. It is used locally in lupus, condylomata, etc., and for cauterization of the nose or throat.

TRICHOPATHY (Trichosis).—Any morbid affection of the hair. See ALOPECIA, CANITIES, HIRSUTIES.

TRICHOPHYTOSIS.—See RINGWORM OF THE SCALP.

TRICRESOL.—A mixture of the three isomeric cresols, respectively named the ortho-, meta-, and paramethyl phenols; it also contains the hydroxyl group, which seems to be a characteristic constituent of antiseptics and germicides. It occurs as a white liquid of creosote-like odor (sp. gr. 1.052 to 1.049), and is soluble in water. Tricresol possesses very high germicidal power, and is said to be practically nontoxic, and less irritating to wounds than either carbolic or sublimate solutions. A 1:1000 solution dropped into the eye produced not the slightest irritation. Such solutions may, therefore, be advantageously employed as menstrua for the stock collyria, especially for those of cocain, physostigmin, and atropin, which are most liable to contamination. Tricresol is particularly fatal to pyogenic cocci, a 1 percent solution invariably killing them in 1/2 minute in watery solutions, and in 1 1/2 minutes in rich albuminous fluids (Grüber). See PHENOL.

TRIFACIAL NERVE, AFFECTIONS.—This important mixed nerve of the face supplies, by its motor trunk, the muscles of mastication; by its sensory portion, the skin of the face, the mucous membrane of the mouth and nasal cavity, the conjunctiva and cornea, also the anterior part of the tongue with gustatory fibers. The gustatory fibers reach the lingual fibers of the fifth by the chorda tympani nerve.

Lesions.—1. There may be lesions of the pons, especially hemorrhage, or spots of sclerosis invading the trigeminal nucleus.

2. Injury or disease at the base of the skull, especially acute and chronic meningitis and caries of the bone; tumor; syphilis; new formations compressing the trunk or Gasserian ganglion. Fracture of the base rarely affects this nerve.

3. Tumors or aneurysms pressing on the first division (ophthalmic) of the nerve through the cavernous sinus, on the second division (superior maxillary) and on the third division (inferior maxillary) by invasion of the sphenomaxillary fossa.

4. There may be inflammation of the nerve, which is rare.

The sensory division may also be affected in hysteria and in lesions of the posterior part of the internal capsule. The gustatory fibers of the trigeminus may be influenced by peripheral lesions of the facial nerve, from which the chorda tympani is derived.

Symptoms. Paralysis of the Sensory Portion.—The distribution of the anesthesia varies according as the whole trigeminus or only a half is involved. In total anesthesia there is loss of sensation in half the corresponding side of the head, including the conjunctiva and cornea, mucosa of the lips, tongue, hard and soft palates, and nose of the same side. Hence on the tongue or mucous membranes there are often ulcers that come from unconscious laceration by the teeth. There is loss of taste and impairment of smell. The muscles of the face are also insensible, hence their movements are slower. The so-called trophic phenomena are also observed, and among them the much-discussed *neuroparalytic ophthalmia*, an ulcerative keratitis, beginning, always in the lower segment of the cornea, and passing over into purulent inflammation of the whole eyeball. It seems, on the whole, more

likely that the inflammation is primarily due to the action of irritants that in health are excluded by the proper closure of the eyelids, though the inflammatory process itself may be trophically influenced. The salivary, lacrimal, and buccal secretions may be diminished, and the teeth may become loose. Herpes is a trophic result that may develop in the course of the nerve, is painful, and may last a long time. So, too, the anesthesia may be preceded by tingling. The skin of the face is sometimes swollen.

Paralysis of the motor portion, which supplies especially the muscles of mastication, the masseters, temporals, and pterygoids, is not common. It is most frequent in diseases of the base of the skull, compressing this branch. Difficulty in chewing is the result. If on one side, the patient can only chew on the other; if on both sides, he cannot chew at all. The lower jaw hangs down and cannot be moved from side to side because of the paralysis of the pterygoids. If on one side, the external pterygoid cannot push the jaw toward the sound side; and when depressed, the jaw is pushed by the muscle of the sound side toward the paralyzed side. Cases have occurred associated with cortical lesion; from one of these Hirt inferred that the motor center for the trigeminus is in the neighborhood of the lower third of the ascending convolution.

Spasm of the muscles of mastication occurs in connection with muscular cramp, the muscular contraction of tetanus (trismus), sometimes in tetany and meningitis, and reflexly through painful affections of the jaw or teeth, or from irritation near the motor nucleus. It is at times hysteric. Clonic spasm occurs in muscles supplied by the fifth nerve, constituting "chattering teeth." It occurs usually in connection with general conditions, such as chorea, but it may arise as a local symptom in women late in life (Tyson).

Diagnosis is not difficult. Sensibility is tested in the ordinary way. The preliminary pain must not be mistaken for neuralgia. Gustatory sense is tested in the anterior end of the tongue by applying weak acid or salt solutions and comparing the effect on the two halves. The motor power is tested by biting on a piece of wood or by moving the jaws against resistance.

Treatment must depend upon the cause, which should be carefully sought. Syphilitic new formations are the lesions most commonly amenable to treatment. In the absence of such causes the treatment must be symptomatic. Stimulating liniments and faradization through the electric brush are often useful. Galvanism may also be used, brushing the part with the kathode. The anesthetic part should be carefully protected against irritants.

TRIGEMINAL NERVE.—See Trifacial Nerve.

TRIGGER FINGER.—Trigger finger or snap finger is an acquired deformity in which one or possibly two fingers can be extended only by great effort or by using the other hand, when the finger flies out like the blade of a penknife. Over 90 percent of the cases are caused by some condition that offers a limited obstruction to the play of the tendon in its sheath, *e. g.*, contraction of the sheath, enlarged sesamoid, ganglion, a growth on the tendon, or, most frequently, a localized fibroid thickening of the tendon, the lesion usually being situated over the metacarpophalangeal joint, at which point the "tendon callus" can often be felt. In less than 10 percent of the cases the trouble is due to an alteration in the relations of the joint surfaces the result of injury or disease. The treatment is removal of the obstruction. In the usual variety it is necessary only to incise the theca over the fusiform enlargement of the tendon (Stewart).

TRIONAL.—Diethylsulphonethylmethyl methane. It is a powder consisting of shining tablets, which dissolve in 320 parts of cold water, readily in alcohol and ether, and have a distinctly bitter taste. Trional is administered in fine powder dissolved in liberal quantities of some liquid. Dose, 10 to 30 grains daily. Trional differs from sulphonal only in the substitution of an ethyl for a methyl group. It is an efficient hypnotic, and is less liable to produce ill effects than sulphonal, but must be given in doses fully as large. In cases of slight psychic excitement accompanied by obstinate insomnia it is peculiarly efficient. See Lambert Treatment for Narcotic Addiction.

TRITICUM (Couch-grass).—The dried rhizome of *Agropyron repens.* It is emollient, diuretic, and antiphlogistic; and is useful in cystitis and irritable bladder. It is best administered in a decoction made from 2 to 4 ounces of the plant in 2 pints of water, and reduced one-half by boiling. The dose of triticin is from 1 dram to 1 ounce in infusion. The dose of the fluid extract is from 1 dram to 1 ounce, well diluted.

TRITURATIONS.—A class of powders having for their diluent sugar of milk, and possessing a definite relation between the active ingredient and the diluent. The Pharmacopeia prescribes a general formula for these preparations, according to which 10 grams of the substance and 90 of sugar of milk are to be well mixed by a spatula, the latter being added in successive quantities, and both triturated in a mortar until the substance is intimately mixed with the diluent and finely comminuted. There is but one official trituration (trituratio elaterini), though the pulvis ipecacuanhæ et opii practically belongs to this class. Sugar of milk is employed as the diluent because of its hardness and its comparative insolubility.

TROCHES (Trochisci).—Also called *Lozenges,* and *Pastilles.* Small, flattened cakes of medicinal substances prepared from a mass consisting chiefly of medicinal powders, sugar, and mucilage. There are 9 official troches:

Title.	Constituents—100 Troches.	Each Troche Contains:
Trochisci: Acidi tannici..	Tannic acid, 6 gm.; powdered sugar, 65 gm.; powdered tragacanth, 2 gm.; stronger orange flower water, a sufficient quantity.	Tannic acid, 1 grain.

Title.	Constituents—100 Troches.	Each Troche Contains
Trochisci: Ammonii chloridi.	Ammonium chlorid, 10 gm.; extract of liquorice, 20 gm.; powdered tragacanth, 2 gm.; powdered sugar, 40 gm.; syrup of tolu, a sufficient quantity.	Ammonium chlorid, 2 grains.
Cubebæ.....	Oleoresin of cubeb, 2 gm.; oil of sassafras, 1 c.c.; extract of liquorice, 25 gm.; powdered acacia, 12 gm.; syrup of tolu, a sufficient quantity.	Oleoresin cubeb, ½ grain.
Gambir.....	Gambir, powdered, 6 gm.; powdered sugar, 65 gm.; powdered tragacanth, 2 gm.; stronger orange flower water, a sufficient quantity.	Gambir, 1 grain.
Glycyrrhizæ et opii.	Extract of liquorice, 15 gm.; powdered opium, 0.5 gm.; powdered acacia, 12 gm.; powdered sugar, 20 gm.; oil of anise, 0.2 c.c.; water, a sufficient quantity.	Powdered opium, ⅛ grain.
Krameriæ.....	Extract of krameria, 6 gm.; powdered sugar, 65 gm.; powdered tragacanth, 2 gm.; stronger orange flower water, a sufficient quantity.	Extract of krameria, 1 grain.
Potassii chloratis.	Potassium chlorate, 15 gm.; powdered sugar, 60 gm.; powdered tragacanth, 3 gm.; water, a sufficient quantity.	Potassium chlorate, ¼ grain.
Santonini.....	Santonin, 3 gm.; powdered sugar, 90 gm.; powdered tragacanth, 3 gm.; stronger orange flower water, a sufficient quantity.	Santonin, ½ grain.
Sodii bicarbonatis.	Sodium bicarbonate, 18 gm.; powdered sugar, 54 gm.; bruised nutmeg, 1 gm.; mucilage of tragacanth, a sufficient quantity.	Sodium bicarbonate, 3 grains.

TROPACOCAIN.—A powerful anesthetic and mydriatic, derived from a small-leaved coca of Java. It has the general qualities of cocain, but appears to be more active and much less toxic. The hydrochlorid is applied in 3 to 10 percent solution in 0.6 percent sodium chlorid solution. See Cocain.

TROPHIC DERANGEMENTS.—See Nervous Diseases (Examination).

TRUSS.—An instrument for maintaining a part in proper position in hernia or other malposition of organs.

Trusses should exert pressure sufficient to a little more than completely retain a hernia under all conditions and in all positions of the body. In reducible hernia continued use of a truss, particularly in young persons, may effect a cure. It is important that a truss should be fastened in position *before* rising in the morning and that it shall be removed *after* lying down at night. During the night a light or special truss may be worn, and also in bathing. When a portion of omentum constitutes the hernia, the gut being replaceable, it is very difficult to maintain reduction. A femoral hernia is always more difficult to keep reduced than an inguinal hernia; and in fleshy persons adjusting a truss is troublesome.

Trusses are always uncomfortable at first, a feeling which is soon overcome. If a truss fits, it retains the hernia reduced even in sitting so that the abdominal walls are relaxed, and when coughing and straining occur. If pain results from the use of a truss, or it does not retain the hernia, it is harmful. A spring which is too strong will enlarge the hernial opening, and may aggravate the case. A truss should be worn for a long time after an apparent cure.

To measure for a truss (MacCormac's rule).—In either inguinal or femoral hernia the lower part of the hernial opening is the point of starting for measurement; thence measure up to the anterior superior spine of the ilium on the same side, thence around the body 1 inch below the crest of the ilium to the other or opposite anterior superior iliac spine, and then to the upper part of the hernial opening.

Trusses are composed of different materials **elastic** as steel or vulcanite, and **inelastic,** as leather, calico, or jean. The last kind does not exert sufficient pressure, but is sometimes of service in a large irreducible or umbilical hernia.

The pad is usually made of hard rubber, vulcanite, or xylonite, or of cork covered with flannel, linen, and wash-leather. Water- and air-cushions may be used, especially if the surface is painful or irregular. Boxwood, ebony, ivory, or other firm, nonabsorbable materials are sometimes employed. The pad for an inguinal hernia is pear-shaped, and about 3 inches long, 2 inches at its broadest part, and about 3/4 of an inch in thickness. The outer surface is flat, and has two studs for attachment of straps. The inner surface is convex, looking upward as well as backward—especially so when the abdomen is protuberant—and it lies upon the internal ring and the inguinal canal, and although not touching, may come quite close to the pubic spine. When the hernia is congenital, the so-called rat-tailed shape is usual. The pad is prolonged downward between the thigh and scrotum, gradually tapering off. A double truss is sometimes here preferable, particularly if the deformity is direct or is an old oblique hernia, the rings of which have been dragged nearly opposite to each other. A double truss is not more inconvenient than a single one.

The pad for an oblique inguinal hernia is sometimes cut like a horseshoe with one side (which covers the inner pillar) longer than the other. The rupture is prevented from descending by the tension across the opening. For a direct hernia this principle requires that the shape of the pad be that of a ring, the center of which corresponds with the axis of the hernial opening.

For femoral hernia the pad is smaller, and is beveled a little on the outer side, to avoid pressure upon the femoral vein, and is also beveled above, so that it may fit well under Poupart's ligament and bring the walls of the canal together.

A shallow concave plate is used for umbilical hernia, the truss at the same time supporting the lower parts of the abdomen. Nipple-shaped projections only enlarge the hernial openings.

As a rule, the pad is rigidly fastened to the spring,

but a ball-and-socket joint is sometimes used, and in other trusses the pad may be shifted up or down and fastened in any position. The under-strap of a truss should always be fastened to the lower stud on the back of the pad, to prevent its riding up. It should be moderately tight when the patient is in the upright position.

To test a truss, the patient should sit on the edge of a chair, with the knees separated so that the structures around the ring are relaxed. He should then be directed to strain downward. If the rupture does not escape, the pad fits the opening and the pressure is sufficient. Too strong pressure tends to cause absorption of tissues beneath. If the skin beneath the truss or pad becomes sore or excoriated, it may be bathed in cologne water or alcohol to harden it, and dusted with violet powder.

An irreducible hernia may be inclosed in a hinge-cup made of rim-plate covered with leather, or may be supported in a laced bag-truss. Belts may be required for ventral or umbilical protrusions. For the congenital hernia of children a skein of Berlin wool may be used. For irreducible hernia in the aged a bag-truss, laced up on one side, or a cup made of soft leather supported by a metal rim, may be used. Sometimes the truss may be made of metal molded on a cast taken from the hernia while it is smallest. See HERNIA.

TRYPANOSOMIASIS.—See SLEEPING SICKNESS.

TRYPSIN.—The proteolytic enzyme of pancreatic juice. Its powers are manifested in an alkaline medium, converting proteids into peptones. Traces of trypsin are said to have been found in urine, but this is doubtful. It is recommended for spraying the throat in membranous or diphtheritic croup. Thirty grains are dissolved in 1 ounce of water, 10 grains of sodium bicarbonate are added, and the mixture is applied by means of a brush or as a spray.

TUBAL ABORTION.—Internal rupture of a tubal pregnancy, with extrusion of blood, and possibly of the ovum, through the fimbriated extremity of the tube into the abdominal cavity. See EXTRAUTERINE PREGNANCY.

TUBAL PREGNANCY.—See EXTRAUTERINE PREGNANCY.

TUBERCULIN.—Koch's lymph. A glycerin extract of cultures of the bacillus of tuberculosis. For a time tuberculin was thoroughly discredited. It has, however, become of interest again by reason of the efforts to extract from it a germicidal constituent free from toxins, also by the results obtained in tuberculosis with the blood serum of animals immunized by its repeated inoculation. It is extremely valuable in the diagnosis of tuberculosis in cattle and recently it has been gaining favor in the diagnosis of human tuberculosis. See TUBERCULOSIS (Pulmonary).

Test.—A hypodermic injection of 1 to 10 mg. of pure tuberculin is given. "Reaction" consists in a rise of temperature of 1 1/2 to 2° F. within 12 hours after injection.

Modifications.—The ophthalmo-reaction of Wolff-Eisner and Calmette. See VACCINE THERAPY.

Cutaneous Reaction (of von Pirquet). Technic.—After the skin of the fore-arm has been scrubbed with ether, two drops of undiluted tuberculin are dropped on it about 4 inches distant from each other. Then with a special vaccination-lancet a superficial scarification is made between the two drops on the dry surface. Finally the same scarification is made inside of the two drops. A few fibers of cotton are put on the drops so that they will not flow. After five minutes the cotton is

taken off, but no dressings are to be applied. The reaction is best examined after 48 hours. It is considered positive when the tuberculous scarifications are clearly different from the control place, but the ordinary reactive area must measure at least 1/6 of an inch.

Remarks on the Technic.—Scrubbing the skin with other substances than ether is not advisable, because if one applies a watery solution of an antiseptic character (or alcohol) the skin does not dry very quickly and so the drop of tuberculin runs, and is diluted; ether alone allows a very quick drying.

Old tuberculin in full strength has the advantage over diluted tuberculin in that no preparation is necessary, and that the substance keeps an indefinite time, as it contains a large amount of glycerin and some carbolic acid. The old tuberculin used is the extract of tubercle bacilli which was indicated by Koch in 1891. It is perhaps best to use the original preparation bought of Lucius and Bruning in Hoechst a/M, but similar preparations are also manufactured in America.

The special vaccination lancet, advised by v. Pirquet for this purpose differs from an ordinary one in the form of its tip, which is not pointed but has a crescent shape like a small chisel. This tip is made of platinum, so that it can be cleaned by exposing it to heat. The abrasions are not made as in vaccination, by scratching; but by turning the instrument quickly. As the point is about 1/12 of an inch, it gives a round abrasion of the same diameter. The turning should be made with a slight pressure, the intensity of which must vary with the quality of the skin. In small children very slight pressure is sufficient; in adults one must exert more. The abrasion should be quite superficial, taking off the epidermis only, and no blood should escape. The abrasion which is made first is used for the control of the traumatic redness. Each scratch on the skin causes a slight traumatic reaction, the intensity of which depends on the individual. It is therefore necessary to compare the tuberculin points with an

ordinary scratch of the same size. One could apply for that purpose some fluid, such as physiologic salt solution or bouillon, but as it was proved that scratches with these different fluids show no more reaction than a scratch with no fluid, it is simpler to make it without the fluid. The fibers of cotton are only to be used if the drops are large. Pirquet usually allows them to fall from a dropper, but one can also do the following: The tuberculin is kept in a glass tube with a long glass stopper; the point of the lancet is moistened with the end of the glass stopper; in this way there is practically no drop left, and the cotton need not be used The best moment of control is after 48 hours; but it is advisable to look at the points several times, say after one, two and seven days.

Description of the Reaction.—(1) Traumatic reaction: The vaccination and control points show the same condition at first. Within a few minutes a hive-like appearance is noticed, with a slight red margin; this disappears after some hours. After 24 hours one finds in the control point a brown scab with a slight redness around it which disappears in 48 hours.

(2) Vaccination points with negative reaction act like the point of control, only at times they are a little bit more elevated. In case there is any doubt of a positive reaction, the vaccination is to be repeated.

(3) The positive reaction. (a) *Time of latency* (3 hours to several days). During the first hours no specific action of the tuberculin is noticed, but only the traumatic one. In most cases the reaction is in its full height in 24 to 48 hours. (b) *Growth.* The inflammatory reaction begins usually as a slightly elevated papule at the point of scarification, which increases in height and diameter; the final diameter of a positive reaction is on an average about 1/2 inch, but is sometimes one inch or more. There are also great individual differences in the exudation. If the papules are very large, the central part is also usually very elevated, with sometimes small serous blisters, or even one large blister on the top of it. The color too is very different; a a rule, strong individuals with a good general color of the skin show papules of intense redness, while anemic individuals show slightly colored reactions. Sometimes there is scarcely any hyperemia, and one notices the papule on palpation only. This is often the case in colored people. On the other hand, reactions may occur which consist only in redness, and show no exudation. This is especially the case in miliary tuberculosis or in tuberculous emaciation. The outlines of the papule are generally distinct, and circular in outline; but sometimes it shows irregular rays, which point in the direction of the lymphatic vessels. In cases of scrofulo-tuberculosis, one often finds very small papules near the reaction but not in direct connection with it. The hyperemia does not generally extend over the margin of the exudation; but in intense reactions one often meets after 48 hours a slightly reddened margin surrounding the central exudation, which margin may be even 2 inches in diameter. (c) *Reformation.*—Generally papules begin to decrease 48 hours after the vaccination. The redness at first changes to violet and then to a brownish color followed by pigmentation which may persist for a month or longer, whereas the exduation disappears within the first week. (d) *The Slow and Secondary Reaction.*—There are cases in which the positive reaction appears only after two, three, or six days. They have a somewhat different meaning from the early reaction, and are very nearly related to the cases of "secondary reaction," in which the positive issue of a second vaccination occurs five to ten days after the first one.

Other Actions of the Cutaneous Test.—In v. Pirquet's method of making only very superficial abrasions, a general reaction of the organism practically never occurs; a slight elevation of temperature being noted in about 1 percent of cases. However, minimal amounts of tuberculin certainly enter the general circulation, for we often see that the sensitiveness to tuberculin is increased after a vaccination. The cutaneous reaction has practically no contraindication. One can use it at every age and in spite of every degree of fever.

Histologic Findings.—The inflammation of the cutis shows a tuberculous inflammation but without tubercle bacilli. It contains specially a large number of mononuclear cells.

The Meaning of Positive and Negative Reactions.—A positive reaction means that the organism contains antibodies against tuberculosis. As these antibodies are only acquired by an infection of the individual, it means consequently that the organism has had to struggle against the infection with tuberculosis. The reaction itself does not say at all what the result of that struggle was. It may be that the infection led to a very large focus formation of the microorganism, or it may be that only some glands became tuberculous. That every positive reaction means infection with tuberculosis, has been proved by a great number of postmortem examinations. In autopsies of 164 children who had given a positive reaction, in 161 a tuberculous focus was found, and only in three cases the pathologic investigation was negative. It is very probable that even in these cases some small focus escaped detection. The cutaneous reaction is practically the same as Koch's fever reaction; and we know, that in cattle, with every distinct positive reaction we find some tuberculous lesion also, the size of which may be very variable. An intense positive reaction means that a tuberculous infection has occurred recently, or that in an old tuberculosis some progress or some reinfection has taken place. As to the extent and the localization of the focus, we can say nothing from the size of the reaction, but we must use all methods of physical examination to determine where the lesion is.

(2) A negative reaction means in general that the patient has no tuberculous affection. One cannot absolutely depend on a single negative issue, and it is safer to repeat the reaction after a week. In case it is then negative again, we can say almost with certainty that the patient does not contain a tuberculous focus. This certainty, however, is never an absolute one, because there

are several reasons why a patient in spite of his tuberculous focus may contain few or no antibodies. In this way the following reasons for a negative issue have to be noted. (a) Last stage of lung tuberculosis or emaciation from tuberculosis of other organs. In very progressive tuberculosis the reaction often fails, so that it was even found that one could use a negative reaction in a certain tuberculosis as a sign of an unfavorable prognosis. Stress should not be laid on the issue of the cutaneous reaction in progressive tuberculosis. (b) In acute miliary tuberculosis and in tuberculous meningitis the reaction generally fails one or two weeks before death, but here also this is not invariable, as we see cases in early childhood retaining a positive reaction up to the last day of life. (c) During tuberculin treatment: If a patient is treated regularly with an ascending amount of tuberculin injections, he loses his cutaneous reactivity after a certain point of immunization is reached. (d) During measles with the onset of the exanthem, the positive reaction of tuberculous patients disappears and reappears only about a week afterward. This point up till now has found no exception, so that one is able to make the diagnosis of measles if a tuberculous child loses its reactivity during an exanthem of a doubtful character. (e) Besides these example there are some cases with little or no reactivity in spite of a tuberculosis, in which we cannot yet indicate the reason why the antibodies are lacking. As a rule, cases with a very slight reactivity, that is with a small papule or a late or secondary papule formation, denote some slight and inactive tuberculous lesions, but one cannot depend on this rule in every case.

As to the practical application, adults and children must be considered separately. In adults slight affections of tuberculosis are so common that the presence of a positive reaction alone does not tell us very much. There are only two things in adults which can be used: (1) A very intense reaction after the first trial, which indicates a fresh infection or reinfection; (2) a repeated negative issue of the trial, by which one is able to exclude tuberculosis. In children the infection with tuberculosis is not so common as in adults, and the younger the children are, the more dangerous is the infection. Thus, in an apparently healthy child of 10 years, showing no organic lesion, a positive reaction will not disturb us, whereas in a child of one year every positive reaction means a serious danger. In children, furthermore, the positive reaction gives a great aid to the diagnosis of some disease in question, as at this age infections with several kinds of bacteria are not so common as in adults, and therefore one can be almost certain that some symptom in question, say a bronchitis, if the tuberculin reaction is positive, is due to the same microorganism.

The cutaneous tuberculin reaction should be used in private practice only if some symptom leads to the suspicion of tuberculosis; for instance, if children are pale or without appetite, or have a bronchitis, some skin affection, etc. In hospitals, however, the test has been recommended as a routine examination of every child accepted, in the same way as we examine the urine in every case. Finally in orphan asylums which treat children up to 5 or 6 years, the cutaneous test should be used as a prophylactic means to segregate the tuberculous children from those who are free from tuberculosis. See Serum Therapy and Vaccine Therapy.

Moro's Inunction Test.—An ointment of 50 percent tuberculin in lanolin is rubbed into the skin of the chest or abdomen which is felt exposed for 15 minutes. In a few hours to three days, papules and probably erythema will appear if the individual is affected.

The methods of von Pirquet and Moro are entirely innocuous.

TUBERCULOSIS.—An infectious disease due to the introduction into the system of the bacillus tuberculosis, discovered by Koch in 1882. It has a very wide-spread, almost a universal, distribution, and it is estimated that fully one-seventh of all mankind die of it.

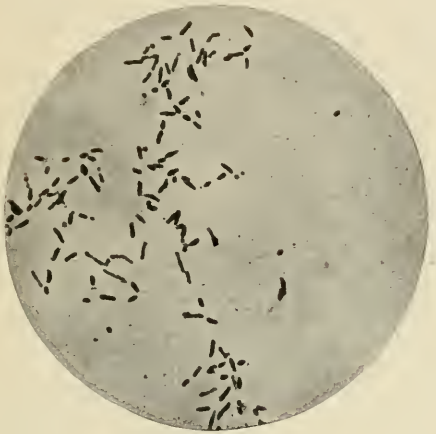
Etiology.—The bacillus, the essential **etiologic factor,** gains entrance into the body with the inspired air, with the food, and by direct inoculation. The commonest **mode of introduction** is by inhalation; in consequence, the respiratory tract is the most frequent seat of tuberculosis. The bacilli become disseminated in the air chiefly through the agency of the sputum of persons afflicted with pulmonary tuberculosis. The sputum of such individuals contains countless bacilli, which are held in it as long as it is moist, but are scattered through the air when the sputum becomes dry and pulverulent. When tuberculosis is acquired through the food—an occurrence not rare in childhood—it localizes itself primarily in the intestinal tract. The food that most often conveys the disease is milk from tuberculous animals, more rarely tuberculous meat. Direct inoculation does not play an important rôle in the causation of the disease.

The status of **heredity** as a factor in the propagation of tuberculosis is not yet fully settled. Isolated instances of apparently hereditary transmission, both in man and in animals, are recorded and demonstrate that the disease *may be* inherited; but in the majority of cases the acquisition of tuberculosis is postnatal. There is, however, a manifest tendency of the disease to attack the offspring of tuberculous parents, which, as it is not the result of hereditary transmission, must indicate the existence of a predisposition or susceptibility, which is transmitted from parent to child.

The bacillus of tuberculosis is a short, rod-shaped, nonmotile bacterium, 3 to 4 micromillimeters in length, and from 1/6 to 1/8 as broad as it is long, often slightly curved, and when properly stained with anilin dyes, occasionally has a beaded appearance. Its characteristic staining property is due to the fact that after being stained with carbolfuchsin it is not subsequently decolorized by immersion in a strong solution of nitric acid.

Methods of Staining. *Ziehl-Neelsen Method.*—Float the cover-glass preparation upon Ziehl's carbolfuchsin—saturated alcoholic solution of

fuchsin, 10 c.c.; 5 percent phenol water, 90 c.c. Heat until vapor arises (about 3 to 5 minutes), wash in water, and decolorize in 15 percent nitric, or 5 percent sulphuric, acid, then in 60 to 80 percent alcohol to remove the remnant of color. Wash well, dry, and mount in balsam. In the case of tissue-sections stain cold for 15 minutes, and decolorize as detailed; upon removal from the alcohol, counterstain with methylene-blue, wash, dehydrate, clear, and mount.

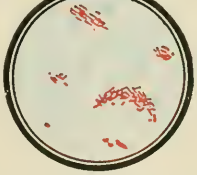


Bacillus Tuberculosis, from a pure Culture. (×1000).—(*Williams.*)

Gabbett's Modification of Fränkel's Method.—Stain in Ziehl's carbolfuchsin for about 2 minutes without heating, wash in water, stain in 25 percent sulphuric acid (100 c.c.) and methylene-blue (2 c.c.) for 1 or 2 minutes, wash in water, dry, and mount. In the case of sections dehydrate with alcohol, clear, and mount. A good and quick method but not so reliable as the preceding.

Koch-Ehrlich Method.—Stain the cover-glass preparation for 24 hours at the temperature of the room, or for 15 minutes with heat in anilin water, alcoholic solution of fuchsin, gentian-violet, or

Tubercle Bacilli in Sputum.—(*Greene.*)



Tubercle Bacilli in Urine. — (*Greene.*) Observe tendency to form groups.

methyl-violet (prepared by adding to anilin water enough of a concentrated alcoholic solution of the dye to produce opalescence). Then immerse the preparation in 33 percent nitric acid, and when it assumes a yellow-green tint, transfer to 70 percent alcohol. Counterstain 1 to 5 minutes in methylene-blue, malachite green, or picric acid for fuchsin; in Bismarck brown for gentian-violet or methyl-violet. Wash in water, dry, and mount in balsam. Prolonged action of the nitric acid will decolorize the bacilli.

. *Unna's Method.*—Stain for from 10 minutes to several hours in polychromic methylene-blue (Grübler's) wash in water, and treat with a 33 percent aqueous solution of tannic acid for from 2 to 5 minutes. Wash thoroughly, and transfer to absolute alcohol, gold-orange alcohol, or to 25 percent nitric acid; follow with dilute alcohol, water, and absolute alcohol. Clear in bergamot oil. This process double stains tubercle bacilli and leprosy bacilli.

Diagram of the Minute Structure of Tubercle. (*Walsham.*)

And see Urine Examination.

The lesion produced by the growth of the bacillus of tuberculosis is known as the **tubercle** (miliary or gray tubercle or nodule). This is a small, grayish, translucent nodule, from 1/10 to 2 mm. in diameter, firmly embedded in the surrounding tissues. By the coalescence of neighboring tubercles large masses, the so-called **tubercular infiltrations**, are produced. Histologically, a typical tubercle consists of 3 groups of cells—the epithelioid, the giant cells, and the round or lymphoid cells. The first are oval in shape, have a vesicular nucleus, and are the result of the proliferation of the fixed connective tissue and endothelial cells; perhaps, also, of epithelial cells. The formation of the oval cells is the first effect produced by the tubercle bacillus. The giant cell is a large, multinuclear mass, usually situated in the center of the tubercle. It may be the product of repeated nuclear multiplication in a single cell, without division of the cell protoplasm, or the result of the coalescence of several adjacent cells. The round cells are leukocytes that have emigrated from the blood-vessels, and they may be so numerous as to conceal the other cells (**lymphoid tubercle**). The bacilli are found in the giant cells, between and in the epithelioid cells, and, in later stages, in the round cells. New blood-vessels are not formed in the tubercle.

The tendency of the tuberculous formation is to undergo a peculiar form of coagulation, known as **cheesy necrosis**. This gives rise to a structureless, yellowish-white mass, which microscopically shows

an almost total absence of nuclei in the central area, while at the periphery, nuclei, both normal and in various stages of degeneration, are found. The necrotic tissue does not, as a rule, take any stain. For this degeneration two factors are responsible—the absence of blood-vessels and the action of peculiar poisons elaborated by the bacillus. The breaking down of tuberculous areas in the interior of organs gives rise to *cavities*, which may be seen in muscles, bones, brain, lymphatic glands, and elsewhere, but are most pronounced in the lungs, where they may attain a very large size. On surfaces—skin and mucous membranes—tuberculosis often leads to the formation of *ulcers*, which are characterized by an irregular, eroded appearance, and by the presence of tubercles. Tuberculous areas occasionally become secondarily infected with pyogenic or saprophytic organisms. The tubercle bacillus itself is capable of producing pus, but the majority of the so-called tuberculous cold abscesses are merely collections of fatty and disintegrated cells and tissue detritus.

Tuberculosis is primarily a local disease—extension takes place by continuity and contiguity along the lymph channels, along the respiratory and intestinal tracts, and through the blood. It is usually possible in secondary tuberculosis to demonstrate the original focus, but in the case of tuberculous lymphatic glands the source of infection is not always discoverable. This has been explained by assuming that infection may take place *in utero*, and the bacilli lie dormant in the lymphatic glands for varying periods after birth (**latent tuberculosis**). The possibility has also been suggested that the bacilli may penetrate a mucous membrane, be carried to the nearest lymphatic gland, and unfold their activity there.

In the human subject **tuberculosis** appears under various forms, presenting clinical differences, but identical from the pathologic standpoint. Since the discovery of the tubercle bacillus such diseases as scrofula, lupus vulgaris, Pott's disease, many forms of chronic joint-disease, and the anatomic tubercle have been proved to be tuberculous in nature. The most frequent seats of tuberculosis are the lung, the intestinal tract, the lymphatic glands, the serous membranes, the bones, the skin, the testicle, the epididymis, the brain, the Fallopian tubes, the uterus, and the spleen. Tuberculosis is very frequent in the lower animals, attacking especially the domestic herbivora and fowls and wild animals kept in captivity. In cattle the lesions take the form of nodes and conglomerates, which, on serous membranes, may be pedunculated (**pearl disease**). Histologically, there is in bovine tuberculosis a greater tendency to the formation of fibrous tissue than in the human form. The symptoms of tuberculosis vary with the localization of the disease.

A few **general phenomena** are common to nearly all forms—viz., emaciation, loss of strength, anemia, fever, and sweats. Amyloid degeneration may occur in various organs when the disease is associated with prolonged suppuration. In the diagnosis of tuberculosis the demonstration of the presence of the bacillus is of the highest importance.

TUBERCULOSIS, ACUTE MILIARY (Diffuse General Tuberculosis).—An acute and rapid form of tuberculosis in which the tubercle bacilli are distributed throughout the entire system without seeming predilection for any special organ.

It generally occurs in persons between 12 and 20 years of age.

Three varieties are observed (1) general infection; (2) general infection with pulmonary symptoms; (3) general infection with cerebral and spinal symptoms.

Etiology.—It arises most commonly from a caseating focus in some portion of the body—especially in a lung or a lymphatic gland—which breaks down, distributing the bacilli to other parts of the system by the blood current. The natural defenders of the body—the leukocytes, serum, and internal secretions—are thus overpowered before a reactionary force sets in. Typhoid fever, la grippe, or any disease that lowers the vitality may aid in causing the onset.

Pathology.—All the organs are involved, and contain small, miliary, discrete tubercles resembling mustard seed. They are very abundant in the lungs, brain, and may be detected on the choroid or retina by means of an ophthalmoscope.

Symptoms.—The general or typhoid form of acute tuberculosis is very often mistaken for typhoid fever. The onset usually lasts a few days or weeks, with loss of flesh and strength, night-sweats, slight fever, especially in afternoon, cough, rapid respiration, feeble pulse, flushed cheeks, and, later, delirium and stupor.

Instead of the regular diurnal variation of temperature it may be very irregular, jumping suddenly from 99° to 104° F., marked by rapid delirium, and possibly convulsions. The general symptoms depend upon the organs mainly involved.

Focus of Disease in the Lungs. Phthisis Florida, Galloping Consumption.—There are two forms: (1) the lobar form of miliary tuberculosis following chronic bronchitis, chronic pulmonary tuberculosis, whooping cough, measles, etc.; (2) pneumonic or bronchopneumonic phthisis. There are a severe cough with an acute pain in the side, accompanied by a purulent expectoration, often tinged with blood; intense dyspnea; cyanosis; subcrepitant râles over the basis of the lungs; the lungs may give a normal note on percussion except over the seat of focus, which is seldom found. Tubercles may be found in the choroid.

Focus of Disease in the Meninges. Tuberculous, Meningitis.—There are intense headache, high fever, delirium, convulsions, stupor, coma, irregular pupils, local paralysis, irregular, slow pulse, and other symptoms of inflammation of this tissue. See Meningitis, (Tuberculous).

Focus of Disease in the Intestines or Peritoneum.—There are intense pain over the affected area, tympanites, sudamina, harsh, dry skin, diarrhea, disturbed digestion, and dilated pupils.

Diagnosis.—Tubercle bacilli are often found in the blood therefore it should be examined in doubtful cases.

Acute General Tuberculosis.	Typhoid Fever.
1. Epistaxis not common.	1. Epistaxis and diarrhea.
2. Irregular temperature with rapid exacerbations.	2. Temperature shows a regular diurnal variation.
3. Rash infrequent.	3. Rose-red spots on abdomen.
4. Hurried respiration, cyanosis, dyspnea.	4. Respiratory rhythm regular.
5. Moist subcrepitant râles.	5. Dry râles, sonorous and sibilant.
6. Intestinal hemorrhage rare.	6. Intestinal hemorrhage common.
7. Tubercles often present in meningeal variety.	7. No tubercles on retina or choroid.
8. No Widal reaction.	8. Widal reaction.

Typhoid fever is generally more protracted in duration and there is a leukopenia, while in acute tuberculosis upon the incidence of mixed infection there is a leukocytosis. It is differentiated from intermittent fever by the temperature, absence of hematozoon of malaria, and negative therapeutic test.

Prognosis.—The disease always terminates fatally.

Treatment is purely symptomatic. If the meninges are involved, excruciating pain must be combated by hypodermics of morphin, 1/4 grain every 3 or 4 hours. A combination of bromid of potassium (30 grains) and morphin (1/4 grain) may be given to produce sleep. In all varieties a light, nutritious diet should be given.

TUBERCULOSIS, OCULAR.—Since the employment of the tuberculin tests, ocular tuberculosis has been found to be much more common than was formerly supposed. The consensus of opinion to-day seems to be that tuberculin (*q. v.*) is of decided value not only in the diagnosis but also in the treatment of tuberculosis of the eye. For a positive diagnosis a local reaction must be obtained with the tuberculin test. If two tests are negative, tuberculosis can be excluded with reasonable probability. According to Darier, a violent local reaction in the eye may be controlled by guaiacol injections (1 to 2 percent) subconjunctivally. If the reaction is positive tuberculin injections, forced feeding, rest, fresh air, etc., should be instituted at once. If in 2 to 3 months, no decided improvement is noticed, the human tuberculin should be supplanted by the bovine strain as a mixture of the two should be substituted, for the bovine strain may be the agent of infection. If the eye disease is secondary to glandular infection the bovine strain should be used; if secondary to pulmonary infection, the human is generally indicated.

As adjuvant to the tuberculin injections, Darier advocates the use of guaiacol in inunctions or subconjunctival injections, the guaiacol being preferable in the form of the cacodylate. See special headings: Conjunctivitis, Cornea, Iritis, etc.

TUBERCULOSIS, PULMONARY (Phthisis).—A specific infectious disease, due to the tubercle bacillus; characterized by the formation of tubercles in the lungs, which have a tendency to undergo necrosis; and manifested clinically by dyspnea, progressive loss of flesh and strength, night-sweats, hemoptysis, evening rise of temperature, and the expectoration of sputum containing tubercle bacilli.

Chronic Ulcerative Phthisis. Symptoms and Signs of the Early Stage. Subjective Symptoms.—(1) Progressive weakness and emaciation without apparent cause; (2) nocturnal sweats; (3) cough, especially in the morning, with expectoration of a whitish or yellowish mucus often tinged with blood (hemoptysis); (4) morning nausea; (5) local chest pains or tightness across affected area; (6) dyspnea; and (7) laryngitis.

Objective Symptoms.—(1) Diminished expansion over the affected area; (2) slightly increased tactile fremitus; (3) impaired resonance on percussion; (4) inspiration harsh and high pitched, and expiration prolonged; frequently "cogged-wheel" respiration; (5) exaggerated vocal resonance; (6) presence of mucous râles (often subcrepitant) at the apices of the lungs, sometimes posteriorly over base of lungs, and best heard when the patient coughs; (7) afternoon rise of temperature, with flushed face, usually after 4 o'clock; (8) a rather rapid and feeble pulse; and (9) generally the appearance of tubercle bacilli in the sputum.

Symptoms of the Late Stage.—The symptoms of the early stage exaggerated: Bacilli more abundant, the weakness and emaciation become more profound, night-sweats excessive, higher temperature and hectic symptoms, diarrhea, mucus often greenish, containing small, nummular lumps, cheesy in character, and containing many bacilli.

Predisposing Causes.—

1. **Hereditary tendency** is probably the most potent etiologic factor in the determination of tuberculosis. A phthisical chest may be thus inherited.

2. **Sequel of certain diseases** is the next most common cause. Of predisposing diseases may be mentioned pneumonia, typhoid fever, influenza, bronchitis, asthma, pleurisy, diabetes, and cirrhosis of the liver.

3. **Occupations,** such as coal-mining, glass-workers, mattress-makers, stone-cutters, street-sweepers, and close confinement in shops.

4. **Improper habits,** such as from alcohol, neglect of proper amount of food and sleep, exposure, overstudy and sedentary habits.

5. **Residence** in a low, damp, ill-ventilated, imperfectly drained, dusty locality; sleeping with a person suffering from tuberculosis.

6. **Age.**—From 20 to 35 is the period of life at which the disease is most often manifested.

7. **Cold climate** is a predisposing factor.

Method of Entrance of Tubercle Bacillus into the System.—(1) **Respiratory tract,** as from inhalation

of dust which carries the bacilli; (2) **Gastrointestinal tract,** as from infected milk (common in children); (3) **Inoculation;** (4) **Direct parental transmission** through the placenta (very rare).

Pathology.—There is no doubt some underlying condition of the system that the eye has not been able to perceive, or some chemic change produced in the fluids and tissues of the body that causes certain *foci of least resistance,* and renders the affected parts vulnerable to the attack by the tubercle bacillus. When the bacilli come in contact with such tissue, they are distributed throughout these foci by the lymph, blood, wandering connective-tissue cells, and leukocytes. The characteristic inflammatory process is usually a slow one, and the dominant action tends toward degeneration, with but a slight apparent attempt to form new tissue from the newly formed granulation cells.

The characteristic lesion produced by the bacillus of tuberculosis is a **tubercle,** which is a minute nodule, often the size of a millet seed, grayish or whitish in color, and quite translucent. If a section is made of a tubercle, it will be seen to have a certain arrangement: in the center of the nodule are a few large cells, with many nuclei (20 to 30), and two or three times the size of the surrounding granulation cells, called "giant cells," in which are lodged tubercle bacilli. The central portion of a tubercle has very few cells. Immediately surrounding the central portion of the tubercle are arranged a considerable number of epithelioid cells (wandering connective-tissue cells), and beyond them concentrically are found an abundance of small, round, granulation cells, between which are densely packed myriads of bacilli and many leukocytes. A few giant cells may be seen scattered throughout this area.

Guiteras compares the arrangement of cells from within outward to a "raked field." Cheesy necrosis, with subsequent liquefaction, begins in the center of the tubercle, usually in the giant cells and spreads peripherally. If calcification sets up in the area of granulation cells, there will be spontaneous recovery. Usually septic organisms gain entrance into the tubercle, causing rapid fatty degeneration and excessive ulceration of the surrounding tissues, with the development of cavities. The blood changes show a moderate degree of anemia.

Diagnosis rests upon the physical signs and the presence of tubercle bacilli in the sputum.

Inspection.—The chest is long and flat, the subclavicular region depressed, and the clavicles are very prominent. The angles of the scapulæ bulge, and the ribs are at an oblique direction downward from the sternum. There is diminished expansion over the affected area.

Palpation shows increased vocal fremitus.

Percussion shows impaired resonance or dulness below the clavicle and between the lower border of the scapulæ. If a cavity is present, a tympanitic note will be obtained.

Auscultation.—The inspiration is harsh, high pitched; the expiration prolonged and harsh; cogged-wheel respiration. There is increased vocal resonance. There are mucous râles over the apices of the lungs anteriorly, and over the base of the lungs posteriorly. Pectoriloquy with large râles and amphoric breathing may be detected if there is a cavity.

In doubtful cases the tuberculin test may be resorted to.

Krause claims to be able to make a diagnosis of early tuberculosis especially in children by means of the fluoroscope or radiography before it can be made by any other method.

Acute Phthisis.—A form of phthisis clinically resembling pneumonia in its early stages, usually terminating in death within a few weeks.

Fibroid Phthisis.—A slow form of phthisis in which the physical signs and symptoms gradually develop.

Complications of All Forms of Phthisis.—Pulmonary hemorrhage, pneumonia, pleurisy, diarrhea, extension to other organs, as the larynx, brain, kidneys, liver, peritoneum.

Distribution of Tubercles in the Body.—(1) Lungs (adult); (2) Lymph-glands, bones, and joints (in children); (3) intestines; (4) peritoneum; (5) kidneys; (6) brain; (7) spleen; (8) liver; (9) generative organs; (10) pericardium; (11) heart.

Prognosis is in the main unfavorable, although under proper treatment, change of climate, and other favorable conditions life may be prolonged for years.

Treatment.—In the treatment of pulmonary tuberculosis the first and most essential element is confidence on the part of the physician in the resources of his art. The prognosis is yearly becoming more favorable as the probability of recovery under good management is better realized, and the principles of treatment become better understood. It is, moreover, necessary for the attendant to be assiduous and minute in his care of the details of treatment, for upon these depends success or failure. Each patient must be an individual study, and the general plan should be modified in accordance with his reaction to remedies, and with the progress of the case. It is necessary to dwell upon these points, for they are often neglected.

Of the remedies useful in the management of pulmonary tuberculosis drugs occupy a distinctly secondary position. The chief reliance is to be placed upon hygienic measures—the scientific use of air, sunlight, water, food, rest, exercise, etc. —that will improve nutrition and increase vital resistance. Especially does this apply to the preventive regime that should be instituted from birth, if possible, in the case of those specially liable to the disease by heredity, whether the ancestral taint be tuberculosis itself or some other condition—for example, syphilis or carcinoma—likely to produce hypotrophy in the offspring. The patient's daily life must, therefore, be controlled as far as circumstances will permit. The treatment of tuberculosis among the well-do-do is thus both easier and more successful than among the poor. For both classes sanatoriums are often to be preferred; but the personal, mental, and

moral equation must be considered in deciding this.

The principal subjects of care are:

1. Place of residence, including both climate and dwelling-house.
2. Clothing.
3. Rest and exercise in general; including exposure to light and air, occupations and amusements.
4. Food.
5. The use of water, internally and externally.
6. Special pulmonary exercise, including the use of air at modified pressure.
7. The regulation of secretions and excretions.
8. The use of drugs (1) to improve general nutrition, (2) to improve special functions, (3) to antagonize the tuberculous processes, (4) to meet special indications.

These may first be considered in a general way, and later the modifications for special cases and stages of the disease may be indicated.

Place of Residence.—The subject of climate is more fully considered under CLIMATOLOGY (*q. v.*). Climatic treatment is desirable whenever possible. In many cases it is best to find a place where the patient can spend his life, and follow his vocation. Whether for this, or for temporary sojourn until health is regained, the place should be one where the patient can be out-of-doors most of the time and at all seasons of the year; though moderate change of location with seasons is sometimes beneficial for the sake of physical and mental variety. In many cases, especially in early tuberculosis, and in cases characterized by persistent high temperature, an ocean voyage, preferably of not less than a month's duration is the best therapeutic measure available.

With reference to climate the majority of patients fall into one of two principal classes—the robust and those needing protection. This may depend upon original constitution or upon the type and stage of the disease.

As a rule, the robust are benefited by cold and altitude, and some, in addition, by a certain degree of hardship—roughing it, as in lumbermen's camps and upon cattle-ranches. Good judgment is needed in the gradual increase of hardship, as sudden change from coddling to the opposite extreme would be likely to prove fatal. Among counterindications to altitude that need to be insisted on are (1) readiness of disturbance of cardiovascular balance, (2) cardiac weakness, (3) small size of heart, (4) neurotic or erethistic temperament, (5) persistent high temperature.

Those that need protection do better, as a rule, in warm or equable and comparatively dry places at the sea-level or but little elevated. Between these classes is a third to whom cold and moderate elevation, say not over 2000 feet, proves stimulating and restorative. In all cases purity and reasonable dryness of the atmosphere is a desideratum. The best of judgment is necessary in the choice of climate, and routine direction of every patient to one place or one class of places is productive of much harm. When patients cannot go far from home, something may still be done to improve their surroundings. Thus, both for air and light, the country is preferable to the city, a wide street to a narrow one, a detached house to one shut in on both sides. A hillside is better than a valley, a dry, sandy soil than moist clay. When the subsoil water approaches within 6 feet of the floor of the cellar, the first floor of the house should be sufficiently elevated; a cemented cellar is desirable. The air of the house should not be too dry, as air devoid of moisture provokes cough, and may induce hemorrhage. It should be constantly renewed, preferably through open windows. Other means of ventilation should be provided for bad weather. The temperature should be equable and not too warm. Except when special indications require it otherwise, 65° F. is a desirable standard. The temperature of the bedroom, which should be occupied only at night, and by no other person, should rarely exceed 60° F. The bedroom should have a high ceiling, and be as large and as sunny as possible, 1500 cubic feet of air-space being the minimum. There should be several windows for constant ventilation during the day. If there is a fire in the room, it should be in an open grate. The furniture should be as simple as possible. Electric light is preferable to any other, and lamp or candle to coal-gas.

When there is no counterindication, at least one window should be open at night, the patient being protected from draft.

The clothing should be warm, but light, loose, and not oppressive. As far as possible it should be of open texture, and should be changed with climate, seasons, and weather. Woolen or silk underwear, or a mixture of wool and cotton so arranged as to absorb the perspiration quickly and as quickly yield it to the outer air, should be worn both winter and summer. Protection is needed for the entire body, including the extremities; and the stockings are as important as the undershirt. Corsets, close-fitting waists, low-bosomed gowns, and tight belts are to be forbidden. Close-fitting scarfs, fur boas, and the like, around the neck are harmful, as are wadded flannel and buckskin "chest protectors," plasters, and similar abominations so often discovered upon stripping the patient for examination. In our northern climates extra wadding in and between the shoulders of the coat worn in the late fall and early spring, and a cape to the winter overcoat are often desirable. Sealskin and other heavy wraps are to be avoided. Patients with weak circulation should be well wrapped when driving, and when necessary, should use muffs and foot-warmers. Waterproof outer garments are in some cases a less evil than a wetting; they should be removed immediately on going indoors. As little clothing as possible should be worn in bed, the bed-covers being varied as necessary. A long woolen night-gown of light weight, or a "union" suit of the same material is the best in most cases. Hair mattresses with spring supports are best. Metal is better than wood for the bedstead, being more easily cleansed. Night-dress, underwear, and bed-covers must be changed even more frequently than ordinary cleanliness requires.

Rest and exercise must be considered together, the usual fault of physicians and patients alike being to insist too much upon one or the other. Individualization, the key to successful treatment generally, is in this matter specially necessary. When there is as yet no demonstrable lesion, and one merely suspects tuberculosis, a weak patient—especially a young, anemic girl—should be put to bed, if possible, and the Weir Mitchell "rest cure," or some modification—with massage and electric applications, and perhaps a daily drive or other nonfatiguing outing—be instituted. Later, and, on the other hand, from the beginning in a fairly robust person, active physical exercise should be gradually begun and increased, and preferably such as will keep the patient out-of-doors. Sports of various kinds, especially those which gently exercise the chest muscles, and afford pleasant diversion to the mind; systematic gymnastics, especially of the respiratory muscles; walking, bicycling, horseback riding, and even driving in an open carriage, are to be recommended; always in moderation, and according to the patient's condition. When there are extensive lesions, especially if there is constant and decided elevation of temperature, rest is absolutely necessary; and exercise should be the least and gentlest. It is not always necessary to rest indoors; a hammock swung in sun or shade, according to season and climate, a steamer-chair on porch or deck, are frequently preferable to couch and bedroom or cabin. As the patient improves, the period of rest is to be diminished, and exercise is to be quantitatively and qualitatively increased. Besides these illustrative extremes (and, indeed, in every case, as it passes through its stages of betterment or deterioration), there are many varieties of physical and mental conditions to which the physician's advice as to judicious alternation of rest and exercise must be adapted. Thus, when a patient with moderate lesions and no fever is unable to leave the city, a good plan of outdoor exercise is to have him walk slowly along the street in the opposite direction to the car-track, so that before fatigue occurs he may ride home. Or he may ride to a park (such as Fairmount in Philadelphia), and there walk and sit, again walk and sit, and, finally, after an hour or so, ride home. In many cases where the character of the country permits, ascents proportionate to the age and strength of the patient may be prescribed. They should be made with slow and measured steps and rests by the way. To expand the lungs while climbing, the elbows may be approximated behind the back, and a walking-stick may be supported between them. Whether walking on a level or climbing, the patient should be instructed to breathe deeply and slowly. Whether with the weak or the comparatively strong, fatigue is always to be avoided; exercise, therefore, should be instituted in a mild form and gradually increased.

Open-air treatment is of decided value. Exposure to **open air** and to **sunlight** should be as frequent, as long, and as thorough as the climate, season, weather, and patient's condition and endurance permit. The roof or back yard may be used on pleasant days. Even if circumstances compel housing, the endeavor should be made to get the sun and fresh air into the room where the patient sits or reclines. He should rest, warmly wrapped, before the open window. At night the windows should be kept open. The importance of this treatment cannot be too often reiterated.

In choosing an **occupation** for one thought to be liable to tuberculosis, or in the management of a patient already showing symptoms of the disease, the desirability of open-air life must be borne in mind. Many persons recover through change of business. Quite in point is Benjamin Franklin's celebrated instance of the man who contracted consumption while a shoemaker, and recovered while riding as post-boy between New York and the Connecticut River (about 140 miles) in all seasons and weathers. Most patients are kept indoors too much on account of weather. While care is necessary, it is best to be out whenever possible.

Amusement is quite as important as occupation, and requires equally good judgment. When the patient has tastes and means for a pleasant avocation, his desire should be gratified. In any case the endeavor should be made to divert the mind from self by reading, music, games, theater, concert, and lecture (when this does not involve too long a stay in an overcrowded hall), or whatever means are available. Undue excitement, however, is to be avoided.

Food is to be carefully chosen with due consideration of the habits and digestive capacity of the patient. Nutrition, nutrition, nutrition, is the essential of treatment; and food the essential of nutrition. Two mistakes are to be avoided—overfeeding and underfeeding. Often the patient lacks appetite, but is able to digest and assimilate much more food than is required in health. In such cases it is wise to feed up to the limit of digestive capacity, and for this purpose twice daily, after a preliminary lavage with a warm solution of sodium bicarbonate (1 dram to 1 pint), about a quart of fully peptonized milk, with one or two eggs, an ounce of beef-powder, 30 drops of dilute hydrochloric acid, and 5 or 10 grains of pepsin may be introduced through the stomach-tube. The ingredients are to be thoroughly mixed, and the temperature of the mixture should be about 100° F. In addition to the gavage, the patient may be allowed to eat a midday meal of such permissible food as pleases his palate. Other patients will need only to be encouraged to eat sufficient food, and gavage will be unnecessary. In other cases the digestive capacity and the exercise taken become important factors in permitting the amount of food given to be increased. The assimilative power is impaired, and until, by proper management, this has been restored, it will be necessary to restrict the quantity and kinds of food. As a general rule, subject to modification in individual cases, patients having good prospects of recovery or partial recovery should be fed as bountifully as possible; while those in the later stages, with the

end nearing, especially when active exercise has been interdicted, should not be given large quantities of food. In the average case the meals should be comparatively frequent—say 6 *per diem*, at intervals of about 3 hours. At three of these meals there should be taken as much as one in good health ordinarily eats. The others may consist of a plate of soup or a glass of milk or of cream or a half-dozen oysters or a sweetbread or a squab or something similar. It is often well to drink a glass of hot milk just before going to bed; and in some cases milk or a liquid preparation of so-called peptones or a glass of a good wine of coca should be at hand to be taken if the patient awakes during the night. A half-hour before meals 1/2 of a pint or a pint of hot water is often of use in preparing the gastric mucous membrane for the reception and disposition of the food. Simplicity in diet is necessary. Nitrogenous and fatty elements should predominate, sugars and starches be reduced to a minimum.

Cod-liver oil, plain, or emulsionized with the aid of pancreatin, is one of the best of fatty foods. It may be given in doses of 1/2 of an ounce or less after meals. In some cases beef or mutton fat, butter, olive oil, and the like, serve equally well, and, being utilized in the ordinary way, seem less like medicine. Milk, preferably hot, is to be taken freely; if possible, a quart and a pint of milk and a pint of cream daily. Koumiss, kefyr, and the like may be substituted for plain milk or alternated with it. Soups, such as bouillon, oyster broth, clam broth, mutton broth, beef broth, turtle soup, barley, rice, bean and pea soups and purées, celery broth made with milk and thickened, are useful. Beef, underdone, roast or broiled; mutton or lamb roast, or broiled chops; sweetbread; brain; poultry, broiled, roast, or stewed; nearly all kinds of game; fresh fish; salt codfish; salt mackerel; eggs, steamed, boiled, poached, beat up with milk, should be the principal articles of diet. Nothing should be fried. The green vegetables—lettuce, spinach, asparagus, watercress, and the like—are of great service; as are, likewise, the legumens—peas, beans, lentils, etc. Fresh fruits of all kinds are to be freely used in the absence of special counterindication. Of starchy foods, rice, well cooked, and occasionally sago, tapioca, etc., are the best. Potatoes, turnips, carrots, beets, and other starchy and sugary roots and tubers are to be avoided altogether or used very sparingly, for occasional variety. The infrequent potato should be "roasted in the jacket" until it becomes ready to fall into powder when opened; or, if necessary, "twice baked." Other desirable vegetables are tomatoes, onions, and celery. Cereals—hominy, oatmeal, cracked wheat and similar preparations—may be used in moderation if well digested. Bread should be reduced to the minimum consistent with comfort—toast, zwieback, and pulled bread being preferable to ordinary bread. Hot bread, cakes, pies, pastry, sweetmeats, made dishes, rich gravies, crabs, lobsters, and, among meats, pork and veal are to be strictly avoided.

The best beverage is water, to be taken freely; the purer the better. Mineral waters offer no special advantage unless needed as laxatives or diuretics. In some cases alcohol is of the highest use, in others useless, and in others harmful. It should not be given as a routine. When given, it should be used in comparatively large quantities —from 4 to 8 ounces of good whisky daily. When the patient is taking sufficient other food, the heart is acting well, and the digestion is good, alcohol is usually unnecessary. When there are fever, impaired appetite, poor digestion, and feeble action of the heart, alcohol usually helps temporarily. While by no means advocating this plan, reference may be made to three cases of remarkable recovery—*i. e.*, restoration to good health of patients with decided pulmonary lesions—upon the old treatment of whisky and cod-liver oil—the quantities ordered having been "as much as you can stand." The period over which the treatment extended in these cases varied from a few months to several years.

Water is to be used freely both internally and externally. Not only the drinking of hot water before meals, but, if necessary, lavage of stomach and intestines with physiologic saline solution or some alkaline detergent solution of about the same specific gravity is to be practised in order to keep the alimentary canal clean, as free as possible of ptomains and other toxins, and the mucous membrane active. In addition pure, cold water, carbonated or still, as may be most palatable, is to be imbibed freely between meals; and may also be taken with meals, in moderate quantity, if preferred. Wine and water (claret or Burgundy) is better than plain water with meals.

Hydrotherapy is of the greatest importance not only as a curative, but also as a prophylactic measure.

Water should also be freely used externally, not merely for cleanliness but as a direct stimulant to the skin and its vessels, and immediately to circulation, respiration, and general nutrition. According to the patient's age, temperament, and strength, the stage of the disease, the condition of the heart and vessels, the individual reaction, the climate, season, and weather, various hydrotherapeutic measures are useful. For details, treatises on hydrotherapy should be consulted. As a prophylactic measure cool or cold sponging on rising in the morning is generally applicable. Those who react well may substitute for add a gentle shower bath or douche—at first for 20 or 30 seconds, later for a minute for more. This is to be followed by forcible, dry friction; and the patient having dressed and having swallowed, not hastily, a glass of hot milk, should take a walk, not long enough to cause fatigue, and then return for breakfast. In unpropitious weather, indoor exercise, gradually increased in activity, may be substituted.

Delicate and sensitive persons not inured to cold bathing must be accustomed to it gradually, tepid water being used at first. In every case the physician should prescribe the temperature

of the water and the details and duration of the bath, douche, or other application, with the same care that he gives to the dosage of medicine.

Counterirritation is sometimes useful in the early stages of pulmonary tuberculosis, and especially when there is softening. Cantharidal collodion or a mixture of tincture of iodin, croton oil, ether, and collodion may be employed. The best plan is to irritate successive small portions of the skin over the seat of lesion, allowing one spot to heal before the next application is made.

Pneumotherapy, or the use of air at modified pressures, is among the most important, as it is the most neglected, of our means of defense against pulmonary tuberculosis. The literature of the subject should be carefully studied by every physician. In many cases the use of appropriate apparatus under the physician's direction will obviate the necessity of seeking a change of climate.

There are two forms in which condensed and rarefied air may be utilized. These have been termed the *absolute* and the *differential* methods. The first is carried out by the use of pneumatic chambers modeled after the diving bell, the first of which was constructed for Tabarie in 1838. The patient remains for an hour or more in air gradually raised to a pressure far exceeding the normal (from 1 1/2 to 2 atmospheres), and then gradually lowered. Rarefied atmospheres are theoretically useful, but have not been used in medicine in these chambers. The disadvantage of this method is that its use is limited to certain resorts. The differential method is carried out by apparatus of two different types. In one, the patients remain in the ordinary atmosphere and inhale from or exhale into (or both) cylinders containing condensed or rarefied air. In the other, patients enter an apparatus in which the air about them is condensed or rarefied, while they inhale from and exhale into the ordinary air. The type of instruments of the first class is the gasometer of Waldenburg—the modification of S. Solis-Cohen being the most convenient for use at the patient's home. The type of instruments of the second class is the pneumatic tub of Hauke; the pneumatic cabinet of Williams being the most elaborate.

The physiologic and therapeutic effects of the two types of instruments do not differ; the questions to be considered being merely of expense and mechanic convenience. While the pneumatic cabinet is theoretically capable of the same variation in use as the gasometers, in practice it is impossible to alter its pressure rhythmically with the patient's respiration; hence the air it contains must be either rarefied or condensed during an entire sitting; the patient thus both inhaling from and exhaling into air relatively higher or lower than that surrounding him. The most common use is to rarefy the air of the cabinet, and the patient thus continuously respires relatively condensed air.

In the gasometer instruments any of the following 8 modifications are perfectly practicable:

Inhalation from	Exhalation into
1. Condensed air.	Unaltered atmosphere.
2. Condensed air.	Condensed air.
3. Condensed air.	Rarefied air.
4. Rarefied air.	Unaltered atmosphere.
5. Rarefied air.	Condensed air.
6. Rarefied air.	Rarefied air.
7. Unaltered atmosphere.	Rarefied air.
8. Unaltered atmosphere.	Condensed air.

In pulmonary tuberculosis the expedients numbered 1, 2, and 3 are those employed, and chiefly 1 and 3. The most useful is generally 3; which fact alone serves to give this method the preference over the pneumatic cabinet.

If desired, the air inhaled, which is drawn from out-of-doors, and filtered through cotton on its way to the cylinder, may be artificially cooled, warmed, dried, or moistened. The air may be impregnated with the vapor of any medicinal substance, by passing it through a solution in a wash-bottle, by suspending in the condensation cylinder a vial or a sponge containing the drug, or by inserting a sponge or cotton wad, appropriately moistened, in the mouth-piece. The pressures (positive or negative) employed, which are to be gradually increased as the case progresses, range from 1/75 to 1/30 of an atmosphere (1/5 to 1/2 pound to the square inch); and are regulated by weights or counterweights as condensation or rarefaction is desired. The inhalations and exhalations are to be made as slowly and perfectly as possible, the rate of respiration being reduced to 10 or less a minute, if possible; the volume of air inhaled or exhaled being brought up to 200, 250, 300, or even 400, cubic inches as recovery progresses. From 5 to 20 minutes continuous respiration is followed by a rest of the same length, and a repetition of the process. The patient should stand, if able to; the clothing should be loosened, outer garments being removed, and, if necessary, the physician or an attendant should assist respiration by pushing the patient's shoulders back during inspiration, and pressing the arms against the sides of the chest during expiration. The treatment is time consuming and requires intelligent care and supervision; but should not therefore be omitted. When patients can afford to buy or rent an apparatus for use in their own homes, a member of the family or a nurse can readily be instructed in its use. It is worth all the drugs in the Pharmacopeia as a therapeutic measure in pulmonary tuberculosis.

Briefly, inhalation of condensed air produces the following effects: Diminution of muscular effort; increased dilatation of alveoli; increased volume and penetrating power of tidal air; consequent increase of gaseous exchange and volume of expired air; increase of volume of pulmonary circulation; increased absorption of oxygen; increased peripheral circulation; increased metabolism. There result: Diminished frequency of respiration, increased expansion and ventilation, with great increase of vital capacity; diminished frequency, with increased force of heart's action and increased fulness of the pulse.

Exhalation into rarefied air produces the following effects: Contraction of the thorax is facilitated; expiration is made more complete; subsequent inspiration is easier and deeper; pulmonary congestion is diminished; the heart is more thoroughly emptied, and diastole is facilitated. The combination of these procedures is, therefore, an effective means of pulmonary ventilation and of relieving local stases. It acts as a stimulus and a regulation to respiration and circulation, and thus becomes an effective means of restoring both local and general nutrition. The vital capacity of patients is permanently increased, especially by calling into use portions of lung not fully expanded; appetite is improved, and the greater quantities of food consumed are oxidized and utilized. Secretion is stimulated and excretion facilitated. Cough and expectoratiou are at first increased, from dislodgement of accumulated materials, afterward diminished. Sleep is promoted.

When there is elevation of temperature to 100° F., the method is to be employed only with caution, and not at all if the fever is continuous and marked local changes are in progress. Active softening without fever is also a counterindication. Pneumatic treatment should not be used when there is a large cavity with fluid or semifluid contents; but dry cavities present no objection. If hemorrhage occurs, inhalation should be intermitted, but may be resumed cautiously some time after the bleeding has ceased.

After patients have sufficiently recovered to omit the constant use of the apparatus described, the good effects may be kept up by use of S. S. Cohen's pneumatic resistance valve. By adjusting the springs as shown upon the scale above each valve to one of the fingers, 6, 5, 4, 3, there is secured a pressure approximately of 1/60, 1/50, 1/40, or 1/30 of an atmosphere, in resistance to inspiration or expiration or both, as desired; that is, practically, inspiration of rarefied air and expiration into condensed air. The effect is to necessitate greater muscular effort in respiration, and thus to secure regulated pulmonary gymnastics, with stimulation of circulation. It cannot take the place of the other method, but is applicable only with patients able to make the increased exertion; the gasometer being employed when patients need assistance in respiration. It is especially applicable as a prophylactic measure in the young and fairly robust, who need to be given a proper respiratory habit. The inspired air may be medicated by placing a few drops of any suitable volatile drug or mixture (eucalyptol, creosote, chloroform, ethyl iodid, terebene, etc.) on cotton in the receiver.

Sometimes patients may be induced to respire properly through the device of Dr. Ramadge: A tube (a section of ordinary "speaking-tube," with a proper mouth-piece will answer) about 4 feet long, with the far end slightly narrowed, which is to be placed out of the window every morning and noon, while slow, full respiration is practised for from 5 to 30 minutes.

The secretions and excretions are likely to be kept in good order by following the plans detailed as to clothing, outdoor life, food, rest, exercise, and the use of water and of air, but sometimes special treatment or medication is temporarily necessary. These measures do not differ in principle or method from those employed in other affections. Some authors recommend, however, the more or less constant administration of cardiant diuretics, such as spartein sulphate.

Tuberculin Treatment.—The present opinion with regard to tuberculin therapy is divided. There are excellent observers who claim that it is useless, and others who claim for it a distinct therapeutic value. Practically all are agreed that when given it should be administered in such small doses at first to render a general reaction unlikely and to increase the dose of subsequent administration at specific times with the greatest caution to prevent reactions. This will necessitate starting with doses considerably below the tuberculin tolerance of the individual. Subsequent doses are given at 5 and 7 day intervals, and by some observers, twice weekly. The initial dose, the increment of increase, the length of time between doses depend so largely upon the various factors present in a given case, that specific rules cannot be stated. Individualization is of such vital importance in the success of tuberculin therapy, that the failure to appreciate it has led to many failures in its use. Brown recommends the following beginning doses which have been used by the writer. For old Tuberculin (O. T.) and Bouillon Filtrate (B. F.) the usual beginning dose may be 0.0000005 or 0.000001 mil, though in a few, especially if febrile it may be 0.0000001 or 0.00000001 mil. Bacillen Emulsion (B. E.) and Tuberculin Residuum (T. R.) the initial dose should be 0.00001 gm. for afebrile and 0.0000001 gm. for febrile patients. In children and in febrile patients the dose is smaller than in afebrile adults. New Tuberculin (T. R.) is the mildest of all preparations and is very suitable for the beginning treatment of susceptible individuals (Citron). The various tuberculins have their advocates, Funk prefers Bacillen Emulsion. Certain observers have noted that this preparation tends to produce infiltrations at the site of injection. Meyer and Rupple have advised the employment of sensitized Bacillen Emulsion by which is meant an emulsion treated with tuberculous serum of a cow containing so-called anti-tuberculin, with the result that infiltrations are much less or entirely absent (Citron). If at any time during the course of treatment a reaction occurs the dose should be reduced to, or below, the doses which previously gave no reaction and the subsequent advance made more cautiously. The maximum dose to be reached varies in different individuals; in B. E. 5 mg. should not be exceeded, while in O. T. and B. F. 1 mil is the usual maximum dose (Brown). Whenever tuberculin is administered the patient should be under direct control of the physician and a careful record of the temperature range, general and focal reaction kept. Better results are obtained if maximum rest, fresh air and good food can be secured with the tuberculin therapy. It is contraindicated in the presence of high fever, marked asthenia, myocardial weakness

with excessively rapid pulse, advanced disease, hemorrhage and the presence of a serious complication such as empyema, etc. The selection of suitable cases for tuberculin treatment is a matter of considerable difficulty. It must be remembered that tuberculin is a poison which acts by stimulating the body forces. In a patient in whom the disease is acute and active the system is more or less overwhelmed with poisons produced at the site of the lesion and in such a case tuberculin is contraindicated. On the other hand, there are cases which are afebrile or have slight fever, slight constitutional disturbance and limited local involvement of a chronic nature in which the warfare between the infecting tubercle bacilli and the body forces seems to be waging in the balance, and the patient seems to gain but little under active, hygienic, dietetic care. In this type of case good results may follow careful use of tuberculin. Tuberculin has been used not only in pulmonary tuberculosis, but in the treatment of tuberculosis of almost every organ, viz., skin, eye, ear, larynx, bones and joints, genito-urinary system, etc., etc.

Preparations (Unofficial).—Tuberculinum (Tuberculin) (Koch), is a glycerin extract of the culture fluid upon which the bacilli have been grown, concentrated to 1/10 its original volume, and filtered through porcelain to remove the bacilli.

Tuberculin Residuum (T. R.) **(New Tuberculin)** (Koch), is prepared by drying living virulent cultures *in vacuo*, grinding them into a fine dust, and after extracting certain soluble constituents with saline solution the residue is rubbed up with water to form an emulsion, which is standardized so that 1 c.c. represents the active substance found in 10 mg. of the dried tubercle bacilli.

New Tuberculin (Bacilli Emulsion) (Koch), is a suspension of pulverized tubercle bacilli in glycerin and water, containing 5 mg. of the bacillar substance in each c.c. Initial dose, 1/100 mg., diluted with normal salt solution.

Tuberculin Denys (Bouillon Filtrate) (B. F.), consists of the filtrate from bouillon cultures of the tubercle bacillus, and contains all the soluble products elaborated by the bacilli while growing on bouillon. It differs from the original tuberculin in that no heat is used in its preparation and that it is not concentrated. Initial dose, 1/1000 mg.

Medication in pulmonary tuberculosis may be directed against some symptom, or may be directed generally to improving nutrition: *i. e.*, vital resistance. Next to cod-liver oil, the most efficient drugs are the creosote group and the iodin group.

The creosote group includes creosote, creosote carbonate, guaiacol, guaiacol carbonate, guaiacol salicylate, guaiacol benzoate, and potassium guaiacol sulphonate (known as thiocol). *The iodin group* includes metallic iodin, Lugol's solution, arsenic iodid, Donovan's solution, diisobutylorthocresoliodid (known as europhen), ethyl iodid, and iodoform.

Of good beechwood creosote large doses may be given by gradual increment without disordering digestion; but many of the commercial preparations contain gross impurities, and are unfit for internal use. Some patients cannot take large doses, or even small doses, of even the best creosote; in which case one of the substitutes mentioned may be used. Creosotecarbonate (creosotal), a syrupy liquid, is even better than creosote and is best given in hot milk, and in doses of from 5 to 60 minims, 3 or 4 times daily. The guaiacol salts are tasteless or nearly tasteless powders, and may be given as such or in capsule, in doses aggregating from 15 to 75 grains daily. Duotal or guaiacol carbonate is sometimes better borne than creosotal. It is given in doses of 3 to 7 1/2 grains three times a day. Beechwood creosote may be given in doses of from 1 to 40 minims 3 or 4 times daily. The average dose is 10 minims. It is best given in milk, about 2 hours after meals. It may be shaken up with a tablespoonful of cod-liver oil, which some patients like, comparing the taste to fat smoked mackerel. Creosote or guaiacol may be given with alcohol, in the form of sherry wine or rum, with or without the addition of gentian or glycerin; or in emulsion with cod-liver oil or olive oil; or in capsule with morrhuol or cod-liver oil. These drugs should not be given in capsule without an oily vehicle. They may be given with milk as a rectal injection or in oily solution of 10 percent or more by intratracheal injection or hypodermically. The dose is generally to be somewhat below the point of tolerance, the urine being carefully watched. Cases of sudden nephritis and other forms of poisoning are on record. Inunctions of guaiacol are valuable, especially in children. Gomenol is said to be a valuable substitute for creosote.

Preparations of the creosote group are most useful in cases in which active inflammatory processes, catarrhal or tuberculous, are in process, and in cases with persistent high temperature, though they may be of service at all stages. Their action has not been satisfactorily explained. They probably have a good local influence during their elimination by the bronchial tract.

Of *the iodin group*, iodoform is the most useful. It is best given in pill (sugar-coated) form. An excellent combination is iodoform and reduced iron, made into pills containing 1 grain of each, the dose being gradually increased to 3 or even 5 pills at a time, after meals, thrice daily. It may sometimes be useful to combine other drugs than iron with the iodoform, in which case gelatin capsules may be used, Peruvian balsam being employed as the vehicle. Iodoform may also be given by inunction, in cod-liver oil or lanolin, as advised by Flick, who employs europhen also in this way. It is most useful in the early stages of the disease or during periods of quiescence in the chronic forms. Creosote and iodoform may be given to the same patient in alternate doses or on alternate days, when the signs in various portions of the lungs so differ as to indicate an advanced or active process here, and a quite recent or sluggish process there.

Cinnamic acid by intravenous injection is highly praised by Landerer, who reports a large proportion of successful cases. The dose is from 1/2 milligram, gradually increased to a maximum of

25 milligrams of *sodium cinnamate*, or cinnamylate dissolved in physiologic salt solution. The injections are repeated about every 48 hours, and continued for several months. The drug acts by increasing leukocytosis. During the past few years good results have seemed to follow the use of a solution of *palladium chlorid* (made with the aid of nitro-hydrochloric acid) of a strength of 15 grains to the ounce, in doses of from 3 to 10 drops thrice daily in water, half an hour before meals. In several cases it seems to have been useful as a substitute for iodoform, rather than for creosote. If given for too long a time, or in too large doses, it causes rapid and irregular cardiac action. Extract of kalagua is the most recent drug that comes well recommended. It is given in doses of from 9 to 20 grains *per diem*.

Mercuric succinimid in intramuscular injections—extolled so highly by Barton Wright and others—has according to recent report proved not only worthless, but injurious.

Of the drugs employed for the *stimulation of general nutrition* strychnin, arsenic (especially in the form of sodium cacodylate), iron, nuclein preparations, and the hypophosphites are the most useful. The best results usually follow from small, long-continued doses and alternation of remedies; though individual cases are benefited by rapid increase to the point of tolerance.

Digitalis is often useful as an adjunct to the roborant treatment, especially in cases of small heart and feeble circulation. In some instances nitroglycerin may be well combined with it. Digitalis has also special indication during acute processes, as long ago pointed out by Beddoes. In acute phthisis or in febrile exacerbations of chronic phthisis, it should be pushed to the point of tolerance. A good preparation, free from irritating impurities, is necessary. Pepsin preparations given at the same time will help gastric toleration. When the leaves or tincture cannot be used, Merck's German digitalin, as recommended by Beates, may be tried.

Oxygen is useless as a remedy, and may hasten death; but is among the best of palliatives in the latest stages. Combined with nitrous oxid, its inhalation relieves dyspnea and promotes the sense of well being.

Nitrous oxid is among the best palliatives for the relief of cough, of insomnia, and of hectic fever. It is usually best to give it during the forenoon, at two periods separated by about 2 hours. Each inhalation may consist of from 3 to 8 gallons, air being allowed to enter through the nostrils and by the side of the mouth-piece. The patient breathes more freely and more deeply after the inhalation, and cough is quieted, but unconsciousness is not produced.

Certain symptoms require special medication.

Indigestion is to be treated on general principles, but carefully.

Diarrhea is often troublesome, especially toward the end. Diet is to be regulated, milk being excluded, if necessary. Among useful drugs are beta-naphthol, benzonaphthol, beta-naphthol-bismuth, bismuth salicylate, bismuth subnitrate or bismuth carbonate in large doses, bismuth subgallate, hematoxylin, silver nitrate, cupric sulphate, zinc phenolsulphonate, plumbic acetate, and solution of potassium arsenite in small doses. Often morphin or opium is necessary. Before any drug is given the bowel should be thoroughly irrigated with saline solution, and a good cleansing from above with calomel or castor oil and aromatic syrup of rhubarb is often useful.

Vomiting is often the result of cough, especially when there is much effort. In some cases it is nervous, and can be relieved by strychnin given at bedtime. Strontium bromid is among useful gastric sedatives. Otherwise general principles apply.

Night-sweating can usually be checked by atropin in massive or divided doses of from 1/480 to 1/40 grain at bedtime; it should be tried first in small doses, and increased, if necessary. Other useful drugs are picrotoxin, from 1/60 to 1/10 grain hypodermically, if necessary; strychnin sulphate or strychnin nitrate in the same dose; homatropin, of which the dose is said to be from 1/2 grain to 2 grains; agaracin, from 1/8 to 1/2 grain, 2 or 4 times daily; camphoric acid, from 10 to 20 grains in capsule at bedtime; ergot; aromatic sulphuric acid. Dusting with zinc oxid, or sponging with a saturated solution of quinin in alcohol or with a saturated solution of alum in alcohol often helps to control this symptom.

Hemorrhage varies from slight blood-spitting to considerable flow. It may be due to oozing from small vessels, to perforation of a large vessel, or to rupture of an aneurysm within a cavity, and the management varies accordingly. In many cases the bleeding ceases spontaneously, especially if the patient is kept at rest, and doubtless the popularity of many remedies is thus to be explained. If there is more than a mere trace of blood in the sputum the patient should be put to bed and given cracked ice, which is to be allowed to melt slowly in the mouth from time to time. According to the severity of the case, some or all of the following measures are to be adopted:

An ice-bag may be applied to the precordium, and kept on constantly, especially if there is an elevation of temperature. Tincture of aconite may be given in sufficient dosage to quiet the heart and to reduce and keep the pulse-rate to 60 a minute. Crystallized calcium chlorid may be given in solution in doses of 15 grains every second hour, for about 4 days; it is then to be intermitted for 4 days or more, and used again, if need be. In the interval lead acetate, in doses not exceeding 5 grains, thrice daily for 3 days, may be given, to be followed for 2 days by aromatic sulphuric acid in doses of 30 drops, well diluted, thrice daily or oftener. Hydrastinin hydrochlorid in doses of 1/24 to 1/8 grain hourly or less often is sometimes useful. Among drugs to be recommended are also the turpentine group, of which erigeron is among the best. Fluidextract of matico is recommended by Da Costa. Codein may be given by the mouth in doses of from 1/8 to 1/2 grain every second hour or less often; or morphin acetate may be given by the mouth in doses of 1/8 grain

every hour or two; or morphin sulphate hypodermically in dose sufficient to prevent coughing absolutely in severe cases.

Atropin sulphate, from 1/200 to 1/60 grain, may be given hypodermically at the beginning of the attack, and will often cut it short.

The patient must be forbidden to speak, except in a labial whisper. Cold liquid food should be given in small quantities at intervals of about 2 hours. The bowels should be moved daily, without straining, by enema, glycerin suppository, or saline purge, as necessary. In desperate cases tannin has been injected into the lung, as also have gelatin solutions.

Fever is best treated by rest (not necessarily indoors) with cold applications, of which the precordial ice-bag is the best. The coal-tar antipyretics may be cautiously used as palliatives, if necessary. Digitalis is often useful. Nitrous oxid is to be tried.

Cough should not be interfered with unnecessarily. It should be sufficient to expel the accumulations of mucopus in the trachea and larger bronchi. The expectorated matters are to be properly received disinfected, and disposed of (see COUGH). Cough may be checked, when excessive, by opium, hydrocyanic acid, chloroform, or bromids. When unproductive, it needs to be made freer. The ammonium compounds are not often useful. As a rule, terebinthinates and balsamics, menthol, eucalyptol, terebene, terpin hydrate, and myrtol are the best agents for this purpose, internally or by inhalation. Steam inhalations are to be avoided, but dry inhalations of any volatile oil, of creosote, of well-diluted formaldehyd, or of ethyl iodid are serviceable. No apparatus except a containing phial is usually necessary, but various convenient forms of inhalers are manufactured. When cough is due to ulceration of the larynx, it is to be treated skilfully, as described under LARYNGITIS (Chronic).

Dysphagia, as a rule, is due to ulceration of the epiglottis, which requires local treatment. The food should be semisolid and bolted hastily. Cocain or other local anesthetic may be used with caution before meals. Rectal feeding or feeding through a nasal tube may have to be employed.

Pain in the chest may often be relieved by rubbing in a few drops of a solution containing one or more of the following agents with camphor (liquefaction taking place on mixing): Chloral, menthol, guaiacol, oil of gaultheria. Counterirritation with iodin or croton oil, or even the thermal point, is sometimes necessary.

TUBERCULOSIS, SURGICAL.—See BONES (Diseases), JOINTS (Diseases), LYMPHATIC GLANDS (Diseases), etc.

TUMENOL.—A dark brown fluid, obtained by treating the unsaturated hydrocarbons of mineral oils with concentrated sulphuric acid. It is said to be a nontoxic and nonirritant protective and palliative to the skin. It is recommended in eczema, excoriations, erosions, superficial ulcerations and burns. The tincture is an efficient application in all forms of pruritus. Tumenol is of no service in erysipelas, and not a parasiticide.

TUMORS, CLASSIFICATION.*—In deference to the needs of the various registration authorities, a distinction between malignant and nonmalignant new growths is made in the general and local tables. The tumors are here classified, however, according to their structure and the type of normal tissue thay most closely resemble. To facilitate returns under the general tables, the malignant growths are marked by two asterisks. In certain cases malignant and nonmalignant growths are unavoidably associated under one head, as, for instance, under sarcoma; the name is then marked with one asterisk.

Cysts are placed in a separate class, and may be returned severally among the local affections of organs; or among new growths, if connected therewith; or as malformations, if congenital; or as parasites, if parasitic.

Class I.—Tumors composed of one of the modifications of fully developed connective tissue.

(The name of the typical normal tissue is printed first in each case; that of the tumor second.)

1. **Adipose Tissue.** Lipoma (fatty tumor).
   - (*a*) Circumscribed.
   - (*b*) Diffuse. *Synonym*, fatty outgrowth.
   - (*c*) Multiple.
   - (*d*) Nevolipoma.
   - (*e*) Fibrolipoma.
2. **Fibrous Tissue.** Fibroma.
   - (*a*) Firm or hard fibroma (desmoid tumor).
     Fibrous epulis.
     Fibrous polypus of nose.
     Fibroma of nerves. *Synonym*, false neuroma.
     Keloid.
   - (*b*) Soft or areolar fibroma.
     Molluscum fibrosum.
3. **Cartilage.** Chondroma.
   - (*a*) Ossifying. *Synonym*, spongy or cancellous exostosis.
   - (*b*) Nonossifying.
     *Enchondroma (when growing in bone).
     Ecchondrosis (when growing from cartilage).
   - (*c*) Myxochondroma (when undergoing mucous softening).
4. **Bone.** Osteoma.
   - (*a*) Developing from cartilage.
     Cancellous or spongy exostosis.
   - (*b*) Developing from membrane.
     Compact or ivory exostosis.
   - (*c*) Of teeth.
     - (1) Growing from the cement.
       Dental exostosis.
       Hypertrophy of cement.
     - (2) Growing from the dentin.
       Odontoma.
5. **Mucous Tissue.** *Myxoma.
   Mucous polypus.
6. **Neuroglia.** *Glioma.

Class II.—Tumors more or less closely resembling in structure one of the more complex tissues or organs of the body.

(The name of the typical tissue or organ is placed first; that of the tumor second.)

1. **Muscle.** Myoma.
   - (*a*) Unstriped (leiomyoma).
     Fibromyoma, uterine fibroid, fibroid tumor of prostate.
   - (*b*) Striped (rhabdomyoma).
     *Myosarcoma.

*Revised nomenclature of the Royal College of Physicians, 1896.

2. **Nerves.** Neuroma (true neuroma).
   (*a*) Medullated.
   Plexiform neuroma (in part). Bulbous nerves. *Synonym*, amputation neuroma.
   (*b*) Nonmedullated.
3. **Blood-vessels.**—Hemangioma, angioma, or nævus.
   (*a*) Capillary. *Synonyms*, port-wine stain; mother's mark; telangiectasis.
   (*b*) Venous. *Synonyms*, erectile tumor; cavernous nævus.
   (*c*) With adipose tissue (nævolipoma).
4. **Lymphatic Vessels.** Lymphangioma, lymphatic nævus, congenital cystic hygroma of neck, macroglossia.
5. **Lymphatic Glands.** Lymphadenoma.
   Hodgkin's disease.
6. **Papillæ of Skin or Mucous Membrane.** Papilloma.
   (*a*) Squamous papilloma (wart).
   (*b*) Columnar papilloma (villous growth).
   Of rectum. Of bladder.
7. **Secreting Glands.** Adenoma.
   (*a*) Racemose adenoma (spaces lined with glandular or spheroid epithelium).
      (1) Resembling normal gland tissue (true adenoma).
      (2) With excess of firm fibrous stroma (adenofibroma; adenoid tumor).
      (3) With stroma of imperfectly developed fibrous tissue (adenosarcoma).
      (4) With stroma containing mucous tissue (adenomyxoma).
      (5) With large cysts throughout the tumor (adenocystosarcoma; cystosarcoma).
      With simple cysts. With intracystic growths.
   (*b*) Tubular adenoma (spaces in tumor lined with columnar or cubic epithelium).
   (*c*) Adenoma of ductless glands (thyroid adenoma).
   (*d*) Ovarian adenoma.

Class III.—Tumors composed of cells of an embryonic type sometimes tending to develop into one of the forms of connective tissue.

*Sarcoma:
1. Composed of small round cells.
   (*a*) With homogeneous intercellular substance (granulation sarcoma; encephaloid sarcoma).
   (*b*) With reticulate stroma (lymphosarcoma).
   (*c*) Ossifying sarcoma (osteoid sarcoma; osteoid cancer).
   (*d*) Chondrosarcoma (malignant chondroma).
   (*e*) Gliosarcoma.
2. Composed of large round cells.
   With alveolar stroma (alveolar sarcoma).
3. Composed of oval cells.
   With mucous intercellular substance (myxosarcoma).
4. Composed of large spindle-cells (fibroplastic tumor).
   (*a*) Ossifying.
   (*b*) Chondrifying.
5. Composed of small spindle-cells.
   (*a*) Developing into fibrous tissue (recurrent fibroid tumor).
   (*b*) Ossifying.
6. Composed of round and spindle cells.
7. Containing giant cells (myeloid sarcoma).
8. Melanotic sarcoma (pigmented sarcoma).
9. Plexiform sarcoma (cylindroma).
10. Psammoma (brain-sand tumor).

Class IV.—Tumors composed of epithelial cells arranged in the spaces of a stroma of more or less perfectly developed and vascular connective tissue.

**Carcinoma, or True Cancer.
1. Glandular or spherical carcinoma.
   (*a*) With little stroma and abundant vessels (encephaloid cancer).
   (*b*) With dense fibrous stroma (scirrhus, or hard cancer).
   Variety: Atrophic cicatrical scirrhus.
   (*c*) With colloid degeneration of cells (colloid cancer—reticular or alveolar cancer in part).
   (*d*) With a myxomatous stroma (carcinoma myxomatodes).
2. Squamous carcinoma. *Synonyms*, epithelioma; squamous epithelioma.
   Note.—Chimney-sweeper's cancer is to be returned under squamous carcinoma.
3. Rodent cancer or rodent ulcer.
4. Columnar carcinoma. *Synonyms*, Columnar epithelioma; adenoid cancer.
   (*a*) With colloid degeneration of cells (colloid cancer in part).
   (*b*) Arising in ducts (duct cancer).
5. Thyroid carcinoma (resembling in structure the thyroid gland).

Class V.—Cysts.

1. **Cysts Arising from the Distention of Preexisting Spaces**
   (*a*) *Spaces lined with secreting epithelium (retention cysts).*
      (1) Acinous or glandular cyst of breast, pancreas, and other glands.
      (2) Duct cyst of the breast, pancreas, testicle, and other glands.
      (3) Galactocele.
      (4) Spermatocele.
      (5) Mucous cyst. Ranula. Labial cyst.
      (6) Sebaceous or atheromatous cyst (wen).
      (7) Ovarian cyst from Graafian follicles.
   (*b*) *Spaces lined with flattened endothelium (distention or exudation cysts; lymphatic cysts).*
      (1) Bursal cysts.
      (2) Ganglion.
      (3) Serous cysts.
2. **Cysts in which the Fluid is Contained in a Space of New Formation.**
   (*a*) Blood cyst. Apoplectic cyst in brain.
   (*b*) Degeneration cyst. In brain. In tumors.
3. **Cysts of Congenital Origin.**
   (*a*) Inclusion cyst. Dermoid cyst.
   (*b*) Cysts arising in the remains of fetal structures.
      (1) Unobliterated branchial clefts.
      Deep cysts of neck.
      (2) Unobliterated canal of His.
      Sublingual cysts in part.
      Subhyoid cysts in part.
      Cysts in front of larynx.
      (3) Remains of Wolffian body.
      Encysted hydrocele in male (in part).
      Cysts of the broad ligament in female (in part).
      (4) Partially unobliterated processus vaginalis testis.
      Encysted hydrocele of cord.
      (5) Partially unobliterated canal of Nuck.
      Hydrocele of canal of Nuck.
      (6) Cysts of postanal gut.
4. **Parasitic Cysts.**

TUMORS, TABLE OF

Name.	Histologic Constituents.	Physical Manifestations.	Appearance of Section.	Size.
Adenoma.				
1. *Acinous.*	Acini lined with spheroidal epithelium, with varying amount of connective tissue, as in a normal gland.	1. *Acinous.* Firm, rather hard consistence; inelastic; lobulated; light-gray or slightly yellow color; movable; encapsulated; generally single; rounded; when on mucous surfaces, flat and irregular.	Gray or yellowish-white; of variable density; often intermingled with cysts.	1. *Acinous.* Cherry or walnut; in the breast; large.
2. *Tubular.*	Tubules lined with cylindrical epithelium.	2. *Tubular.* Soft; frequently pedunculated; grayish-white or reddish color; translucent.		2. *Tubular.* Small.
Angioma.				
1. *Telangiectatic.*	1. *Telangiectatic.* Dilated blood-vessels.	1. *Telangiectatic.* Surface often covered with small, granular elevations, resembling a strawberry; often well circumscribed.	Red color; affecting in part the corium; in part the subcutaneous adipose tissue.	Patch on the skin the size of a millet-seed to several inches in extent.
2. *Cavernous.*	2. *Cavernous.* Spaces lined with endothelial cells and filled with blood, like corpora cavernosa of penis.	2. *Cavernous.* Soft, doughy; nonpulsating; leaden or blue color.		2. *Cavernous* Usually small.
Carcinoma.				
1. *Scirrhous* (hard, spheroidal-celled).		1. *Scirrhous.* Hard, irregular, tuberous; adherent to surrounding tissues; ulcerated. Nonencapsulated. *Ulcer.*—Irregular in outline and depth; margins hard, nodular, everted.	1. *Scirrhous.* Firm; white; often traversed by fibrous septa; creaking under the knife; cupped. Scraping exposes a milky fluid, the so-called "*cancer-juice.*"	1. *Scirrhous.* Moderate.
2. *Encephaloid* (soft, spheroidal-celled).	Large epithelial cells containing one or more nuclei, without visible intercellular matrix, grouped into acini (*cancer-nests*). Vessels have walls of norma thickness and constitution, and ramify in the stroma, and not among the cells themselves.	2. *Encephaloid.* Soft, globular, or bossellated; elastic, compressible; fluctuating; nonencapsulated.	2. *Encephaloid.* Resembles brain-tissue.	2. *Encephaloid.* Considerable.
3. *Colloid* (probably a degeneration of one of the preceding varieties).	Three varieties are described histologically: (*a*) squamous, made up of squamous or flat epithelium; (*b*) cylindrical, containing columnar cells; (*c*) glandular, composed largely of polyhedral cells, like those of secreting glands.	3. *Colloid* (usually mucoid). Soft; jelly-like; contains mucoid material; semitranslucent; glistening; at places diffluent.	3. *Colloid.* Amorphous; jelly-like.	3. *Colloid.* Large or small.
Chloroma.	A form of round-celled sarcoma (*which see*).	Small nodules.	Greenish or dirty color on section.	Small.

TUMORS, TABLE OF

Seats of Predilection.	Degeneration to which Subject.	Age.	Growth.	Nature.	Frequency.	Illustrations. (*From Ziegler and Woodhead.*)
1. *Acinous.* Mamma, lip, ovary, testis, prostate, thyroid, parotid, lacrimal gland, sudoriferous and sebaceous glands. 2. *Tubular.* Rectum and other portions of intestines; uterus.	Mucous. Fatty. Colloid. Cystic.	Young adults.	Slow.	Benign; the flat adenoma may become malignant.	Rare.	1. *Telangiectatic.* Skin, mucous membrane, brain, bones, and mamma. 2. *Cavernous.* Liver, kidney, spleen, uterus, bones, muscle. (*Illustrated*).		Usually congenital.	Usually slow.	Benign.	Common.	1. *Scirrhous.* Mamma; alimentary tract (especially the pyloric end of stomach); glands of the skin (rare); rectum, uterus. 2. *Encephaloid.* Testicle; ovary; mucous membranes. 3. *Colloid.* Stomach; intestine; ovary; mamma; thyroid. (*The illustration is of Myxomatous Carcinoma.*)	Horny. Fatty. Cystic. Colloid. Mucoid. Hyaline. Caseous. Pigmentary. Ulcerative. Calcareous (rare).	Adults past 40 years of age.	Slow, but may be rapid.	Malignant. Metastasis takes place by means of the lymphatics, but carcinoma of the stomach and intestines invades the liver by the portal blood-paths.	Common.	  Periosteum of skull.	Fatty.	Young adults.	Rapid.	Malignant.	Rare.	Same as *Round-celled Sarcoma.*

TUMORS, TABLE OF

Name.	Histologic Constituents.	Physical Manifestations.	Appearance of Section.	Size.
Fibroma.	1. *Hard.* White, fibrous tissue, consisting of fibers and few connective-tissue corpuscles; blood-vessels few. 2. *Soft.* Few fibers, many cells.....	1. *Hard.* Ovoidal or spherical; lobulated; nodular or bossellated; pedunculated or sessile; firm, elastic; encapsulated; glistening white, yellowish, or slightly red color; unattached to overlying tissues; single or multiple. 2. *Soft.* Soft, compressible; sessile or pendulous; single or multiple; encapsulated.	1. *Hard.* Smooth, glistening, firm; grayish-white color. 2. *Soft.* Moist, not so glistening; more reddish.	From a grain of shot to fetal head or much larger.
Glioma.....	Round cells, with large nuclei, embedded in a scanty, granular, intercellular substance. After the type of the neuroglia of the brain.	Soft, gelatinous, glue-like tumor; not distinctly outlined; somewhat translucent. Usually single.	Like brain-tissue, but usually a little harder and more reddish in color.	Small, rarely larger than a fist.
Lipoma.....	Adipose tissue (fat-vesicles larger than normal) bound together by delicate connective tissue.	Circumscribed; lobulated, soft, doughy, pseudo-fluctuating, inelastic; attached to the skin—hence dimpled; ovoidal, spherical, or flattened; occasionally pedunculated; usually surrounded by a thin capsule; usually single; when multiple, usually hereditary.	Like adipose tissue...	From size of hickory-nut to very large size.
Lymphangioma..	Aggregation of dilated lymphatic vessels and lymph-spaces supported by connective tissue.	Soft, doughy, transparent sacs or vesicles, filled with lymph; often feels like a series of tangled cords.	.....	From a cherry to fetal head.
Lympho-sarcoma	Hyperplasia of the lymphoid cells of the lymphatic glands.	Glands for a time preserve their shape, but soon extends to neighboring itssues.	.....	Large.
Myoma. 1. *Leiomyoma.*	Smooth, non-striated, muscular fibers, such as occur in the uterus, with varying quantities of fibrous tissue; few blood-vessels. The fibers are composed of spindle-shaped cells containing large, rod-shaped nuclei.	Rounded or pyriform, well-circumscribed; hard; firm; smooth or nodular; white or flesh-colored; encapsulated or non-encapsulated; often multiple.	A striated appearance as in the fibroma.	Often quite large.
2. *Rhabdomyoma.*	Striated muscular fibers, often undeveloped, being spindle-shaped, and associated with sarcomatous tissue.	Large roundish masses or small nodules.	.....	Very large if in kidney; small in heart.

Uterus; periosteum; ovary; labium majus; mamma; testicle; tendons; aponeurosis; neurilemma of nerves; around articulations; subcutaneous tissue; rectum.	Ulceration. Calcification. Myxomatous. Fatty. Telangiectatic.	Chiefly in adults from 35 to 55 yrs. of age.	Slow.....	Benign.....	Very common.	Brain; retina; spinal cord; optic and auditory nerves; suprarenal capsules.	Mucoid. Fatty. Calcareous. Telangiectatic.	Particularly in children.	Slow.....	Benign, except in the eye, where it is usually combined with sarcoma.	Rare	Back of neck; shoulders; back; nates; inside of arm and thigh; submucous and subserous connective-tissue.	Calcareous. Myxomatous. Cystic. Inflammation. Ulceration (rare).	Chiefly during adult life.	Slow.....	Benign.....	Very common.	Posterior and inner surfaces of thigh; genitals; anterior abdominal wall, neck, nates, axillæ, groin, penis, tongue, cheeks, lips, liver, kidney.	.....	Usually congenital.	Slow.....	Benign.....	Rare.	
Neck, groin, axilla, mediastinum, etc.	.....	Young adults.	Rapid....	Very malignant.	Rare.	Uterus, esophagus, intestine, prostate, stomach.	Calcareous. Fatty. Myxomatous. Cavernous.	Mature or advanced life.	Slow.....	Benign.....	Very common.	
Kidney, ovary, testicle; tongue, heart.	.....	Congenital.	Rapid....	Malignant in the segmental organs and kidney, ovary, testicle when combined with sarcoma.	Rare.	

TUMORS, TABLE OF

Name.	Histologic Constituents.	Physical Manifestations.	Appearance of Section.	Size.
Myxoma.....	Delicate network of stellate cells enclosing a mucoid intercellular substance. *Type*—Wharton's jelly; vitreous humor.	Round or lobular; soft, gelatinous; semi-translucent; encapsulated; elastic; may be fluctuating.	Pinkish or yellowish-gray, exuding a glairy fluid, or a trembling, gelatinous mass.	Usually small.
Neuroma.....	Medullated or non-medullated nerve-fibers. Very rarely may contain ganglionic cells; usually combined with fibrous tissues.	Spheric, ovoid, oblong, or bulbous, sometimes plexiform; firm; painful on pressure; few or many (even hundreds).	Often resembles fibroma.	Small.
Osteoma.....	Osseous tissue (cancellous or compact bone).	Hard; often lobulated; sometimes spheric; may be spinous or spiculated; pedunculated or sessile; usually single; may be multiple and symmetric.	Like bone-tissue.....	Variable; grain of coffee to cocoanut.
Papilloma.....	Hypertrophied papillæ of the skin; varying amount of connective tissue surrounding two or more central blood-vessels, and covered by several layers of epithelial cells.	Circumscribed; hard (on the skin); soft (on mucous membrane); surface smooth, brush-like, or cauliflower-like; single or multiple.	.....	Usually small; may be large.
Psammoma.....	A form of sarcoma (*nest-celled*). Connective tissue composed of flat, elongated cells of great size and in which are embedded gritty concretions that are composed of calcium carbonate.	Hard, circumscribed; light color.	White; gritty on section.	Small.
Sarcoma.				
1. *Round-celled*..	Embryonic or immature connective tissue. Blood-vessels without walls, or thin-walled, ramifying among the cells. Small or large round cells, embedded in a small amount of granular or homogeneous intercellular substance.	Soft; vascular; whitish; somewhat translucent; on pressure after some hours exudes a milky fluid; round or ovoid, or oblong.	Resembles brain-matter; of a yellow, gray, or brick-dust hue.	Often very large.
2. *Spindle-celled.*	Cells varying much in size, spindle-shaped, with long, fine tapering extremities, separated by very little intercellular substance. Often have a fibrous appearance (Recurrent Fibroid).	Firm; reddish; does not exude milky fluid. Shape as foregoing.	Fibrous or flesh-like aspect; pinkish color.	May be large.

TUMORS, TABLE OF

Seat of Predilection.	Degeneration to which Subject.	Age.	Growth.	Nature.	Frequency.	Illustrations. (*From Ziegler and Woodhead.*)
Nasal cavities; mamma; intermuscular spaces; submucous and sub-serous tissues; back; thighs; lip; cheek; labia; clitoris; prepuce; scrotum; axillæ; parotid; ear; more rarely periosteum, bone, heart, and nerve-sheaths.	Fatty Ulceration. Telangiectatic.	Any age; may be congenital.	Slow.....	Benign.....	Common.	Cut ends of nerves; as in stumps of amputation, on skin.			Slow.	Benign.	Somewhat rare.	
Cranial bones, maxilla, orbit; ends of phalanges; juxta-epiphyseal portions of long bones (tibia, femur, humerus, etc.); dura mater; muscle; aponeurosis; lungs.		Congenital or early life.	Slow.	Benign.	Not common.	
Skin of hands and genitalia; larynx; bladder; rectum; nose.		At all ages.	Slow or rapid.	Benign.	Common.	Membranes of brain, choroid plexus; pineal gland; spinal cord; nerves.	Calcareous.	Early life.	Rapid.	Malignant.	Rare.	
Periosteum; bone; lymphatic glands; subcutaneous tissue; testicle; eye; ovary; lungs; kidneys; intermuscular septa.	Mucoid. Fatty. Ulceration. Calcareous. Ossification. Telangiectatic. Cystic.	Youth, or before 35th year.	Very rapid.	Malignant. Early metastasis. Dissemination by the blood-vessels and not by the lymphatics.	Common.	Subcutaneous tissue; fasciæ and intermuscular septa; periosteum; interior of bones; eye; antrum; breast; testicle.	As foregoing.	As foregoing.	Rapid.	Malignant by recurrence.	Common.	
TUMORS, TABLE OF

Name.	Histologic Constituents.	Physical Manifestations.	Appearance of Section.	Size.
Sarcoma (*Contd.*)				
3. *Giant-celled (Myeloid.)*	Masses of protoplasm containing two or more nuclei—up to 20 or 50—with a varying amount of round and spindle cells.	Jelly-like consistence or firm, like muscle. Shape as foregoing.	Smooth, shining, succulent; no appearance of fibrillation; greenish or livid red or maroon color, varied by pink or darker red spots, due to extravasation of blood.	Large.
4. *Alveolar.*	Alveolar space filled with sarcoma cells; the trabeculæ composed of spindle-cells.	Very vascular; soft.		Small or large.
5. *Melanotic.*	Sarcomata of various kinds in which brownish or black pigment becomes deposited as amorphous granules in the cells as well as the connective tissue and blood-vessel walls of the tumor.	Rounded, nodular, dark colored tumors of varying size and consistency, usually hard.	Brownish or black.	May be large.
Dermoid Cyst...	Cyst wall contains hair-follicles and sebaceous glands. *Contents.*—Disintegrating epithelial cells, hair, sebaceous matter, teeth, etc.	Globular; tense; smooth; freely movable.		May be large.

TUMORS, ETIOLOGY.—It is not improbable that different tumors arise as a result of the action of various causes. As, however, we know very little concerning the exact etiology of any particular tumor, certain general considerations are permissible. The older theories, attributing the occurrence of tumors to alterations in the humors of the body, particularly of the blood, and similar hypotheses, may be at once discarded. The following hypotheses are deserving of consideration:

1. *The Durante-Cohnheim Inclusion Theory.*—This theory is based upon the supposition that, during embryonic development and the specialization of the cells entering into the formation of organs and adult tissues, more embryonic elements are produced than are necessary, and that these cellular elements become quiescent in the tissues, where they may remain, constituting embryonic "rests" or "remnants," from which, later, tumor formation takes place. Such embryonic rests or remnants would be exceedingly likely to occur where developmental processes are complex, as, for example, where different forms of epithelium join. Such points of tumor election undoubtedly occur, as is shown by the development of cancer at the various orifices of the body and at points of epithelial transition, such as the lip, cervix uteri, etc. This theory also explains to advantage the occurrence of chondroid tumors in or from bone, and of melanotic sarcomata from quiescent pigmented cells in moles, and affords a most acceptable explanation for the development of dermoid cysts. The theory, however, is wanting in several ways. In the first place, admitting the occurrence of these remnants, it would appear that a further etiologic factor is necessary in order to stimulate them to renewed activity. Another objection is afforded by the fact that many localities in which complex developmental processes occur, such as the heart and the nervous system, are singularly free from tumors, and that when they do occur in such tissue, they are not commonly situated at points at which the complexity of development is most marked. Epithelial rests are sometimes demonstrable, and yet no tumor formation occurs. The occurrence of tumors as

TUMORS, TABLE OF

Seat of Predilection.	Degeneration to which Subject.	Age.	Growth.	Nature.	Frequency.	Illustrations. (*From Ziegler and Woodhead.*)
Lower and upper jaw; lower end of femur; head of tibia.		Usually in adults over 40.	Slow.	Comparatively benign. Metastasis rare.	Rarer than the preceding forms.	
Skin; eye; bone; lymphatic glands, pia mater of brain. Often springs from warts.		In the young.	Rapid.	Malignant.	Rare.	Where pigment occurs normally; the eye and the skin, the pia; secondarily, especially in the liver.	As other sarcomata.	As other sarcomata.	Usually rapid.	Very malignant.	Common.	Outer angle of orbit; over root of nose; ovary; testicle.		Congenital.	Slow.	Benign.	Common.	

the result of trauma (to be considered later) is inconsistent with this theory.

2. *Injury and inflammation* appear to be, in a certain percentage of tumors, important etiologic factors. Persistent or long-continued irritation seems to favor the development of tumors belonging to the epithelial group. As examples of such tumors the following may be mentioned: Carcinoma of the scrotum in chimney-sweeps; epithelioma of the arm in workers with paraffin and tar; smoker's cancer of the lip or tongue and cancer of the tongue apparently due to injury by a carious tooth; and epithelioma originating in the margins of chronic ulcerative processes. Among the nonmalignant epithelial tumors the development of which appears to be favored by injury or irritation may be cited the papillomatous masses due to the accumulations of irritating discharges, particularly around the anus and external genital organs, when the parts are not kept properly cleansed. Sarcoma following fracture or injury of bone, and fibroneuromata of the severed ends of nerves after amputation, may be mentioned as connective-tissue tumors offering strong support to this theory. The occurrence of tumors at points particularly liable to injury is another argument in its favor.

Numerous objections have been made to the acceptance of this theory. In about 85 percent of all tumors no history of injury can be obtained. On the other hand, the frequency with which injuries are received is out of all proportion to the total number of tumors occurring. Parts particularly subject to injury, such as the hands and feet are not commonly affected, and the nipple, which is frequently injured, is rarely the seat of a tumor.

3. *Parasitic Influence.*—The germ theory has been invoked to explain the formation of tumors, particularly the malignant neoplasms, in which metastases are conspicuous. By some the essential parasitic body is believed to be an animal parasite belonging to the protozoa and resembling, if not identical with the coccidia. Others believe that the infecting body is a vegetable organism belonging to the blastomycetes. In further sup

port of the parasitic origin of tumors the demonstrable autoinoculability of cancer is adduced. Thus, it has been shown that cancer of one labium may attack the point of contact upon the opposite labium; cancer of the cervix may attack the contiguous vaginal vault; and cancer reaching the peritoneal surface may show a similar inoculability.

4. *Parasitism of Cells.*—It is not impossible that normal cellular elements may take on a certain parasite-like property that, in the presence of reduced resistance afforded by other elements, permits of their extension beyond normal limits. Thus, in cancer cellular elements that we believe to be of epithelial origin are found abundantly infiltrating connective tissues. Normally, epithelium does not so extend, nor, in most instances, even when introduced experimentally, does it acquire any such property. Should further experiment show that conditions may arise under which epithelium can acquire or manifest the faculty of intraconnective-tissue growth, without the intervention of any other factor, we may assume that the manifestation of this parasite-like character leads to the development of cancer.

5. Adami presents a most fascinating argument in favor of his view that whatever may be the origin of tumors, the most important element in their production is the fact that the cells forming the neoplasm give up the habit of function and acquire the *habit of growth.* Reproduction is of course an essential function in all cells, but in addition to proliferative power every cell is endowed with the inherent capacity to perform some specific duty, in the consummation of which it utilizes more or less of the energy that it is able to transform from the nutrition supplied. If the cell ceases to perform this specific function, whatever that duty may be, the energy previously converted in that direction is now transferred to the reproductive capacity of the cells, thereby leading to proliferation in excess of the normal. The originator of this suggestive hypothesis fully recognizes the necessity for some reason accounting for the cell's acquisition of the habit of growth at the expense of the habit of function. The fact that malignant neoplasms of epithelial origin, and particularly those arising from the mammary gland and uterus, appear at a time when function is on the decline, is fully in support of Adami's view. He further maintains that irritation, parasitic or otherwise, may so modify the cell that proliferation becomes excessive and secretion or other specific function proportionately diminishes.

6. *Predisposing Causes.*—The foregoing brief consideration of the most plausible reasons advanced to explain neoplastic growths indicates our ignorance of the essential etiologic factor in tumor formation. There are, however, certain predisposing elements worthy of consideration. Some of the conditions previously considered may be active only in this way. Trauma and inflammation may predispose to tumor formation, just as they predispose to infection, and long-continued irritation or prolonged ulceration may act only as predisposing elements. With regard to age, it may be said, in a general way, that physiologic activity favors the development of sarcoma, while senescence, or physiologic decline, predisposes to the occurrence of cancer (Da Costa). The influence of inheritance cannot be entirely ignored, although it is probably slight (Coplin).

TUMORS, TREATMENT.—See special articles, Bones, Breast, Carcinoma, Epithelioma, Sarcoma, Stomach, Uterus, etc.

TURPENTINE (Terebinthina).—A turpentine means a vegetable exudation, liquid or concrete, consisting of resin combined with a peculiar essential oil named *oil of turpentine*, $C_{10}H_{16}$, and generally procured from various species of the natural order Pinaceæ. Of the many turpentines two only are official, viz.—

Terebinthina, *Turpentine*—a concrete oleoresin from *Pinus palustris*, the yellow pine, and other species of *Pinus*. It occurs in tough, yellowish masses, brittle when cold, crummy-crystalline interiorly, of terebinthinate odor and taste. Dose, 5 to 30 grains as a stimulant, antispasmodic or diuretic; 2 to 4 drams as an anthelmintic.

Terebinthina Canadensis, *Canada turpentine* (*balsam of fir*)—a liquid oleoresin obtained from *Abies balsamea*, the silver fir or balm of Gilead. A yellowish, transparent, viscid liquid, of agreeable, terebinthinate odor and a bitterish and slightly acrid taste, slowly drying on exposure, forming a transparent mass; completely soluble in ether, chloroform or benzol. Dose, 10 to 30 grains.

Turpentines are stimulant, diuretic, anthelmintic, and hemostatic; in large doses laxative and irritant, and externally used are rubefacient and antiseptic. Their virtues depend entirely on the volatile oil.

Oil of turpentine is employed externally as a rubefacient and counterirritant in many conditions producing pain and inflammation. Cloths wrung out of hot water and then sprinkled with the oil (turpentine stupes) are useful applications in sciatica and other neuralgias, lumbago, chronic rheumatism, chronic bronchitis, peritonitis with tympanites, pleurisy, and renal colic. It is one of the most efficient agents in hospital gangrene, applied in full strength to the part affected. The liniment is in constant use for sprains, neuralgia, and other slight local affections.

Internally it is best employed in ulceration and hemorrhage of the intestines and in passive hemorrhages from other organs. Active bleeding with a plethoric condition and hematuria are states in which it is contraindicated. It is often used with ether (1 to 3) in biliary and flatulent colic as an anodyne and antispasmodic.

Preparations.—**Oleum Terebinthinæ,** $C_{10}H_{16}$, commonly called Spirit or Spirits of Turpentine, is a volatile oil distilled from turpentine. A thin, colorless liquid of characteristic odor and taste; soluble in 3 times its volume of alcohol, mixes with other volatile and fixed oils, and dissolves resins, wax, sulphur, phosphorus and iodin. It is a mixture of several hydrocarbons (*terpenes*), each having the same formula as itself. **Oleum Terebinthinæ Rectificatum,** prepared by shaking oil of turpentine with an equal volume of solution of sodium hydroxid, distilling three-fourths, and

separating. This preparation should always be dispensed when oil of turpentine is required for internal use. Dose, as a stimulant or diuretic, 5 to 25 minims, in emulsion 3 to 6 times daily; as a cathartic or anthelmintic 4 drams or more, combined with other cathartics. A little glycerin and oil of gaultheria will disguise the taste. **Emulsum Olei Terebinthinæ** has of the rectified oil 15, expressed oil of almond 5, syrup 25, acacia 15, water to 100. Dose, 1/2 to 2 drams. **Linimentum Terebinthinæ**, *Turpentine Liniment*, has 35 parts of the oil of turpentine with 65 of resin cerate.

TUSSOL.—Mandelate of antipyrin. Tussol combines the antipyretic, analgesic and sedative action of antipyrin with the stimulant action of mandelic acid on glandular secretions. It is recommended in whooping cough. Dose, 1/2 to 8 grains according to the age of the patient.

TWILIGHT SLEEP.—The German word Dämmerschlaf (of which "Twilight Sleep "is the equivalent) is the term used by Krönig and Gauss of Freiburg, to designate a condition of partial analgesia with subsequent amnesia of events occurring while in this state. The agents employed are scopolamine, and morphin or narcophin (a mixture of morphin and narcotin meconates). The condition is employed for obstetric cases, and it has also been used in surgical operations.

Technic.—All outside stimuli must be minimized; with this end in view the room is darkened, the patient's ears are stopped with cotton, and the eyes are lightly bandaged. The drug is withheld until labor is well under way. The patient is then put to bed, and about 1/130 grain scopolamine hydrobromid is injected, with 1/6 grain morphin or 1/2 grain narcophin. In one hour 1/450 grain scopolamine hydrobromid is again injected. Thirty minutes later memory tests are made; for instance, the patient is asked if she has received any hypodermatic injections, and how many; some object may be brought to her attention, then after an interval she is asked whether she has seen it before. Injections of scopolamine hydrobromid, 1/450 grain, are repeated at intervals of 1 1/2 hours or longer depending upon the degree of amnesia present. The object is, primarily, *not to abolish pain but to abolish the memory of pain.* Water must be given freely.

The fetal heart beat must be carefully watched, and in case of weakening, delivery must be hastened by forceps. Chloroform is used as a re-enforcement just as the head is born.

Contraindications.—The following are generally agreed upon as contraindicating the use of Twilight Sleep:

1. Primary uterine inertia.
2. History of previous short and easy labors.
3. Hemorrhage in connection with labor or the puerperium.
4. Weak fetal heart beat.
5. Eclampsia.
6. Pelvic contraction.

Disadvantages.—The second stage of labor is prolonged and the use of forceps or the administration of pituitrin may be required. The children more frequently exhibit delayed respiration and marked cyanosis. Mental excitement and restlessness are present in some cases, necessitating restraint and rendering it difficult to maintain asepsis Cases of prolonged drug psychosis due to the scopolamine, have been reported.

Requisites.—A stable solution of scopolamine hydrobromid, prepared with mannite, or a fresh solution of a reliable tablet must be used. The patient must be in a hospital, or under the constant attendance of the obstetrician and a qualified nurse. Additional attendants may be required to restrain the patient. All preparations should be made for rapid delivery in case of need.

To an impartial observer, over a year after its sensational re-introduction to American practice (for hyoscin morphin was essentially the same in principle), it would seem that many of its erstwhile advocates are now limiting its use to patients who persist in demanding it after its dangers and disadvantages have been candidly explained. It is even stated that in fairness we must not promise the patient a painless labor. The fact is better realized that narcosis and analgesia are inconstant and incidental results of the treatment; in a successful case the patient may complain bitterly of pain, during the labor, but after the birth she will deny having ever experienced it. In 10 to 15 percent of cases the method is an admitted failure.

TWIN BIRTHS.—See Labor, Pregnancy (Multiple).

TWITCHING.—See Blepharospasm, Chorea, Tremor.

TYMPANIC INFLATION.—See Ear (Examination).

TYMPANITES.—The symptom which is popularly known as "drum belly," a distention of the abdominal walls caused by paralysis of the muscular coat of the intestines and their inflation with gas. In slight degree tympanites accompanies all forms of chronic gastric and intestinal disturbance. It is due partly to the formation of gas and partly to the paralytic condition of the intestinal walls. In acute intestinal obstruction and in intussusception tympanites is not marked. Indeed, in the latter disorder there may be marked depression and sinking instead of distention due to flatus. In peritonitis tympanites may be the occasion not only of discomfort, but also of danger to life. In intestinal tuberculosis tympanites is due to loss of tone of the muscular walls of the gut; and it may also occur in long-standing cases in which adhesions have taken place between the visceral and parietal layers. In typhoid fever tympanites of moderate grade is a frequent but not a serious symptom, but it is of grave import when excessive. The walls of the gut become infiltrated with serum, and gas accumulates in the small and large intestines, particularly in the latter. When extreme, the diaphragm is compressed and the action of the heart and lungs is very much interfered with. Tympanites undoubtedly favors perforation.

Treatment must be directed to the cause. When due to obstruction by cancer, operation

being contraindicated, the aspirating needle may be plunged through the abdominal wall. This procedure is not altogether free from danger, and, as a rule, affords little relief. The long tube introduced high up into the rectum is almost useless. It may be necessary to make an opening in the middle line of the abdomen and to secure the first coil of distended intestine and open it, leaving it *in situ* in the abdominal wall. Of drugs, asafetida is used as a carminative, affecting chiefly the lower bowel. In the intestinal indigestion of the aged, when associated with flatulence, and in the flatulent colic of children, asafetida is efficient. By rectal injection this drug is of much value in the tympanites of children and in that of adults in typhoid fever. The following pill is useful for flatulence in the aged:

℞. Extract of nux vomica, gr. v
Extract of physostigma, gr. iij
Asafetida, gr. xl.
Divide into 20 pills. Give 1 pill night and morning.

For speedy results in nonchronic cases, 30 minims of the aromatic spirit of ammonia may be tried, or brandy may be given. Hoffmann's anodyne, in combination with the compound tincture of cardamom, is often effective. Turpentine, creosote (alone or combined with galbanum), musk, ammonia, alcohol, charcoal, ginger, capsicum, cajuput, and peppermint may be administered.

TYMPANUM.—See Ear (Diseases).

TYPHLITIS.—A catarrhal inflammation of the mucous membrane of the cecum and ascending colon; it is characterized by pain, tenderness, constipation, and in certain cases by a characteristic vomiting. In the majority of cases it is due to the accumulation of feces in the cecum.

Symptoms.—Pain and tenderness in the right iliac fossa and along the ascending colon, with some prominence of this region; the bowels are distended with gas (meteorism) and are usually constipated, or small liquid stools may occur from time to time, due to the accumulation of hardened feces in the sacculated periphery of the cecum, leaving a central canal, through which the liquid contents of the upper bowel can pass. In severe cases the local pain, tenderness and swelling are greater and there is impaction of feces. There are decided fever, restlessness, and also nausea and vomiting. The vomited matters consist at first of the contents of the stomach, then of the duodenum, with bilious matter, and, ultimately, if the impaction persists, of material having the odor of feces. With these symptoms occurs great depression of the vital powers. Peritonitis is finally developed by contiguity of tissue or by rupture of the bowel.

The temperature, even in mild cases, is one or two degrees above the normal, and in some cases an eruption is seen upon the abdomen, consisting of one or two dark red spots the size of a pinhead, which are of short life and disappear on pressure.

The mild form lasts about one week. The severe form may terminate in subacute peritonitis, continuing about two weeks.

Diagnosis.—The mild form is distinguished from other intestinal affections by the localized pain, by tenderness and prominence, and by the constipation.

The severe form can only be distinguished from the other forms of intestinal obstruction by the history of the case and of the attack, and by the results of treatment.

The prognosis in the mild form is favorable. In the severe form it is grave, although not necessarily hopeless.

Treatment.—The patient should be kept in bed, and receive a strictly milk diet in very limited amounts for a few days. If the pain and suffering are intense, a hypodermic injection of morphin should be immediately administered.

For the removal of the impacted feces, which in the majority of cases is the cause of the inflammation, use the following:

℞. Magnesium sulphate, ℥ xij
Dilute sulphuric acid, ℥ ij
Tincture of opium, ℥ iv to vj
Spirit of chloroform, ℥ ij
Peppermint water, enough to make ℥ iij.
One teaspoonful every hour, diluted.

The following should be useful in some cases:

℞. Calomel, gr. ij
Sodium bicarbonate, gr. xxiv
Sugar of milk, ℥ ss.
Make 12 powders. Give 1 every hour until 12 have been taken, followed by 4 ounces of hot Hunyadi János water.

In severe cases opium is to be immediately given, by hypodermic injections of morphin guarded with atropin, continued until all symptoms of inflammation have subsided, when attempts to remove the accumulated feces may be made by irrigation of the bowel with warm soapsuds and by the cautious administration of magnesium sulphate in dram doses every 2 hours. Locally, hot dry applications or the ice-bag may be used. See Appendicitis.

TYPHOID FEVER (Enteric Fever). Definition.—A general infection, caused by the bacillus typhosus, characterized anatomically by hyperplasia and ulceration of the lymph follicles of the intestines, swelling of the mesenteric glands and spleen, and parenchymatous changes in the other organs.

Period of Incubation.—From 8 to 23 days.

Etiology.—The disease is widely distributed throughout the world, and especially prevails in temperate climates. Contaminated water, milk or food such as oysters bedded near sewer exits, or green vegetables fertilized by means of sewage or washed with infected water, and defective drainage are the most important factors in the etiology. It is most prevalent in the autumn months. Young adults are most prone to be attacked. Males and females are equally affected. Idiosyncrasy plays a rôle in some families. The

typhoid "carrier" is an important factor in the dissemination of the disease.

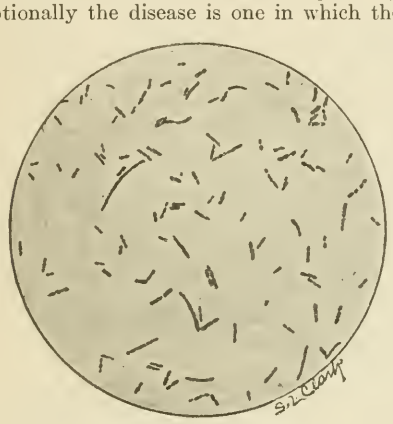
Description of Bacillus Typhosus.—A rather short, thick, flagellated, motile bacillus with rounded ends; it grows readily on nutritive media, and can be distinguished from the colon bacillus, which it closely resembles. It stains well with the ordinary anilin dyes. To stain for bacilli in tissues, allow the specimen to remain in Loeffler's alkaline methylene-blue solution for from 15 minutes to 24 hours, wash in water, dehydrate rapidly in alcohol, clear up in xylol, and mount in Canada balsam.

The Bacilli Outside the Body.—In drinking-water they retain their vitality for weeks, and in the soils for months. They are not destroyed by freezing.

Modes of Conveyance.—By "food, fingers, and flies" mainly.

Modes of Infection.—While infection usually takes place through the intestines, the researches of Chiari, Kraus, Hodenpyl, Flexner, and others, show that even in the early stages the bacilli are widely distributed throughout the system.

In the immense majority of cases of typhoid fever marked enteric lesions are present, but exceptionally the disease is one in which there is



Bacillus Typhosus.
Pure culture containing a few irregular forms.—(*Coplin.*)

a general infection, without special local manifestations; or the localizations may be other than enteric; or there may be a mixed infection of the typhoid bacillus with the colon bacillus, streptococcus, staphylococcus, pneumococcus, or bacillus of tuberculosis. In the tropics, more rarely in temperate regions, typhoid fever occurs in persons already affected with malaria.

Morbid Anatomy. Intestines. *Hyperplasia.*—The glands of Peyer in the jejunm and ileum, and to a variable extent those in the large intestine, are swollen, grayish-white in color, and may project to a distance of from 3 to 5 mm. This condition may disappear by a fatty and granular change in the cells, which are destroyed and subsequently absorbed, or it may pass on to—

Necrosis and Sloughing.—When the hyperplasia of the lymph follicles reaches a certain stage, resolution is no longer possible. The blood-vessels become choked, there is a condition of anemic necrosis, and sloughs form, which are subsequently thrown off. The process has a predilection for the area nearest the ileocecal valve.

Ulceration.—The separation of the necrotic tissue—the sloughing—is gradually effected from the edges inward, and results in the formation of an ovoid ulcer, the floor of which is formed by the submucosa and muscularis. The edges are usually swollen, soft, sometimes congested, and often undermined. These ulcers of the intestine are characteristic, and can be *differentiated from tubercular ulcers* in the same situation, as follows: In the **typhoid ulcer** (1) the main axis of the ulcer lies parallel with that of the intestine; (2) it lies opposite to the mesenteric attachment; (3) it has smooth floor and undermined edges; (4) it commonly leads to perforation. In **tubercular ulcer** (1) the long axis of the ulcer lies at right angles to that of the intestine; (2) it is not necessarily situated opposite the mesenteric attachment; (3) its floor is not smooth nor are its edges undermined, but rather funnel-shaped and irregular; (4) it is not apt to perforate, but it does not tend to heal, rather to spread.

Healing begins by the formation of granulation tissue at the base of the ulcer. The mucosa extends from the edge, and a new growth of epithelium is formed. Later the glandular elements are restored.

Perforation of the Bowel.—In 2000 autopsies performed in Munich perforation occurred in 114 instances, or 5.7 percent. In 80 autopsies performed at the Montreal General Hospital perforation was present in 22 cases. Perforation generally occurs within the last foot of the ileum. Multiple perforations may be present.

The mesenteric glands are greatly swollen; and spots of necrosis or suppuration may occur.

The spleen is invariably enlarged in the early stages of the disease, and rupture may occur spontaneously or as the result of trauma.

The liver shows signs of parenchymatous degeneration. Early in the disease it is hyperemic, and in a majority of instances is slightly swollen, Microscopically, the cells are very granular and are loaded with fat.

The gall-bladder not infrequently contains a pure culture of the bacilli, and acute cholecystitis is not very uncommon.

The kidneys show a degree of cloudy. swelling, with granular degeneration of the cells of the convoluted tubules.

Ulceration of the **larynx** has been noted in a considerable number of cases.

Changes in the Circulatory System.—Endocarditis is rare, as is also pericarditis. Myocarditis is more frequent. *Inflammation of the arteries*, with formation of thrombi, may take place, and bacilli have been found in them. Thrombosis of the femoral vein is common; most frequently on the left side.

Disposition of Bacilli in the System.—Typhoid bacilli have been found in the blood, in the spleen, in the liver, in the vegetations on the valve leaflets, in thrombi, and in the exudation from the men-

inges. They are always present in the affected areas of the bowel.

Symptoms. First Week.—The onset is rarely abrupt. Prodromal symptoms are generally present over a period of several days, and are manifested by a feeling of restlessness, vague pains, faint rigors, nausea, loss of appetite, pains in the head, back, and limbs, and nose-bleeding. The bowels may be constipated or diarrhea may be present; most frequently the latter.

There is a steady rise of temperature to 103° or 104° F. The pulse is rapid (100 to 110), full in volume, of low tension, and dicrotic. At this time there may be mental confusion, particularly at night. Toward the end of the first week the spleen becomes enlarged and a rash appears in the form of discrete, rose-colored spots, slightly elevated, and first seen on the abdomen. They disappear on slight pressure. The spots may also be found on the chest and back, and occasionally on the limbs and face.

Second Week.—The fever becomes higher or remains steady, the pulse is rapid and loses its dicrotic character, the face has a dull appearance, mental activity is slow, and the lips and tongue may get dry. The abdominal symptoms, if present, are diarrhea, tympanites, and tenderness. Hemorrhage or perforation may occur. In mild cases there is a gradual decline of the fever to the normal after the fourteenth day.

Third Week.—The temperature shows marked morning remissions, with a gradual decline. The pulse ranges from 110 to 130. Diarrhea and meteorism may now occur for the first time, and there is a special liability to hemorrhage and perforation.

Fourth Week.—The morning temperature has usually reached normal, but there is an evening exacerbation of one or more degrees, the diarrhea stops, the tongue becomes clean, and there is a craving for food.

The fourth week generally marks the beginning of convalescence. In aggravated cases the disease may continue over a period of 5, 6, or even 8 weeks.

The Fever.—In the stage of the invasion the fever steadily rises during the first 5 or 6 days. The evening temperature is about 1 degree or 1 1/2 degrees higher than the morning record. In certain instances there may be a difference of 3 or even 4 degrees. The temperature falls by lysis, and is not considered normal until the evening record is at 98.2° F.

A fever with regular remissions is considered of favorable prognosis. A sudden drop in the temperature may mark the occurrence of hemorrhage or of perforation of the bowel.

Post-typhoid Elevations. *The Fever of Convalescence.*—Frequently, after the temperature has remained normal for several days there is a sudden rise (102° to 103° F.), and a drop at the end of 24 or 48 hours. It is generally dependent upon errors in diet, constipation, or excitement brought on by visits of friends. It may, however, inaugurate a relapse, or mark the onset of a complication. *The fever of relapse* partakes of the same nature as in the original attack, but is milder, and rarely continues longer than 10 days or 2 weeks.

The Skin.—The characteristic eruption of typhoid fever has been described. Sometimes there may be areas of erythema, confined to the abdomen or chest. Sudamina are very common, and result from profuse sweating. The facial expression is dull and listless, but differs from that of malarial fever, as the anemia is not so marked.

The pupils are usually dilated.

Respiratory Symptoms.—Respirations are somewhat hurried, and frequently bronchial râles are heard. There may be an early acute bronchitis.

Circulatory Symptoms.—Dicrotic pulse (in first week), of low tension; heart-sounds at first clear and loud, but later the first sound becomes feeble, and along the left sternal margin or at the apex a soft systolic murmur may be heard.

Gastric Symptoms.—Loss of appetite is an early symptom; rarely nausea and vomiting occur. The edges of the tongue may be reddened, while the center is coated.

Intestinal Symptoms.—Diarrhea is present in from 25 to 30 percent of the cases. It is a mistake to believe that it is an invariable symptom in typhoid. Abdominal tenderness and distention and gurgling in the right iliac fossa occur in a large proportion of cases. Diarrhea is most common toward the end of the first week, but it may not occur until the second or even the third week. The stools, which range from 3 to 10 within the 24 hours, are thin, offensive, granular, and resemble pea soup. On standing they separate into a thin, serous layer, containing albumin and salts, and a lower stratum, consisting of epithelial debris, particles of undigested food, and triple phosphates. Blood-corpuscles may be found.

Nervous Symptoms.—Headache, slight deafness, and mental torpor may be present in the early stages; and later, in severe cases, profound stupor, muttering delirium, subsultus tendinum, and coma-vigil.

The blood presents no material changes until about the third week. At this time there is a reduction in the number of red corpuscles, which may fall as low as 1,300,000 to the cubic millimeter (Thayer), together with the hemoglobin, which is reduced in a greater relative proportion than the red cells. The absence of leukocytosis may aid in differentiating typhoid from septic and acute inflammatory processes.

The Urine.—Retention of urine is an early symptom in many cases. In the early stages, as in other febrile conditions, the quantity is reduced and of a higher color; later it becomes more abundant and possesses a lighter tint. Ehrlich has described a reaction that he believes is rarely met with except in typhoid fever. This so-called **diazo-reaction** is produced as follows: Two solutions are employed, kept in separate bottles, one containing a saturated solution of sulphanilic acid in a solution of hydrochloric acid (50 c.c. to 1000); the other a 0.5 percent solution of sodium nitrite. To make the test, a few cubic centimeters of urine are placed in a small test-tube with an equal quantity of a mixture of the solution of sulphanilic

acid (40 c.c.) and the sodium nitrite (1 c.c.), the whole being thoroughly shaken. One cubic centimeter of ammonia is then allowed to flow carefully down the side of the tube, forming a colorless zone above the yellow urine, and at the junction of the two a deep brownish-red ring will be seen if the reaction is present. With normal urine a lighter ring is produced, without a shade of red. It is very important to bear in mind that countless millions of bacilli may be present in the urine, which should always be disinfected.

Russo's Test.—This is also used as an aid in the diagnosis of typhoid fever, and it is said to be of more value than Ehrlich's diazoreaction. A few drops of methylene blue (1 : 1000) are added to the urine on the second day of the fever, an emerald-green tint results in the presence of typhoid; normal urine gives a light green or bluish-green color. The same reaction occurs in small-pox and measles, but it is absent in miliary tuberculosis.

Convalescence ordinarily begins at the fourth week. In certain cases it may be protracted, and may be marked by falling of the hair, great enfeeblement of the system, and transitory mental derangement.

Varieties of Typhoid Fever. 1. Mild and Abortive Forms.—In the mild form the symptoms are similar in kind, but less intense, than in the graver attacks, although the onset may be sudden and severe. The spleen is enlarged, and rose spots are marked. Diarrhea may or may not be present. The duration is about 8 to 10 days.

In the abortive form the symptoms of onset may be marked, with shivering and fever of 103° F., or higher. The date of onset is definite. Rose spots may develop from the second to the fifth day. At the end of the first week or the beginning of the second week convalescence is established.

2. **The grave form** is usually characterized by high fever and pronounced symptoms affecting the nervous system, the gastrointestinal tract, and the renal or pulmonary organs.

3. **Latent or Ambulatory Form.**—In this variety the onset is very mild, and the patient does not feel ill enough to go to bed. It is marked by languor and perhaps slight diarrhea. In certain cases delirium may be present. Death is common from neglect of treatment.

4. **Hemorrhagic Form.**

5. **A febrile form** recognized by Liebermeister is very rare.

Typhoid Fever in Children.—Infants under the age of 2 years are rarely attacked; cases are not infrequent in children between the second and tenth years. Epistaxis rarely occurs; the rise in temperature is gradual; bronchial catarrh is often observed; nervous symptoms are prominent, and are manifested by wakefulness and delirium; diarrhea is often absent; the eruption is slight; the abdominal symptoms are mild; and perforation rarely occurs.

Typhoid Fever in the Aged.—After the age of 40 the disease is very rare.

Typhoid fever is rare in **pregnant women.** Abortion or premature delivery usually occurs in the second week of the disease. The mortality is high (17 percent).

A condition known as the **Typhoid State** frequently occurs in the latter half of the second week. It is characterized by delirium, carphologia, coma or drowsiness, a tendency to slip to the foot of the bed, muscular weakness, subsultus tendinum, soft and rapid pulse, dry and furred tongue, and sordes in the teeth and lips. This condition is not peculiar to typhoid fever, but is found in all malignant types of fever such as small-pox, pneumonia, and typhus.

Relapse is prone to occur. The true relapse sets in after complete defervescence of the fever and follows a somewhat milder course than the original type, and lasts from 2 to 3 weeks. Two, 3, or even 4 relapses may occur. The condition depends upon a reinfection, probably due to errors in diet, to constipation, or to overexertion of any kind.

Complications.—Hemorrhage from the bowels, a serious complication, occurs in from 3 to 5 percent of all cases, most commonly between the end of the second and the beginning of the fourth week—at the time the sloughs separate. The onset is often marked by a rapid fall in the temperature and by symptoms of collapse, both of which may occur some time before the blood makes its appearance in the stool. The mortality is from 30 to 50 percent of the cases.

Perforation occurs in from 5 to 6 percent of all cases, and is more frequent in men than in women. The peritonitis that it causes is marked by a sudden acute pain in the abdomen and by symptoms of collapse, followed by marked tenderness and rigidity of the abdominal walls, vomiting, a pinched expression of the face, dyspnea, and a small, rapid pulse. Great abdominal distention is usually present.

Peritonitis without perforation may occur by extension of the inflammation to the peritoneum surrounding the intestine.

Pneumonia.—Pneumonia and hypostatic congestion occur in about 8 percent of the cases.

Bed-sores are less frequently encountered than formerly, owing to the proper nursing now general.

Thrombi in the veins occur in about 1 percent of the cases, and the left femoral vein is usually affected. Thrombosis is indicated by enlargement and edema of the limb affected.

Among **other complications** are excessive diarrhea, meteorism, gangrene, parotitis, pharyngitis, endocarditis, bronchitis, nephritis, and pyuria.

The Widal reaction is as follows:

Macroscopic.—The blood or serum to be tested is added either "to a young bouillon culture of the typhoid bacillus or to sterile bouillon, which is then at once inoculated with the bacillus. In the former case the reaction with typhoid serum appears usually within 2 or 3 hours, and consists in clarification of the previously turbid fluid and the formation of a clumpy sediment composed of accumulated bacilli. In the latter case the tube is placed in the incubator, and within 15 hours the

reaction is manifested by growth of the bacilli in the form of a sediment at the bottom of the tube, the fluid remaining nearly or quite clear."

Microscopic Test.—The blood or serum is mixed with "a young bouillon culture or with a suspension in bouillon or salt solution of a fresh growth of the typhoid bacillus, and a drop or two of the mixture is examined at once under the microscope. With a dilution of 1 : 10 this microscopic typhoid reaction appears, as a rule, immediately or within a few minutes, and is evidenced by loss of motility and by clumping of the bacilli into masses of various sizes and shapes." When this reaction occurs, it is spoken of as a "positive reaction;" and when not present, it is said to be "negative."

Typhoid Agglutination Test.
Upper segment shows the freely moving germs. The lower the typical "clumping."—(*Greene.*)

The reaction is present in about 95 percent of cases.

Prognosis.—The mortality in private practice is from 5 to 12 percent, and in hospitals it is from 7 to 20 percent. Unfavorable symptoms are hemorrhage, delirium, meteorism, excessive diarrhea, and suppression of urine.

Prophylactic Treatment. Antityphoid Inoculation.—A. E. Wright has prepared a *vaccine*, a dead sterile culture of the typhoid bacillus, that has been used extensively in the British and United States armies; and that gives immunity for 2 to 3 years, while at the same time it is absolutely innocuous.

Two or three injections should be made at intervals of 10 days, the first of 500 millions, the second and third of 1000 millions each.

For the prevention of the resulting lessened coagulability of the blood Wright advises 30 to 40 grains of calcium chlorid, and alcohol should be forbidden. It has been found to diminish both the incidence and the mortality of typhoid fever. Leishman reports: "In 5473 soldiers vaccinated against the disease, 21 took it and 2 died; in 6610 soldiers practically under the same conditions, who were not vaccinated, there were 187 cases and 26 deaths; that is, among the vaccinated soldiers there were 3.8 cases per thousand, and among the unvaccinated 28.3 per thousand." It is recommended for troops, especially when concentrated in camps, for nurses and physicians, and all persons exposed in time of epidemic. Castellani advises for prophylaxis an inoculation of dead culture to be followed a week later by the inoculation of an attenuated live culture, maintaining that the degree of immunization obtained by the latter is greater, while at the same time the reaction is not severe and the person does not become a "carrier."

In the United States army over 8500 persons had been inoculated up to June, 1910, and none of them contracted typhoid, although among the unprotected in the same period of time there occurred more than 200 cases.

Under conditions of careful asepsis the injection is made subcutaneously into the arm at the insertion of the deltoid muscle, preferably at about 4 P. M., so that the greater part of the reaction may take place before morning- The reaction is in most cases very slight; severe general reactions occurring with headache, backache, vomiting, nausea, and is in every case entirely over in 48 hours. During this period it is best to abstain from active exercise.

The following procedures, suggested by Gilman Thompson, should be carried out in hospital practice, and, with modifications, in private houses:

1. The best disinfectants of typhoid urine and stools for practical use are: (*a*) 1:500 acidulated solution of corrosive sublimate; (*b*) a 1:10 crude carbolic acid solution; (*c*) chlorinated lime.

2. Owing to the possibility of injury to plumbing, the carbolic acid solution is preferable wherever plumbing is concerned. The lime is best for country use, in privies and trenches.

3. The disinfectant should be thoroughly mixed with the stool, and left in contact with it for fully 2 hours. Enough of the disinfectant must be added completely to cover the stool with the solution.

4. The bed-pan should be kept filled at all times with at least a pint of the disinfectant, into which the stool is at once discharged, and should be cleaned with scalding water and one of the disinfecting solutions.

5. Rectal thermometers, syringes, tubes, and all utensils coming in contact with any of the fecal matter must be disinfected with the corrosive sublimate or carbolic acid solution.

6. After each stool the patient's perineum and the adjacent parts should be washed and sponged with a 1:2000 corrosive sublimate solution.

7. Nurses and attendants should be cautioned to wash their hands thoroughly, and to immerse them in a 1:1000 corrosive sublimate solution after handling the bed-pan, thermometer, syringe, or patient, or after giving sponge or tub-baths.

8. All linen or bedclothing used by the patient should be soaked in 1:20 phenol solution, and subsequently boiled for fully 2 hours.

9. Disinfection of the stools should be begun as soon as the diagnosis of enteric fever is established, and should be continued for 10 days after the temperature has remained normal.

10. In localities where a proper drainage system is lacking, the stools should either be mixed with sawdust and cremated or buried in a trench 4 feet deep after being covered with chlorid of lime.

When epidemics are prevalent, the drinking-water and milk should be boiled.

Important for the patient and for the public is the removal of typhoid bacilli from the urine by the administration of urotropin in doses of 7 1/2 grains three times a day beginning the third week at least, and continued for several weeks during convalescence.

General Treatment.—The physician and attend-

ants should ever keep in mind the fact that each individual case of typhoid fever is a focus for the spread of the disease. To carry out effective measures of prophylaxis is quite as much a part of the physician's duty as is the care of the patient.

General Management.—Careful nursing and a regulated diet are the essentials in a vast majority of cases. The patient should be kept in a well-ventilated room, *strictly confined to bed* from the onset, and remain there until the evening temperature has been normal for a period of at least 8 days. The constant use of the bed-pan should be strictly enjoined.

Diet.—A liquid diet should be begun at the onset, and should be continued throughout the course of the disease. Milk is the best food. If not well digested, a tablespoonful of lime-water may be added to each glass of milk, or it may be peptonized. The stools should be frequently examined, to see if they contain much fat. Other varieties of liquid foods may be given, such as strained soups, mutton or chicken broth, consomme, barley gruel, albumen water, and beef-juice. A pleasant fresh beef-extract may be made in the following manner: A thick piece of steak is seasoned with a small amount of butter, pepper, and salt, and subsequently placed on the top of a hot stove for a minute or two; it is then turned quickly to the opposite side, and allowed to remain until slightly browned; it is then cut into small pieces, to be masticated by the patient, only permitting the liquid portion to be swallowed. This diet may be allowed to patients in private practice when the persons are well known. In hospital practice it may prove dangerous, from the fact that solid particles might be swallowed surreptitiously. If diarrhea is present, soups, beef-juice, and beef-extracts may aggravate the condition, and milk, strained gruel, and barley-water should be substituted.

Plenty of cold water should be given to the patient. Fruits should not be given, but the juice of an orange or of a lemon may be taken at intervals.

Typhoid patients should be fed every 3 hours throughout the day. If there is great exhaustion, milk or liquid foods may also be given once or twice during the night, but in mild cases this is not necessary.

The Coleman-Shaffer High Calory Diet.—This has been tried, with success, in several cases of typhoid fever, and has been suggested in other fevers as well. We append herewith the conclusions of Dr. Coleman, with an account of the administration of the diet.

"Conclusions.—(1) None of the older diets for typhoid fever furnishes the patient with sufficient energy for his metabolic exchanges. Therefore a patient taking any of these diets is compelled to live in part upon his own tissues.

"(2) The amount of food which a patient requires can be determined only by his individual needs. The clinical guides to these needs are the weight of the patient and the state of his appetite. A patient who is losing weight should be given more food if he can digest and absorb it. A patient who is hungry should be given sufficient food to appease his appetite. In the early stage of severe cases it is always difficult to give more than 3000 calories a day; in the steep-curve period and in convalescence, patients take readily from 4000 to 6000 calories a day.

"(3) If any article of food causes persistent disturbances of digestion, the quantity given should be diminished, or the food should be stopped; otherwise the object of the high calory diet, the maintenance of the patient's nutrition, is defeated. If a patient cannot take all the food he requires, he should be given all he can digest and absorb.

"(4) Carbohydrates should furnish the greater part of the energy of the diet. The daily protein ration should not be below 62 grams, nor greatly exceed 94 grams. Clinical evidence indicates that a diet rich in fat may be taken by typhoid fever patients with benefit. Fat has furnished in some cases from one-third to one-half of the total energy of the food.

"(5) In the cases studied, the high calory diet has apparently modified the course of the disease, shortened convalescence, and reduced the mortality.

"Details of Administration.—The successful administration of the high calory diet depends upon unremitting attention to detail. It is a good plan to make a frank statement to the patient regarding the object of the diet whenever, in the opinion of the physician, this can be done. However, it is not always wise to enter too fully into particulars. Very often I tell patients that the more they eat, the sooner they will get well, and the effect of the suggestion upon the quantity of food which they will take is sometimes surprising. I tell every patient who is capable of appreciating the advice, to ask the nurse for more food if he wants it, and I tell the nurse to give the patient all the food he can digest and absorb.

"Typhoid fever patients cannot all be fed alike. Their preferences for and idiosyncrasies to foods are not removed by the fever. Yet often the judicious substitution of one article of food or dish for another will increase the fuel value of the diet by several hundred calories. Sometimes patients who complain that the milk is too sweet when it contains one-half to one ounce of milk sugar will take eagerly from two to four ounces of milk sugar in custard, ice cream, or lemonade. As in every other illness, the physician should permit as great variety of foods as is consistent with the patient's wellbeing.

"Ordinarily, when a patient first comes under observation he is put upon plain milk for a day or two. The subsequent procedure depends upon the patient's condition; that is, whether he is suffering from a mild or severe attack of the disease. In the former case he may be allowed foods which require mastication; in the latter, the diet should be liquid.

"Foods and Their Calory Values.—All of the foods and recipes which follow have been given thorough trial, and are recommended with confidence for appropriate cases.

Name.	Amount.	Calories.
Apple sauce	1 ounce	30
Bread	Average slice (33 grams)	80
Butter	1 pat (1/3 ounce)	80
Cereal (cooked)	1 heaping tablespoonful (1 1/2 ounces)	50
Crackers	1 ounce	114
Cream (20%)	1 ounce	60
Egg	1 (2 ounces)	80
Egg, white	1	30
Egg, yolk	1	50
Lactose	1 tablespoonful (9 grams)	36
Milk (whole)	(1 pint 350) 1 ounce	20
Potato (whole)	1 medium	90
Potato (mashed)	1 tablespoonful	70
Rice (boiled)	1 tablespoonful	60
Sugar, cane	1 lump	16
Sugar, milk	1 tablespoonful (9 grams)	36
Toast	Average slice	80

"Rubner's figures for calculating the calory values of the different foodstuffs will be found useful: 1 gram pure protein furnishes 4.1 calories; 1 gram pure carbohydrate furnishes 4.1 calories; 1 gram pure fat furnishes 9.3 calories. Nitrogen multiplied by 6.25 equals protein.

"Food Combinations and Recipes.—For the convenience of those desiring to use the high calory diet, the following combinations of foods are given. They are most useful in the early stages of the disease, or in the case of patients who are unable to take solid food.

	Calories.
For 1000 calories a day:	
Milk, 1 quart (1000 c.c.)	700
Cream, 1 2/3 ounces (50 c.c.)	100
Lactose, 1 2/3 ounces (50 grams)	200
This furnishes 8 feedings, each containing:	
Milk, 4 ounces	80
Cream, 2 drams	15
Lactose, 6 grams	24
For 1500 calories a day:	
Milk, 1 1/2 quarts (1500 c.c.)	1000
Cream, 1 2/3 ounces	100
Lactose, 3 1/3 ounces (100 grams)	400
This furnishes 6 feedings, each containing:	
Milk, 8 ounces	160
Cream, 2 drams	15
Lactose, 16 grams	64
For 2000 calories a day:	
Milk, 1 1/2 quarts	1000
Cream, 8 ounces (240 c.c.)	500
Lactose, 4 ounces (125 grams)	500
This furnishes 7 feedings, each containing:	
Milk, 7 ounces	140
Cream, 1 ounce	60
Lactose, 18 grams	72
For 2500 calories a day:	
Milk, 1 1/2 quarts	1000
Cream, 8 ounces	500
Lactose, 8 ounces (250 grams)	1000
This furnishes 7 feedings, each containing:	
Milk, 7 ounces	140
Cream, 1 ounce	60
Lactose, 36 grams*	144
For 3000 calories a day:	
Milk, 1 1/2 quarts	1000
Cream, 1 pint (480 c.c.)	1000
Lactose, 8 ounces	1000
This furnishes 8 feedings, each containing:	
Milk, 6 ounces	120
Cream, 2 ounces	120
Lactose, 1 ounce (30 grams)	120
For 3900 calories a day:	
Milk, 1 1/2 quarts	1000
Cream, 1 pint	1000
Lactose, 16 ounces (480 grams)	1900
This furnishes 8 feedings, each containing:	
Milk, 6 ounces	120
Cream, 2 ounces	120
Lactose, 2 ounces	240

*If this and the following combinations are too sweet, a portion of the milk-sugar may be given in some other form.

"When the above combinations are employed, it is generally desirable to add eggs to the diet in order to raise the nitrogen to the desired amount. The eggs may be soft-boiled or be shaken up in any of the above feedings unless distasteful to the patient, though the addition of an egg makes the stronger mixtures very rich. Milk toast with the addition of butter or cream, is relished by many patients." (From Coleman's article in the *American Journal of the Medical Sciences*, Jan., 1912.)

Hydrotherapy.—Since 1861 the value of bathing in fevers has been specially emphasized by the late Dr. Brand, of Stettin. Hydrotherapy may be carried out in several ways, of which, in typhoid fever, the most satisfactory are (1) by *sponging*, (2) the *wet pack*, and (3) the *full bath*.

Cold Sponging.—The water may be tepid, cold, or ice cold, according to the height of the fever. A thorough sponge bath should require a period of not less than 15 minutes. When from any cause a full bath cannot be given, sponging with ice-cold water may be used. It is specially valuable in the case of children and for delicate persons. At times it may be less objectionable to sponge one extremity at a time; then the abdomen and back, in regular order.

The cold pack is of special service in cases with pronounced nervous symptoms. The patient should be wrapped in a sheet wrung out of water at 60° or 65° F.; cold water is then sprinkled over the body with an ordinary watering-pot or a similar utensil.

The Bath (Brand Method).—The tub should be of such dimensions that the entire body except the head may be immersed. It seems best to give the bath every third hour when the temperature rises above 102.5° F. The temperature of the water at the beginning of the bath should be about 70° F., and it should be kept at this point by the addition of pieces of ice from time to time. The duration of the bath depends upon the height of the fever and upon individual susceptibility. In the majority of instances the duration varies from 15 to 20 minutes. When the colder (70° F.) bath is not borne well, it may be best to start with a higher temperature (80°-90° F.), and gradually to lower it by the addition of ice. After the first or second bath less objection is usually encountered.

The tub should be wheeled to the bedside, and after enveloping the body (in the case of women) in a sheet, two assistants gradually lower the patient into the water. As soon as the body (except the head) has been immersed, the head should be sponged, and afterward should be kept cool. From the moment the patient is placed in the water, and in order to prevent chilling, shivering, and cyanosis, and to stimulate the circulation,

the extremities and trunk should be constantly rubbed, paying especial attention to the feet and hands, which first feel the effects of cold. The abdomen may be rubbed only lightly or not at all. After removal from the bath the patient should be wrapped in blankets, and, if necessary, hot-water bottles or bags containing hot water may be applied to the extremities.

In private practice a substitute for the tub may be devised as follows: Place a quilt or blanket on a cot, cover with a piece of thick black oilcloth, and over this place a sheet; upon the latter the patient may be placed, and the bath may then be conducted as described. It will be of great advantage to elevate the end of the cot upon which the head rests, in order to assist drainage into a receptacle placed at the foot.

Contraindications to the bath are peritonitis and hemorrhage. Pregnancy, bronchitis, and pneumonia are not contraindications.

Advantages of the Bath.—(1) The fever is reduced; (2) the intellect becomes clearer, stupor is lessened, and the muscular twitchings disappear; (3) there is a general tonic action on the nervous system, and particularly on the heart; (4) insomnia is lessened, the patient usually falling asleep for several hours after the bath; and (5), most important of all, the mortality is much reduced. Under the expectant and general medicinal plans of treatment the mortality ranges from 12 to 17 percent; with the Brand method the mortality in many instances has been reduced to a fraction above 7 percent.

Medicinal Treatment.—It should be constantly remembered that in the treatment of typhoid fever overdrugging does harm. In many cases all that may be required is a mild purge at the onset, and subsequently a mild diuretic, continued for a day or two. The daily use of medicinal antipyretics is to be deprecated, from the fact that they are depressing, especially to the heart. In obstinate cases, when it seems impossible to control the temperature by baths, and when they are demanded too frequently, a single dose (5 grains) of phenacetin or antipyrin or pyramidon may be administered.

Antiseptic Medication.—Remedies that have been recommended are acetozone, beta-naphthol, naphthalin, salol, guaiacol, carbolic acid, corrosive sublimate, iodin, and calomel. Irrigation of the colon has been advised.

Antitoxin and Vaccine Treatment.—Pfeiffer (1894) was the first to prepare typhoid toxin and antitoxin; and he produced a serum which gave good results in some cases. As yet a generally satisfactory serum has not been produced although Chantemesse of Paris claims good results with one which he prepared. At present, interest centers around the typhoid vaccine which has acted so efficiently as a prophylactic. For this purpose three injections of a suspension of killed bacteria are given at intervals of 10 days. The first dose is 500,000,000 and the second and third doses 1,000,000,000 bacteria. The vaccine as usually prepared contains 1,000,000,000 to the mils and can readily be administered subcutaneously with a small, sterile syringe after the part has been sterilized with iodin. It was first utilized as a prophylactic on a large scale in the British Army in India. Its subsequent adoption by other countries and the United States marked the death knell of typhoid which so long had been among the scourges of armies encamped, particularly, in times of war. In the Spanish-American War 20,728 out of 107,973 men had typhoid fever and 1580 died. Vaccination in the United States army was begun in 1909 and made compulsory in 1911. The result has been the practical eradication of the disease from the service. The following table is from Russell's recent article:

TYPHOID FEVER, 1907 TO 1913, FOR THE WHOLE ARMY, OFFICERS AND ENLISTED MEN, AMERICAN AND NATIVE TROOPS.

	Cases.			Deaths.			Occurring Among Those Who Were Vaccinated.	
Year.	Mean Strength.	No.	Ratio per 1000 of Mean Strength.	No.	Ratio per 1000 of Mean Strength.	Percentage of Total Cases.	Cases.	Deaths.
1907	62,523	237	3.79	19	0.30	8.0		
1908	74,692	239	3.20	24	0.31	10.0		
1909	84,077	282	3.35	22	0.26	7.8	1	0
1910	81,434	198	2.43	14	0.17	7.1	7	0
1911	82,802	70	0.85	8	0.10	11.4	11	1
1912	88,478	27	0.31	4	0.044	14.8	8	0
1913	90,646	3	0.03	0	0.00	0.0	1	0

Antityphoid vaccination is safe and is destined to become more and more in use in private practice, particularly in localities where typhoid is endemic and among youths and young adults, the age of greatest susceptibility. It has been practised with success in a number of hospitals where nurses and others are exposed to infection. It is to be recommended to tourists and vacationists who while travelling are subjected to varying water and food supplies. Following the injection there is not infrequently a local reaction consisting of redness and tenderness and in some instances slight tenderness of the adjacent lymph glands. A systemic reaction, slight fever and malaise, oc-

curs in 5 to 10 percent of the cases. The injection is contraindicated in the presence of an acute illness such as tonsillitis, gonorrhea, etc. It is generally acknowledged that the preventive inoculation produces only a temporary immunity lasting about two to two and one-half years and that under its influence the disease, if it occurs at all, pursues a milder and less fatal course than is usual. Typhoid vaccination has not been found of value in the treatment of the disease except in those patients in whom the bacilli persist in the urine and feces after the attack has subsided. These patients are prone to become carriers of the infection and are sources of danger. The treatment of chronic carriers is often unsuccessful. The use of an autogenous vaccine offers the best chance for success (McCrae).

Treatment of Special Symptoms.—The abdominal pain and tympanites are best treated with fomentations or with turpentine stupes. A flannel roller is placed beneath the patient, and then a double layer of thin flannel, wrung out of very hot water, with a dram of turpentine mixed with the water, is applied to the abdomen and covered with the ends of the roller.

Meteorism.—Turpentine internally has been highly recommended by the late Dr. George B. Wood. It may be given in the form of an emulsion, as follows:

℞. Turpentine, Compound tincture of lavender, Sugar, each, ʒ jss
Acacia, ʒ ij
Water, enough to make ℥ iij.
Two teaspoonfuls every 3 or 4 hours.

℞. Beta-naphthol, ʒ ss
Bismuth subnitrate, ʒ j.
Divide into 6 powders. One powder every 3 or 4 hours.

The following may also be tried:

℞. Guaiacol, Salol, each, gr. v
Beechwood creosote, ♏ v.

In some cases soups, beef-extracts, and similar foods give rise to the disturbance, and peptonized milk should be substituted. The rectal tube may give relief; also injection of milk of asafetida (5 to 6 ounces).

Diarrhea.—In this condition no medicines should be given unless the stools number 3 or 4 daily. As in the case of meteorism, it sometimes ensues from animal foods, for which albumin water, barley-water, strained gruel, and the like, should be substituted. Boiling the milk is frequently all that may be necessary. In some cases lime-water added to milk will do good.

℞. Bismuth subnitrate, ʒ ijss
Paregoric, Compound tincture of lavender, each, ʒ j
Elixir of curacoa, ʒ iij
Water, enough to make ℥ iij.
Two teaspoonfuls every 3 or 4 hours.

℞. Codein sulphate, gr. iij
Bismuth subnitrate, ʒ j.
Divide into 6 capsules. One every 3 hours.

℞. Dover's powder, ʒ ss
Bismuth subcarbonate, ʒ j.
Divide into 6 powders. One every 3 hours.

Constipation should be relieved every 2 days by enemata of water containing a small amount of soapsuds.

Hemorrhage.—Elevate the foot of the bed; allow the stools to be passed into the draw-sheet; apply an ice-bag or ice-coil to the abdomen; and give a hypodermic injection of morphin (1/4 grain), though it has the disadvantage of masking the symptoms. Administer internally opium (1 grain) every 3 hours, or the lead and opium pill. The diet should be very bland, consisting of peptonized milk, or malted milk.

Peritonitis without perforation may have a favorable outcome if absolute rest be insisted upon. Morphin (1/4 grain hypodermically) should be given, and repeated if necessary.

Perforation and peritonitis, as a rule, end fatally. Laparotomy should be done as soon as the diagnosis is positive; of about 120 cases collected by Finney, 20 percent recovered. G. E. Armstrong well says: Local anesthesia has very materially altered our attitude towards early operations. It is no longer necessary to administer a general anesthetic. The abdomen can be quite well opened under local anesthesia without causing the patient any pain whatever. A 1 percent solution of novocain, with the addition of two drops of adrenalin, 2 min. to 1 dr., is thorougly satisfactory and may be used freely. First inject the skin and subcutaneous tissue, and then with a needle 1 in. long, penetrate the deeper muscular layers along the line of incision. Either a gridiron incision or one along the outer border of the right rectus answers admirably. . . . . But early operation is most essential if success is to be obtained."

Heart-failure.—When the pulse grows successively weaker, whisky (3 ounces) should be allowed every 3 hours, day and night, if necessary.

℞. Aromatic spirit of ammonia, ʒ iv
Tincture of digitalis, ʒ ij
Elixir curacoa, ʒ iij
Water, enough to make ℥ iij.
Two teaspoonfuls in water every 3 hours.

Strychnin (1/40 grain) or ether (30 minims) may be given hypodermically. From 1/2 to 1 liter of salt solution may be infused beneath the skin 3 or 4 times a day. Collapse may be treated by camphor (1 grain) in olive oil (15 minims) given hypodermically.

Nervous symptoms are best treated by hydrotherapy. In the cases that show meningeal symptoms the cold pack should be used. An ice-cap may be applied to the forehead and one to the back of the neck. Blisters are of doubtful benefit, and add to the distress. For insomnia sulphonal (15 grains), or chloralamid (30 grains) or trional (10 to 15 grains) may answer. As a last resort

give chloral or morphin (1/4 grain) hypodermically twice daily.

℞. Strontium bromid, Sodium bromid, } each, ʒ vj
Peppermint water, enough to make ℥ iij.

A tablespoonful every 3 hours.

℞. Extract of opium, gr. iij
Asafetida, ʒ ss
Extract of henbane, gr. iij.

Add enough cacoa-butter to make 6 suppositories. One to be used every 4 hours.

℞. Chloral, gr. xv
Strontium bromid, ʒ jss
Water, ℥ vj.

Use an enema with a long rectal tube, inserted about 18 inches.

Diuretic solutions:

℞. Sweet spirit of niter, ℥ ss
Solution of potassium citrate, ℥ ijss
Elixir curacoa, ʒ iij
Water, enough to make ℥ iv.

A tablespoonful every 3 hours. Large quantities of water may be given immediately after each dose of medicine.

Also—

℞. Potassium acetate, Tincture of digitalis, } each, ʒ jss
Elixir curacoa, ʒ ijss
Water, enough to make ℥ iv.

A tablespoonful every 3 or 4 hours.

Suppression and Retention of Urine.—Suppression of urine is a rare complication. Retention, however, frequently occurs, and may be relieved with a sterilized catheter 2 or 3 times daily.

Bed-sores.—Prevent bed-sores by hydrotherapy and by sponging the back frequently with diluted alcohol. Should they form, treat them antiseptically.

Sore Mouth.—Cleanliness of the mouth in the treatment of typhoid fever becomes of the greatest importance. One of the chiefest aims should be to keep the appetite and digestion in the best condition possible. Remedies given for other conditions arising during the course of the fever are seldom received with more gratefulness than those used for this purpose. If the teeth, tongue, and gums of the patient are sponged daily with a very weak (0.5 percent) carbolized glycerin solution, many cases of diarrhea and tympanites will be prevented. Sordes accumulate upon the teeth, the appetite is lost, the lips become parched, the thirst is unquenchable, and a condition of much discomfort supervenes when cleanliness is neglected. It should be remembered that in this disease mouth-breathing is common, causing the tongue to become dry and brownish; and, if it is neglected, it may become fissured.

℞. Phenol, gr. v
Glycerin, ʒ iij
Peppermint water, ℥ j
Water, enough to make ℥ iv.

To be used with tooth-brush at least once daily.

TYPHUS FEVER.—An acute, infectious, and epidemic fever, highly contagious, and characterized by sudden invasion, profound depression of the vital powers, sickening odor, and a peculiar maculated and petechial eruption, favorable cases terminating by crisis about the fourteenth day. There is no constant lesion.

Etiology.—It is due to a special organism, the *Bacillus typhi exanthematici*, recently (1915) isolated by Plotz. The organism is gram-positive, from 1 to 2 mikrons in length, the breadth being about one fourth of the length. It has no capsule, and is not acid fast. It is probably carried by bedbugs and body lice. It is rarely seen in the United States except in seaports. The period of incubation is about 12 days.

Symptoms.—It begins abruptly with a chill, followed by violent fever, the temperature within a few days reaching 104° to 105° F. There is a frequent, bounding pulse, soon becoming small, weak, and rapid. The cardiac impulse and first sound are almost effaced, there is severe headache, followed by violent delirium. From the fifth to the seventh day a coarse, red, diffused, measly eruption, with a mottling of the skin, develops all over the body except the face, not disappearing on pressure. The face is apathetic and has a uniform deep, dusky flush, the skin has a glazed appearance, the pupils are contracted, and the conjunctiva is red and congested. With the development of the disease there is cutaneous hyperesthesia, muscular soreness, and tenderness over the tibia. There are great prostration and muscular feebleness, vertigo, tremor, and subsultus. Constipation is the rule. At the end of the second week the temperature suddenly declines and the patient passes into a rapid convalescence.

Brill's disease is a mild atypical form of typhus.

Complications.—Pneumonia and swollen parotid glands are common.

Diagnosis.—It is differentiated from **typhoid fever** by the age, season of the year, onset of the disease, character of the eruption, intestinal symptoms, and the Widal reaction. The following is a comparative table, showing the main points in differential diagnosis.

Typhus Fever.	Typhoid Fever.
Attacks quickly; incubation 9 days.	Commences slowly; incubation about 13 days.
Occurs at any age.	Most common in youth and childhood; rarely occurs after 40.
Rare among the higher classes, except those exposed.	As common among the rich as among the poor.
Mulberry eruption on fourth or fifth day, on extremities, lasts until close.	Rose eruption on seventh to tenth day; isolated, flattened papules (few) on abdomen and back, in successive crops, which fade and disappear.

Typhus Fever.	Typhoid Fever.
Brain chiefly affected; bowels often but little so; abdomen natural; evacuations dark, but never bloody (these are occasionally reversed).	Bowels chiefly affected; evacuations ocher color and watery; sometimes hemorrhage or even ulceration; abdomen tumid.
Contracted pupils; dusky face.	Dilated pupils; cheeks flushed.
Pulse increases to 120, and temperature rises to 105° F., until third day; high for 6 days, then fall.	Pulse and temperature rise and fall independently, and without uniformity, but both are usually high to fifteenth day.
Lasts from 2 to 3 weeks.	Lasts from 4 to 6 weeks or longer.
Relapses rare.	Relapses frequent.
Death from coma or from congestion of the lungs in first or second week.	Death from asthenia, pneumonia, hemorrhage, or perforation of intestine, in or after third week.
Arises from destitution, overcrowding, bad ventilation; is highly contagious and generally epidemic; no microbe determined.	From poisoned drinking water, putrid animal matter, bad drainage; is not contagious, often sporadic; Eberth's bacillus present in the intestinal lesions, and in the spleen, liver, blood, etc.
Postmortem: changes not constant; the most frequent are dark blood, enlarged spleen, soft heart.	Postmortem: morbid Peyer's patches; enlarged mesenteric glands; ulcerated mucous coat of intestines; enlarged and soft spleen; ulcerated pharynx.
	Responds to the Widal reaction.

Measles begins milder, with coryza and cough, and never shows such pronounced nervous phenomena; but an early eruption occurs, appearing on the face.

Cerebrospinal fever has many symptoms in common, and but for the rarity of typhus in this country would be more confusing. The headache and rigidity of the muscles of the neck are much more pronounced in cerebrospinal fever and the prostration is less than in typhus fever. The eruption of typhus is characteristic, and should prevent error. Specific microorganisms are found in cerebrospinal fever.

In the early stages small-pox and bubonic plague have been mistaken for typhus fever.

Prognosis.—The unfavorable indications are high temperature, frequent pulse, early stupor, presentiment of death. The favorable indications are youth, moderate temperature and pulse, and mild nervous phenomena.

The duration is about two weeks. The mortality varies from 10 to 30 percent.

Treatment is symptomatic. As typhus fever is distinctly contagious, isolation is imperative, with immediate removal and disinfection of the patient's excreta. Body lice and bed-bugs (the carriers of the disease) are best destroyed by steam. All cases are benefited by small doses of the mineral acids, alternating with quinin sulphate. For high temperature, cold sponging, cold pack, or full doses of quinin, antipyrin, acetanilid, or acetphenetidin, or the systematic use of the cold bath, or "tubbing," as now used in typhoid fever.

For the headache and delirium, cold to the head is indicated. In the young and strong a few leeches to the temple, and chloral, with or without the bromids, may be used. For constipation mild laxatives are given. For the debility give alcohol early and in full doses, and spirit of chloroform in dram doses whenever there is danger of collapse. During convalescence such tonics as quinin and strychnin may be given. The patient may be nourished by nutritious liquids, such as milk, broths, egg-nog, etc.

TYROTOXICON.—A ptomain obtained by Vaughan from poisonous cheese, poisonous milk, poisonous ice-cream, etc. Chemically, it is very unstable; it may disappear altogether in 24 hours from milk rich with the poison. It induces vertigo, nausea, vomiting, chills, rigors, severe pains in the epigastric region, dilatation of the pupils, griping and purging, a sensation of numbness, or "pins and needles," especially in the limbs, and marked prostration or death. The symptoms may vary somewhat in different individuals. The poison is thought to be the cause of the summer diarrhea of infants.

Treatment of Poisoning.—It is best to give emetics if vomiting is not free, or to employ the stomach-pump or siphon to wash out the stomach, and to administer thymol in alcoholic solution, or salol, napthalin, or other antiseptics. The antagonists are opium and other sedatives. Stimulation is necessary when there is prostration. See Ptomain-poisoning.

U

ULCERS.—An ulcer is the term applied to an open sore produced by a loss of substance of the free surface of the skin or mucous membrane in the process of ulceration, or of ulceration and gangrene combined. The term, moreover, is sometimes extended to any open granulating wound the result of an injury or operation.

Varieties.—The various names given to ulcers are derived either from their local conditions and surroundings or from their specific cause. The characters of the specific ulcers, however, often become obscured by accidental local conditions; and these latter, again, are constantly changing from day to day, so that an ulcer which at one time would be called callous, may at another time be in a sloughing state. The following are examples of the chief types of ulcers, but in practice many minor shades of difference in the local appearances occur, so that it may be difficult or impossible to assign a given ulcer to a particular type.

The Simple, Healthy, or Healing Ulcer.—The edges are smooth and shelving, and extend in the form of a bluish-white film over the marginal granulations. The base is level, or nearly so, and is covered with healthy granulations. The discharge is inodorous pus, or if the ulcer is dressed antiseptically, and all irritation avoided, merely healthy serum. The surrounding skin is healthy. This is the type that all ulcers assume when healing.

Treatment.—Rest and protection by any light unirritating dressing are all that is usually required. When large, cicatrization may be promoted by skin-grafting. Two methods are employed. See PLASTIC SURGERY.

The exuberant or fungous ulcer is generally due to obstructed venous return from the granulations, the result of undue contraction of surrounding tissues, as seen for example, after a burn. The edges are healthy, but the granulations rise above the surface, and are turgid, dark red, redundant, and bleed readily. The discharge is purulent.

Treatment.—Solid nitrate of silver or sulphate of copper should be rubbed over the granulations until they are reduced to healthy proportions.

The edematous or weak ulcer generally occurs in connection with tubercular bones or joints, but any ulcer may become edematous if healing is delayed by the prolonged use of emollient applications. The edges and adjacent tissues are generally healthy; and the granulations are upraised, flabby, bulbous, semitranslucent, watery, and friable. The discharge is profuse and watery.

Treatment.—Removal of the cause, when possible, uniform pressure, and applications of lotions of nitrate of silver or similar astringents.

The Inflammatory and Inflamed Ulcers.—These terms are applied to ulcers in which the inflammatory phenomena are the most marked features. The inflammation may depend on some constitutional disturbance consequent upon alcoholism, improper food, and the like; or it may be the result of local irritation applied to any ulcer, whatever its previous character. For the purpose of distinction, the term "inflammatory" is applied to the former condition, while the term "inflamed" is generally restricted to ulcers of the latter class. Inflammatory ulcers are usually of irregular shape: the edges are ragged and shreddy, or abrupt or sharp-cut; the surrounding skin is red and edematous, and the base void of granulations, dry, livid red, or covered with a serous or sanious discharge mixed with tissue debris, and, if the inflammation is very acute, with yellow sloughs. When inflammation attacks a previously granulating ulcer, the granulations become florid and swollen, and generally slough, while the surrounding parts present the ordinary inflammatory phenomena.

The treatment should consist of rest, elevation of the part, removal of all local irritation, application of warm antiseptic lotions (as boric acid) on lint, attention to the constitutional state, and regulation of the secretions.

The Sloughing Ulcer.—This is merely a severer degree of the former, and it differs from it in that the inflammatory process is more intense and of a spreading character. It seldom occurs except in connection with venereal disease. The microorganisms at work in this and in the phagedenic form of ulcer are probably only the ordinary pyogenic micrococci found in all ulcers, but here acting with greater intensity in a vitiated constitution. The ulcer spreads with great rapidity, the edges are undermined, inverted, and dusky red, and the base is covered by an ash-gray or black slough. There are, commonly, much pain and severe constitutional fever.

The treatment is similar to that of the inflamed variety. Antiseptics should be freely used if the ulcer is foul, and opium should be given if there is much pain. When due to syphilis, the proper remedies for that affection should, of course, be given; but mercury should be used cautiously or should be altogether withheld until the sloughing has ceased.

The phagedenic ulcer, owing to improved sanitation and hygiene, and to the more scientific treatment of wounds, is seldom seen at the present day, except in connection with venereal disease in persons whose constitution is thoroughly broken down by intemperance, defective nutrition, and general neglect. The edges of the ulcer are irregular, swollen, and undermined, and the surrounding skin is of a dark, purplish, and dusky

red color. The surface is devoid of granulations, and is covered with a dark, blood-stained, ichorous discharge, often mixed with sloughs. When the sloughing proceeds to any extent, the ulceration is spoken of as **sloughing phagedena**. The ulcer spreads with fearful rapidity, and often destroys the whole organ, as the penis or vulva, and is attended with severe constitutional disturbance.

Treatment.—The patient should be placed under an anesthetic, the surface of the ulcer dried, and then thoroughly destroyed with fuming nitric acid. Some surgeons apply carbolic acid (1 : 20) or perchlorid of mercury (1 : 1000), and then dust with iodoform. Application of pure bromin is very effective. The continuous use of the hot bath is often of much service in phagedena of the penis and vulva. Internally, opium should be given in full doses, with tonics, nourishing diet, and, when indicated, stimulants. Thorough ventilation and good hygiene generally are imperative.

The Chronic, Callous, or Indolent Ulcer.—This condition of an ulcer is the result of continued irritation and neglect, in consequence of which the edges become infiltrated with inflammatory material, which impedes the circulation and prevents healing. It is very common in the lower third of the leg in the poorer classes. The edges are smooth, white, callous, rounded, steep, and quite insensitive when touched. The adjacent skin is generally congested or eczematous. The base is covered with a thin, sanious discharge, while there are either no granulations, or those present are small, flabby, pale, and ill formed. These ulcers often exist for years, and are usually attended with but little pain, and though they are at times small, at other times they extend nearly round the leg. They are often adherent to the fascia, periosteum, or bone. Old, callous ulcers, when subjected to continued irritation, are apt, as age advances, to become epitheliomatous.

Treatment.—The callous edges should first be softened by emollient dressings, and uniform pressure subsequently applied by a Martin's bandage or by strapping and a bandage. The strapping plaster, cut into strips 1 1/2 inches wide, should be evenly applied and should extend 2 inches below and the same distance above the ulcer. Holes should be cut in the strapping opposite the ulcer to allow of the escape of the discharge. Over the strapping a bandage from the foot to the knee should be applied. The bandage should be changed daily; the strapping once or twice a week. Iodoform or some other antiseptic powder should be sprinkled on the ulcer beneath the strapping. Other applications which have been found useful are Unna's paste, spirit of camphor, tincture of iodin and a weak solution of sulphate of copper, two or three grains to the ounce.

Cases intractable to other treatment have been much benefited and sometimes cured by baking in the hot air oven for thirty minutes daily.

When these ulcers are adherent to the fascia or periosteum their base should be liberated either by multiple radiating incisions or by a circular incision about a half an inch from their edge. When the ulcer is very large or extends quite round the leg or shows signs of becoming epitheliomatous, amputation is indicated.

The Varicose and Eczematous Ulcer.—These terms are applied to any ulcer, whatever its other characters, when associated respectively with a varicose state of the veins or an eczematous condition of the skin. Both conditions frequently occur together.

The Irritable or Painful Ulcer.—Though any ulcer may be irritable or painful, these terms are generally restricted to a small, painful ulcer around the anus, and to a small, superficial, generally congested ulcer, commonly situated near the ankle, and occurring chiefly in women beyond middle life. The pain is often intense, and is generally believed to depend upon the involvement of the nerve-endings.

Treatment.—The improvement of the general health, small doses of opium, and cauterization with nitrate of silver, will often suffice to cure the ulcer. In inveterate cases an attempt may be made to divide the nerves subcutaneously, after the manner of Hilton.

Tuberculous or strumous ulcers are generally due to the breaking down of enlarged tuberculous lymphatic glands, the bursting of subcutaneous tuberculous abscesses, or the ulceration of the so-called tuberculous or strumous nodules. They are generally multiple, and often confluent, forming an irregular indolent sore. The edges are pale, bluish-pink, thin, and undermined. The granulations are pale, edematous, protruding, and bleed readily on handling. The discharge is thin, yellowish-green, and scanty. Enlarged glands and cicatrices of former ulcers are frequently present in their vicinity. The cicatrices are generally raised, pale pink or white, while the skin is often puckered around them.

Treatment, constitutionally, is that for struma and tubercle. Locally, the sore should be destroyed by paring away the edges and scraping the base with a Volkmann's spoon. The cicatrices may sometimes be dispersed by repeated blisterings or by subcutaneous division.

Syphilitic Ulcers.—Primary ulcers or chancres are described under Syphilis (*q. v.*). Those occurring in the course of constitutional syphilis may be divided into the superficial and deep, and are treated locally as well as constitutionally.

ULNA.—See Forearm.

UMBILICAL CORD (Funis).—A vascular, cord-like structure connecting the fetus with the placenta.

Origin.—It is derived from the pedicle of the allantois, appearing about the third week of gestation. When fully formed, it is composed of two arteries, one vein, the omphalic duct, the remains of the umbilical vesicle, and the pedicle of the allantois, surrounded by a covering of mucous tissue (Wharton's jelly), and insheathed by a layer of amnion. At term the cord is from 50 to 60 cm. in length, and from 1 to 2 cm. in thickness.

Function.—It is the medium of communication between the mother and child. It supplies the fetus with rich arterial blood, and returns to the mother impure venous blood.

Abnormalities. Length.—The cord may be very much longer (250 cm.) or very much shorter (1 cm.) than normal. If too long, it is likely to be coiled about the fetus or is liable to prolapse; if too short, it may prevent descent of the fetus, causing great pain at the placental site and, finally, premature detachment of the placenta.

Thickness.—Sometimes there may be an excess of mucous tissue, causing great increase in the thickness of the cord. This does not usually involve its entire length.

Torsion.—From 8 to 12 twists in the cord are normal; they are caused by the twisting of the arteries around the vein. Extreme torsion may sometimes occur, rarely causing interference with the blood supply to the fetus.

Coils and Knots.—True knots have been found in the cord, although they are not usually tight enough to interfere with the circulation. The cord is frequently found coiled around the child's body. In about 25 percent of cases it is coiled around the neck.

Insertion.—The cord is usually inserted into the central part of the placenta, occasionally into the periphery (battledore placenta). When the vessels run between the amnion and chorion before entering the placenta, it is said to be a velamentous insertion.

Cysts, Tumors, and Calcareous Deposits.—These conditions are occasionally found in the cord, but they are, as a rule, of no significance.

Care after Labor.—After the pulsations in the cord cease it should be ligated, a piece of narrow iodoform tape or aseptic silk being used for this purpose. Only one ligature should be used, placed about 1 1/2 inches from the child's abdomen. It should first be secured by an ordinary surgeon's knot and then by a bow-knot, the ends being left long, so that it may be tightened after the child has had its bath. The cord should now be cut about 1/2 of an inch beyond the ligature, care being taken that no part of the child is injured by the scissors. The free end of the cord is allowed to drain into a vessel, thus decreasing the size of the placenta, facilitating its separation from the uterus, and hastening its expulsion. After the child has received its bath, the ligature around the cord should be tightened, and the cord dusted with a powder composed of salicylic acid and powdered starch, 1 part to 4 respectively. It should now be inclosed in a piece of salicylated cotton and the binder applied. The cord usually drops off about the fourth day; the granulating ulcer remaining gradually heals and retracts, forming the umbilicus.

Septic Infection.—This is a rare condition if proper asepsis is observed in ligating and dressing the cord. When present, the cord is inflamed and thickened, and a grayish, diphtheritic membrane may cover its distal end. High fever is a usual accompaniment.

The treatment consists of applications of a strong solution of mercuric chlorid (1:500) and in proper dressing, as described.

Umbilical Fungus.—An overgrowth of granulations may occur about the umbilical ulcer or the cord may remain as a projection of well-organized connective tissue. In the former case the granulations should be cauterized with nitrate of silver; in the latter the cord should be religated close to the abdominal wall and the excess removed with scissors.

Hemorrhage (Omphalorrhagia).—This may be primary, from imperfect ligation of the cord, or secondary, occurring after the cord has fallen. The mortality is very high, being probably 75 percent or more.

Treatment.—In primary hemorrhage the cord must be religated; occurring from the umbilical ulcer, after the cord has fallen, the bleeding point, if seen, should be ligated, or pressure and astringents may be tried. If these fail, a fold of the abdominal wall should be transfixed with a hare-lip pin passing below the umbilicus, the pin passing beneath the hypogastric arteries; over this a figure-of-eight ligature should be applied. Occasionally, it may be necessary to pass a second pin above the umbilicus, so as to occlude the umbilical vein.

Prolapse.—The descent of a loop of cord in advance of the presenting part of the fetus. This is not a very rare complication, occurring once in about 250 labors.

Causes.—The principal causes are: (1) Lack of conformity between the presenting part of the child and the maternal pelvis, as in deformed pelves, small head, and abnormal positions; (2) hydramonios; (3) excessive length of cord; (4) placenta prævia.

Prognosis.—The fetal mortality is high, over 50 percent of children losing their lives from asphyxia.

The treatment consists of prompt replacement of the cord, if possible. This may be accomplished by the fingers alone or by the aid of some instrument, such as a catheter and string. A piece of string about 4 inches long is passed through the eyelet of the catheter, and the ends are tied; the cord is placed in the angle made by the loop and catheter, and the free end of the loop is hooked over the top of the catheter. In this way the cord is held fast, and may be carried back into the uterus. When the catheter is withdrawn, the loop passes over the end and the cord is released. If the patient is placed in the knee-chest posture, reduction will be very much facilitated.

After reduction has been accomplished, the patient should be kept in the knee-chest posture, or, at least, should have the buttocks elevated, so that the prolapse may not recur. This precaution is unnecessary after the presenting part has descended to the pelvic floor.

If it is found impossible to reduce the cord, it should be placed in a position in which it will be least liable to suffer severe compression—usually over the left sacroiliac joint—and rapid delivery of the child should be effected, either with forceps or by version.

UNCINARIASIS.—See Ankylostoma, Hookworm Disease.

UNCONSCIOUSNESS.—See Coma.

UNGUENTUM.—See Ointment.

URANOPLASTY.—See CLEFT PALATE.

URATES.—Combinations of uric or lithic acid with a base. See URINE (Examination).

UREA.—$CO(NH_2)_2$. The chief solid constituent of urine and the principal nitrogenous end-product of tissue metamorphosis. See URINE (Examination).

UREA-QUININ.—See QUININ AND UREA HYDROCHLORID.

UREMIA.—The name given to a certain group of symptoms resulting from nephritis, and due to the circulation in the system of the effete products that should be eliminated by the kidneys.

Etiology.—The exciting agent is unknown. Certain facts, however, lead to the belief that there is an accumulation in the system of organic basic products—ptomains and leukomains—which may cause uremia.

Symptoms and Clinical Course.—These are mainly referable to the nervous system. In acute uremia the symptoms may appear without any previous warning. In the more chronic form there are such premonitory symptoms as headache, vertigo, morning nausea, indistinct vision, drowsiness, cool skin, obstinate constipation, various cutaneous eruptions, and a diminution in the amount of the urine, which usually contains albumin and casts. See PHENOLSULPHONEPHTHALEIN TEST.

The uremic attack may manifest itself in a variety of ways:

Gastrointestinal Variety.—The patient suddenly experiences attacks of vertigo, pallor of face, nausea and vomiting, with fever, the temperature varying between 100° and 103° F., pulse tense and rapid, respiration hurried, and the urine scanty, with low specific gravity; unless the symptoms are promptly relieved, convulsions may occur, followed by coma and death, or drowsiness may supervene, followed by coma, which is really nothing but a profound sleep. Rarely, an acute maniacal outbreak follows the gastrointestinal symptoms.

Convulsive Variety.—Without any appreciable prodromes there are epileptiform convulsions, with or without loss of consciousness. The convulsions may consist of a single paroxysm, or a succession of fits may follow one another at intervals of a few minutes or of several hours, the patient being in a condition of more or less profound insensibility during the intervals. The fits almost exactly simulate true epilepsy. In this variety the temperature is high—from 103° to 106° F., or more; the pulse is rapid, with or without tension; the respirations are quickened. Coma, followed by death, is a very common ending of this variety of uremia, or after a profound sleep of hours the patient gradually recovers his usual health. Alcoholic excesses are responsible for many of these attacks.

Cerebral Variety, or Uremic Coma.—This form develops either gradually, with an increasing drowsiness, associated with headache and irritability of temper (mild mania), nausea, vomiting, and rise of temperature, often reaching 105° F., rarely 107° F., with rapid, full pulse; or the patient may fall suddenly into a condition of profound coma, the symptoms closely resembling an apoplectic stroke, except the high temperature. Uremic coma is always accompanied by rise of temperature and stertor. This stertor is peculiar; it is not the "snoring" of apoplexy, but a sharp, hissing sound produced by the rush of expired air against the teeth or hard palate. The respirations are accelerated and the pulse is rapid, but of low tension. This variety may suddenly terminate fatally with a convulsion, or a deepening coma with prostration and cold, wet skin, with edema of the lungs. Rarely, there may be gradual recovery.

Pulmonary manifestations are nocturnal dyspnea, usually of a paroxysmal character. Cheyne-Stokes breathing may continue for several weeks, and is not a necessarily fatal symptom.

Abdominal manifestations are obstinate vomiting and profuse diarrhea.

General Manifestations.—The skin is dry and has a dusky hue; the breath has a urinous odor; the urine is scanty, albuminous. contains different varieties of casts, and is deficient in urea. The temperature is normal or slightly subnormal, and the pulse is slow and full, until late in its course, when it becomes rapid and feeble.

Differential Diagnosis.—The clinical history and examination of the urine will aid in determining the diagnosis. See COMA, CONVULSIONS.

Prognosis is unfavorable.

Treatment.—The first indication is to aid the disabled kidneys in eliminating the waste products of the body by stimulating the skin and bowels to activity. Croton oil (1 or 2 drops) with olive oil (1 dram) should be given at once, to produce rapid catharsis. Elaterium (1/8 grain) may be given every 3 or 4 hours until 2 or 3 doses have been taken. Calomel (2 grains) with compound jalap powder (20 grains) every hour until 4 doses have been taken.

A hot bath (110° F.) or a hot vapor bath should be given from the onset of the symptoms to produce free diaphoresis.

The patient may be wrapped in blankets wrung out in hot water and given hot drinks to increase perspiration. If the pulse is full and bounding, venesection may be performed. Chloral (1 dram) may be given by the rectum to control the convulsions. Inhalations of chloroform or nitrite of amyl may also be used.

If the pulse is feeble, the following may be used:

℞.	Tincture of digitalis,	ʒ ij
	Aromatic spirit of ammonia,	ʒ v
	Aromatic elixir,	ʒ iv
	Water, enough to make	℥ iij

Two tablespoonfuls every 3 or 4 hours.

If collapse threatens, give strychnin (1/30 grain), atropin (1/100 grain), or nitroglycerin (1/100 grain) hypodermically. The diet should be composed of liquids. See ECLAMPSIA.

URETERS, CATHETERIZATION.—This method constitutes a real advance in the accurate diagnosis of certain morbid renal conditions. By introducing a catheter directly into the ureter it can be learned whether blood or pus which is contained in the urine comes from the kidneys, and if so whether it is derived from one or both of these

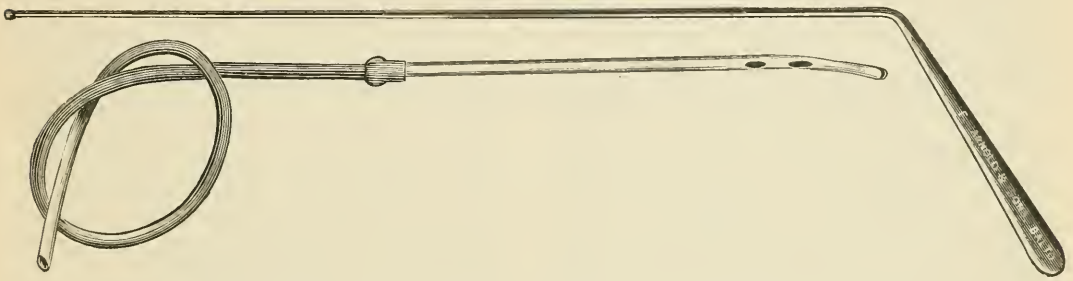
organs. The patency of the ureter can also be determined, and by injecting fluid through the catheter it can be learned whether the pelvis of the kidney is dilated. Suppurative conditions of the renal pelvis may be treated directly by the injection of medicated solutions. The secretory power of the two kidneys can also be determined when this method is employed in connection with certain functional tests. Casper and Richter found that in health the urine secreted simultaneously by the two kidneys contained about the same quantity of nitrogen, urea, and salts and that the freezing-point of both fluids was the same. In disease, however, these relations are altered, the diseased kidney excreting less than the healthy one. The same holds true of the excretion of phloridzin, which produces an artificial diabetes of short duration. Thus it is seen that the possibility of securing urine from each kidney separately by means of the ureteral catheter enables the clinician to obtain valuable diagnostic data concerning the functional capacity of each organ. At present it may be considered an invariable rule in renal surgery to have an examination of the urine obtained separately from each kidney made upon one or more occasions before resorting to operation. If the functional capacity of both kidneys is low, the removal of one might be followed by uremia and death.

mucosa. When they are located the ureteral catheter is made to enter one orifice and passed upward by a slow rotary movement for a distance of about 5 centimeters. The same procedure is then repeated on the other side.

The cystoscope may be left *in situ* while the urine is being collected, or it may be withdrawn, leaving only the catheters in place. With the improved modern cystoscopes the latter procedure is easy and is less disturbing to the patient.

The urine is collected in sterile glass tubes, every precaution being taken to prevent contamination.

URETHANE.—Ethyl carbamate, $C_3H_7NO_2$, is an ester of carbamic acid, obtained by the reaction of ethyl alcohol upon carbamid (urea) or one of its salts. It occurs in colorless crystals, readily soluble in water, alcohol, ether, or glycerin. Dose, 10 to 30 grains; but is best given in doses of 5 grains frequently repeated, up to 20 grains or more, as a full dose may cause vomiting. It is incompatible with many substances, and is best administered by itself. Urethane is a mild hypnôtic for adults, but a safe and efficient one for children. It stimulates the respiration, and in medicinal doses does not affect the circulation; but in very large quantities it slows the heart, depresses the body temperature, and induces muscular relaxation and some degree of general anesthesia.



KELLY'S SEARCHER, ABOVE, FOR INVESTIGATING A DOUBTFUL URETERAL ORIFICE.
SHORT URETERAL CATHETER, BELOW, WITH RUBBER TUBING ATTACHED.

Catheterizing cystoscopes are made both in the direct and indirect varieties. The instruments of Nitze, Casper, Albarran, Bransford Lewis, Brown, and Buerger are most commonly used. They all carry two catheters, which permit simultaneous catheterization of both ureters.

In the female the ureters may be catheterized by the aid of a speculum passed through a dilated urethra, the patient being in the lithotomy position with the pelvis well raised, or in the genu-pectoral position. The modern perfected cystoscopes, however, render such a procedure unnecessary, and moreover, afford an easier method for the average operator.

The technic of ureteral catheterization is the same as that of cystoscopy. The bladder is washed out with sterile water or a weak antiseptic solution, then distended with the same fluid and the cystoscope introduced. The ureteral orifices are situated at the base of the trigone, one at either angle and appear as small slits in the vesical

URETHRA (FEMALE), DISEASES. Inflammation.—Inflammation of the female urethra is almost invariably due to gonorrhea. It may occasionally be due to traumatism, chemic irritants, drugs, and the exanthematous diseases.

Symptoms.—In acute urethritis there is frequent and painful urination. In severe cases blood may appear in the urine. The external meatus is inflamed and swollen, and pressure over the course of the urethra is accompanied by intense pain and by the discharge of a few drops of pus. As the disease becomes chronic the severe symptoms subside; there is little or no pain. Pressure over the urethra reveals some tenderness, and, if the patient has not urinated recently, will probably cause the discharge of a drop of pus. Endoscopic examination will show localized areas of inflammation.

The treatment in the acute stage should consist of rest in bed, a nonstimulating diet, diluent drinks, and rather free purgation. A very good plan is to

put the patient on an exclusive milk diet. The external genitals should be cleansed several times daily with hot boric acid solution (1 dram to 1 pint). After the first two or three days of the attack salol, oil of sandalwood, cubebs, or copaiba, in 5-grain doses, may be given 3 or 4 times daily. If this treatment is ineffectual, irrigation of the urethra with sterile water should be tried, followed by the injection of a solution of nitrate of silver, 2 grains to 1 ounce. In injecting solutions of any kind into the urethra it should be remembered that its capacity is not more than 10 or 15 drops. Occasionally, the condition will persist in spite of this treatment. Such cases require applications of a stronger solution of nitrate of silver (10 grains to 1 ounce) directly to the affected areas through the endoscope.

Caruncle.—See CARUNCLE (Urethral).

Polypus.—Polypi of the urethra are mucous in character. They cause no symptoms except that of obstruction to the flow of urine. They should be excised.

URETHRA (MALE), HEMORRHAGE.—Hemorrhage from the urethra may be caused by the introduction of a bougie, by the opening of a false passage, by the separation of a slough formed by the caustic bougie, or by the rupture of a blood-vessel during acute chordee, or it may result from internal injuries. It may occur from general arterial excitement or may be associated with HEMATURIA (*q. v.*).

Treatment.—The recumbent posture, with application of cold and pressure, should be tried. A flat piece of cork should be pressed by the patient against the perineum, far back, and gradually moved forward until it reaches the right spot, when the dripping of blood will cease. A solution of tannic acid in water may be used as an injection. Gallic acid may be of service. Adrenalin solution has proved efficient. A steel bougie, first put in very hot water and then introduced into the urethra, is often used to arrest this variety of hemorrhage. If the hemorrhage is from the anterior portion of the urethra, a catheter should be inserted and a bandage firmly applied around the penis.

URETHRA (MALE), INJURIES.—Rupture of the urethra is a serious injury, as it exposes the patient not only to the immediate danger of extravasation of urine, but also to the lifelong trouble of a traumatic stricture. It is generally caused by a kick on the perineum, by a fall astride a joist or rail, or by the displacement of a fragment of the pubic arch in fracture of the pelvis. The urethra may also give way behind an old stricture while the patient is straining to empty his bladder.

State of the Parts.—The rupture usually occurs where the urethra passes under the pubic arch: *i. e.*, either just in front of or just behind the triangular ligament. In the former situation urine and blood will be extravasated in the perineum; in the latter, about the neck of the bladder. As the triangular ligament, however, is generally torn, some urine will, as a rule, in the latter case also pass forward into the perineum. The urethra may be completely torn across, or the rupture may only be partial, the upper wall escaping.

The symptoms are usually quite obvious. Together with the history of an accident there will be pain, swelling, and the ecchymosis of the perineum, and escape of blood, often in considerable quantities, from the urethra. The patient is unable to pass water, and any attempt to do so merely forces more urine into the tissues of the perineum, and gives pain. On trying to pass a catheter, some obstruction is generally met with, and will often prove insurmountable; but if the catheter is finally passed, clear urine will escape. These signs distinguish it from ruptured bladder, in which injury the catheter passes easily, but, generally (although the bladder is said to have been full at the time of the injury), only a little urine flows. In mere bruising and ecchymosis of the perineum the catheter will pass easily, and there is, as a rule, no escape of blood from the urethra. See HEMATURIA, URINE (Examination).

Treatment.—A soft catheter should be passed, if possible; if not, a gum-elastic or a silver one; and, in any case, the catheter should be tied in. Failing to pass a catheter, an extravasation of urine in any quantity having already occurred, a silver catheter should be passed down to the obstruction and a free incision through the middle line of the perineum made on its point. If the proximal end of the torn urethra can now be found, the catheter should be passed through it into the bladder and tied in. If not readily discovered, a prolonged search for it need not be made, as with a free incision through the perineum there is no danger of further extravasation of urine. If the urethra is found only partially torn across, an attempt should be made to bring the edges together by suture over a catheter, the external wound in the perineum being then united by deep sutures. The catheter should be kept in place for a week. Should a fragment of the pubic arch be found compressing the urethra, steps must be taken to remove it, the bladder in the mean time being aspirated above the pubes to prevent further extravasation occurring. When the wound in the perineum is left to granulate in the ordinary way, a silver catheter—as the point of this is more under control than that of a soft one—should be passed daily during the healing of the wound, and the patient should be enjoined subsequently to pass one for himself at frequent intervals, and warned that if he neglects to do so, a stricture will gradually form (Walsham).

Foreign bodies introduced into the urethra require extraction. Urethral forceps should be avoided as far as possible; sometimes, by placing the patient in a hot bath, giving him plenty of liquid to drink, and directing him to retain his water, sufficient can be withheld to drive out such an obstruction, for example, as the end of a catheter broken off in a stricture; but this should not be tried too long. Hair-pins, on the other hand, and such structures, nearly always require incision. The cases in which the obstruction is slight and a stone lies out of the way are much more rare, and, as a rule, occur only in elderly men. In a few instances huge cylindric calculi have been found, 3 or 4 inches in length and 1 1/2 inches in circumference. These generally lie in the tissue

by the side of the urethra, occupying a cavity which they have worn out for themselves, and sometimes they are so invested by the mucous membrane that a sound may be passed down by them without any characteristic grating.

URETHRA (MALE), STRICTURE.—In the male, stricture may be either congenital or acquired. Congenital stricture occurs but rarely, and is usually confined to the meatus. Acquired stricture may be defined as an abnormal lessening of the caliber of the urethra, or of the dilatability of the urethral canal, associated with changes in the mucous, submucous, or muscular structures constituting its walls. This definition embraces the varieties of strictures known as inflammatory, spasmodic, and organic.

Inflammatory stricture is a narrowing of the caliber of the urethra, due to inflammation; it is usually of short duration, is seldom attended with retention of urine, and is frequently the starting-point of organic stricture.

Spasmodic Stricture.—This condition is due to contraction of the muscular fibers of the urethra; it is frequently reflex in character, as is shown by the retention of urine that sometimes follows surgical operations on the anus, rectum, penis or scrotum. It may be caused by shame, fear, or anger, or by a hyperesthetic condition of the canal.

Organic stricture may exist in either sex. In the male it occurs early in life; it is most common between the ages of 25 and 45. It is caused by long-standing urethritis, by traumatism, and, according to some authorities, by masturbation.

Symptoms.—As a rule, it will be found that the individual has suffered one or more attacks of urethritis within a year or two previous to presenting himself for treatment. A frequent desire to urinate, more urgent during the day, is usually one of the early symptoms; the stream is much reduced in size, and may be forked, twisted, or spray-like. After the stricture has existed for some time and atony of the bladder has developed, there will be marked diminution of the expulsive force. Dribbling from the urethra is frequently an early symptom, depending on the condition of the circular muscular fibers of the urethra. Late in the disease incontinence of urine sets in, which is the so-called "incontinence of retention;" it is more persistent during the day.

When inflammation of the prostate or bladder exists, ardor urinæ will prevail. The same causes may give rise to vesical tenesmus. Urethral discharge is present in about 50 percent of the cases, and is usually of a mucoid character; retention is, as a rule, a late symptom, and is caused by exposure to cold, unusual exertion, alcoholic excess, or immoderate coition.

Strictures of very small caliber may markedly interfere with the act of coition: the stricture becoming congested during the sexual embrace, prevents the semen from passing forward, and it slowly dribbles away after the erotic act has terminated.

In cases of long standing in which a diseased condition of the bladder and kidneys exists, associated with alternation in the character of the urine, there will frequently be found well-marked constitutional symptoms, such as uremia and septicemia.

Treatment.—The patient must be carefully examined, so as to ascertain the number, position, caliber, resiliency, and relative irritability of the strictures. The condition of the bladder and kidneys must be determined, and a microscopic and chemic examination of the urine must be made, to decide whether any pus, mucus, or blood is present, or whether any casts are to be found. If possible, a bacteriologic study of the urine should be made, as the presence of pathogenic organisms has often a great bearing on the treatment of the case. The quantity of urine passed during 24 hours should be fixed upon and the amount of urea clearly ascertained, together with the aggregate of albumin and sugar. Having obtained these data, the surgeon will be enabled to decide upon the proper operation to be performed.

The numerous methods resorted to for the extirpation of urethral stricture are: (1) Gradual dilatation; (2) continuous dilatation; (3) modified rapid dilatation; (4) internal urethrotomy; (5) dilating internal urethrotomy; (6) dilating internal and external perineal urethrotomy; (7) external perineal urethrotomy with guide; (8) external perineal urethrotomy without guide; (9) electrolysis; (10) urethrectomy; (11) divulsion.

1. Gradual Dilatation.—This is the treatment usually pursued for the relief of stricture, and is by far the safest method, death never having followed its employment. In soft recent strictures the number of permanent cures resulting from gradual dilatation compares favorably with those treated by internal urethrotomy, without incurring the risk attendant upon the latter operation.

To perform gradual dilatation properly the character, position, and caliber of the stricture should be closely ascertained by means of the bougie à boule. If possible, the operator should commence dilatation while the caliber of the stricture is not dense. The instrument to be used should be a conic steel bougie one or two sizes smaller than the contraction, as more or less hyperesthesia of the urethra usually exists, and the onward progress of an instrument large enough to fill or distend the stricture gives rise to great pain, causing more or less spasm and interfering with the passage of the bougie. The canal in the neighborhood of the obstruction is likely to be congested, chronically inflamed, and softened. If there is much distention, the mucous membrane is easily lacerated. Laceration is followed by pain after micturition, with the discharge of more or less blood. In rare cases urine is absorbed into the system by reason of abrasion or laceration, giving rise to urinary fever. By commencing with a bougie of a smaller diameter than the caliber of the stricture, this complication is frequently avoided. The confidence of the patient is gained if the instrument produces but little pain, and thereby more progress is made than if force were used.

The best rule is to increase the size of the instrument as the pain of insertion diminishes and as the amount of blood following the introduction becomes less. The instrument should not be intro-

duced more frequently than every third day, and should be immediately withdrawn after insertion.

Before using an instrument, both it and the urethra itself should be made thoroughly aseptic. Palmer has shown the value of boric acid in sterilizing the urine, administered when the patient is placed under treatment. It should be given for 2 weeks in doses of 10 grains 3 times daily.

Urinary fever is most likely to occur at the beginning of the treatment, when the mucous membrane of the canal is in a condition of subacute inflammation and is somewhat softened. This may be avoided by the use of boric acid.

Examination of the urethra by means of the endoscope will show how rapidly the inflammatory symptoms disappear in the neighborhood of the stricture when partial dilatation has been accomplished. This change possibly accounts for the rapid amelioration of the local symptoms—indeed, it commences after the instrument has been passed but a few times, and before the normal caliber of the urethra has been restored.

The length of time the treatment should be continued will vary with the condition of the obstruction to be overcome. If the stricture is extensive, about 3 months will be required to restore the urethra to its normal size. During this time the patient is to be instructed in the use of the instrument, which he should be directed to pass twice a week for a period of 2 months; after which he must use it once a week for a similar period, then once in two weeks, and finally once a month. The treatment may then be discontinued, the patient being directed to return to the use of the instrument whenever there is an indication of a tendency to recurrence to an abnormal condition.

By faithfully employing the instrument when necessary, the patient can always keep the urethra patulous, and need suffer no further urinary difficulty. In cases of stricture of very small caliber a much longer time will be required to bring about permanent good results. Gradually dilatation may be employed for years, with every advantage to the patient, no symptom of contraction making its appearance nor any indication of trouble from the prolonged use of the bougie.

Recent strictures frequently disappear altogether when the method here prescribed is pursued, when the further use of the instrument may be dispensed with.

Gradual dilatation is indicated in all cases of recent dilatable stricture in any portion of the urethra, or when the stricture is not irritable, resilient, or nodular. Firm, well-organized bands situated within from 3 1/2 to 4 inches from the meatus may require other measures for their obliteration.

When diabetes or advanced disease of the kidneys exists, gradual dilatation is far more safe than any other method of procedure. This, too, is the proper treatment for those suffering from debility, or from disease of the heart, and for individuals broken down in health, and for the very old, especially if chronic urinary fever coexists.

In many cases one of the cutting operations may be advised instead of dilatation, but experience teaches that when a well-organized stricture exists, urethrotomy is as frequently followed by recontraction as is dilatation, the patient at the same time running the greater hazard that always follows a cutting operation, with very little, if any, better chance of permanent benefit in his favor.

It cannot be denied that every urethrotomy is attended with more or less risk to the patient, while dilatation is perfectly safe; moreover, the further the division of the stricture is made from the meatus, the greater will be the danger from the operation.

Death has followed shock after simple division of the meatus. Even in the hands of the most experienced operators the death-rate from internal urethrotomy is 2 in every 100 cases.

Taking the dangers of the cutting methods into consideration, and the fact that they are rarely followed by permanent results, it would seem to be obligatory on the part of the surgeon to give the uninformed the option of the safest course. If the cure from the cutting operations were radical, and if the strictures did not recontract in a large percentage of cases, it would doubtless be the duty of the practitioner to allow the patient to run the risk of urethrotomy; but as the result is by no means certain by any method now employed, there should be no hesitancy in recommending a course that, while it has its disadvantages, yet relieves the symptoms due to obstruction and is absolutely safe.

2. **Continuous Dilatation.**—In resorting to continuous dilatation, the surgeon should begin with a very small instrument, a filiform bougie being usually employed. This must be allowed to remain *in situ* for 3 days, when, as a result of the continuous pressure, the stricture relaxes sufficiently to allow of the introduction of a larger instrument. As a rule, the tunneled catheter is the instrument to be used; this is passed over the whalebone and through the obstruction into the bladder. After this the surgeon is free to deal with the stricture in any manner that he may prefer.

There are two conditions under which this method of treatment is applicable: First, when there is a stricture of small caliber, usually situated in the membranous portion of the canal, and generally accompanied by retention of urine; second, when, although the stricture is tight, the patient is enabled to pass urine with sufficient ease to allow him to be prepared for a radical operation.

In the first instance, when a filiform bougie has been inserted, a Gouley tunneled cathether should, if possible, be threaded over the whalebone and passed through the obstruction, and the urine should then be withdrawn. Should the effort to pass the catheter be unsuccessful, the filiform bougie should be retained in place by means of appropriate dressings, so that it cannot be expelled from the urethra. If the symptoms are urgent, the bladder must be aspirated. If the viscus is not overdistended, the patient should be given 1/2 grain of morphin and should be immersed in a hot bath, when he will have but little further trouble in passing his urine. The stricture should then

be treated as the surgeon may deem most expedient.

Under the second condition, continuous dilatation is employed simply to enable the operator to overcome the contraction by the use of either gradual or modified rapid dilatation, or to enable him to enlarge the stricture sufficiently to pass a Syme's staff, and thus facilitate the performance of external perineal urethrotomy, should this operation be indicated.

The failure of many practitioners to use filiform bougies successfully arises from various causes: the instruments usually sold are often worthless: they are too stiff, not well rounded, do not terminate in a proper neck, and are generally too large to be threaded over the smaller sized catheters. The surgeon should make his own filiform bougies; a dozen, properly constructed, will, with ordinary care, last through several years of active practice. An important rule to follow is to employ the filiform before any bougie, catheter, or other instrument has been introduced into the urethra. If an instrument has been previously used, it is of very little avail to attempt to pass a filiform, as failure will generally result. Great patience is a necessary element to success.

It is well first to inject two drams of adrenalin solution 1 to 4000, let the patient hold it in the urethra for two or three minutes, and then distend the canal by gently injecting a syringeful of warm carbolized oil before inserting the filiform, which has been rendered aseptic, and which is to be introduced into the meatus and passed slowly down to the obstruction, while at the same time the patient's face is carefully watched for the slightest expression of pain, which is an indication that the onward passage of the filiform must cease. The slightest impediment to the passage of the bougie should warn the operator that he has proceeded far enough with the instrument, when a second should be introduced in the same manner, and the process thus repeated until 6 or 8 whalebones have been inserted, when the operator very gently tries each in turn; to see if he can find the opening in the obstruction; beginning on the left and passing to the right side of the patient, the surgeon naturally tending to work toward himself.

If the stricture is excentric, the opening will probably be found by this manipulation; the instrument will glide through the contraction with little or no pain, when, without force being required, it will pass into the bladder, and will be freely movable in the urethra.

These instruments are frequently made with a spiral twist at the end, on the supposition that the physician can more readily pass such a one should the stricture be excentric. However, perfect success with the straight instrument is always possible.

In order to successfully insert a tunneled catheter over the filiform through the stricture, the instrument should be gently passed down to the obstruction, then transferred from the right to the left hand; and while the right hand keeps the penis on the stretch, the filiform is to be withdrawn about 1/4 of an inch, and then both the filiform and the tunneled catheter are to be carried together through the contraction. This procedure prevents the catheter from cutting the filiform into two fragments, and assists in guiding it through the obstruction.

This method of treatment is of great value as an adjunct to the employment of more radical measures. It is of service in relieving retention of urine due to strictures of small caliber, in preparing the canal for gradual or modified rapid dilatation, and in permitting the passage of a staff for external perineal urethrotomy.

If a stricture exists in the neighborhood of the bulbous or membranous portion of the canal, and is not irritable, resilient, or nodular, the employment of continuous dilatation should be followed by the gradual method; and if this is not practicable, modified rapid dilatation is strongly recommended.

3. **Modified Rapid Dilatation.**—The operation to which this name is given is not in favor with many genitourinary surgeons, but undoubtedly gives good results in strictures of small caliber situated in the membranous portion of the urethra.

The patients thus operated on are confined to the house but 4 days, at the end of which time they are allowed to go about, with directions to report to the surgeon at intervals of 3 days in order to have a full-sized bougie inserted, which they soon learn to use themselves. The treatment is to be continued as advised when speaking of gradual dilatation.

It is not observed that strictures thus treated show any greater tendency to recontract than those on which either internal or external urethrotomy has been performed, especially if dilatation is continued afterward.

To carry out this method of treatment properly the patient is to be put to bed, the urethra washed out with a 4 percent solution of boric acid, and an aseptic filiform bougie passed and tied in place. The patient is then given 10 grains of boric acid 3 times daily, and the urethra is to be irrigated daily with boric acid solution; at the end of the third day he is etherized and the urethra is washed with a 1:20,000 mercuric chlorid solution. The Thompson dilator is then passed over the filiform and through the obstruction, when, by means of the thumb-screw attached to the handle, the blades of the instrument are slowly and very gradually separated to a very slight degree; after remaining in this position for 1 minute they are again approximated.

This procedure of alternate separation and approximation is to be repeated, taking care each time to separate the blades of the instrument to a somewhat greater extent, until the stricture is enlarged sufficiently to allow of the insertion of a Gross dilator, which requires that the caliber of the urethra should not be less than 18 F.

The Thompson instrument is then removed, and the Gross instrument inserted. In the same gradual manner the caliber of the urethra is brought to the full size of the canal, which has previously been ascertained by means of a bougie à boule.

Strictures so treated are stretched rather than lacerated or torn; this is shown by the small

amount of hemorrhage that follows. On examination with the endoscope two weeks later the walls of the urethra will be found to be smooth, and not ragged, as would be the case if laceration had taken place.

After the Gross instrument is withdrawn, a full-sized bougie is passed, to ascertain whether all obstruction has been dislodged; if this is found to be the condition, the urethra should be irrigated with a 1 :20,000 mercuric chlorid solution, and a sterilized catheter passed and tied in place; then a small quantity of warm boric acid solution is to be injected into the bladder. The patient is put to bed; the urethra and bladder are to be irrigated daily with a warm boric acid solution, and on the fourth day the instrument is to be removed and a full-sized bougie passed. The patient is allowed to sit up, and may resume his vocation on the following day.

This method is applicable to the treatment of filiform strictures in the neighborhood of the bulbous and membranous portions of the urethra, which are not irritable, resilient, or nodular, and which cannot be treated by gradual dilatation. It likewise is not convenient when time is an object, as, for instance, when the individual is about to undertake a journey or is about to be married. It should not be performed on the aged, or on those suffering from disease of the kidney, urinary fistula, or abscess of the perineum. In many cases in which the stricture is resilient, the caliber very small, and a perineal section is indicated, this operation may be employed primarily to facilitate the passage of the grooved staff, immediately afterward performing the cutting operation.

It would seem that an operation that is so free from complications, attended with so little danger to life, and that at the same time produces such favorable results, with no greater tendency to relapse than is to be encountered after other methods, is entitled to a prominent place among the resources that the surgeon possesses wherewith to overcome obstructions in the bulbous and membranous portions of the urethra.

When it is observed that in performing this operation the stricture is dilated gradually, and that an effort is simply made to restore the contracted portion of the canal to its normal caliber, that it is not overdilated, and that in conjunction with the operation the strictest aseptic and antiseptic precautions are employed, it will be seen that it differs very materially from the method of divulsion, which should become obsolete.

4. **Internal urethrotomy** should be limited to well-organized strictures situated within 3 1/2 or 4 inches from the meatus. If they are of such small caliber that a urethrotome cannot be passed, they should be first cut on the roof of the urethra, from before backward, and the constriction should be divided on the floor of the canal by the cross urethrotome, which, being of the shape of a bulbous bougie, locates the constricting band with great exactness. Stricture of the meatus and of the neighborhood of the fossa navicularis should be divided on the floor of the urethra, especially if they give rise to reflex symptoms.

5. **Dilating internal urethrotomy,** though very thorough, is not indicated in many instances the operation being frequently followed by reformation of the stricture. Its sphere of usefulness is confined to those conditions in which the stricture is well organized, of long standing, situated within 3 1/2 inches of the meatus, and is either nodular or resilient. In the latter condition it is the only operation that offers permanent relief; but unless the patient employs the bougie in the manner recommended when treating of gradual dilatation, the contraction will be likely to return.

Dilating internal urethrotomy should not be employed in a case of ordinary stricture of the penile portion of the canal, unless it is complicated in the manner already described, as the operation will probably be followed by a curvature of the penis, which may last for a period ranging from 6 weeks to a year, and is, of course, a source of great mental anxiety to the individual. What is far worse is that the knife of the instrument cuts so deeply that an extensive division of the muscular fibers of the urethra follows, and, as a result, dribbling after the act of micturition takes place; as the canal is unable to expel the last drops of urine, it slowly oozes from the meatus. This condition is permanent.

If it can be avoided, dilating internal urethrotomy should not be performed on persons suffering from impotence, neurasthenia, abnormal nocturnal losses, or sexual hypochondriasis. Very naturally, the incurvation of the penis and the dribbling of the urine produce very depressing mental effects on the patient, which are difficult to overcome. When these complications exist, it is preferable to rely upon internal urethrotomy by means of the Gross instrument.

6. **Dilating internal and external perineal urethrotomy** is relied upon for the relief of nodular strictures of the penile portion of the urethra, and of strictures of the bulbous portion of the canal. The object in opening the membranous portion of the canal, in cases of nodular strictures situated in the anterior portion of the urethra, which have been divided, is that the parts may be put at complete rest, and that the indurated tissue of which they are formed may be allowed to undergo fatty degeneration, atrophy, and absorption.

Dilating internal and external perineal urethrotomy has frequently been modified, with good results. The strictures upon which this method was resorted to were situated about 2 1/2 inches from the meatus, were nodular, resilient, and of very small caliber. By means of the Maisonneuve instrument they were divided on the roof of the canal, and the insertion of the Otis dilating urethrotome thus permitted; the constricting bands on the floor were freely divided, and the caliber of the urethra brought to its full size. A Jacques' catheter was then passed, fastened in place, and allowed to remain *in situ* for 2 weeks, temporarily removing it every third day for the purpose of sterilization. The urethra and bladder were daily irrigated with a boric acid solution. The induration around the seat of the stricture disappeared,

and the patients recovered without complicating the cases by the addition of perineal puncture.

7. **External Perineal Urethrotomy by Means of a Guide.**—The membranous urethra is opened, the surgeon being guided in reaching that portion of the canal by either the filiform bougie, a Gouley tunnel catheter, Thompson's dilator, or a Syme's staff. This operation is indicated in nondilatable, resilient, nodular strictures of small caliber, in associated with fistulæ and abscesses, and when false passages exist, with retention of urine. It may be performed by carefully dissecting down upon the urethra until the obstruction is found, and then cutting through the stricture, a procedure known as the "Wheelhouse operation." Another method is sometimes employed, known as "Cock's operation."

With the aid of a modification of the Wheelhouse

SYME'S STAFF.

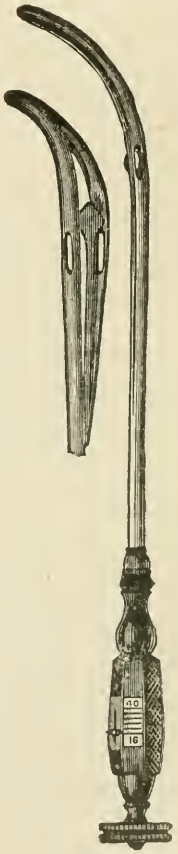
OTIS' URETHROMETER.



GROSS' DILAT R.

obstructions of the canal associated with fistulæ and abscesses of the perineum, and in conjunction with internal urethrotomy performed upon some part of the penile portion of the urethra.

8. **External perineal urethrotomy without a guide,** generally known as "**perineal section,**" is performed when no guide of any kind is passed into the canal. It is generally employed in the cases of stricture of traumatic origin, of obstructions

staff designed by Horwitz, the operation known by the name of that surgeon is very materially altered and simplified. Horwitz's staff consists of two blades in close approximation, which together form a smooth rod with a thumb-screw at one end, by means of which the blades may readily be separated, working upon the same principle as the Otis dilating urethrotome. The distal end of the instrument terminates in a rounded nut, which can

be removed or replaced by a whip filiform; the nut on the end is tunneled, so that an ordinary whalebone filiform can be passed. The filiform is employed when it is not possible to insert the whip bougie, as it frequently happens that the former instrument can be introduced when the passage of the latter cannot be achieved; so that the staff can be employed with either an ordinary filiform or a whip bougie, or without any guide.

When it is possible to introduce the whip bougie through the stricture, it is to be fastened to the perineal staff. The blades of the instrument are closed and then passed into the urethra until arrested by coming in contact with the shoulder of the stricture. The whip bougie being pushed in front of the staff, reaches the bladder and curls up, and when the urethra is opened, serves as a guide to the operator, as it passes directly through the stricture.

In case the whip bougie cannot be passed through the stricture, a whalebone filiform should be inserted; the tunnel at the end of the staff is threaded over with a filiform and is introduced into the urethra until arrested at the contracted portion of the canal.

By means of the thumb-screw the blades are separated, and thus the urethra in front of the stricture is not only fixed, but is made prominent, and the operator, after making the incision through the skin, can readily open the urethra with absolute precision and ease.

If the stricture is impassable and the operation must be performed without a guide, the staff is to be passed down to the seat of contraction; when this point is reached, the blades are to be separated and the urethra fixed and made prominent, when the urethra can be opened in front of the stricture by a few touches of the knife. The modification in the technic of perineal section will now be considered.

When the patient is placed on the operating table, an effort is to be made to introduce the whip bougie; should this fail, a filiform is inserted, over which is threaded the perineal staff, which is passed down to the strictured portion of the urethra; the blades are then separated and the instrument given to an assistant to hold, who at the same time lifts the scrotum well out of the way. The individual is then placed in the lithotomy position, the buttocks projecting slightly beyond the edge of the table. A free insicion is made along the perineal raphe, and the structures overlying the urethra are divided until the canal is exposed at the bottom of the wound. A tenaculum is then passed into the urethra on each side of the staff, and placed in the hands of the assistant who has charge of the leg, with directions to make gentle traction; this brings the urethra prominently into the wound, where it can be readily incised in front of the stricture, when the staff is exposed *in situ*. The Wheelhouse probe is then utilized to search for the mouth of the stricture; as soon as it is disclosed, the probe is to be inserted by the side of the filiform and passed backward until it enters the bladder; it is then handed to an assistant to hold.

With the index-finger of the left hand in the rectum as a guide, and in order to prevent injury to the bowel, a probe-pointed bistoury is passed along the groove on the under sufrace of the staff, so as to divide the stricture throughout its entire length; after which a Teale gorget is to be inserted beside the probe until the instrument enters the bladder. The probe is then to be removed and a soft-rubber catheter passed through the penile urethra until the point of the instrument appears in the perineal opening, when it is to be seized by the surgeon between his finger and thumb, pulled well into the incision, and made to pass along the gorget until it reaches the bladder; the urethra, perineal wound, and bladder are then to be irrigated with a solution of 1:20,000 bichlorid of mercury, and the perineal wound dressed in the usual manner.

In cases in which neither a whip bougie nor a filiform can be made to pass the stricture, a method precisely similar to that just described should be pursued. It sometimes happens that, owing to infiltration against the compact tissue, it is impossible, after the most careful search, to find the proximal end of the urethra. Should the operator be unable to discover the opening to the strictured portion of the canal, the bladder should be opened after the method suggested by Cock. If the patient is in poor physical condition, or if suffering from chronic disease of the kidney, or if he has sustained a rupture of the urethra, with infiltration of urine, valuable time should not be wasted in attempting to reach the bladder through the perineum; the proper method is to proceed at once to perform retrograde catheterization.

Cock's Operation.—The surgeon having failed to pass any instrument through the strictured portion of the urethra to serve as a guide, the patient is to be placed in the lithotomy position; the index-finger of the left hand is introduced into the rectum, and its tip kept in contact with the apex of the prostate gland. A double-edged knife is then thrust directly into the median line of the perineum about one inch above the sphincter ani, and carried toward the tip of the finger in the rectum, opening the urethra at the junction of the membranous and prostatic portions of the canal.

9. **Electrolysis.**—Of 15 cases treated by this means, all did badly: either urethritis, prostatitis, cystitis, or epididymitis followed; and this mode of treatment was necessarily abandoned. In one case slight improvement followed; this was due to the gradual dilatation produced by the electrode. Fort, of Paris, has devised special instruments for this operation, from the use of which he claims to have obtained most excellent results. The experience of genitourinary surgeons throughout the United States is against its general adoption or its value in ordinary cases. It is therefore not recommended.

10. **Urethrectomy.**—This treatment is reserved for traumatic strictures, attended by great resiliency, which promptly recontract, in spite of every effort, after a most thorough and complete operation. It consists in either partial or complete excision of all the nodular and strictured tissue, which is dissected away by means of an incision in

the perineum, a new urethra being formed around a retained catheter.

11. **By divulsion** is understood the passing of a dilator so as to rupture the contracting band. Divulsion of a stricture by Holt's instrument is generally condemned as dangerous to life, as has been abundantly proved by a large mass of clinical testimony. Safer methods offer better results.

URETHRAL CALCULUS.—Calculi are occasionally formed in the urethra, in the dilated and fasciculated pouch that develops behind a stricture; but the nucleus is nearly always carried down from the bladder. The symptoms depend upon the degree of obstruction: if the calculus is large enough to occlude the urethra itself, or is so sharp and angular as to bring about the same result by the spasm that it excites, retention occurs; and if speedy relief is not given, ulceration and extravasation follow. If, on the other hand, it is small and is lodged in a diverticulum, it may continue to increase from the deposit of phosphates on its surface, and to wear its way into the tissues, until at length it forms an enormous mass, lying in the substance of the penis, alongside the urethra, almost buried under the mucous membrane.

Impacted calculus is more common in children than in adults, owing to the greater frequency of stone in childhood and to the small size of the urinary passages. The calculus is washed down from the bladder during the act of micturition and is suddenly arrested, generally in the membranous part or at the meatus.

Symptoms.—The stream stops suddenly, there is a sharp, cutting pain at the end of the penis, with violent straining, and perhaps a few drops of blood exude from the urethra, especially if the calculus is sharp and angular. For a time the straining continues, the bladder becomes more and more distended, and then either sudden extravasation occurs, or, if a small quantity of urine can escape by the side, so that there is not such immediate tension, inflammation sets in, ending in urinary abscess and fistula.

Diagnosis.—There is seldom difficulty in the diagnosis. The history of the case, the way in which the child screams and pulls at the end of its penis, the retention of urine, which is so rare in children from any other cause, and the few drops of blood are distinctive. Very often the calculus can be felt from the outside. If it cannot be felt, a small catheter may be passed down the urethra; sometimes it comes to an abrupt stop against the stone; sometimes it slips by the side of it with a rough, grating sensation, and, entering the bladder, gives relief for the moment. If any time has elapsed since the accident, the bladder may be distended up to the pubes; or there may already be a swelling in the perineum, due to inflammation and commencing extravasation.

Treatment.—A calculus in the penile part can generally be worked forward with the fingers until it reaches the orifice, when a small incision may be necessary to extract it. If this is not successful, a scoop or pair of urethral ("alligator") forceps may be passed down the urethra, and an attempt made to draw the calculus forward; but this may inflict serious injury upon the mucous membrane. If it is fixed or is too far back for this, the patient should be placed in the lithotomy position, the skin over the projection stretched with the finger and thumb of the left hand, and a small median incision made down upon it. Generally the calculus springs out at once, and the wound may be left to granulate. The bulb should, if possible, not be incised. If the calculus is near the neck of the bladder, it should either be removed by the median operation or pushed further back and crushed with a lithotrite.

URETHRITIS.—See GONORRHEA.

URETHROSCOPE.—See ENDOSCOPE.

URETHROTOMY.—See URETHRA (Male) (Stricture).

URIC ACID.—See URICACIDEMIA, URINE (Examination).

URICACIDEMIA.—A constitutional disease arising from disturbed metabolism and an accumulation of uric acid in the blood, and characterized by an excess of uric acid in the urine, by disturbed digestion, and by various nervous symptoms. It differs from gout chiefly in the absence of deposits of urates in the small joints and in the absence of localized manifestations.

Synonyms.—Lithemia; lithic acid diathesis; uric acid diathesis; latent gout; lithuria.

Etiology.—Hereditary influences, overeating, alcoholic excess, impaired digestion, sedentary habits, insufficient exercise, and mental anxiety, with loss of sleep are the principal causes.

Symptoms.—It may be said that, as a rule, in lithemia the nervous symptoms are vague, such as insomnia, pains in the lumbar region, headache, neuralgia, and mental hebetude. The circulation is sluggish, and the patient complains of cold feet. Tonsillitis is common.

Gastrointestinal Symptoms.—In these cases constipation exists, and the tongue is furred. The appetite may be poor or sometimes may be abnormally large. The digestion is always bad and gastralgia and acid dyspepsia may coexist.

Urinary Symptoms.—In nearly every case the urine is loaded with uric acid and the urates. The urine is usually high colored, scanty, acid in reaction, and may cause pain on micturition. See URINE (Examination).

Sequels.—Arteriosclerosis, interstitial nephritis, cirrhosis of liver, gastralgia, dyspepsia, and probably nerve lesions not yet understood.

Diagnosis.—There are but few diseases in which the importance of the examination of the urine is greater. A disease with such vague nervous and gastrointestinal symptoms may simulate any number of other affections, including malaria (very common), rheumatism, and diseases of the brain and of the spinal cord.

If uric acid is present in a sample of urine, it is not absolutely diagnostic of lithemia; but with the history and other symptoms it is not likely that the diagnosis will be mistaken. Next in importance to the examination of the urine is a correct and complete history. It is very often a disease

of neglect, and the patient, as a rule, does not consult the physician until its progress has far advanced, and until the accumulation of the uric acid in the system produces the manifold symptoms which each patient can so accurately portray.

Treatment.—Few diseases yield so rapidly to proper treatment, and a system of hot baths, salines, cathartics, and diuretics may yield truly brilliant results. Meats, coffee, tea, alcohol, malt liquors, and especially tobacco are to be restricted to the greatest degree, and foods easily digested are indicated. All kinds of fruit and vegetables may be eaten, and the diet should be composed principally of these articles. Fats and desserts should be shunned. The bowels, kidneys, and the skin must be kept active by medicines, massage, and the proper amount of outdoor exercise.

For the constipation:

℞.	Tincture of nux vomica,	℥ ij
	Fluidextract of cascara,	℥ jss
	Glycerin, enough to make	℥ iij.

One teaspoonful at bedtime.

Constipation may often be relieved by a pill containing:

℞.	Strychnin,	gr. ss
	Extract of belladonna,	gr. iij
	Aloin,	℥ ss.

Divide into 30 pills. One pill 3 times daily.

Purgative salines may be used, such as Carlsbad salts (1/2 ounce), Rochelle salts, or any of the purgative or laxative mineral waters, such as the Hunyadi and Apenta. Sodium phosphate may be given morning and night. For the kidneys almost any diuretic may be given. Free use of drinking-water is advisable.

To keep the skin active, hot baths should be taken in the middle of the day, 3 times a week. Thorough massage following the baths greatly enhances the value of this treatment. See Acidity, Autointoxication.

URIDROSIS.—See Sweat Glands.

URINARY CALCULI.—Urinary calculi are found in the kidney, ureter, bladder, and urethra. They may be formed from any of the sediments that occur in urine, but the tendency is much greater in the case of some—uric acid, for example—than in the case of others, such as phosphate of lime. The animal matter that holds the particles together is derived from the mucous of the urinary tract, which undergoes a process of fermentation, and either collects layer after layer of uric acid or leads to the formation of sparingly soluble oxalate of lime.

Origin.—The nucleus of a calculus may be hollow or may consist of dried blood; in most calculi, however, it is formed of uric acid or oxalate of lime, held together by a colloid material. These are of renal origin, though they subsequently increase by the deposit of laminæ as they lie in the pelvis of the kidney or in the bladder. Those formed of triple phosphates are only thrown down when the urine becomes ammoniacal, and usually, therefore, originate in the bladder, though they are not confined to it. Nuclei of uric acid are most common in early childhood and in late adult life, especially if there is a tendency to gout. The starting-point is the deposit of crystals in the secreting tubules, and most likely in the actual cells; infarcts of uric acid are often present in the renal tubules of infants shortly after birth; and in gout all stages can be traced, from crystals to the cells and irregular masses in the tubules of the medullary part, to minute calculi projecting from the orifices on the pyramids or lying loose in the cavity of the pelvis. The cause of the precipitation is probably some impairment in power of the cells, whether this arises from weakness, from exhausting illness, or from long-continued overwork, as in gout; and it is assisted by everything that tends to check the flow of urine, whether it is the small size of the secreting passages, as in children, or an actual obstruction, such as an enlarged prostate. When once the pelvis of the kidney or the bladder is reached, the nucleus increases by acting as a focus around which are deposited layers that differ according to the reaction and composition of the urine.

Very little is known with regard to the formation of renal calculi, with the exception of those composed of triple phosphate, which may be formed around anything that causes decomposition of urea. In children of the poorer classes calculi are more common than among the well-to-do, and are nearly always composed of uric acid; possibly this arises from a deficient supply of milk and from improper diet. Gravel, too, is chiefly found among those who have a tendency to gout, or those who consume large quantities of animal food, or those who are addicted to the use of alcohol; but though this points in a general way to increase in the tissue waste, and to the effects of indigestion, acidity, and malassimilation, in causing the precipitation of sediments in the urine, something more is needed to explain the formation of calculi. There must be some condition of the urinary organs leading to the production of the colloid material necessary to cement the particles together.

Calculus is more common in the male than in the female; and this cannot be altogether explained by anatomy, as the same holds good with regard to the kidneys, although to a less extent. Hereditary influence probably does exist, even after full allowance has been made for the effects of locality and for similarity of habit.

Physical Characteristics.—Calculi vary in size from minute bodies, somewhat larger than gravel, to masses of more than a pound in weight. The smaller calculi are frequently numerous; the larger masses are single.

The following is a table of the characteristics of calculi (Moullin):

—	Shape and Size	Surface.	Fracture.	Color.	—
1. Uric acid..	Ovoid or round, varying in size from gravel to that of a hen's egg, or even larger.	Smooth or slightly granular. Susceptible of a fairly high polish.	Crystalline in proportion to purity. Brittle, but hard.	Yellow to red or reddish-brown.	Uric acid calculi are the most common of all, and are always deposited in acid urine. Usually they occur at the extremes of life.
2. Urates.....	Ovoid, rarely as large as the former; often multiple.	Smooth and earthy.	Earthy and inclined to crumble. If it forms the whole, homogeneous; but in general much laminated.	Fawn colored or whitish-gray.	Most common in children, mixed with lime oxalate. Generally acid urate of soda, but sometimes of lime and ammonia.
3. Oxalates...	Irregular, sometimes in the form of hempseed calculi.	Tuberculated...	Crystalline and very hard.	Dark brown, and even black, from repeated hemorrhages.	Usually layers of oxalate with others of uric or urates. Very often coated with phosphates.
4. Mixed phosphates.	Depend on that of nucleus.	Smooth and friable.	Chalky, soft, and breaking easily. Occasionally small crystals on the surface.	White or gray...	Only deposited after decomposition of the urea.
5. Phosphate of lime, or bone earth.	Rarely of any size...	Smooth and soft.	Breaking easily, with crumbling fracture.	White.	
6. Cystin.....	Ovoid and generally of medium size.	Finely granular, with small yellow crystals over it.	Soft and crystalline.	Yellow, turning pale green after exposure, with a somewhat radiated appearance. Waxy.	Usually pure, but sometimes on a uric acid nucleus.

Analysis.

Incineration.	Murexid Test.	Final Test.	Nature of Calculus.
Melts and leaves a fixed residue.	Purple color...	Yellow flame when burned	Sodium urate.
Melts and leaves a fixed residue.	Purple color...	Violet flame when burned	Potassium urate.
Melts and leaves a fixed residue.	No purple color.	Dissolve residue in acetic acid; add ammonia in excess—white, crystalline precipitate.	Ammonio - magnesium phosphate.
Melts and leaves a fixed residue.	No purple color.	Residue insoluble in acetic acid. Dissolves in HCl; add ammonia—white precipitate.	Calcium phosphate.
Does not melt, but leaves a fixed residue.	Purple color...	Dissolve residue in dilute HCl; add ammonia until alkaline, then ammonium-carbonate solution. (*a*) White precipitate (*b*) No precipitate	Calcium urate. Magnesium urate.
Does not melt, but leaves a fixed residue.	No purple color.	Residue dissolved in water is not alkaline. Dissolves in HCl without effervescence. Ammonia in excess causes a white precipitate.	Calcium phosphate.
Does not melt, but leaves a fixed residue.	No purple color.	The calculus is insoluble in acetic acid, but the residue dissolves with effervescence. The calculus dissolves with effervescence in acetic acid...	Calcium oxalate. Calcium carbonate.
No fixed residue.....	Purple color...	Mix powder with lime and moisten. (1) Ammonia is evolved and red litmus paper becomes blue in the vapor. (2) No ammonia	Ammonium urate. Uric acid.
No fixed residue.....	No purple color.	Nitric acid solution grows yellow with evaporation. Residue insoluble in potassium carbonate.	Xanthin.
No fixed residue.....	No purple color.	Nitric acid solution turns dark brown. Residue soluble in ammonia.	Cystin.
No fixed residue.....	No purple color.	The soft calculus grows brown when dry and soft again with heat. Soluble in ether and residue grows violet on heating. Soluble in nitric acid, with slight bubbling; no change of color.	Urostealith.

See Bladder (Stone), Kidney (Stone).

URINARY STREAM, ALTERATIONS. Projective Force of the Stream.—A strikingly strong stream is characteristic of a pathologically developed detrusor, due to hindrances to micturition in the urethra canal, such as follow moderate strictures, a narrow external orifice, or from spasm of the detrusor. A weakening of the projective force

of the current is, at a certain age, pathognomonic of prostatic hypertrophy, and is seen in weakening of the detrusor from chronic inflammation of the mucous membrane and muscular tissue, from neglected gonorrhea, in atony from fatty degeneration of the muscular tissue, as in the course of acute infectious diseases, as typhoid fever or dysentery, and from voluntary retention of the urine when micturition is painful, as in stone in the bladder and fissures of the neck of the bladder. A decrease of force is observed in neurasthenics and in spinal diseases and tabes.

Decreased Caliber of the Stream.—Hypertrophy of the prostate; or stricture, will diminish the caliber. In prostatics the current falls vertically, and in stricture as well; but in the former the force is not increased by pressing, while in the latter it is. Spasmodic contractions of the urethra, from general diseases, may also cause a diminution of the caliber.

Altered Form of the Stream.—A deviation from the round form is observed as the earliest sign of stricture. In decreased force of expulsion the form is changed. Change of form is not a certain sign of stricture.

Continuity of the Stream.—Sudden stopping of the stream is supposed to be pathognomonic of stone, but it is rarely observed except in children. If in adults, the stone must be very small and light. It is sometimes noticed in spasm of the sphincter in neurasthenics.

Starting the Stream, etc.—A drop-by-drop passage of the urine is characteristic of great stricture and great pressure. In some cases there follows a round and strong stream when it started drop by drop (spasm of sphincter).

Dripping of Urine.—Dripping of the urine after passage of the stream is a frequent occurrence, and is of varying importance according as it appears after voluntary urination—a short time after or in the intervals. It is due to a relaxation of the muscular tissue of the urethra, and the urethra lying in a half-opened condition does not press the urine out of the bulbous portions, so that it accumulates and is suddenly ejected after urination, or it drips away slowly during walking. Narrow strictures also cause it, when the portion posterior to the stricture fills like a sack, and unless emptied by milking movements by the patient, it drains away afterward. Abnormal narrowness of the orifice or very great phimosis are other causes. Involuntary urination may occur at any time, while dripping only follows urination.

URINE, EXAMINATION.—The principal duty of the kidney is to eliminate the waste products of the body arising from normal katabolism. To this end excrementitious material is constantly being absorbed from the fluids and tissues of the body, and the same is constantly thrown off through the medium of the kidneys, which have been accurately denominated the "sewers of the human system." By an examination of the urine, therefore, some idea of cellular activity may be formed, as well as of the character of such action as it occurs in the living organism.

Average Composition of Normal Human Urine (Wormley).

	(Parts in 1000.)		Voided Daily.	
			Grains.	*Grams.*
Water	950.00			
Urea	28.00	Organic matter 37.60	520.80	35.00
Uric acid	0.60		11.16	0.75
Hippuric acid	0.35		6.51	0.44
Creatinin	0.65		12.09	0.81
Extractives	8.00		148.80	10.00
Sodium chlorid	8.00		148.80	10.00
Phosphoric acid	2.00	Inorganic matter, 12.40	37.20	2.50

Inorganic matter	12.40	230.64	15.49
	1000.00		

To find the proportion of solids in the urine use **Bird's formula:** The last two figures of the specific gravity of urine nearly represent the number of grains of solids to the ounce contained in the urine. The same two figures multiplied by 2 (**Trapp's factor**) give the parts in 1000. **Haeser's factor** is 2.33.

Chemic Examination of Urine

By the chemic examination of urine is ascertained the (1) quantity; (2) color; (3) odor; (4) reaction; (5) specific gravity; (6) freezing point. Also the presence or absence of (7) albumin; (8) glucose; (9) indican; (10) peptone; (11) propeptone; (12) acetone; (13) diacetic acid; (14) various coloring-matters, as bile; (15) the amount of urea; (16) various ingredients, as mucin, fibrin, inosite, sugar of milk, etc.; (17) urinary calculi.

Quantity.—The whole amount of urine passed within 24 hours must be collected. The normal quantity of urine passed within this time ranges from 40 to 50 ounces, or 1200 to 1500 c.c. The quantity is increased in winter and is less in summer, when there is more evaporation from the skin. The quantity is lessened in fevers and in exhaustive diseases.

CLINICAL SIGNIFICANCE OF VARIATIONS IN THE VOLUME OF THE TWENTY-FOUR HOURS URINE.—(*Bartley.*)

Increased Volume.	Polyuria (*V*+)	Renal affections.	Interstitial nephritis.
			Amyloid degeneration.
		Nutritive disorders.	Diabetes mellitus.
			Diabetes insipidus (phosphaturia).
		Nervous.	Hysteria.
		Essential.	Epilepsy.
			Dementia.

Decreased Volume.	Oliguria ($V-$)	In febrile diseases.	Dermatitis. Gout. Toxic conditions.
		In chronic affections.	Of the heart. Of respiratory organs. Of the kidneys. Of the liver and uterus.
	Suppression, or anuria.		Calculus or tumor. Certain forms of nephritis. Nervous anuria. Traumatic anuria.

Before beginning to collect the specimen of urine, the patient should first empty the bladder. Should any urine be lost at stool, it must be approximately estimated and included in the total quantity.

Color.—Normal urine is pale yellow. Dark amber urine frequently contains large quantities of uric acid.

The color may be changed to black by the administration of carbolic acid or naphthalin, or to yellow after the administration of santonin. In malarial fevers of a pernicious type it is frequently bright red from dissolved hemoglobin.

The following is a table of colors of the urine:

Color.	Cause of the Color.	Pathologic Condition or Cause.
Nearly colorless.	Dilution or diminished pigments.	Various nervous conditions, hydruria, diabetes mellitus, diabetes insipidus, contracted kidney.
Normal color becoming black on standing.	Unknown; glycosuric acid.	Sometimes in pulmonary tuberculosis. Pathology unknown.
Milky.....	Fat globules; pus corpuscles.	Chyluria; fatty kidney; purulent disease in the urinary tract.
Dark amber to reddish-brown.	Increase of normal or occurrence of pathologic pigments; concentration of the urine.	Fever; pernicious anemia; excessive sweating.
Yellow.	Excreted drugs: *e. g.*, picric acid.	
Orange.	Excreted drugs: *e. g.*, santonin, chrysophanic acid.	
Brown to black..	Hematin, methemoglobin, melanin, hydrochinon, and catechol.	Small hemorrhages; methemoglobinuria; antipyrin; chlorate of potassium; melanotic sarcoma: carbolic acid; creosote.
Brownish-yellow to red, becoming blood-red on adding alkalies.	Substances introduced with senna, rhubarb, and chelidonium.	
Red or reddish..	Hemoglobin or free blood. Pigments in food: *e. g.*, logwood, madder, bilberries, fuchsin.	Hemoglobinuria or hematuria.
Greenish to brown or black.	Bile pigments.	Jaundice.
Dirty green or blue.	Dark serum on surface and blue deposit due to indigo-forming substances.	Cholera; typhus; hepatic and intestinal affections. Especially marked in stale urine.

Odor.—Faintly aromatic; rendered strong after eating certain vegetables, as asparagus.

Reaction.—Normally, the urine has an acid reaction, due chiefly to acid sodium phosphate. Uric, hippuric, and lactic acids also aid in rendering the urine of an acid reaction. In herbivora the urine is alkaline in reaction, and in carnivora very acid. A vegetable diet causes an alkaline urine. On standing, urine undergoes ammoniacal decomposition, rendering the reaction alkaline.

To determine its reaction, red and blue litmus papers are used; if the urine is acid, it turns blue litmus red; and if alkaline, it turns red litmus blue.

Specific Gravity.—The specific gravity of normal urine varies from 1015 to 1025. When the specific gravity is above 1030, glucose should be suspected; or when below 1010, albumin. However, the solids dissolved in the urine determine to a great extent its specific gravity, and a sample of urine may vary from 1015 to 1025 and contain albumin or glucose. For the determination of the specific gravity of urine the urinometer is generally used. In order to determine the accuracy of the instrument, it should be placed in distilled water at 60° F., when it should sink to the mark 0 or 1000.

Freezing-point.—See Cryoscopy.

The following table from Bartley is of service:—

THE URINE OF THE TWENTY-FOUR HOURS—NORMAL AND PATHOLOGICAL

Physical Character.	Normal.	Alterations in Abnormal Conditions.
Color.....	Pale straw to reddish yellow. The average color is amber.	Colorless: neuroses, chronic nephritis, diabetes. High-colored: acute fevers, icterus. Blood-red: blood or foreign color. Dark brown: hematuria, poisoning by carbolic acid, potassium chlorate, or iodoform. Smoky brown: presence of decomposed blood, acute nephritis. Yellow or green: presence of bile. White: chyle or pus.

Physical Character.	Normal.	Alterations in Abnormal Conditions.
Transparency.	Clear, with only a slight flocculent cloud of mucus.	Urine turbid when passed, is abnormal. Whitish sediment may be pus, phosphates, or ammonium urate.
Consistence...	When normal, urine is mobile, like water.	When viscid, it indicates albumin, bile, mucus, or pus.
Odor.....	Peculiar to itself.	Urine putrid when passed, indicates cystitis.
Reaction.....	Slightly acid; becomes more acid on standing, then becomes alkaline.	Urine strongly acid in fevers and inflammations of the liver, heart, and lungs; in acid dyspepsia. Urine is alkaline in cystitis, and occasionally in debility, chlorosis, certain organic nervous diseases, typhus, etc.

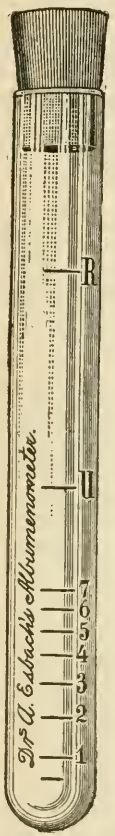
Inorganic. Constituents.	Amount in Grains.	Alterations in Pathological Conditions.
Sulphuric acid.	23 to 38	Having more or less the same source as urea, it will increase or diminish therewith. Occurs as sulphuric esters, and preformed.
Phosphoric acid.	46 to 54	**Increased** in fevers, in nerve-exhaustion, disease of spinal cord, and in tubercle of the lung. In phosphatic diabetes the alkaline phosphates are greatly increased. **Diminished** in many mental diseases, especially mania, in nephritis, and in chlorosis.
Oxalic acid....	0.3	**Increased** in catarrhal jaundice, and in oxalic acid diathesis, mental depression, and certain forms of dyspepsia.
Phosphate of lime.	4 to 5	**Increased** in osteomalacia, rickets, scrofula, carcinoma, long-continued suppuration, organic disease of the spinal cord. **Diminished** in fevers.
Phosphate of magnesium.	7 to 11	
Chloride of sodium.	150 to 250 (Cl = 90 to 150, Na = 60 to 90)	**Increased** in fevers at the onset, and with the reabsorption of dropsical fluids. **Diminished** during apyrexia, dropsies, cholera, typhus, inflammations generally, and especially in the forming stage of pneumonia.
Free acid (calculated as oxalic acid).	30 to 60	**Increased** during the acme of acute febrile affections (on account, probably, of the diminished proportion of water present). **Diminished** in most diseases affecting the nutrition and leading to a deficiency thereof.
Total inorganic salts.	200 to 380	
Potassium.	38 to 48	
Sodium.	140 to 180	
Calcium.	4 to 5	
Magnesium.	2 to 3	

Organic Constituents.	Amount in Grains.	Alterations in Pathological Conditions.
Urea.....	450 to 500 or 30 to 34 gm.	**Increased** after much meat, in fevers, diabetes mellitus, copious drinking of water or alcohol, congestion of liver. **Diminished** in abstinence from meat, rest, hepatic abscess, nephritis, chronic wasting diseases.
Uric acid.....	4 to 15 (ratio to urea, 1 : 40)	**Increased** in leukocythemia, pernicious anemia, gont, rheumatism, deficient oxidation; organic diseases of heart, lungs, liver, or skin; after acute fevers and excessive meat diet. **Diminished** in vegetable diet, gout, before attack, chronic renal disease, outdoor exercise.
Hippuric acid.	5 to 15	**Increased** with vegetable diet, after taking benzoates. **Decreased** in animal diet.
Creatinin.....	8 to 15	**Increased** in meat diet, and increased nitrogenous metabolism. **Decreased** in vegetable diet, and milk diet.
Xanthin bases.	0.5 to 2	**Increased** in splenic disease, meat diet, deficient oxidation. **Decreased** in vegetable diet.
Carbolic acid, Cresol, etc.	0.015	**Increased** in certain diseases of the intestines, causing constipation (ileus, etc.), but has been observed to be increased also in certain cases of diarrhea.
Indoxyl.....	0.07 to 0.05	**Increased** with diseases attended by constipation and intestinal fermentation, and occasionally, also, in cases of diarrhea. After cholera, cancer of the liver and stomach, purulent peritonitis. Valuable diagnostic sign in typhoid fever and cancer of the liver.
Acetone.....	Traces.....	**Increased** in diabetes mellitus; conditions of increased proteid metabolism, with deficient oxidation.
Diacetic acid,	Traces.	
Hydroxybutyric acid.	Traces.	
Albumin.....	None.....	Nephritis, pregnancy, poisoning by certain substances, cold baths, violent exercise, rheumatism, infection, fevers, etc.
Albumose.....	None.....	Presence not clearly diagnostic.
Peptone.....	None.....	Presence not clearly diagnostic.
Dextrose.....	None or trace.	Glycosuria and diabetes mellitus.
Lactose.....	None.....	During lactation, after weaning.
Bile.....	None.....	Obstruction in bile-duct, structural hepatic diseases, malaria, pernicious anemia, yellow atrophy of liver, typhoid fever, and AsH_3 poisoning.
Blood.....	None.....	Hemorrhages, giving hematuria; hemoglobin in malaria, acute nephritis (sometimes).

Organic Constituents.	Amount in Grains.	Alterations in Pathological Conditions.
Pus.....	None.....	Suppuration.
Mucus.....	Present.....	Increased in any irritation along the urinary tract, by uric acid, calcium oxalate, etc., catarrh of bladder, urethra, vagina. Usually increased in acute fevers.

Albumin.—The urine should always be filtered before being tested.

Heller's Nitric Acid Test.—Place in a test-tube about 3 or 4 c.c. (45 to 60 minims) of pure nitric acid, and gently overlay with an equal amount of urine. If albumin is present, a cloudy ring of coagulated albumin will appear at the junction of the two liquids.



Esbach's Albuminometer.

Frequently there will appear an opaque zone immediately above the point of contact of the fluids, which is often due to urea nitrate or to urates. If the urine is heated, this zone will disappear if due to these latter substances; whereas if due to albumin, the precipitate remains permanent.

The Heat-and-acid Test.—In a test-tube place from 6 to 8 c.c. (90 to 120 minims) of urine, and boil. If albumin is present, a precipitate appears, insoluble in a few drops of nitric or acetic acid. Earthy phosphates are also precipitated from the urine by boiling, but these dissolve on the addition of nitric or acetic acid.

Picric Acid.—In a test-tube place from 4 to 5 c.c. of urine, and overlay with a saturated watery solution of picric acid; if albumin is present, a deposit, which is insoluble on boiling, forms at the line of junction.

Quantitative Determination of Albumin.—The albuminometer (a standard graduated glass tube) is filled with acidified urine to U, and the Esbach reagent added to R. This reagent consists of a solution of 10 grams of picric acid and 20 grams of citric acid in 1 liter of distilled water. After closing the tube with a rubber stopper it is inverted several times to mix the contents thoroughly and then placed for 24 hours in a test-tube rack. Then the amount of albumin is noted. The number of grams of albumin in a liter of urine is represented by the graduations on the tube.

Purdy's Centrifugal Method.—To 10 c.c. of the urine in a centrifuge tube 3 c.c. of a 10 percent solution of potassium ferrocyanid and 2 c.c. of 50 percent acetic acid are added. After inverting the tube to mix the contents thoroughly, the thumb being used as a stopper, it is allowed to stand for 10 minutes and then placed in a centrifuge the radius of which with tubes extended must be 6 3/4 inches. The revolutions of the tubes should be at the rate of 1500 per minute and should last 3 minutes. The amount of albumin is then read off in bulk percentage, 1 percent by bulk representing 0.021 percent by weight of albumin. Each division of the tube corresponds to 1 percent, 10 c.c. of urine being used and the divisions representing tenths of a cubic centimeter.

Clinical Significance.—It is stated by von Jaksch that the normal urine occasionally holds a variable quantity of albumin (serum-albumin globulin) as a temporary constituent, while at the same time the kidneys exhibit no alteration of structure; such is "cyclic albuminuria," which occurs during the day and disappears during the night. Many theories exist as to its exciting cause.

When albumin persists in the urine, it must be considered pathologic, and its presence in the urine is looked upon as being indicative of inflammation or degenerative changes in the structure of the kidneys; in other words, of nephritis. However, albuminuria is too often taken as an evidence of nephritis. Careful microscopic study of the urine, together with skilful clinical examination, are necessary to insure a correct diagnosis. Certain associated minor signs of nephritis often neglected are:

1. Auditory difficulties—ringing in the ears and deafness. Mounier has sought to bring the vertigo of Ménière's disease into this category.
2. Numbness of the fingers or hand.
3. Chilliness of legs and feet.
4. Pruritus, likened to the sensation produced by a hair on the skin.
5. Epistaxis, especially in the morning and beginning during sleep.
6. The sign of the temporal artery. The arterial system is tense, the vessels are bent and hard, without there being arteriosclerosis: and this is shown especially well by the temporal artery.

Each of these signs separately has little value; but collectively they are sometimes enough to form the diagnosis.

The following is a table of differential diagnosis between functional and organic kidney-disease (Lane):

Functional.	Organic.
Albumin may be present at infrequent intervals, and may vary in amount from a plain trace to 10 to 20 grains in 24 hours.	Albumin is usually persistent, though not always abundant.
Albumin not found when patient is kept absolutely quiet, and rarely found in urine passed immediately on rising in the morning.	It may be intermittent and still be organic.

Functional.	Organic.
If dropsy is present, it is dependent on insufficient activity of the circulation, rather than on a tardy elimination of the fluids by the kidneys. A very careful examination of the heart and larger vessels is imperative.	Dropsy may or may not be present.
The quantity of urine passed in 24 hours (unless the use of mineral water, beer, etc., is frequently indulged in) will not vary greatly from 3 pints.	The quantity of urine for 24 hours is usually decreased, though in many cases it is greatly increased.
The day urine should exceed the night by double or more its bulk.	The night urine frequently equals and sometimes exceeds that of the day in bulk.
The specific gravity should be between 1015 and 1025, when taken from a sample of 24 hours' mixed urine.	The specific gravity (from a sample of 24 hours' mixed urine) is usually above 1020, though it rarely gets above 1030. In those cases where the quantity of urine is greatly increased, the specific gravity is correspondingly decreased, occasionally falling as low as 1005.
The urea is not diminished for 24 hours.	The urea is diminished for 24 hours.
There is no complication of acute diseases: viz., scarlatina, diphtheria, true gout, or retinal change.	There may be complicating diseases, as scarlatina, diphtheria, etc.
No pus or blood appears in the urine.	There may be both pus and blood in the urine.
No tube-casts are found.	Usually casts of urinary tubules are found.
Patient is under 40 years of age.	If patient is over 40 years of age, the prognosis must be particularly guarded.

Sugar (Glucose, Dextrose).—When the specific gravity of the urine is above 1030, it should be examined for glucose.

Moore's test with sodium or potassium hydroxid, Boettger's bismuth test, and Johnson's picric acid test are all subject to fallacious results.

Those tests which are recommended are Fehling's and Trommer's, which depend upon the reduction of cupric oxid, CuO_2, in alkaline solution by glucose to red cuprous oxid, Cu_2O (Fehling's and Trommer's) or to yellow cuprous hydroxid, $Cu_2(OH)_2$ (Trommer's). In these two tests albumin must first be removed.

Fehling's Qualitative Test.—Fehling's solution deteriorates with age, and it is therefore desirable to keep the copper solution and the alkaline solution separate.

The two solutions may be prepared and the test made in the following manner (Greene): **Solution A.**—Dissolve 34.64 grams of pure, dry, powdered copper sulphate in 200 c.c. of warm distilled water and add distilled water to make 500 c.c. of the *light blue solution*. **Solution B.**—Dissolve in 300 c.c. of hot water 180 grams of Rochelle salt. Filter. Add of pure caustic soda, 70 grams. Cool, and add distilled water enough to make 500 c.c. of a *colorless solution*. Keep in a dark place.

Pour into a test tube one finger's breadth of each of the stock solutions which when mixed should form a deep blue solution.

Heat test solution to boiling-point, add at once 20 to 30 drops of the suspected urine and *boil no longer*, but in the absence of a reaction set aside for from 5 to 30 minutes, and try the polariscopic and fermentation tests, a positive reaction *proves* nothing but the presence of a reducing agent unless the ultimate precipitate is *red*, not yellow or green.

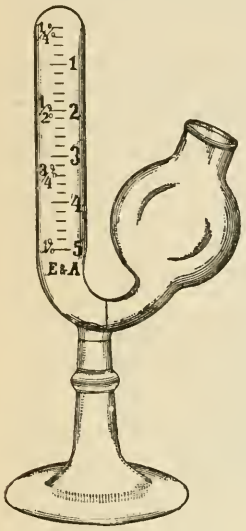
Objections to Fehling's Solution.—Fehling's solution as ordinarily prepared is open to serious objections: (a) It is unstable. (b) An excess of glucose obscures the terminal reaction by becoming caramelized if boiling is prolonged. (c) It cannot be directly applied to ammoniacal urine unless such be especially prepared. (d) A large number of substances may reduce its cupric oxid. Such are glycuronic and glycosuric acid, alkapton creatinin, uric acid, and various drugs, such as benzoic acid, chloroform, chloral, glycerin, the salicylates, turpentine, etc. Hence, if one uses Fehling's solution for qualitative work, he must bear in mind that it is more valuable as a negative than as a positive test. *A urine that does not reduce Fehling's solution is free from glucose, but reduction does not conclusively establish its presence.*

Trommer's Qualitative Test.—To about 6 c.c. (1 1/2 drams) of the urine add about one-fourth its volume of sodium or potassium hydroxid solution. Then add, drop by drop, a solution of cupric sulphate (about 10 percent solution) and agitate the liquid until the bluish-white precipitate of cupric hydroxid, $Cu(OH)_2$, ceases to be dissolved and the liquid presents a slightly turbid or opaque appearance. Heat the liquid, and if glucose is present, the cupric oxid, CuO_2, will be reduced to red or brownish-red cuprous oxid, Cu_2O, or to yellow cuprous hydroxid, $Cu_2(OH)_2$.

Haine's Test.—A much simpler test is Haines' modification of Trommer's test. This test has the advantage of making use of a solution that remains stable almost indefinitely. This solution consists of pure copper sulphate, 30 grains, distilled water, 1 ounce; when a perfect solution is made pure glycerin, 1/2 ounce, is added; then after thorough mixing, 5 ounces of liquor potassæ are added. Of this solution 1 to 2 c.c. are gently

boiled in a test-tube. Then 6 to 8 drops of the urine are added and the upper part of the solution is boiled gently for a second or two only. Presence of sugar is indicated by the formation of a yellow or yellowish-red precipitate.

Fermentation Test.—This test, which depends upon the production of carbon dioxid from glucose by the action of yeast, is best applied by means of an Einhorn fermentation tube so graduated that the amount of carbon dioxid is read off in terms of percent of glucose. The urine must therefore be diluted so as to contain less than 1 percent of glucose, the result being multiplied by the dilution. To the acidified urine is added a piece of compressed yeast the size of a pea and the mixture shaken and poured in the tube without introduction of air bubbles. Controls are also made. The tubes are placed over night in the incubator at 37° C. The percentage of sugar is then read off from the small figures, the larger representing the cubic centimeters of gas.



Einhorn's Saccharometer.

The polariscope is also used to estimate the percentage of glucose in the urine.

Benedict's Test.—The solution is made of:

Copper sulfate (pure crystallized),	17.3 gm.
Sodium or potassium citrate,	173.0 gm.
Sodium carbonate (crystallized),	200.0 gm.
Distilled water, to make,	1000.0 c.c.

The citrate and carbonate are dissolved together (with the aid of heat) in about 700 c.c. of water. The mixture is then poured (through a filter) if necessary, into a larger beaker or casserole. The copper sulphate (which should be dissolved separately in about 100 c.c. of water) is then poured slowly into the first solution, with constant stirring. The mixture is then cooled and diluted to one liter. This solution keeps indefinitely.

For the detection of glucose in the urine about 5 c.c. of the reagent are placed in a test-tube and 8 to 10 drops (not more) of the urine to be examined are added. The mixture is then heated to vigorous boiling, kept at this temperature for one or two minutes, and allowed to cool spontaneously. In the presence of glucose the entire body of the solution will be filled with a precipitate, which may be red, yellow or greenish in tinge. If the quantity of glucose is low (under 0.3 percent) the precipitate forms only on cooling. If no sugar is present, the solution either remains perfectly clear, or shows a faint turbidity that is blue in color, and consists of precipitated urates. The chief points to be remembered in the use of the reagent are (1) the addition of a small quantity of urine (8 to 10 drops) to 5 c.c. of the reagent, this being desired not because larger amounts of normal urine would cause reduction of the reagent, but because more delicate results are obtained by this procedure, (2) vigorous boiling of the solution after addition of the urine, and then allowing the mixture to cool spontaneously, and (3) if sugar is present the solution (either before or after cooling) will be filled from top to bottom with a precipitate, so that the mixture becomes opaque.

It is often convenient to perform the test by placing the tube containing the mixture of the solution and urine in bubbling, boiling water, where it must remain with the water actually boiling for five minutes.

Clinical Significance.—When found in the urine, glucose gives rise to what is called glycosuria, or diabetic urine. While it may be true that at times normal urine may contain a trace of glucose, yet from a clinical standpoint its occurrence and detection by the ordinary tests when accompanied by polyuria, should be looked upon as pathologic, and as indicative of diabetes. Glycosuria is also found in such conditions as cholera, intermittent fever, cerebrospinal meningitis, and in certain diseases of the heart, lungs, and liver, and especially in those diseases that have their seat in the fourth ventricle of the brain.

Indican.—Indoxyl potassium sulphate is an oxidation product of indol in the feces. Its method of formation is thought to be as follows: Indol in the intestines upon oxidation yields indoxyl, after which it combines in the liver with sulphuric acid and is eliminated as indoxyl potassium sulphate, or indican.

Test (Jaffe's).—To a small quantity of urine (4 c.c.) in a test-tube add an equal quantity of pure hydrochloric acid, and subsequently one drop of a saturated aqueous solution of sodium or calcium hypochlorite; agitate thoroughly; now add about one-fourth the volume of chloroform and shake; within a few moments the indican is decomposed into indigo-blue, which is dissolved out by the chloroform.

The hypochlorite solution may be easily prepared by adding 2 or 3 ounces of the commercial chlorid to lime to 8 ounces of water. It should be allowed to stand over a day or two, being shaken frequently, and, finally, filtered under a well-fitting cover. It should be freshly prepared every four weeks. The hypochlorite solution may also be composed of a saturated aqueous solution of sodium hypochlorite. Like the solution prepared from lime, it quickly deteriorates.

Clinical Significance.—At one time indican was thought to represent the amount of putrefaction occurring within the intestines, but this is not the case. In typhoid fever it is often absent. Some have thought that it is increased in wasting diseases and conditions in which the hydrochloric acid in the stomach is decreased, as in gastrointestinal catarrh. It is said to be increased after a meat diet and in obstruction of the bowels, but this does not invariably hold true.

Peptone. Ralfe's Test.—Gently overlay 4 c.c.

(1 dram) of Fehling's solution with a small bulk of urine. If peptone is present, a rose-colored halo will develop immediately *above* the zone of phosphates that frequently occurs at the point of contact of the two liquids.

Clinical Significance.—Peptone frequently occurs in typhoid fever, scarlet fever, miliary tuberculosis, scrofulous pneumonia, jaundice, and cancer of the liver.

Propeptone.—To a small quantity of urine in a test-tube add a few drops of nitric acid, which precipitates propeptones. Now heat, and the solution assumes a yellow color, which precipitates on cooling. It has the same clinical significance as peptone.

Acetone.—In normal urine traces of acetone are found that may be called physiologic.

Legal's Test.—To 3 or 4 c.c. (1 dram) of urine in a test-tube add enough solution of soda or potash to render it alkaline. To this solution then add a few drops of a freshly prepared saturated aqueous solution of sodium nitroprussid, and if acetone is present, a purple or violet-red color will be formed on the addition of chemically pure acetic acid. This test, however, is not distinctive for acetone as it is given by diacetic acid, alcohol and acetic aldehyd.

Trommer's Test.—To 10 c.c. urine strongly alkalinized with potassium hydrate 10 to 12 drops of a 10 percent solution of salicylaldehyd in absolute alcohol are added and the mixture is heated to about 70° C. If acetone is present the fluid changes color and becomes red upon standing. If absent, the color is unchanged. This last is very delicate and distinctive for acetone.

Clinical Significance.—In certain instances acetone precedes the occurrence of diacetic acid in cases of diabetes, and its presence is always considered an unfavorable symptom. It is also said to occur in the urine as the result of cancer and of cerebral disease. See Acetonuria.

Diacetic Acid.—To urine freshly voided add a few drops of a strong aqueous solution of chlorid of iron. If a precipitate occurs, the mixture should be filtered. Heat the filtrate to boiling, and to a small quantity again add the solution of ferric chlorid. If a red color is produced, add sulphuric acid and extract with ether by distillation.

Arnold's Test modified by Lipliawsky is more satisfactory than the above. Two reagents are used: (1) 1 gram of paraamidoacetophenon, 100 c.c. of distilled water, 2 c.c. concentrated hydrochloric acid; (2) 1 percent sodium nitrite solution. To 6 c.c. of solution 1 and 3 c.c. of solution 2 are added an equal volume of urine and 1 drop of ammonia. When shaken, the mixture becomes brick-red in color. Ten drops of 2 c.c. of this mixture, depending on the probable percentage of diacetic acid in the urine, are treated with 15 to 20 c.c. of concentrated hydrochloric acid, 3 c.c. chloroform and 2 to 3 drops of ferric chlorid solution. In the presence of diacetic acid the color of the chloroform changes to violet; if no trace is present the color is yellow or pale red. This test is very delicate and is not given by acetone in oxybutyric acid.

Clinical Significance.—Diacetic acid is never found in normal urine, and when it occurs in diabetes, the disease usually terminates fatally. In this condition it is spoken of as *diabetic diaceturia.* It may occur in certain febrile diseases, as typhoid fever, pneumonia, phthisis, pleurisy, and pericarditis, and in acute exanthematous diseases. See Acidosis.

Coloring-matters (Bile). Gmelin's Test.—To a few drops of urine placed on a marble or porcelain slab add a few drops of impure nitric acid (or of nitric acid containing a few drops of nitrous acid), when a play of colors will be produced, such as green, violet, red, and yellow. The colors are best developed by placing the urine and acid a short distance apart and gradually bringing them together. This test may also be demonstrated in a test-tube by overlaying the acid with the urine.

Clinical Significance.—Biliary pigment is nearly always present in the urine in cases of cholelithiasis and in the acute stage of catarrhal jaundice.

Urea.—Different forms of ureameters are preferred by authors. However, the principle upon which the more reliable appliances are constructed depends upon the decomposition of the urea in the urine when brought into contact with a solution of sodium hypobromite or hypochlorite with the evolution of nitrogen.

Many forms of ureameters are too complicated, and cannot be used by the general practitioner. Simpler forms, while not so delicate, are more frequently employed, and only vary within a few grains of the correct amount of urea. Albumin should always be removed before estimating for urea.

Estimation of Urea by Doremus' Apparatus.—The sample of urine must be selected from the amount passed within 24 hours.

To employ this method the following solutions are required, and must be freshly prepared.

Alkaline Hypobromite Solution

Dissolve 100 gm. of sodium hydrate in 250 c.c. of water and allow to cool.

Bromin Solution

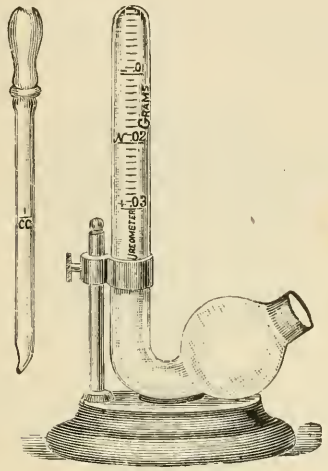
Bromin,	1 c.c.
Sodium hydrate solution (as above),	25 c.c.

Fill the upright graduated tube of the apparatus with the hypobromite solution as thus prepared to the mark .03, and add enough water to about half fill the bulb; mix thoroughly. Tilt the instrument forward, and by means of the pipet, pushed well into the head of the upright tube, slowly add 1 c.c. of urine. After about 15 or 20 minutes read off the volume of gas, which gives the percentage of urea to 1 c.c. of urine. To determine the total amount of urea, multiply this percentage by the

number of cubic centimeters of urine passed within the 24 hours.

Frequently the percentage of urea is so great that the volume of nitrogen presses the hypobromite solution below the .03 mark. When this is the case, dilute the urine with an equal amount of water and proceed as before. Multiply the percentage obtained by 2, which gives the percentage of urea in the specimen of urine.

Clinical Significance.—The normal quantity of urea within the 24 hours fluctuates greatly. From 308 to 617 grains, or 1.5 to 2.5 percent, is the normal amount as stated by Tyson. In midwinter the urea may fall to 130 or 140 grains in those who lead sedentary lives. Urea is the chief organic



Ureameter of Doremus.

constituent of the urine, and through its determination furnishes an index to the rapidity of metabolic changes taking place within the body. However, this change is not the only governing factor, since the quantity of urea depends also upon the amount of nitrogenous food ingested. The urea is *increased* (1) in diabetes mellitus; (2) by the use of nitrogeneous foods; (3) after copious ingestion of water; (4) in acute febrile diseases; (5) in dyspepsia; (6) in nervousness. The urea is *decreased* (1) after prolonged rest; (2) by the use of vegetable foods; (3) by starvation; (4) by the excessive use of tea or coffee; (5) in nephritis. Muscular exercise has but little effect upon the excretion of urea.

Uric acid exists in the urine for the most part in the form of soluble urates of sodium, potassium, and ammonium.

Amount.—The amount of uric acid excreted daily by a healthy man ranges from 7 to 10 grains.

Uric acid is soluble with difficulty in water (in 18,000 parts of cold and 15,000 parts of hot water), and is insoluble in alcohol and ether.

In the urine it exists for the most part in the form of acid urates of sodium, and potassium.

It is frequently found as a sediment in urine, having the color of cayenne pepper granules.

Estimation of Uric Acid.—Probably the best and most accurate method for the estimation of uric acid by the general practitioner is that known as the Hopkins' method, which has been modified by Maisch as follows: To 100 c.c. (3 1/3 ounces) of urine add 30 gm. (1 ounce) of ammonium chlorid (or until saturated), and then add 5 c.c. (75 minims) of water of ammonia; allow the mixture to stand for from 15 minutes to half an hour and then filter. The flask in which the precipitation is to be carried out is thoroughly washed with a saturated aqueous solution of ammonium chlorid and poured upon the filter, and is subsequently washed several times with the saturated aqueous ammonium chlorid solution. The filter is then pushed through and the precipitate is transferred to a beaker (of 6 to 8 ounces capacity) with hot water by means of a Spritz bottle; to this fluid is then added 1 to 2 c.c. (15 to 30 minims) of pure hydrochloric acid, and the liquid is evaporated to 20 or 15 c.c. (1/2 of an ounce), when it is allowed to stand for 1 hour, or until cool.

The precipitated uric acid is then collected upon a filter-paper, washed several times with water, and finally the filter is punched through and the uric acid is transferred to a porcelain capsule or a watch-glass with alcohol by means of a Spritz bottle, dried, and after removal of the small particles of filter-paper that appear on the top of the precipitate, it is weighed. The product obtained is a reddish-brown amorphous powder which under the microscope is crystalline and light yellow or reddish-yellow in color.

Clinical Significance.—When uric acid is not eliminated by the kidneys, it becomes stored up in the body and gives rise to what is known as the uric or "lithic" acid diathesis. Owing to the fact of its insolubility, uric acid is supposed by some to be deposited in the tissues, such as the serous membranes, giving rise to joint pains. By others its failure of elimination is supposed to give rise to headache, hemicrania, neuralgia, despondency, lumbago, and rheumatism.

It is stated that uric acid and urea are eliminated in the urine in the relative proportion of 1 part of the former to 33 parts of the latter. This relation must, however, be accepted as subject to wide variations, depending upon such factors as the amount of exercise, the variety of food and drink, and the season of the year.

While it was formerly held that uric acid has its origin for the most part in nitrogenous elements taken as food, the more recent opinion is that it arises in the system from the disintegration of the leukocytes and nuclein.

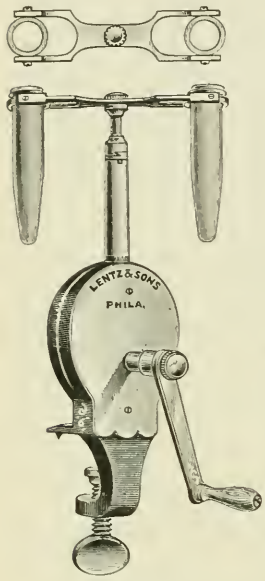
Uric acid is *diminished* in diseases interfering with the process of elimination, such as nephritis, and in diabetes, in chronic rheumatism, before paroxysms of gout, and in chlorosis. It is *increased* in leukemia, in indigestion, after attacks of gout, in acute fevers, in functional diseases, and in heart- and lung-diseases in which there is much dyspnea. Physiologically, it may be said to be increased or diminished *pari passu* with urea.

Various Ingredients (Mucin, Fibrin), etc.—The importance of these ingredients in the urine has not been finally settled.

Ehrlich's Diazo Reaction.—See Typhoid Fever.

Microscopic Examination

The microscopic examination of urine determines the presence or absence of (1) casts, (2) spermatozoa, (3) blood, (4) mucus or pus, (5) epithelium, (6) fungi, (7) uric acid, (8) urates of sodium and ammonium, (9) calcium oxalate, (10) calcium carbonate and sulphate, (11) triple phosphates, (12) leucin and tyrosin, (13) cystin.



Centrifuge.

To examine the urine microscopically the sediment is first obtained, either by means of the centrifuge or after the urine has stood for a period of from 12 to 24 hours. The urine may be preserved for a considerable length of time by the addition of a small quantity (from 5 grains to 1 dram) of chloral hydrate, or by adding 1 part of carbolic acid to 100 parts of urine or 1 part of mercuric chlorid to 3000 parts of urine.

Casts.—These bodies are molds of the uriniferous tubules, and are composed of the coagulable constituents of the blood that are pressed out of the blood-vessels into the tubules, and are afterwards excreted in the urine. This process forms the hyaline or granular cast. In some instances the cast also involves the epithelial cells of the tubule, which become detached, giving rise to an epithelial cast. Blood may also be entangled in the coagulable particles. Usually, this process is accompanied by the occurrence of albumin in the urine, but casts may be present in urine without albuminuria.

a. Blood cast and hyaline cast carrying blood-cells. *b*. Leukocyte or pus-cast. *c*. Hyaline cast carrying renal cells. Epithelial casts.—(*Greene.*)

Granular casts light and dark, coarse and finely granular. (*Greene.*)

a. Waxy casts. *b*. Fatty or fat-bearing casts.—(*Greene.*)

a, *a*, *a*. Round epithelium from bladder. *b*, *b*, *b*, *b*. Columnar epithelium from ureters and urethra. c^1, c^1, c^1. Columnar and squamous epithelium from deeper layers of epithelium of bladder. c^2. Squamous epithelium from superficial layers of epithelium of vagina.—(*Tyson.*)

Tube casts vary in size, shape, and appearance. Their length ranges up to 200μ or more; their diameter from 4μ to 40μ. They are usually straight, but may be curved, twisted, convoluted, or branched.

Varieties.—*Blood casts* are those composed of coagulated blood with corpuscles embedded. They show that the hematuria originates in the secreting structure of the kidney.

Epithelial casts are those composed of plastic matter with cells embedded and denoting desquamative inflammation.

Fatty casts are those containing free fat globules in the coagulated matter, indicating fatty degeneration in a chronic nephritis.

Granular casts are those containing finely divided, granular débris, either in scattered masses or completely filling the casts. They are usually found in cases of contracted kidney.

Hyaline casts are transparent, soft, delicate casts, also called *mucous casts*.

Pus casts are those that contain degenerated leukocytes; indicative of involvement of the interstitial kidney substance.

Seminal casts are molds of the seminal tubules found in the urine, and are recognized by the presence of spermatozoids.

Waxy casts are those that give the amyloid reaction; they are large and yellowish in appearance, and are indicative of serious nephritis.

Clinical Significance of the Different Varieties of Casts.

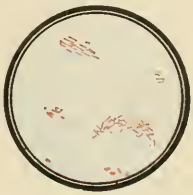
Acute Parenchymatous Nephritis.	Chronic Parenchymatous Nephritis.	Chronic Interstitial Nephritis.
Only a few casts present.	Many casts seen.	Few casts present.
Blood casts, epithelial casts, leukocytes.	In *early* stages large hyaline and dark granular casts. In *later* stages epithelial, large and small granular casts, hyaline casts, and compound granular cells.	Large and small hyaline casts, waxy casts, fatty casts, oil droplets.
During convalescence fatty casts may be present.	In acute exacerbations, on account of the inflammatory processes, there may be present epithelial casts and many leukocytes.	In acute exacerbations on account of the inflammatory process, there may be present all varieties of casts, especially large and small granular casts.

During most acute fevers hyaline casts are found. **Cylindroids** have no clinical significance.

Epithelium.—When the renal epithelium is found in the urine, it generally denotes a grave form of kidney-disease. It may be recognized by the large, oval nuclei. An excessive amount of epithelial cells from the bladder, in combination with pus, denotes cystitis. See also Hematuria.

Bacteria are frequently found in the urine.

Tuberculosis of the urinary tract is often diagnosticated by discovery of the tubercle bacilli in the urine. To examine the urine for *tubercle bacilli*, the sediment must be thoroughly centrifuged, and then examined in the same way that sputum is (see Tuberculosis); but a small amount of egg albumin is added to the specimen before it is placed on the slide or coverslip.



Tubercle Bacilli in Urine.—(*Greene.*) Observe tendency to form groups.

Yeast fungi are found in nearly all specimens of urine after they have been exposed to the air.

Spermatozoa and Associated Substances in Urinary Deposits.

a, a, a, a. Spermatozoa. *c,c.* Spermatozoa, tail out of focus. *d,d,d.* Amyloid corpuscles. *e.* Prostatic cast. *g.* Crystals. *h.* Lecithin-granule cells. *k,k,k.* Epithelium.—(*Greene.*)

Spermatozoa may be found in the urine. See Semen.

Calculi.—See Urinary Calculi.

Urinary Sediments.—See the following table.

URINARY SEDIMENTS, TABLE OF

Variety.	Gross Appearances and Characters.	Microscopic Features.	Tests.	Significance.	Illustrations. (*After Tyson, Greene, Casselman Landois, Beale, Jakob and von Jaksch.*)
Blood.....	A flocculent, red deposit.	Blood-corpuscles.	Equal parts of tincture guaiac and mature oil turpentine or ozonicether cause green line at junction with urine.	Disease of kidney, bladder, or urethra.	
URINARY SEDIMENTS, TABLE OF

Variety.	Gross Appearances and Characters.	Microscopic Features.	Tests.	Significance.	Illustrations. (*After Tyson, Greene, Casselman, Landois, Beale, and von Jaksch.*)
Calcium carbonate.	Whitish sediment (rare); urine alkaline.	Amorphous granules; small spheric or dumbbell crystals.	Soluble in acids with effervescence.	No special significance.	Calcium oxalate.	Cloudy, whitish, often highly refracting sediment.	Transparent, refracting octahedra. Sometimes "dumbbell" shaped.	Soluble in mineral acids, not in acetic.	Vegetable diet, especially rhubarb; oxaluria; often with uric acid in lithemia.	
Calcium phosphate.	Whitish or yellowish sediment; urine feebly acid or alkaline.	Amorphous granules, or wedge-shaped crystals, separate or in roset-like clusters.	Insoluble by heat; soluble in acetic or mineral acids.	Phosphaturia; dyspepsia; alkaline fermentation.	Calcium sulphate.	Not distinctive: rare; urine acid.	Elongated, transparent needles or tablets.	Insoluble in ammonia or acids.	No special significance.	Cholesterin.....	Not distinctive; very rare; urine alkaline.	Large, transparent plates, often superimposed; one corner frequently defective.	The microscopic appearances.	Pyelitis, cystitis, etc.	
URINARY SEDIMENTS, TABLE OF

Variety.	Gross Appearances and Characters.	Microscopic Features.	Tests.	Significance.	Illustrations. (*After Tyson, Greene, Casselman, Landois, Hawk, Beale, and von Jaksch.*)
Cystin.....	White or yellowish-gray deposit; rare; acid, neutral, or alkaline urine.	Six-sided plates, often superimposed.	Crystals burn on platinum with a bluish-green flame without melting; if heated with caustic potash on silver plate leave a permanent, dark stain.	Cystinuria may be an hereditary and insignificant condition; or it may indicate the presence of a cystin stone in the kidney.	Hippuric acid...	Not distinctive; whitish deposit; urine acid.	Four-sided prisms with two or four beveled edges at the ends.	Dissolved in ammonia, but not in hydrochloric acid.	Diet of cranberries and other vegetables; administration of benzoic acid; in diabetes.	Indigo.....	Amorphous fragments or concretions of blue color; urine alkaline or acid.	Amorphous granules, fine needles and crystals of a blue color.	The color is distinctive.	In decomposing urine.	
Leucin and tyrosin.	Usually a bile-stained deposit; often scanty; rare; urine acid.	*Leucin:* Yellowish highly refracting spheres, containing radiating lines. *Tyrosin:* "Needles" arranged in "sheafs."	*Leucin:* Heating with protonitrate of mercury in solution deposits metallic mercury. *Tyrosin:* Crystals dissolved in hot water, and treated with mercuric nitrate and nitrate of potassium, giving a red solution and red precipitate.	Destruction of liver; especially acute yellow atrophy, and phosphorus-poisoning.	Magnesium phosphate.	Not distinctive; rare; urine concentrated, but feebly acid or alkaline.	Large, strongly refracting plates, in the shape of elongated rhombic tablets.	Soluble in acetic acid, re-precipitated by carbonate of sodium.	No special significance.	
Mucin.....	Cloudy turbidity or a viscid, gelatinous sediment.	Epithelium and leukocytes, held in a stringy, transparent mass.	Acetic acid causes cloudiness or precipitate.	Genito-urinary catarrh, especially cystitis.	

URINARY SEDIMENTS, TABLE OF

VARIETY.	GROSS APPEARANCES AND CHARACTERS.	MICROSCOPIC FEATURES.	TESTS.	SIGNIFICANCE.	ILLUSTRATIONS. (*After Tyson, Greene, Casselman, Landois, Hawk, Beale, and von Jaksch.*)
Phosphates, Triple—Ammonio-magnesium phosphate.	Heavy, white deposit; urine feebly acid or alkaline.	Triangular prisms with beveled edges— "coffin lids." Also feathery, star shapes, and other forms.	Insoluble by heat. Soluble in acetic or mineral acids.	Dyspepsia; alkaline fermentation of urine; cystitis.	
Pus.....	Compact, thick, viscid sediment; urine acid or alkaline.	Degenerated leukocytes.	The dark-red color of pus corpuscles on adding iodo-potassic-iodid solution.	In acid urine, with uric acid and no mucus; pyelitis; or alkaline urine with triple phosphates; cystitis.	
Tyrosin.....	See *Leucin*.				
Urates of sodium, ammonium, and potassium. (*The illustration is of ammonium urate.*)	"Brick-dust" deposit, the color due to the color of the urine. Dissolved and cleared by heating. Urine acid; sometimes alkaline.	Amorphous granules. Ammonium urate appears as spheric crystals surrounded by spicules—"hedge-hog crystals."	Dissolved by heat or on adding acids.	Lithemic and rheumatic diathesis. Fever. Ammonium urate occurs when an acid urine is undergoing alkaline fermentation.	Uric acid.....	Small grains, resembling red pepper; urine acid.	Crystals of various shapes colored brownish-red by the urinary pigments. The commonest form resembles a whetstone.	The crystals dissolve in caustic potash. The murexid-test produces a purple color.	Lithemic or rheumatic diathesis.	
Xanthin.....	Not distinctive; urine acid; very rare.	"Whetstone" crystals.	Insoluble in acetic acid; soluble in ammonia.	Xanthin-stone in the kidney.	

URINE, EXTRAVASATION.—Extravasation of urine is commonly, though not always, the result of stricture, and is then due either to the dilated urethra behind a stricture ulcerating and giving way, or to a lacunar abscess bursting into the urethra. In either case the urine is forced by the contraction of the bladder into the surrounding cellular tissue.

The urethra may give way (1) in front of the anterior layer, (2) between the two layers, or (3) behind the posterior layer of the triangular ligament. In the first and by far the most common situation it is the bulbous portion of the urethra that gives way. Here the urine is prevented from passing (1) backward into the pelvis by the anterior layer of the triangular ligament which is attached to the rami of the pubes and ischium and to the subpubic ligament; (2) downward into the ischiorectal fossa by the anterior layer of the triangular ligament continuous around the transverse perineal muscle with the deep layer of the superficial fascia of the perineum; (3) laterally, on to the thighs, by the deep layer of the superficial fascia of the perineum attached to the rami of the pubes and ischium. Hence it passes in the middle line into the cellular tissue of the scrotum and penis, and laterally on to the abdomen, where it is prevented from passing down the thigh by the deep layer of the superficial fascia of the groin (which is continuous with the deep layer of the superficial fascia of the perineum) which is attached along the line of Poupart's ligament.

When the membranous portion of the urethra is ruptured, the urine is confined at first between the two layers of the triangular ligament, and if not released, will make its way (1) forward, through the anterior layer, and take the course given; or, rarely, (2) backward, through the posterior layer, and then, as when the urethra gives way behind the posterior layer, will make its way around the neck of the bladder, and finally induce a fatal result. Wherever the urine spreads it causes inflammation and sloughing.

Symptoms.—The history of a case of extravasation is not uncommonly as follows: A patient with a tight stricture is straining to pass water; he feels something give way, experiences a sensation of relief, and perhaps owing to the tension being removed by urine being forced into the cellular tissue, the superadded spasm for a time ceases, and a few ounces of urine are passed through the urethra. In half an hour or so a pricking or burning sensation is felt in the perineum, soon followed by pain, and by rapidly increasing swelling of the perineum, scrotum, and penis. If the urine is not let out by timely incisions, the swelling extends to the groin, and in some cases has been known to reach as high as the axilla. The skin now appears dusky or purplish-red and edematous, and gangrene and sloughing of the infiltrated tissues rapidly ensue. The absorption of the septic products gives rise to constitutional disturbance and to fever, which, though it may at first run high, soon assumes a low typhoid character, and the patient, especially if the subject of chronic kidney-disease, frequently sinks into a comatose state and dies. When the extravasation occurs between the two layers of the triangular ligament, it may remain localized, giving rise to a hard, circumscribed swelling in the perineum, which may slowly make its way toward the scrotum; and, lastly, when the extravasation occurs behind the posterior layer of the triangular ligament, and the urine is extravasated into the pelvic cellular tissue, the symptoms resemble those of extraperitoneal rupture of the bladder (Walsham).

Treatment.—A catheter should be passed into the bladder, or, when this is impossible, down to the stricture, and in either case a free incision, extending into the urethra, should be made on the catheter, in the middle line of the perineum. Free incisions through the skin of the scrotum, penis, and groins—in fact, wherever the urine has penetrated—should likewise be made, to allow of its draining away, and the wounds should be rendered as far as possible aseptic by the free application of iodoform or other antiseptics. At the same time the patient's strength must be supported by fluid nourishment and stimulants; opium should be given, unless contraindicated on account of kidney-disease.

URINE, INCONTINENCE (Enuresis).—Nocturnal enuresis may occur in adults or in children. It is more common in boys than in girls. It rarely persists beyond puberty; if so, it is usually incurable; such cases are most often met with in girls. Urination may occur once or several times during the night—most often during the first sound sleep—and again in the early morning.

During the first months of life the urine is retained in the bladder for only a short time, but after the first year constant or very frequent micturition indicates some abnormality or disease, although it may be due to mere habit. Paralysis; malformation; the secretion of a large amount of urine, as in diabetes insipidus; hyperacid urine; calculus; cystitis; irritation of the penis, from adhesions to the glans penis, etc.; a tight prepuce or contracted meatus; worms or other rectal irritation; unduly profound sleep, from the semi-asphyxiated condition caused by enlarged tonsils or postnasal adenoids; dreams or gastric disturbance, from late or unwholesome meals, and masturbation—these are all causes. Ill health, conjoined with an unstable and easily excited mind, may give rise to enuresis. The condition has been known to subside in delicate children on the correction of eye-strain. Renal calculus or pyelitis of tubercular origin may be possible causes.

In adults enuresis may arise from an overdistended bladder, from which urine continually dribbles. This is nearly always the result of impacted urethral calculus, phimosis, hypertrophied prostate, paralysis, or stricture. The use of a filiform bougie or a very finely calibered catheter on the first attempt to withdraw the urine will differentiate from incontinence, while the associated paralysis, if any, will confirm the diagnosis.

Incontinence of urine in women may occur from injury to the neck of the bladder or to

the urethra, from the prolonged pressure of the child's head during labor, or from instruments, or the removal of stone. It may be nocturnal or daily.

Treatment.—In the treatment of nocturnal incontinence of urine, apart from paralysis and irremediable malformations, the cause is to be looked for and all sources of irritation are to be removed. If due to phimosis, circumcision should be done; if to adhesions, these must be broken down; if the meatus is too small, dilatation or meatotomy should be performed. The urine should be examined for overacidity and for evidence of cystitis, and these conditions should be corrected by the use of potassium citrate or of liquor potassæ. If the diet is at fault, it should be corrected and irritating food should be forbidden. Worms must be removed by appropriate treatment. Late or undigestible meals are to be forbidden, and the habit of sleeping on the back is to be avoided. Too great weight of bedclothes is often provocative, and is to be remedied.

The most serviceable drug, after alkaline diuretics, is belladonna, or its alkaloid, atropin. Belladonna should be given in full and increasing doses (from 5 to 10 drops of the tincture 3 times daily; increase to from 10 to 20 drops in 12 hours) until physiologic results are obtained. Atropin is sometimes effective when belladonna fails. Potassium bromid may be given alone or with belladonna, while ergot, cantharides, potassium nitrate, camphor, and other drugs have been employed. In the incontinence of adults resulting from sudden movement or from excessive laughter, drop doses of the tincture of cantharides, 3 times daily, will do much to effect a cure, alkaline diuretics being employed at the same time. Punishment, by severe scoldings or whippings, is useless, and makes the sufferer sullen, and probably augments the trouble. If enuresis results from habit, it may be necessary to administer diuretic waters for a long time. The habit of passing urine just before retiring, and of arising for the same purpose several times during the night, should be encouraged.

The following prescriptions are useful:

℞. Potassium citrate, ʒ ss
Spirit of nitrous ether, ʒ vj
Water, enough to make ʒ j.
Give a dessertspoonful every 4 hours in an equal quantity of water.

℞. Arsenic trioxid, gr. 1/3
Extract of nux vomica, gr. ij.
Make into 20 pills. Give 1 pill 3 times daily after meals to a child of 8 or 10 years.

When enuresis results from paralysis or from retention and distention of the bladder, the catheter is to be used. Asepsis must be strictly maintained, and the bladder washed out with a weak antiseptic fluid, such as boric acid solution or a solution of 1:10,000 of bichlorid of mercury, or of 1:100 of phenol, when paralysis is responsible for the condition. In some incurable cases a urinal must be worn.

URINE, RETENTION.—Retention of urine is either partial or complete. In the former condition a certain amount of urine is never expelled, and the capacity of the bladder is proportionately diminished; in the latter it is distended until it can hold no more.

Etiology.—Either the expulsive power of the bladder is defective or there is some obstruction to the exit of the urine; or both may happen.

1. The former may arise from failure of the muscular power or of the nervous stimuli, or of both. Atony and peritonitis, spreading to the muscular coat, are instances of the first named cause; paralysis from disease or injury of the spinal cord or of the sacral nerves, hysteria, exhaustion (as in fevers), alcoholic excesses, shock, and, perhaps, belladonna poisoning, of the second. Railway accidents, operations around the rectum, such as ligation of piles, and injuries in the region of the pelvis are especially likely to cause it; but in old people, and in those in whom the wall of the bladder is already in a condition of partial atony, retention may follow the slightest accident, even a fall on the trochanter or the passage of a catheter.

2. Obstruction to the flow of urine may be situated:

(*a*) In the interior of the canal: impacted calculus, for example.

(*b*) Outside the urethra: such as a string tied around the penis by a child to check nocturnal incontinence or the pressure of a gravid or displaced uterus.

(*c*) In the wall itself. This is by far the most common. The affection may be permanent, as stricture or enlarged prostate; or temporary, as congestion and spasm. In most cases temporary and permanent causes act together. An impacted calculus, for instance, may occupy only a small part of the interior, but the spasmodic contraction that it causes prevents the passage of a drop of urine; a stricture which admits a No. 7 or No. 9 French catheter may suddenly become closed in the same way, owing to alcoholic excesses or to exposure to cold; an enlarged prostate may have existed for years without serious inconvenience, until suddenly congestion sets in, and the mucous membrane becomes so swollen that the weakened muscular fiber gives way.

Symptoms.—When retention has come on slowly, as from the gradual contraction of an organic stricture, there may be but little local pain and no constitutional disturbance, even though the bladder may be distended by many ounces of urine. When, however, it is produced suddenly, there is usually great pain, followed by severe constitutional symptoms—a small and frequent pulse, a dry and brown tongue, and perhaps delirium, symptoms probably due to the sudden check to secretion by the kidneys and to the stretching of the bladder. The bladder itself, unless greatly hypertrophied and contracted, rises out of the pelvis, and may be felt as a distinct tumor, dull to percussion, and at times extending as high as the umbilicus, or, in extreme

cases, even to the ensiform cartilage. The patient, unless drunk, usually complains of inability to pass urine. When, however, the bladder has become gradually distended and urine is passively flowing away, he may complain of inability to hold his urine, and be quite unaware that the bladder is full, and may object to having a catheter passed until the condition has been explained. The presence of a swelling in the abdomen, and the flowing of urine through the catheter immediately after the patient has passed urine and believes that he has emptied his bladder, should serve for the diagnosis. In suppression of urine the bladder is found empty on passing a catheter.

Results of Retention.—If the bladder is soon relieved, no apparent harm may ensue. If neglected, however, the overdistention may lead to (1) atony of the muscular coat; (2) cystitis; (3) nephritis; (4) rupture of the urethra behind the obstruction; (5) rupture of the bladder itself (rarely); and (6) passive overflow of urine, the bladder remaining full.

Treatment.—The distended bladder must be relieved, and if the distention is extreme and the symptoms urgent, at once.

As a rule, the patient is to be kept warm and should lie on his back. The administration of a hot bath and an opiate, or of a few drops of chloroform, may suffice, but usually resort must be had to instrumental aid. If success at passing an instrument into the bladder is not shortly obtained, it may be necessary to administer an anesthetic. In hysteric retention in women judicious indifference is best. After a safe interval the bladder should be relieved by the passage of a soft-rubber or gum catheter and withdrawing the urine. A hot hip-bath or cold water thrown suddenly over the back will often produce the desired effect.

In cases of retention of urine in young children an enema thrown into the rectum will often so stimulate both the center for defecation and the genitospinal center for urination as to bring about micturition without catheterism—a proceeding always dangerous in young children, unless they have been anesthetized. When retention is due to cyst of the sinus pocularis the passage of an instrument will rupture the cyst and the infant will be relieved.

When the cause of the retention is a stricture, it is well to try to pass first a soft catheter, then a hard catheter, employing large sizes at first, although some surgeons advise the immediate use of the filiform bougie. It is advantageous to withdraw but half of the retained urine, withdrawing the remainder after waiting half an hour, and then washing out the bladder with hot boric acid solution. After withdrawal of the urine hot blankets should be wrapped around the patient, and a hot sand-bag may be placed against the perineum and a hot water-bag over the hypogastrium. A suppository of opium and belladonna and tablets of salol and boric acid may be employed for several days subsequently.

If failure ensues from the use of rubber or silk or hard catheters, filiform bougies are to be employed. This form of bougie acts as a capillary drain, and will empty the bladder in a few hours. It is, of course, to be allowed to remain in the bladder until this is accomplished. Successively larger bougies are to be inserted alongside of the filiform for several days. No attempt is to be made to dilate the stricture forcibly until retention has ceased and inflammation has subsided.

Aspiration and suprapubic or perineal cystotomy must be resorted to when other means have failed. See URETHRA (Stricture).

In simple inflammation of the urethra the hot hip-bath, the use of suppositories of opium and belladonna, and the application of the hot sand-bag to the perineum and of the hot water-bag over the hypogastrium are means usually employed with success. A soft catheter is to be used if these measures fail, or if the symptoms are very urgent.

In spasmodic stricture a metal catheter of good size should be held firmly against the spasmodic area a sufficient length of time to cause the stricture to relax.

The occluded meatus of a new-born child may be incised with a tenotome or may be dilated. In complete phimosis the prepuce is to be slit up. A urethral stone may be removed by the urethral forceps or may be pushed in or out. When fecal impaction causes retention, the feces must be removed by enema, by the hand, or with a scoop. When prostatic hypertrophy is causative, a filiform bougie is first passed, and over a catheter. A silver instrument with a large curve is sometimes employed. A soft catheter is to be employed when expulsive defect exists. See PROSTATE (Diseases).

The administration of laxatives, maintenance of the free action of the skin, warmth, and confinement to bed are general means of treatment commonly employed, while the use of such drugs as salol, boric acid, and quinin is advised to render the urine antiseptic. It is, of course, understood that asepsis and antisepsis are important in the use of instruments.

Aspiration is to be employed, under antiseptic precautions, when other means fail. The trocar or aspirator needle should be passed in the median line just over the pubes, its course being downward and backward. The puncture must be antiseptically dressed: *e. g.*, with iodoform and collodion. See BLADDER (Paracentesis).

When rupture of the urethra has taken place and retention of urine ensues, perineal incision is advised, but otherwise it is not now resorted to. It must always be borne in mind that the horizontal position is to be maintained when passing the catheter, as this position lessens shock. See URETHRA (Injuries) URINE (Extravasation), URINE (Suppression).

URINE, SUPPRESSION.—Suppression of urine is the term applied to the nonsecretion of urine by the kidneys, and it must not be confounded with retention of urine, in which the urine is secreted as usual, but its passage from the bladder is obstructed. In the former condition the bladder is empty; in the latter, distended. Suppression of urine may

be due to obstruction of the ureter by a calculus, acute nephritis, or sudden shock. The usual causes of such shock are genitourinary operations. Suppression of urine is also caused by acute poisoning by phosphorus, lead, turpentine, cantharides, etc. It is seen in the collapse stages of cholera and yellow fever and in hysteria. If suppression of urine is not relieved, coma, convulsions, and death from uremia quickly ensue.

Treatment.—Dry or wet cupping of the loins, hot vapor baths, free purging, as by elaterium or croton oil, the administration of diuretics, injections of pilocarpin, and hot enemata by the rectum are, at times, successful in relieving the congested kidney. Large, hot irrigations of normal salt solution, with the double current rectal tubes, or infusion of saline fluids in the tissues or veins, may be tried. See NEPHRITIS, URINE (Retention).

UROTROPIN (Hexamethylenamin). $C_6H_{12}N_4$. —A compound produced by the action of formaldehyd on ammonia. The drug has other trade names—cystogen, aminoform, formin, uritone. Urotropin increases the excretion of the urine and of uric acid, the solution of the urates beginning within 24 hours. Urotropin is decomposed in the organism, formaldehyd being set free and being eliminated in the urine. Ordinary medicinal doses cause no general effects as a rule, but in susceptible persons it may cause gastric and renal irritation, with hematuria, hemoglobinuria, and albuminuria, also diarrhea, abdominal pain, a measley rash, headache, tinnitus aurium, and strangury. It is an excellent urinary and intestinal antiseptic, and possesses considerable power as a solvent of uric acid, the excretion of which it promotes. It is particularly efficient as an alterative and diuretic in the treatment of cystitis, pyelitis, and phosphaturia. It is advocated as a prophylactic against scarlatinal nephritis and threatened meningitis. The dose for adults is 7 1/2 grains, 2 or 3 times daily, best administered in 1/2 pint of plain or carbonated water. No more than 30 grains should be given in a day.

URTICARIA (Hives; Nettle-rash).—An inflammatory affection of the skin, characterized by the formation of evanescent whitish and pinkish elevations, attended by intense itching.

Symptoms.—The eruption appears suddenly, manifesting itself as firm, circumscribed, whitish or pinkish elevations (wheals, pomphi) with a reddish areola. The wheals last from a few minutes to several hours, disappear, and are succeeded by others. They are asymmetric, though usually bilateral, pea-sized or bean-sized, and irregular in shape, often, however, being linear. They may involve any portion of the cutaneous surface, or even the mucous membranes. When the pharynx or larynx is involved, alarming suffocative attacks may occur.

The itching in urticaria is intense, the relief produced by scratching being purchased at the cost of the excitation of new lesions. The skin is markedly sensitive to all sorts of irritation, and responds by the production of wheals. The artificial production of wheals gives rise to the form termed *urticaria factitia.* In some urticarial subjects a word may be inscribed upon the skin with a pointed instrument, and in a few minutes the letters will stand out in wheals as if embossed.

In children urticaria is apt to take the papular form—*urticaria papulosa* (*lichen urticatus*). In such cases there are actual inflammatory papules present, with or without the presence of wheals. The summits of the papules are apt to be excoriated on account of the scratching prompted by the intolerable itching. In some individuals wheals attain the size of an egg or even larger. This form is called *urticaria tuberosa* or *urticaria gigans* (giant urticaria). Hemorrhage into the wheal occurs occasionally, giving rise to the form known as *urticaria hæmorrhagica.* At times the upper layers of the wheal are raised into a bleb by the subjacent serum; this type is designated *urticaria bullosa.*

Urticaria, as a rule, runs an acute course, subsiding in a few days. In exceptional instances, however, it may become chronic, wheals appearing, disappearing, and reappearing, the process extending over a period of months or even years.

Etiology.—The great majority of cases of acute urticaria are produced through the alimentary tract. Substances taken into the stomach may cause urticaria, either by a mechanic irritation of the stomach or bowel or by producing a toxemia. Intestinal parasites and undigested aliment act by mechanic irritation. The substances capable of producing toxemia are almost numberless. They may be primarily toxic, or may only develop their toxicity through putrefactive changes while in the bowel. Again, a large number of substances, both foods and drugs, perfectly innocuous to the ordinary individual, act, on account of idiosyncrasy, as poisons to others. The following articles of food are particularly apt to produce hives: lobsters, crabs, mussels, cheese, sausage, pork, nuts, strawberries, etc.

The following drugs are prone to produce urticarial eruptions: quinin, copaiba, cubebs, salicylic acid, morphin, turpentine, chloral, etc. Urticaria may be produced reflexly also by irritation of viscera other than the alimentary tract. It is sometimes associated with rheumatism and tonsillitis. Thus, irritation of the uterus and adnexa may act as an etiologic factor. Rupture or puncture of hydatid cysts or puncture of pleural effusions may be followed by hives. Again, the disease may be produced by direct local irritation, such as the sting of the nettle, the bite of jelly-fish, mosquito, wasp, etc.

Pathology.—The wheal is produced as a result of direct reflex disturbance of the vasomotor apparatus. The lesion consists of a circumscribed edema of the cutis. A momentary spasm of the cutaneous vessels is followed by a dilatation, with exudation of serum and some leukocytes. At the summit of the lesion the effusion is so great as to produce a pressure anemia, hence the whitish coloration. The peripheral vessels are engorged, which gives rise to the reddish areola.

Diagnosis.—The characteristic features of urticaria are the presence of wheals, their rapid evolution and great evanescence, and the intense itching.

Prognosis.—Acute cases recover in a few days. Chronic cases may persist for a long time, and may exhaust the entire therapeutic armamentarium of the physician.

Treatment.—In severe acute cases seen early an emetic should be administered to get rid of the offending substance. Later, magnesium sulphate is to be employed until free catharsis is produced. In subacute cases salol or phenacetin, in 5- to 10-grain doses after meals, may be used with good results. In chronic cases most earnest efforts should be directed toward the discovery of the cause. The patient's dietary must be the subject of the most careful study. Every detail of occupation, of mode of living, and of habits must be scrutinized. The most careful examination, however, will sometimes fail to disclose any discoverable cause. Most cases will be found to be due to gastrointestinal disturbances. In such the most simple diet should be prescribed. In obstinate cases one will do well to restrict the patient for a few weeks to a milk diet.

In obscure cases some of the following remedies may be tried: atropin by mouth or hypodermically, antipyrin or phenacetin, quinin in full doses, sulphurous acid in dram doses, long-continued course of arsenic in small doses, bromid of potassium, pilocarpin, etc.

Local treatment is necessary to give relief from the harassing itching. The best antipruritic lotions are: Phenol, 1 to 3 drams to the pint; menthol, 5 to 15 grains to the ounce; liquor carbonis detergens, 2 to 3 drams to 8 ounces of water; saturated solution of benzoic acid; alkaline baths (1/4 of a pound of washing soda to 20 gallons of water), etc.

URTICARIA PIGMENTOSA.—An inflammatory affection of the skin, beginning in the first 6 months of infancy, and characterized by buff-colored, wheal-like nodules, with or without itching.

Symptoms.—The eruption is most abundant upon the neck and trunk. It consists of yellowish-red, split-pea-sized nodules or wheals with pinkish areolas. The nodules later become yellow, and may remain stationary for months. Some undergo involution, leaving brownish stains. Itching is often severe, but may be moderate or entirely absent. The disease is very rare.

Prognosis.—The affection usually disappears at or before puberty.

Treatment.—Locally, antipruritic applications. Internal treatment is to be based upon general indications.

UTERUS, ANTEFLEXION.—A bending forward of the fundus of the uterus upon the cervix. This is the normal position of the uterus, but it may be exaggerated sufficiently to cause obstruction of the cervical canal—producing dysmenorrhea and sterility—when it is regarded as pathologic. The point of flexion is usually at the site of the internal os.

Causes.—It is usually congenital in origin, and is due to imperfect development of the body of the uterus. It is frequently associated with imperfect development of the rest of the genital organs—tubes, ovaries, and vagina. It is possible that it may be caused by improper hygienic conditions about the age of puberty, such as improper clothing, insufficient exercise, etc. It is extremely rare to find pathologic anteflexion in a woman who has borne children.

Symptoms.—The most important symptom is dysmenorrhea. The pain is quite characteristic. It is expulsive in character, and is situated in the center of the hypogastric region. It begins several hours before the appearance of the menstrual discharge, and is gradually relieved as the bleeding becomes free. The blood is usually dark colored and clotted. Sterility is commonly present in anteflexion of the uterus, since the obstruction in the cervical canal prevents the entrance of spermatozoa. The imperfect development of the genital organs is a further cause of sterility. The interference with the menstrual flow will finally cause endometritis, which, in its turn, may cause inflammation of the tubes and ovaries.

Diagnosis.—Bimanual examination will reveal the anterior position of the fundus, with the sharp angle of flexion between it and the cervix. These physical signs and the symptoms just described will make an absolute diagnosis of pathologic anteflexion.

Treatment.—Pathologic anteflexion of the uterus should be treated by rapid and forcible dilatation of the cervix. This is performed in the following manner: The patient is etherized and placed in the lithotomy position; the vulva, vagina, hands, and instruments are thoroughly sterilized. The anterior lip of the cervix is seized with a double tenaculum and drawn well down toward the vulva. The small uterine dilator (Wathen's) is introduced, and the cervix is gently dilated 1/2 of an inch or more. This is followed by the introduction of the larger dilator. With this instrument the cervix is gradually dilated up to 1 inch or 1 1/4 inches. To secure a more permanent result, the instrument should be allowed to remain in place 10 or 15 minutes after full dilatation has been accomplished. The instrument is withdrawn and the cervical canal and the vagina are douched with sterile water. A tampon of iodoform gauze is inserted into the vagina; this is removed at the end of 24 hours, and a douche of sterile water is given. The patient should remain in bed a week or 10 days after the operation. The first menstrual period following the operation may be attended by some pain, but usually the subsequent periods are painless. In exceptional cases it may be necessary to repeat the operation.

UTERUS, CARCINOMA.—For description of carcinoma of the cervix see CERVIX UTERI.

Cancer of the body of the uterus is a somewhat rare condition when compared to cancer of the cervix. It occurs in only about 2 percent of all cases of cancer of the uterus. It originates in the epithelium of the endometrium.

The causes of cancer of the body of the uterus are not known. Chronic inflammation of the mucous membrane may be a predisposing cause. It occurs later in life than cancer of the cervix—usually between the fiftieth and sixtieth years—and it may attack the nulliparous as well as the parous woman.

The symptoms of cancer of the body of the uterus are about the same as those of cancer of the cervix. There are pain, hemorrhage, and leukorrheal discharge. Vaginal examination shows an enlarged uterus and a patulous cervical canal. When any doubt exists as to the nature of the condition, the uterus should be curetted and the scrapings examined under the microscope.

The treatment should be complete Hysterectomy (*q. v.*). Either the vaginal or the abdominal route may be selected for this operation. Early hysterectomy in these cases offers a very favorable prognosis.

In inoperable cases recently acetone applications or douches have been advocated to stop the bleeding and discharge and improve the general condition. The chief palliative measure is curettage followed by the use of Paquelin's thermocautery. Hemorrhage may be controlled by injections of adrenalin chlorid. It is advisable after the cauterization to apply for a few minutes a tampon soaked with formalin. After the curettage some advocate the application of zinc chlorid or iodized phenol. Permanganate of potassium solution is an excellent disinfectant.

When the area of disease is very extensive tamponades wet or dry may be used to control the hemorrhage and irrigation with potassium permanganate solution should be employed for the copious offensive discharge.

Sarcoma of the uterus is rare. Two varieties have been described: diffuse sarcoma of the mucous membrane and sarcoma of the uterine parenchyma. The symptoms of the former closely resemble those of cancer of the body of the uterus; of the latter, those of fibroid tumor of the uterus. The treatment is complete hysterectomy.

UTERUS, CERVIX.—See Cervix Uteri.

UTERUS, FIBROID TUMORS.—Fibroid tumors of the uterus are benign but not harmless. They undermine the health and shorten life by hemorrhage, interfere mechanically with the functions of vital organs, become septic, and undergo transformation into sarcoma.

Structure.—Uterine fibroid tumors consist of elements similar to those composing the normal structure of the uterine walls, in which they originate. Connective tissue and muscular fibers are found in varying proportions. The terms used to designate these growths are fibroma, myoma, fibromyoma, and myofibroma; the two latter indicate the varying preponderance of fibroid or muscular tissues. While of mixed character histologically, the natural history of the several varieties is practically the same; hence the common term of fibroid tumors will serve to designate the neoplasms under consideration. These growths vary in size from a small nodule the size of a pea to an immense mass weighing more than 100 pounds. They are seldom single, though one or more may outgrow all others and present the appearance of a single rounded or nodular tumor. They originate in the body of the uterus, most frequently from the posterior wall.

Classification.—It is customary to classify them in accordance with their relation to the normal uterine structures. When situated in the uterine wall, they are termed interstitial; when projecting outward beneath the peritoneum, they are called subserous; and when protruding into the cavity of the uterus, they are known as submucous. When starting from the supravaginal cervix and growing outward between the folds of the broad ligaments, they are termed intraligamentous. The tumors grow in the direction of least resistance and the proximity of the point of origin to the peritoneum or uterine cavity will determine whether a given fibroid tumor will be subserous, submucous, or interstitial. The tumor may be so connected with the uterine wall as to become pedunculated. As a result of traction, pressure, or atrophy the pedicle may become twisted, producing gangrene. When the tumor originates near the uterine mucosa and grows beneath that membrane, it may become extruded into the uterine cavity, forming a pedunculated tumor. This is known as a fibroid polypus. Such a tumor will gradually adapt itself to the form of the uterine cavity. Its presence excites uterine contraction, and after a time it will be forced through the cervix into the vagina. The vascular supply is lessened by this process, and sloughing is very common. The fibroid polypus is more frequently single than any other variety of fibroid tumor of the uterus.

Progress.—Uterine fibroid tumors vary in consistence from the soft, edematous myofibroma to the hard nodules almost wholly composed of fibroid tissue. As a rule, they are of slow growth; in exceptional instances they increase with the rapidity which characterizes ovarian tumors. They frequently cease to grow after the menopause, while in exceptional instances they take on increased activity after that change. In some cases the tumor reaches a certain growth and remains inactive, while in other instances it steadily increases until it occupies the entire abdominal cavity and causes serious symptoms by pressure. During menstruation and pregnancy tumors increase in size. After parturition marked diminution in size takes place, so that a tumor that was conspicuous becomes almost imperceptible.

Sequels.—The tumors under consideration are subject to several forms of degeneration. Edema of these growths is quite common. The entire structure of the tumor becomes infiltrated with a serous fluid. This condition is closely allied to cystic degeneration, in which the constituent elements of the tumor are displaced by serous fluid. Cystic cavities may occur as the result of several degenerative changes, the growth being then known as a fibrocystic tumor. Inflammation may be present in fibroid tumors, often resulting from instrumentation and other agencies. Suppuration may take place. Fibroid tumors of the uterus are prone to sarcomatous degeneration. Some pathologists maintain that uterine sarcoma invariably begins in degeneration of a fibroid tumor. Clinical observation has so far confirmed this view that fibroid tumors are generally regarded as predisposing to sarcoma. Carcinoma is frequently associated with fibroid tumors; but since carcinoma most frequently occurs in the cervix,

and fibroids in the body of the uterus, it cannot be claimed that fibroids are disposed to undergo carcinomatous changes.

Age, Race, etc.—Uterine fibroid tumors are common in both the white and black races, but more frequent in the latter. They are found in both nulliparous and multiparous women; indeed, these tumors are among the most common of all the diseases peculiar to women. Unmarried women and married women who have never conceived are especially prone to this disease; from which it is apparent that the arrest of menstruation by pregnancy and lactation, and the retrograde changes accompanying involution, are means of protection against the development of these neoplasms.

Symptoms.—Hemorrhage is the most conspicuous symptom of fibroid tumors of the uterus. While this symptom is observed in the majority of cases, it is not invariably present. Large interstitial and subserous tumors may exist without hemorrhage. Small subserous tumors may present no symptoms. Hemorrhage may occur as a profuse and prolonged menstrual period (menorrhagia), or as a continuous uterine hemorrhage (metrorrhagia). Hemorrhage may be so profuse as to exhaust the patient, or it may be only sufficient to produce a moderate degree of anemia. In cases of submucous tumors (fibroid polypi) the hemorrhage may be so severe as to exsanguinate the patient. The increased area and diseased condition of the endometrium account for the hemorrhage. The site, more than the size of the growth, determines the severity of the hemorrhage.

Pain is a common accompaniment of these tumors. It is the result of various causes, and hence varies in character. The pain of pressure corresponds more to the location than to the size of the growth. When the tumor springs from the lower uterine segment and fills the pelvic excavation, the pressure upon bladder, bowel, and nerve-trunks will give rise to more severe pain than when the tumor rises free above the pelvic brim. Pressure upon the bladder, producing vesical irritation, and pressure upon the bowel, inducing constipation and hemorrhoids, are common. Endometritis, salpingitis, and peritonitis are frequent complications, and cause constant and severe pain. The expulsion of submucous fibroid tumors from the uterus is accompanied by the pain of uterine contraction. The bladder and urethra may be so distorted by the growth of a fibroid tumor that the urine is voided with much pain and difficulty.

The diagnosis is made by observing the symptoms just described, together with careful physical examination. The presence of a tumor, its irregular outline and solid structure, together with its immediate attachment to the uterus, can be determined by bimanual examination. If the tumor is large, its firm consistency and nodular character can be detected by palpation through the abdominal parietes. Interstitial fibroid tumors producing symmetric hypertrophy of the uterus are liable to be mistaken for pregnancy. This is especially marked in the soft and edematous tumors. While generally the diagnosis between uterine fibroma and pregnancy is not difficult, yet one condition has been mistaken for the other, and the error was not discovered until the abdomen was opened. The coexistence of fibroid tumors and pregnancy is not very infrequent, and this fact should be borne in mind.

The differential diagnosis between ovarian cystoma and the soft, edematous variety of uterine fibroid tumors is often most difficult, and to distinguish between a fibrocystic tumor and an ovarian cystoma is also at times exceedingly difficult. Fluctuation exists with all of these alike, and the differential diagnosis can only be made by determining the relation of the growth to the uterus, as indicated by direct mobility of the cervix when the tumor is manipulated through the abdominal parietes. An error in diagnosis here is fortunately not of serious consequence, since the treatment of all tumors of such magnitude consists in removal by abdominal section.

Fibroid tumors springing from the lower segment of the uterus, with adhesions, may readily be mistaken for intrapelvic inflammatory exudate associated with pyosalpinx and ovarian abscess. The reverse of this is also true.

In the diagnosis of submucous fibroids direct exploration of the interior of the uterus with the finger will usually suffice to disclose the character of the growth.

Treatment.—The tendency of **submucous fibroid tumors** of the uterus is to spontaneous cure by becoming polypoid in character, to be afterward extruded from the uterine cavity by persistent uterine contraction. In a majority of cases presenting this form of fibroid growths the tumors will be found projecting from the external os. They vary in size from that of a walnut to large rounded tumors as large as the fetal head at term. If the tumor has been extruded from the uterine cavity through the cervical canal, its removal may be readily and safely accomplished. The danger of hemorrhage after excision in such cases is not serious. Indeed, the blood supply in such growths has been so reduced by the process of pedunculation and protrusion by uterine contraction that the tumor very frequently sloughs from obstructed circulation. It is, however, safer to constrict the pedicle with a wire snare or écraseur, thus slowly crushing the pedicle containing the vascular supply, than to divide it with knife or scissors. In cases of large fibroid polypi that fill the vagina completely it will often be necessary to remove the greater part of the tumor by morcellation before the surgeon can gain access to the pedicle. If the pedicle persists in bleeding after excision of the tumor, the vessels may be caught in a clamp forceps, and left thus secured for 24 hours. Usually, firm packing with gauze will suffice to control the bleeding. This, of course, should only be done after thorough scrubbing of the external genitals with hot water, soap, and brush, the application of an antiseptic douche, and all other aseptic precautions. For the operation, the patient should be placed on a table in the lithotomy position, the perineum should be retracted with Sims' speculum,

and the uterus should be brought down and steadied by means of strong tenaculum forceps.

If a submucous fibroid tumor is within the uterine cavity, it will be necessary to dilate the cervix in order to reach the growth and remove it. If the tumor is sessile and low down, and if it can be drawn down near the internal os, the capsule will have to be opened at the most dependent point and stripped away, when the tumor can be seized with the volsellum upon its uncovered surface and enucleated by the finger of the surgeon. Care must be observed, if instruments are used in enucleating, not to penetrate the wall of the uterus. If the capsule is not injured in this procedure, the hemorrhage will be slight, and gauze packing will readily control it. After completing the operation the vagina should be lightly packed with gauze, a pad applied to the vulva, and the patient kept quiet in bed for a week. After from 24 to 48 hours the gauze should be removed and the vagina douched with pure hot water.

The treatment of subserous and interstitial fibroid tumors of the uterus requires the exercise of sound judgment, based on the requirements of individual cases. When the tumor is of small size, unaccompanied by pain, hemorrhage, or other serious symptoms, operation should not be advised, and no special treatment will be required. Under these conditions the patient should be kept under occasional observation and no treatment need be instituted so long as the growth does not markedly increase and while health and comfort are maintained. This course is especially applicable to women with tumors of considerable size who are near the menopause. The mere presence of a small subserous or interstitial fibroid does not indicate any form of treatment and does not forbid activity and exercise on the part of the patient. It is only when such symptoms as hemorrhage with anemia, pressure, and pain are present that symptomatic and palliative treatment is indicated. For all these symptoms rest is most important. Especially should rest be observed during the menstrual periods. Mild purgation with salines relieves congestion by depleting the pelvic circulation, and should be conjoined with rest during the periods. For excessive hemorrhage various drugs —such as ergot, gallic acid, hydrastis, and some preparations of iron—are in popular favor for controlling the bleeding of uterine fibroids, but usually have proved wholly inefficient; and their use begets constipation and congestion, impairs the appetite and digestion, and interferes with the eliminative functions generally. Hemorrhage will be more restrained by rest, saline purgatives, unstimulating diet, and the moderate use of the hot vaginal douche than by the remedies mentioned. Recently, thyroid extract, internally administered, has been highly recommended to control the hemorrhage and to arrest the growth of uterine fibroids, but experience with its use, though limited to a comparatively few cases, has failed to justify the claims made for this remedy. For excessive hemorrhage the most efficient treatment is to curette the uterine mucosa and to pack the cavity with sterilized gauze. This operation, of course, should be done with careful observance of all antiseptic precautions and in a thorough and surgical way.

Electricity does not arrest the growth of the tumor, and the results claimed for it as a hemostatic have not been verified by general experience. Electropuncture has proved harmful instead of efficacious, on account of the traumatic peritonitis following this procedure.

With the improved technic of modern pelvic surgery the operation for removal of uterine fibroid tumors has become so perfected that palliative and expectant methods of treatment have given way to surgical intervention. In skilled hands, and especially with the facilities of modern hospital requirements, the mortality of operations for removal of these growths has been reduced quite as low as that following operations for the removal of ovarian tumors.

While the methods of treatment outlined may alleviate symptoms and prolong life, and while such treatment is eminently appropriate in cases of small tumors without active hemorrhage or severe pain, surgical measures alone can afford the patient permanent relief and cure. Hence, in the majority of cases resort to operative intervention is indicated. The adaptation of the operative procedure to individual cases requires the highest surgical skill and experienced judgment.

Formerly, when the results of operation were marked by severe mortality, women suffering from these tumors were consigned to invalidism, with much suffering, through the active period of life, looking to the menopause for relief. Many died from the pressure effects and hemorrhage of large tumors; others succumbed to the accidents, complications, and degenerations to which these growths are prone; while still others found the menopause deferred or the tumor growing actively after that period. With the perfected methods of modern surgery the dangers of operation have been reduced until they are less than the dangers inseparably connected with the natural progress of these tumors. Operative treatment is now so safe that it is not to be restricted to large tumors, or to smaller growths complicated in various ways by which life is directly threatened; but in cases of fibroid tumors in which the health is impaired by hemorrhage and pressure of less urgency, but sufficient to beget invalidism, permanent relief should be sought through operative intervention. When the tumor is growing actively, and the patient is suffering from pressure and is weakened by hemorrhage, protracted delay to await the increase of symptoms is inadmissible.

The operations which have been devised for the cure of uterine fibroids are: (1) Removal of the uterine appendages; (2) ligation of the uterine arteries through the vagina; (3) myomectomy; and (4) hysteromyomectomy. The first two procedures are practically abandoned. The operation of myomectomy (removal of the tumor and preservation of the uterus) is practised whenever practicable. In most cases of multiple fibroids, and in cases in which the uterus is distorted and enveloped by the growth, hysteromyomectomy is indicated. See Hysterectomy.

UTERUS, INFLAMMATION OF THE MUCOUS MEMBRANE (Endometritis).—Inflammation of the mucous membrane of the body of the uterus, or corporeal endometritis, may be acute or chronic.

Acute corporeal endometritis is the result of the introduction into the uterus of septic microorganisms. This usually occurs during labor or miscarriage, or it may result from operations, such as dilatation, or from the introduction of an unclean sound. It sometimes occurs as a complication of the exanthems. If the process is severe enough, it may involve the muscular tissue underneath the mucous membrane, when it is called metritis; or the peritoneal covering of the uterus may be invaded, when it is called perimetritis. See Colon Bacillus Infection.

Symptoms.—Acute corporeal endometritis is usually attended by considerable pain, of a dull, aching character. There are constipation and vesical irritability. The pulse is rapid and temperature in some cases is very high—from 104° to 106° F. Vaginal examination reveals a patulous cervical canal with a profuse purulent discharge escaping from it. The uterus is enlarged, boggy, and tender.

Treatment.—Acute corporeal endometritis following miscarriage or labor should be treated actively. The uterus should be thoroughly curetted, in order to remove any portions of decidua or membranes remaining after parturition. If the symptoms do not subside in the course of 24 hours, intrauterine douches of sterile water may be given 2 or 3 times daily. Free purgation, hot stupes to the lower abdomen, a generous diet of milk and broths, and an abundance of stimulation will be required. In the gravest cases hysterectomy will have to be performed. In less severe cases of acute endometritis rest in bed, vaginal douches of hot, sterile water, and purgation will be sufficient.

Chronic corporeal endometritis may result from an acute attack or it may be chronic from the beginning. One of the most frequent causes of this condition is gonorrheal infection. Chronic endometritis accompanies a variety of pathologic conditions of the uterus, such as displacements, subinvolution, laceration of the cervix, and fibroid tumors.

Two varieties of chronic endometritis have been described—glandular and interstitial.

The symptoms of chronic endometritis are usually well marked. There is pain, of a dull, aching character, most evident in the back and extending down the thighs. Leukorrhea is constant, and is quite characteristic. The discharge is thin, purulent, and blood-streaked. Menstruation is profuse, and lasts usually from 5 to 7 days. The patient's general health suffers; she loses weight and becomes anemic; there is a sense of great reduction in physical strength. Headache is a very common symptom. Nervous, digestive, and circulatory disturbances appear sooner or later. Physical examination reveals an enlarged, tender uterus. The cervical canal is patulous; the external os is eroded. The characteristic discharge can be seen escaping from the cervix.

The treatment of chronic corporeal endometritis will depend upon its cause. It may be necessary to replace a displaced uterus, to remove a fibroid polypus, or to repair a lacerated cervix or perineum. If the condition is due to gonorrheal or septic infection, or if the foregoing measures fail, curettage should be perforemd.

The steps of the operation are as follows: The patient is prepared for the operation, anesthetized, and placed upon the table in the dorsal position. The anterior lip of the cervix is seized with a tenaculum and is drawn well down toward the vulva. The cervical canal is dilated about 1 inch. A Sims sharp curette is introduced, and the anterior, lateral, and posterior surfaces of the uterus are carefully and thoroughly scraped. This is followed by careful scraping of the fundus and of the region around the uterine opening of the Fallopian tube with a Martin curette. The uterus is now irrigated with sterile water, and the vagina is packed lightly with iodoform gauze. The gauze is removed at the end of 24 hours, the bowels are evacuated at the end of the second day, and the patient is allowed to get out of bed at the end of 10 days or 2 weeks.

If the disease is gonorrheal in origin, the uterine cavity, after curettage and irrigation, should be wiped out with pure carbolic acid. The excess of carbolic acid may be removed by another douche. After curettage the first and sometimes the second and third menstrual periods are missed. Attention to the general health, diet, exercise, and condition of the bowels, and the administration of tonics will be required before complete cure is accomplished.

Tuberculous endometritis is rare and is generally secondary to tuberculosis of the tubes or cervix. Diagnosis may be made by the removal of caseous material by means of the curette, or by the tuberculin test. See Endocervicitis under Cervix Uteri.

UTERUS, PROLAPSE.—A sinking of the uterus below its normal level. There are a great many degrees of prolapse of the uterus. It may vary from a slight sinking of the organ to complete extrusion from the vulvar orifice.

Causes.—The most frequent cause of prolapse of the uterus is injury at childbirth—laceration of the perineum. Other causes are: relaxation and elongation of the uterine ligaments; loss of rigidity of the abdominal walls; diminution of the cellular tissue and fat of the pelvis; increase in the weight of the uterus from subinvolution or congestion; and, finally, anything that may cause an increase in intraabdominal pressure, as constant coughing, violent straining, or heavy lifting.

Symptoms.—The symptoms of prolapse of the uterus are not characteristic; neither do they correspond in severity to the degree of prolapse. Slight descent of the organ may cause more disturbance than complete prolapse. The patient usually complains of pain in the back, head, and thighs. The pain in the back is dull and aching in character, and is usually felt most severely over the sacrum. Added to this there is a dragging and feeling of loss of support in the pelvis. Constipation and irritability of the bladder are usually present.

Diagnosis.—Physical examination will readily reveal the condition. The cervix or body of the uterus may project from the vulva. In less severe cases the cervix may be found resting on the pelvic floor. Slight cases of prolapse are the most difficult to diagnose. It will be found, however, that the cervix is lower than normal, and that the uterus can be pushed further upward than usual. It should be remembered that when the patient lies on her back, the prolapse is less marked than when she is erect. Complete prolapse of the uterus should never be mistaken for inversion of the uterus or for a uterine polypus, since their only point of resemblance is in shape.

Treatment.—The treatment of prolapse of the uterus is operative, unless some contraindication to operation exists. In such a case some **mechanic device** should be tried for the support of the uterus. Pessaries are not to be recommended, as their constant use leads to irritation and excoriation of the vaginal walls. Probably the best means for supporting the uterus is by an instrument called Braun's colpeurynter. This instrument is worn only during the day, and can be introduced by the patient herself every morning. The uterus is replaced and the colpeurynter, well anointed with carbolized vaselin and containing about an ounce of water, is introduced into the vagina. It is then distended with air, thus making an even pressure on the vaginal walls and not causing ulcerations.

Operative treatment gives the most satisfactory results in prolapse. In slight cases of prolapse repair of the PERINEUM (*q. v.*) will effect a cure. The severer grades will require, in addition, some operation on the anterior vagina—anterior colporrhaphy. The best of these is Martin's operation for cystocele. Dudley advocates an elliptical bilateral denudation of the vaginal walls. See CYSTOCELE.

If the cervix is hypertrophied it should be amputated. See CERVIX UTERI.

These three operations—Emmet's operation on the perineum, Martin's operation for cystocele, and amputation of the cervix—are required in the usual case of prolapse. In addition, hysterorrhaphy may be advisable, since there can be no prolapse so long as the uterus maintains its normal position of anteflexion. These operations failing, HYSTERECTOMY (*q. v.*) may be performed.

UTERUS, REMOVAL.—See HYSTERECTOMY.

UTERUS, RETRODISPLACEMENTS.—Retrodisplacements of the uterus comprise retrolocation, retroversion and retroflexion. In **retrolocation** the organ may retain its normal relation to the pelvic axis, but the entire organ is displaced backward. This displacement is the result of some inflammatory process in the pelvic peritoneum by which the uterus has been fixed, most frequently by a collection in the retrouterine pouch which has been absorbed.

Retroversion is a rotation of the uterus on its transverse axis by which the fundus of the organ is carried backward and the cervix looks forward.

Retroflexion is a change in the vertical axis of the uterus in which there is a more or less acute angle on its posterior surface between the fundus and cervix. It is usually associated with retroversion, indeed, may be regarded as a later stage of that displacement. Both retroversion and retroflexion may vary from a slight backward displacement, to one of extreme degree, where the fundus in the former, is situated in the pouch between the rectum and the vagina, while the cervix looks directly forward or forward and upward. In the latter, the cervix may occupy the axis of the vagina, while the fundus is below its level. Retroversion is the first stage of prolapse, consequently it is very frequently associated with the latter condition. Not infrequently an anteflexed uterus will also be found retroverted.

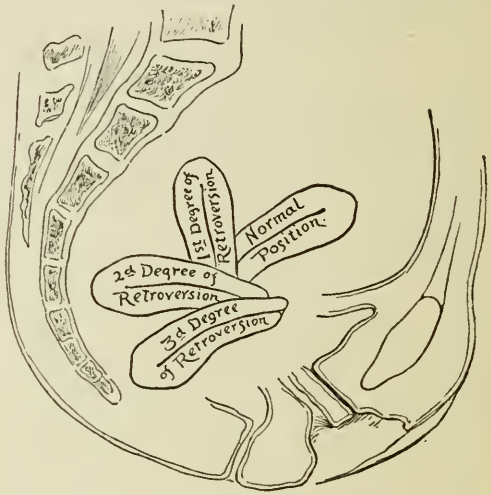

DIAGRAM OF THE DEGREES OF RETROVERSION OF THE UTERUS.—(*Penrose.*)

Etiology.—Backward displacements of the uterus are most frequently sequels of parturition. Without doubt, infection, to a more or less degree, is an essential factor. The uterus remains large and heavy, its ligaments, relaxed by the previous pregnancy, are kept in a continuous state of tension which prevents their involution, while the relaxed condition of the abdominal muscles from overdistention suspends the power of aspiration. Improper hygiene in both the pregnant and nonpregnant is an important consideration. Habitual distention of rectum and bladder, and the straining of constipation result in loss of muscular power and increased uterine displacement. Maintenance of the same waist measure, notwithstanding increase of size from pregnancy or additional adipose, necessarily causes greater intraabdominal pressure, and as the enlargement is unable to find accommodation elsewhere it is forced downward, not only adding to the displacement, but making it permanent. Flexions may be produced by irregular involution; thus an inflammation of the site of a placenta which had been implanted on the anterior uterine wall would result in more rapid involution of the posterior wall, causing it to become the string of the bow and draw the fundus

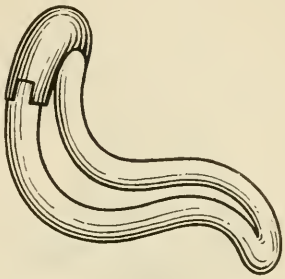
backward. Displacements are produced by growths as fibroids, in the uterus or, from the pressure of external tumors, as ovarian cysts, tubal enlargements and pelvic exudates. These displacements may occur in either the single or the married, the nulliparous or parous woman, though more frequent in the latter.

Symptoms are not characteristic. Patients complain of headache, backache, a sensation of weight and dragging in the pelvis, pain and points of anesthesia down the thighs, menorrhagia and leukorrhea, dysmenorrhea, vesical irritability, obstinate constipation, hemorrhoids and anal fissures increasing discomfort in standing and walking, all of which may be aggravated just preceding menstruation, but, as is well-known, these symptoms may be produced by other conditions. Their existence, however, should be sufficient cause for subjecting the patient to a careful pelvic examination.

Diagnosis.—Retrodisplacements are readily determined by the bimanual examination. The cervix is situated near the vaginal outlet, in the axis of the vagina, looking forward or even upward. The fundus is absent from its normal situation behind the symphysis, lies posteriorly, and sometimes on the rectum. In retroflexion there is a distinct angle between the fundus and the cervix. Retrolocation is recognized by the organ being drawn upward and fixed near the sacrum. The only condition in which the diagnosis is difficult is when the uterus is surrounded by a mass of exudate in which its relations are more or less lost, but here the inflammatory condition is the condition of greatest significance.

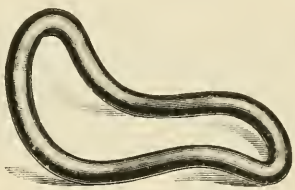
Treatment.—Mechanical and surgical measures may be employed. The mechanical measures—pelvic massage, medicated tampons and pessaries—are applicable where the condition is recent. Where the uterus is still heavy from subinvolution following a recent pregnancy its elevation and maintenance in a proper position by a tampon or suitable pessary so improves the circulation as to rapidly restore it to its proper size, when its ligaments will be sufficient to retain it. Tampons medicated by glycerin preparations have a hydragog effect on the uterus promoting its circulation and the more rapid absorption of the inflammatory or other products which caused the enlargement. They are especially beneficial as a supplementary treatment to pelvic massage in fixation of the uterus by inflammatory exudate. The necessity for operation in recent cases may frequently be avoided by the employment of this combined treatment. The exudate is absorbed, the uterus freed, and the abnormal position corrected. This plan of treatment is futile in old inflammatory conditions, and positively dangerous in the presence of suppuration. The maintenance of the uterus by the pessary in a corrected position is efficacious where the displacement and the condition is uncomplicated. The uterus must be capable of being placed in the correct position, and be so placed, before the pessary is inserted. The pessary does not correct the malposition, but maintains the organ when replaced.

Reposition and Insertion of the Pessary.—The uterus may be placed in its proper position in one of two ways. 1. With the patient in the dorsal position, the operator introduces, where possible, two fingers into the vagina with which the fundus is pushed up and the cervix backward; the other hand, on the abdomen, grasps the fundus and



Thomas' Retroflexion Pessary.

pulls it forward. The manipulation must be practised with the greatest gentleness and the continued cooperation of the patient be secured, otherwise but little can be accomplished. Occasionally, the prominence of the sacrum will be so marked that, by the methods just suggested, the fundus cannot be raised over it; in such circum-



Smith-Hodge Pessary.

stances, the cervix should be drawn upon with a tenaculum, or tenaculum forceps, and the fundus pushed forward with the finger in the vagina, after which the cervix can be carried backward with the forceps until the fundus is recognized by the external hand. 2. The patient should be placed in the genupectoral position and the vulva

Mundé Pessary.

opened with a retractor, when the atmospheric pressure will carry the uterus upward, but not necessarily with the fundus forward. Should it still remain retroverted, the cervix can be grasped with the tenaculum forceps and drawn downward, and then carried backward, when it will be replaced unless there are firm adhesions fixing it. In this position the pessary can be

introduced and carried under the uterus and its relation to the surrounding parts will be apparent to the eye of the physician. In the dorsal position the correction of the malposition is followed by the insertion of the pessary in the following manner: the left hand of the operator separates the labia

Pessary in Faulty Position.—(*Montgomery.*)

while the pessary, with its posterior bar held anteroposterior to the vulvar outlet, is made to impinge against the perineum and thus inserted until more than one-half the instrument is buried within the vagina, when it is rotated with the concavity of the greater curvature forward, and the

Pessary in Proper Position.—(*Montgomery.*)

index-finger of the right hand carries the posterior bar behind the cervix. The pessary should be sufficiently long to occupy the posterior vaginla fornix without undue pressure, and wide enough to fill the vagina and prevent displacement. The proper size of the pessary can be determined by measuring on the inserted fingers the length from the sacral promontory to the inner surface of the symphysis, and its width by the extent to which the fingers can be separated. An unduly large instrument will soon produce such ulceration and pain that it can not be worn and the cicatricial changes following its use will preclude the employment of any other instrument. An instrument too small will be inefficient and necessarily prejudice the patient against further mechanical procedure. Pessaries of infinite variety have been devised. They are all, however, modifications of the original Hodge pessary. Instruments with a thick and wide posterior bar, are, generally the best, and of these the Mundé and the Thomas are preferable.

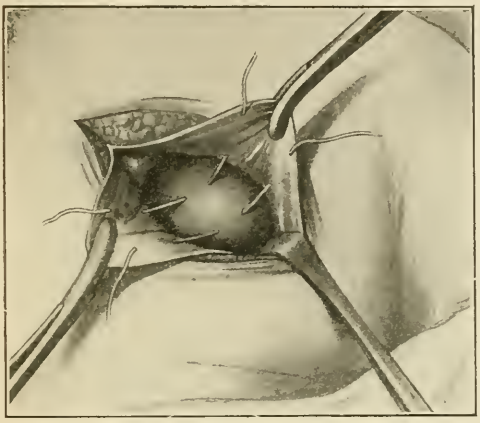
After the pessary has been inserted the patient should be directed to rise and sit down, if the presence of the instrument is unrecognized, she can be sent away with the assurance that it is unlikely to produce inconvenience. Should the instrument be partially protruded by straining at stool she should assume the genupectoral position before pushing it back. She should be instructed as to its removal and to permit the physician an opportunity within a week to see that it is causing no inconvenience. No pessary should be retained longer than two months without medical supervision, and the vagina should be kept clean by douching. Alkaline astringent douches should not be employed as they cause salts to be deposited on the pessary which roughen it and render its subsequent use a source of danger. When the pessary is continuously worn for a long period, it produces irritation and not unfrequently becomes more or less imbedded. In cases of chronic displacement, the pessary is objectionable as it is merely palliative and not curative. In retroflexion, it is very unsatisfactory as the uterus is likely to fold over the pessary, and the same condition occurs when the organ has not been properly replaced before the introduction of the instrument. It will be appreciated that the uterus must be freely movable and capable of replacement to make the employment of a pessary practicable. The pessary is contraindicated in lacerations of the cervix, and will not be retained when there has been extensive laceration of the pelvic floor, or in great relaxation of the vagina. At best, the instrument is a crutch, requiring care that it does no injury, and should be regarded as only a temporary expedient.

Surgical Measures.—The number of operative procedures devised for the correction of retrodisplacements is indicative that there exists no ideal procedure applicable to all cases, and that the operation must be adapted to the particular conditions present in the individual patient. Operations have been adapted to the round ligaments at their exit from the inguinal canal and within the peritoneal cavity, to the uterosacral ligaments, through the abdomen or the vagina, and various suspension or fixation operations through either vaginal or abdominal incision.

The Alexander operation was the earliest suggested and performed for the radical restoration

of the retrodisplaced uterus. (See Alexander's Operation). It is, however, applicable only to cases in which the uterus is freely movable, and consequently to those in which the operation is least demanded. It is a blind operation and not to be considered when the uterus is fixed by internal adhesions.

Ventrosuspension or *Ventrofixation* devised by Olshausen and perfected by Kelly was for a time performed more frequently than any other operation for retrodisplacements and afforded the advantage over the previously named operation that it permitted treatment of diseased conditions and freeing the fixed organ.



Sutures Introduced for Ventrosuspension. —(*Montgomery.*)

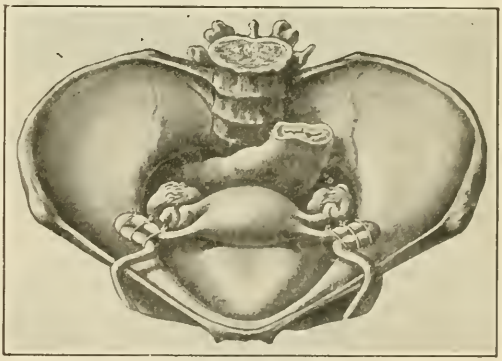
The operation consists of an incision about 2 inches long in the median line just above the symphysis through which the fundus uteri is brought up, and two sutures of silk, silkworm-gut or chromic catgut are passed through the fundus and peritoneum and a portion of the muscle on each side of the incision. The first stitch is on a line with the uterine cornua and the second, one-fourth of an inch behind it. The wound in the abdomen is closed by inserting a chromic catgut suture external to the aponeurosis on the right side of the upper angle of the wound, bringing it through the peritoneum and uniting the latter with a continuous stitch until the lower end is reached, when it is brought through the aponeurosis on the left side; silkworm sutures are then inserted through all the tissues above the peritoneum and the ends temporarily secured with hemostats when the aponeurosis is closed with the continuation of the peritoneal suture and tied at the upper angle of the wound. The tying of the silkworm sutures and the approximation of the skin edges between with plain catgut sutures completes the operation.

Chromic catgut sutures are preferable for securing the uterus as they will ultimately be absorbed and if they become infected are not the cause of the formation of a sinus and of prolonged suppuration as would occur in the nonabsorbable suture.

The portion of the fundus taken up in the suture is not more than one-half an inch in width as the aim is to construct a ligament which will lengthen and not firmly fix the uterus against the abdominal wall.

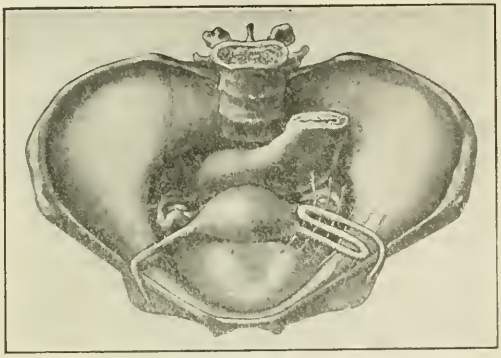
Vaginal Fixation.—Procedures aimed to maintain the uterus forward through an incision of the anterior vaginal fornix have been devised. Duhrrsen secured the anterior wall of the uterus without opening the peritoneum, Mackenrodt opened the peritoneum and placed the suture higher on the fundus, Gottschalk and Vineberg secured a loop of the round ligament in the vaginal wound, Ries through the vaginal incision made a slit in the anterior wall of the uterus and secured a loop of each round ligament in it. Experience disclosed that fixation operations exercised a baneful influence in subsequent pregnancy, producing more or less discomfort during the gestation and became a cause of dystocia at its termination. In spite of careful precautions the operator would sometimes find that as a result of a slight infection or some other cause, an intended suspension had become a fixation. When most favorable a cicatricial ligament was formed which, in quite a number of instances, permitted a knuckle of intestine to become wrapped about it and thus the result was peril, or even, death to the patient. The ligament frequently became attenuated and even broken, permitting the displacement to recur. A fixation operation is no longer considered as applicable to the child-bearing woman.

Intraperitoneal shortening has been done by folding the round ligaments as in the Wylie, Baer, and Mann operations; by denuding the peritoneum over a portion of the ligament, and suturing this to a raw surface on the front of the uterus, the desmopycnosis of Palmer Dudley; by carrying a loop of each ligament through a slit in the anterior uterine wall (Ries); by pushing a loop of each ligament through the broad ligament beneath the ovarian and securing it to the posterior uterine wall (Webster); or, by cutting the ligament near the uterus, tying the proximal end and securing the distal as in the Webster operation (Baldy); by resecting the ligament and uniting the divided ends, at the same time folding the



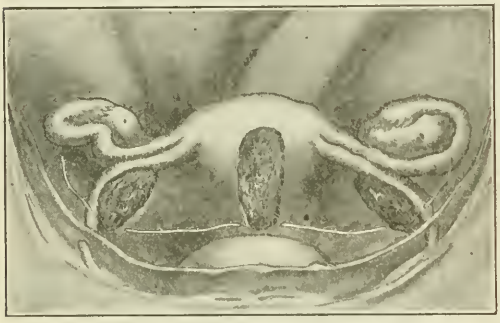
Wylie's Operation for Shortening the Round Ligaments within the Abdomen.—(*Montgomery.*)

anterior surface of the broad ligament (Bissell); by dragging a loop of each ligament through the abdominal wall and securing it on the external surface of the aponeurosis (Gilliam); by carrying



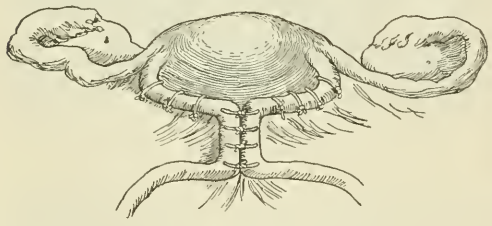
Mann's Operation for Intra-abdominal Shortening of Round Ligaments.—(*Montgomery.*)

this loop through an incision in the anterior leaflet of the peritoneum and securing it to the under surface of the rectus muscle (Simpson); or by carrying it outward between the layers of the



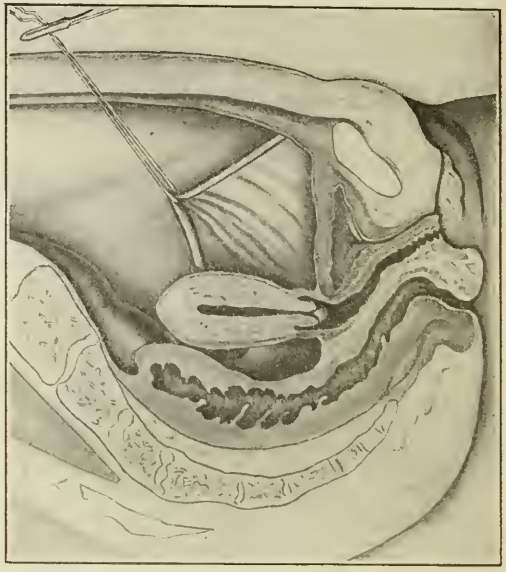
Dudley's Operation of Desmopycnosis.

broad ligament suturing it on the aponeurotic layer (Montgomery). Coffey depends on the cicatricial results of folding the peritoneum, especially in front of the uterus.

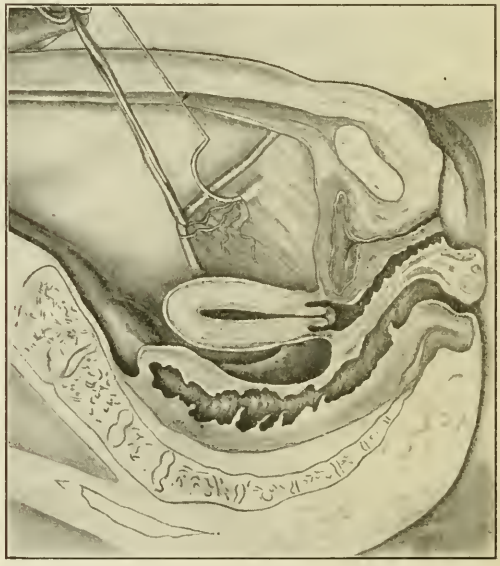


Dudley's Operation Completed.

A transverse crescent incision (Pfannenstiel) is made just above the symphysis, in the majority of cases in the hair line, through the skin, superficial fascia and the aponeurosis, the latter stripped from the muscle, when the recti and pyramidales muscles are separated in the median line and the peritoneum opened vertically. This incision permits ready access to the pelvic structures as it is



First Step in Montgomery's Modification of Gilliam's Operation.

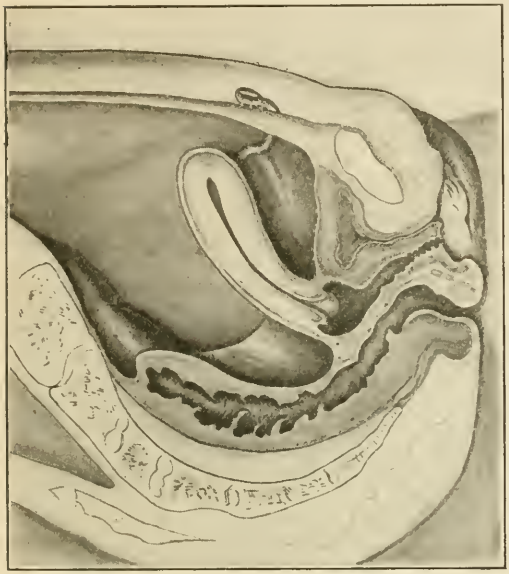


Second Step in Montgomery's Modification of Gilliam's Operation.

Showing ligament fixed with hemostat while temporary ligature is carried beneath anterior leaflet of broad ligament with a Deschamps needle.

directly over them. Diseased conditions of the tubes and ovaries are treated and adhesions separated.

A ligature is passed beneath the round ligament on either side, the ends of each ligature threaded into the eye of a sharp needle, while the round ligament is held tense in a pair of forceps, the threaded needle is carried through an opening in the anterior leaflet of the broad ligament between its layers until the reflexion of the peritoneum on the anterior wall is reached when it is plunged through and the ends of the ligature removed from the needle and temporarily secured by hemostat. After the opposite ligature is brought through, it is drawn taut and a pair of pointed scissors closed pushed through the opening made by the needle and the blades slightly separated, when



Completed Operation.—(*Montgomery.*)

the loop of the ligament is easily drawn through. Each loop is secured, by a few chromic catgut stitches. The wound is closed by a chromic catgut suture passed at its upper angle through muscle and peritoneum and afterward as a continuous suture through the peritoneum only, until the lower angle is reached when it is brought out through the muscle and continued in the reverse direction through the muscle edges to the upper angle, where it is tied. Care is exercised not to produce such traction on this suture as to strangulate the muscle. The aponeurosis is likewise closed with a continuous chromic catgut suture, while the skin is united by a continuous suture of plain catgut. Consequently, there are no sutures to remove, and the deeper surfaces are maintained in firm apposition.

This procedure has a number of advantages: there is no place for the intestines to become imprisoned and form unfortunate adhesions, the uterus is supported by ligaments capable of involution and evolution, the patient has the minimum danger of subsequent hernia, and the scar is obscured by the regrowth of the pubic hair.

As has been indicated, there is no operative procedure which will serve in all cases. Where the displacement is accompanied by prolapse, it may be necessary to supplement the procedure by plastic operation on the anterior vaginal wall and the pelvic floor. Lacerations of the cervix should be repaired or the cervix amputated when the latter procedure is preferable.

Intraperitoneal shortening of the uterosacral ligaments, or in case of their extreme attenuation, the quilting together of the peritoneum behind the cervix to lessen the depth of the retrouterine pouch may be necessary to maintain the uterus.

UTERUS, RUPTURE OF.—See Postpartum Hemorrhage.

UVA URSI (Bearberry).—The dried leaves of *Arctostaphylos uva-ursi*. It contains gallic and tannic acids, and 3 principles, *arbutin*, a bitter glucosid, neutral, crystalline, resolvable into glucose and hydroquinone; *ericolin*, bitter and amorphous; *ursone*, resinous, neutral, crystalline and tasteless. It is astringent, tonic, and diuretic. It was formerly much employed in calculous disorders of the bladder. It is given in chronic gonorrhea or gleet, in pyelitis, and in cystitis. It turns the urine dark colored or black when taken in overdose. It has been used in incontinence of urine, in dysuria and strangury, and in uterine hemorrhages; also as a diuretic in cardiac dropsy. Dose, 10 grains to 1 dram in infusion or decoction. **Arbutin** is the glucosid. Dose, 5 to 15 grains.

UVULA, DISEASES.—**Inflammation of the uvula** (**uvulitis**) often accompanies severe pharyngeal catarrh. The uvula appears red, swollen, and edematous, and often considerably lengthened. If the treatment for the associate pharyngeal catarrh does not relieve the condition, scarification may be practised.

Elongation of the uvula may be due to chronic pharyngeal catarrh or to enlargement of the tonsils and associate conditions. If the elongated uvula comes in contact with the back of the tongue or with the mucous membrane of the larynx, there is a troublesome, tickling cough. The treatment for the causative conditions should be instituted, and if they fail, the organ must be amputated. See Palate, Pharyngitis (Chronic), Rhinitis (Chronic), Tonsils.

V

VACCINATION AND VACCINIA (Cow-pox).—Vaccina is an eruptive disease of the cow, horse, camel, or other animal. Transferred to man by inoculation, it affords protection for varying periods against small-pox. This fact was discovered by Edward Jenner in 1798.

Vaccination is performed by scratching the cuticle slightly and rubbing virus obtained from a calf, or child suffering from vaccinia into the scarifications or abrasions.

The etiology of cow-pox is unknown, though there is strong presumptive and experimental evidence that it is but a modified form of small-pox. Jenner believed this to be the case, and his observations have been confirmed by Gassner, Viborg, Theile, Ceely, Babcock, and many others, down to the present day, when King, Simpson, Leonhard, Voight, and Fisher claim success in producing vaccine of variolous origin; and while it is rather at variance with many known biologic factors, still the so-called spontaneous cow-pox almost invariably makes its appearance in the immediate neighborhood of genuine small-pox.

The Virus.—Undoubtedly, the best form of vaccine virus to use is a glycerinated emulsion of the pulp of the vesicle from a healthy calf. Under the modern method of preparing, this is stored for from 4 to 6 weeks. During this time the glycerin destroys all extraneous organisms, while the organisms of vaccinia increase in power. Prepared in this form, the vaccine virus retains its activity for many months, and when used, produces the typical pock of vaccinia and is accompanied by very moderate local or constitutional disturbances and by only a slight febrile reaction. There is no doubt that the pronounced areola, swelling of the limb, tenderness of neighboring glands, and more or less grave depression occasionally seen, are the results of the accompanying organisms either contained in the vaccine or accidentally introduced subsequently; but as they were inseparable under the old methods of production, many laymen and some physicians still regard with doubt the success of a vaccination unaccompanied by "sore arms."

Virus dried on points cannot be sterilized by any process known at the present time, and under the strictest precautions that can be observed it will be contaminated in the vast majority of cases; hence it is wise to use the glycerinated virus when obtainable. Every physician appreciates the fact that it is difficult thoroughly to disinfect the human skin, for the reason that several varieties of organisms find their habitat upon its surface, in and under the superficial layers and also deep down in the hair follicles. In the cow this is more marked.

It has been found by repeated culture tests that the normal serum, which in health is sterile, drawn from the scarifications on an animal before vaccination, and after a most thorough antiseptic toilet, is in the vast majority of cases contaminated by a variety of organisms, most, if not all, of a non-pathogenic character; but one especially persistent streptococcus has certain cultural and microscopic characteristics leading to the belief that under proper stimulus it might be awakened into harmful activity.

Deep pitting of the resulting cicatrix is probably caused by the action of some of these extraneous organisms. Thorough immunity can be conferred by subcuticular inoculation with sterile virus in which very little, if any, scar is left.

Technic.—It is well to bear in mind, when vaccinating a child, that the remaining scar is unsightly, and on a girl's arm, in certain stations of life, a disfigurement to be avoided, if possible. This fact cannot be overlooked, and it is well to be guided by the mother's wishes, as there is no reason why some other portion of the body, such as the outer aspect of the thigh or the calf of the leg, should not be selected, provided the parts where the blood-vessels are thinly covered or where there are large masses of lymphatics are avoided. In the absence of such reason or in the case of a boy the classic site, above the insertion of the deltoid on either arm, possesses advantages besides that of custom. This area is readily accessible for operation and inspection, and can be protected from violence.

Vaccination is usually performed during the first 4 months of life, and, if unsuccessful, should be repeated at intervals, immunity, so called, being rare; the failure, in a vast majority of cases, is due to poor or inert virus.

Having selected a site, cleanse the surface with alcohol or ether, applied with a piece of absorbent cotton; then wash thoroughly with boiled water, or, if there is reason to suspect infection of any sort—such as suppurating wounds, contagious diseases, etc., in the same family or house—it is well to use a solution of bichlorid of mercury 1:5000 or 5 percent phenol solution, being careful to wash away every trace of the antiseptic with boiled water; otherwise, the vaccination will probably be unsuccessful. It is rarely necessary to use the stronger antiseptics in children or adults of cleanly habits and surroundings.

Grasp the limb with the left hand, stretching the skin between the index-finger and the thumb, blanching it and scarify one or two spots by cross-hatching, thus bringing to the surface a little serum, each spot to be about 1/3 of an inch square, and to be separated by an inch of healthy skin in order to prevent coalescence of the vesicles if more than one scarification is made. Bear in mind that one typical vesicle the size of a pea affords as much and as thorough protection as will a dozen larger ones. However, it is well, at times, to perform

multiple vaccinations on a child whose parents are at all reluctant and not likely to return in case the primary vaccination fails, the larger number of spots lessening the danger, as one is almost certain to introduce the active principle of vaccinia into one or more of the spots. Care and thoroughness, if virus is active, will insure success in single-spot primary vaccinations.

An ordinary sewing-needle is by all means the best kind of scarifier. It can be obtained in every house, and is furnished by some of the producers with each vaccination. It is readily sterilized by passing it through the flame of a match, candle, gas, or other light. It will tear rather than cut the cutaneous vessels and absorbents, doing away with bleeding, and by slightly bruising the tissues, prepares a more favorable soil for the vaccine organism to grow upon. If virus dried on ivory points is used, the point itself makes a good scarifier. The physician should never use a pocket lance or scarifier unless it can be, and is, thoroughly sterilized before each vaccination. And he should not overlook the fact that all these precautions are useless if his own hands are not surgically clean. The virus selected is rubbed into the scarification, either by reversing the needle and using the eye, or by, what is preferred, a little splint of hard wood (an orange-wood toothpick with one end spade-shaped answers perfectly). Rub the virus well into the scarification, and keep uncovered until dry. It is well to protect the forming scab, especially in young children, by some form of shield. Many, however, prefer a sterile gauze compress fastened by adhesive plaster. It is important to protect the crust or scab from violence, as it undoubtedly is the best protective, unless it becomes very purulent. In this case it should be removed with a sharp curette and treated as an infected wound.

Hutchin has suggested a method which is especially valuable in children: After the site selected is cleansed, a bit of cotton wet with liquor potassæ is applied for 2 or 3 minutes. After its removal, the site is dried and gently rubbed with moist cotton. Thus the epidermis is readily removed and the vaccine may be applied and allowed to dry.

In normal vaccination there is a gradual increase of redness at the point of inoculation, and on the third day there is a slight shotty feeling, followed by small vesicles on the fourth and more pronounced vesicular on the following day, the vesicles becoming confluent on the seventh day, when the temperature reaches its maximum. About the eleventh or twelfth day the areola should disappear and the scab begin to dry. This continue until about the twenty-first day, when it becomes detached, leaving a healthy, cicatrized base. See also SMALL-POX.

VACCINE THERAPY.—See SERUM THERAPY AND VACCINE THERAPY.

VAGINA, HEMORRHAGE.—Hemorrhages from the genital tract of the female are naturally divided into two classes: (1) Hemorrhages complicating pregnancy, labor, or the puerperium; (2) hemorrhages occurring in the nonpregnant woman.

1. **Hemorrhages Complicating Pregnancy, Labor, or the Puerperium.**—

A. **Hemorrhages of Pregnancy.**—

(1) Placenta prævia.

(2) Premature separation of a normally situated placenta.

(3) Rupture of varicose veins of the vagina or vulva.

(4) Apoplexy of the decidua or placenta.

B. **Hemorrhages of Labor.**—

(1) Placenta prævia.

(2) Premature separation of a normally situated placenta.

(3) Relaxation of the uterus.

(4) Lacerations of the cervix, vagina, or vulva.

(5) Rupture of the uterus.

(6) Inversion of the uterus.

(7) Hematoma of the vulva or vagina.

C. **Hemorrhages of the Puerperium.**—

(1) Retained secundines.

(2) Displaced uterus.

(3) Displaced thrombi.

(4) Fibroid tumors.

(5) Pelvic engorgement.

(6) Hypertrophied decidua.

(7) Carcinoma.

2. **Hemorrhages Occurring in the Nonpregnant Woman.**—

A. **In Virgins before the Age of Thirty.**—

(1) Uterine congestion the result of cold or exposure.

(2) Endometritis.

(3) Polypi and fibroid tumors.

(4) Retrodisplacement of the uterus.

B. **In Married Women before the Age of Thirty.**—

(1) Subinvolution.

(2) Laceration of the cervix.

(3) Endometritis.

(4) Retrodisplacements of the uterus.

(5) Polypi and fibroid tumors.

C. **In Virgins or Married Women after the Age of Thirty.**—One should always suspect, in addition to the above conditions:

(1) Carcinoma of the cervix.

(2) Carcinoma of the body of the uterus.

(3) Sarcoma of the uterus.

Hemorrhage from the female genitalia may also occur as the result of traumatism of any kind. Certain constitutional disturbances may cause it, such as purpura, scorbutus, and hemophilia.

For the differential diagnosis of the various conditions causing hemorrhage from the vaginal orifice, see under the respective headings, as CERVIX UTERI, LABOR, PLACENTA PRÆVIA, POST-PARTUM HEMORRHAGE, UTERUS (Fibroid Tumors), etc.

VAGINAL DOUCHE.—The value of the hot douche was made known by Emmet. It should be given with a gravity syringe while the patient is in a recumbent position; the more prolonged, the larger the quantity, and the higher the temperature (115° to 120° F.), the more enduring will be the effect. The ordinary fountain syringe, a large vessel with a tube leading from its lower end, or an ordinary pitcher with a rubber tube carried to and

held at its bottom by a weight, may be used. Instead of the ordinary rubber, wooden, or metal nozzle, a glass end-piece is preferable as it can be more readily cleansed. When preferred, the water may be medicated with astringents, such as alum, sulphate of zinc, acetate of lead, hydrastis, or hamamelis; or with antiseptics, as boric acid, carbolic acid (2 to 5 percent), or permanganate of potassium (1 to 2 percent), and acid sublimate (1 : 5000 to 1 : 2000) are valuable. The antiseptic injections are of especial value in vaginal discharge, more particularly when of a specific character. The advent of menstruation is considered as contraindicating irrigation, but it may be resumed before it ceases, particularly when the odor is offensive or the parts are irritated. using plain water at a temperature of 100° F. If the vaginal discharge is particularly offensive, as in malignant disease, a douche of thymol solution, 1 or 2 percent, is a most excellent deodorizer. Astringent douches are used in excessive vaginal secretion, but should not be used when the patient is wearing a pessary; as the salts are deposited upon the instrument, roughen its surface, and thus increase the irritation (Montgomery).

VAGINAL FISTULA.—Fistulous openings may exist between the bladder, the urethra, the rectum, the ureter, and the vagina.

Vesicovaginal fistula is much the most frequent. It is usually the result of labor.

Symptoms.—Incontinence of urine is the first symptom. It usually appears about 6 or 8 days after labor, and is constant or not, depending upon the position of the opening. If the fistula is in the upper part of the vagina, incontinence may appear only when the bladder is distended or when the patient assumes the recumbent position.

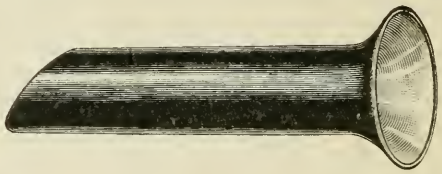
As the result of incontinence of urine, irritation, inflammation, and sloughing of the vaginal mucous membrane may occur. The vulva and inner part of the thighs become affected, and phosphatic deposits accumulate on the skin and mucous membrane. The kidneys may become infected secondarily.

The treatment consists in closure of the fistulous opening by a plastic operation. The edges of the opening must be denuded, and then closely approximated by interrupted sutures of silkworm-gut. If the condition has existed for some time and there are inflammation, excoriation, phosphatic deposits, and contraction, preparatory treatment will be necessary. This consists of rest in bed, frequent vaginal douches of boric acid solution, applications of nitrate of silver solution to the excoriated areas, and stretching or incision of any contracting or adhesive bands that might interfere with the result of the operation.

Rectovaginal fistula is also the result of labor. The important symptom is the passage of flatus and feces into the vagina. Treatment should consist in closure of the fistulous opening by a plastic operation.

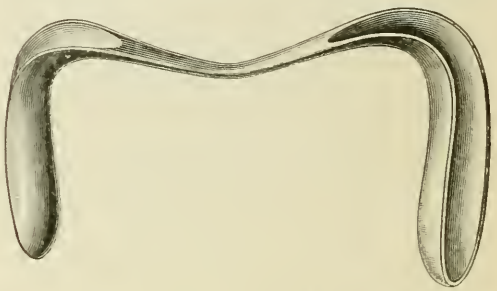
VAGINAL SPECULUM.—A vaginal speculum is an instrument through which a visual examination is made of the cervix and the vaginal walls. The instruments most commonly used are some form of bivalve speculum and the Sims duckbill speculum. They have largely supplanted the tubular (Ferguson) speculum by reason of their far wider range of application. They have the advantages of being self-retaining and of affording a much better exposure.

Popular forms of bivalve specula are those of Collins and of Goodell. The bivalve speculum is



Ferguson's Speculum.

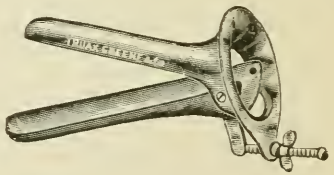
introduced with the woman in the lithotomy position; the plane of the blades held obliquely, so that the edges may correspond to the vaginal sulci. The tip of the instrument should be passed directly toward the cervix. After it has been partially introduced, the blades should be turned so that they lie transversely, and as they are separated by the thumb-screw at the handle, the



Sims' Speculum.

cervix and the vaginal vaults come into view. This instrument can be used for inspecting the external os uteri, the cervix, and the vaginal vaults and walls; for applications to the uterus, cervix, and vagina; and for dilating and curetting the uterus.

The Sims speculum may be introduced with the woman in the dorsosacral, the Sims, or the genu-



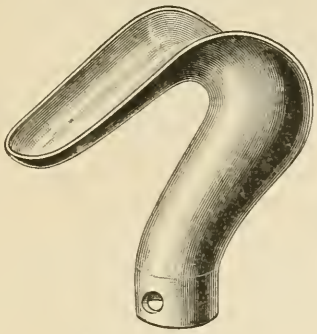
Higbee's Bivalve Speculum.

pectoral position. In some cases the examination is facilitated by the use of an instrument for depressing the anterior vaginal wall. The Sims speculum gives the most perfect view of the cervix and vagina, and can be used advantageously in all operations upon the cervix and vagina.

In the lithotomy position for retracting the

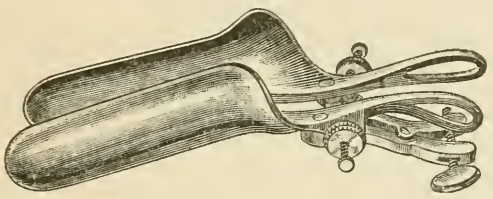
perineum the Edebohls speculum to which a weight is attached is the most satisfactory.

VAGINISMUS.—A painful, spasmodic contraction of the muscles surrounding the lower part of the vagina and the vulva. It is caused by attempts at coitus or by digital or specular examination.

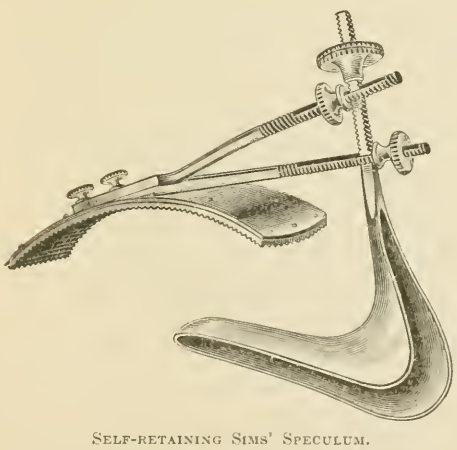


Edebohl's Speculum.

This condition is usually seen in newly married neurotic women. There is usually some exciting cause, such as a rigid hymen, a small vaginal orifice, a urethral caruncle, or an ulcer, a fissure, or some inflammatory condition around the vulva. Occasionally, it is a purely neurotic condition. It is sometimes seen in old women as a complication of kraurosis vulvæ.

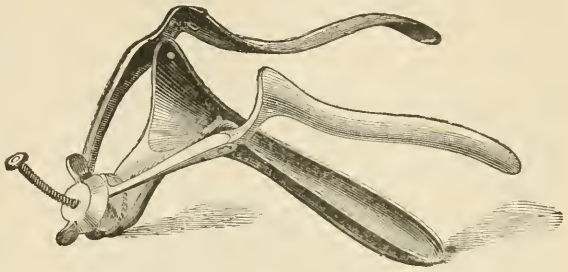


Goodell's Speculum.



Self-retaining Sims' Speculum.

The treatment of this condition consists, first of all, in ascertaining its exciting cause. This, if possible, must be removed. A rigid hymen may be incised and a small vaginal orifice may be dilated. A urethral caruncle should be excised, and any inflammatory condition around the vulva should be appropriately treated.



Trivalve Speculum.

A vaginal suppository containing 1/2 grain of cocain, introduced 15 minutes before intercourse, will sometimes prove effective. Gradual or forcible dilatation of the vagina will occasionally give relief.

In the gravest cases it will be necessary to make incisions in the direction of the posterior vaginal sulci. These incisions should be deep enough to divide the underlying muscles and fasciæ; and to prevent retraction a glass vaginal plug should be worn for a few days. When the condition is a purely neurotic one, constitutional remedies should be employed.

VAGINITIS.—Inflammation of the vagina, or vaginitis, is usually secondary to some other condition, such as vulvitis, endometritis, or a fistula of the bladder or rectum. Occurring as a primary condition, it is usually due to gonorrhea. Four varieties of vaginitis have been described—simple, granular, senile, and emphysematous.

The symptoms of vaginitis are pain and a sense of fulness in the pelvis—which are increased by walking or movement of any kind—and a purulent discharge. As the disease becomes chronic it tends to localize itself particularly to areas about the ostium and vaults.

The treatment in the acute stage consists of rest in bed and mild purgation, and in the employment of vaginal douches. The douches should consist of a gallon of hot boric acid solution (1 dram to 1 pint) every 2 or 3 hours. After the acute symptoms have subsided, douches should be given every 3 hours of potassium permanganate (1:4000), or bichlorid of mercury (1:4000). After 2 weeks the douches may be given 4 times a day of double the strength. In chronic cases after the subsidence of acute symptoms, astringent douches are employed, *e. g.*, zinc sulphate (1/2 dram) and powdered alum (1 dram) added to a quart of water, or potassium permanganate (1:2000) or argyrol solution 25 to 50 percent. The vaginal walls are cleansed and painted with nitrate of silver solution (1 dram to 1 ounce) and boroglycerid tampons are inserted. Tampons of ichthyol in lanolin (1:4) are valuable. Treatment should be continued until all evidence of the disease has disappeared.

VAGUS NERVE.—See Pneumogastric Nerve.

VALERIAN.—The dried rhizome and roots of *Valeriana officinalis*. It contains a *volatile oil*, from which are developed by oxidation *valerene*, $C_{10}H_{16}$, a terpene; *valerol* or Baldrian Camphor, $C_{12}H_{20}O$; and *valeric acid*, $C_5H_{10}O_2$, which occurs also in many other plants and in cod-liver oil. The valeric acid of pharmacy is obtained as a product of the oxidation of amylic alcohol, and from it are formed the various valerates. It is not therapeutically identical with the natural acid. Dose of the powdered root, 10 to 45 grains. It is antispasmodic and is gently stimulant to the nervous system and the organs of circulation. In full doses it increases heart action, producing exhilaration; in toxic doses, diarrhea, vomiting, reduced sensibility, and mental disturbance. It is excellent in hysteria, in convulsions due to worms, in the coma of typhus fever, and in whooping-cough.

Preparations.—**V., Flext.** Dose, 10 to 45 minims. **V., Tinct.,** 20 percent. Dose, 1/2 to 2 drams. **V., Tinct., Ammoniat.,** valerian 20, aromatic spirit of ammonia enough to make 100 parts. Dose, 5 to 45 minims. **V., Ol.,** the volatile oil (unofficial). Dose, 1 to 5 minims. The oil is the best preparation to use, as the tinctures are extremely nauseous, and the fluidextract is too bulky.

VALGUS.—See Talipes Valgus.

VALIDOL.—The menthol-ester of valeric acid containing 30 percent of free menthol. A carminative and antihysteric, combining the activities of its components. It is said to produce no gastric irritation and is recommended in hysteria and seasickness and the vomiting of pregnancy. Dose, 10 to 15 drops on sugar.

VALVULAR DISEASE.—See Heart-disease (Organic).

VALYL.—Valeryldiethylamid. A compound of valeric acid and diethylamin. It is a sedative, nervine, antispasmodic, similar to valerian. Dose, 2 or 3 gelatin capsules, each containing 2 grains.

VANILLA.—The fruit of *V. planifolia*, an orchid found in tropical America, and of other species of the genus. Its odor is due to a methyl-ether, *vanillin*. It is an aromatic stimulant, sometimes employed in hysteria and low fevers, but it is used chiefly as a flavor. **V., Tinct.,** 10 percent. Dose, a few drops, according to the flavor desired. **Vanillin,** $C_8H_8O_3$, crystallizes in stellate groups of colorless needles, is soluble in hot water, alcohol, and ether. It has a warm, aromatic taste. Commercial vanillin is in part prepared from the inner bark of white pine and from eugenol. Dose, 1/4 to 1 grain.

VAPOR BATH.—The application for therapeutic purposes of steam (medicated or otherwise), or of some other vapor, to the surface of the body, in a suitable apartment or apparatus. See Bath.

VAQUEZ'S DISEASE.—See Erythremia.

VARICELLA (Chicken-pox).—Varicella is an acute contagious disease, characterized by a cutaneous eruption of papules, vesicles, and, occasionally, pustules; by mild constitutional symptoms, and by the absence, as a rule, of complications and sequels.

Etiology.—The specific poison has not been isolated, but it has been proved that the contagium of the disease is found in the vesicles. Varicella is directly very contagious, and it may, in rare cases, be carried by a third person. Children of any age may be affected by it, but one attack gives immunity. The period of incubation is from 14 to 16 days.

Symptoms.—In many cases the eruption is the first symptom, though there may be noticed slight fever and general indisposition for 24 hours preceding it. The eruption consists of first a macule and then a papule, but these so rapidly become vesicular that the vesicle is usually the first lesion noticed. The vesicle is tense transparent or slightly yellow, and is about the size of a split pea. The eruption appears first upon the upper part of the body and upon the neck, scalp, and face. Usually, the face escapes with a few lesions, but the hairy scalp contains quite a number.

The vesicles frequently form on the mucous surface of the lips, mouth, throat, conjunctiva, and progenital region; and when occurring on these parts, bear a characteristic appearance, owing to the fact that they quickly lose their delicate covering, and then resemble aphthous ulcers with a well-marked red zone around them.

The eruption appears in successive crops, and different stages are found at the same time and in close proximity. The eruption begins to disappear in a few days after its appearance. Some of the vesicles become flaccid or slightly umbilicated from the absorption of their contents, and others rupture, either spontaneously or from scratching. They finally dry up and the crusts drop off, leaving small circular marks, which soon disappear. In cases in which the vesicles have become infected or in which they are very deep, permanent scars or pits remain.

Pustules may develop in consequence of irritation or infection, or in feeble or poorly nourished children. In rare cases there may be necrotic inflammation around the site of the pock, a condition to which is given the name **varicella gangrænosa.**

In mild cases about a dozen vesicles may appear upon the body; but when severe, the skin may be covered in certain regions. In mild, uncomplicated cases the temperature reaches 101° to 102° F., and lasts only two or three days, being highest when the eruption is appearing and falling gradually as it fades. There are no characteristic constitutional symptoms, but there is present more or less severe indisposition, as found associated with any febrile disease, the child frequently not being ill enough to remain in bed.

Complications.—Erysipelas may occur from infection by the vesicle, and acts as a serious complication. Mild adenitis is occasionally seen. Nephritis may occur, but it is rare as a result of varicella. The other infectious diseases of childhood (measles, scarlet fever, etc.) quite frequently occur just before, at the same time, or closely following chicken-pox, and when present at the same time, render the diagnosis in some cases very difficult.

Diagnosis.—As a rule, the diagnosis of varicella offers no special difficulty. The fact that the eruption appears in crops, so that papules, vesicles, and crusts are seen in close proximity; that the vesicles are unilocular; and that they are never confluent, serve to distinguish it from other eruptive affections. In certain cases, however, it is difficult, if not impossible, to distinguish this disease from a mild form of variola. The following table will aid in the diagnosis:

	Varicella.	Variola.
Incubation,	Two weeks.	One to two weeks.
Prodromes,	None, or slight.	Three or four days in duration; active; severe.
Efflorescence,	On the skin; rapidly becomes vesicular; not umbilicated; unilocular; irregular; numerous; universally distributed in successive crops; vesicles differ greatly in size; on pricking, collapse entirely.	Under the skin; a slow progressive development from a macule to a papule, to an umbilicated vesicle, to a pustule; multilocular; regular; not numerous; defined in its localization; lesions, as a rule, of uniform size; on pricking, collapse partially.
Desquamation,	Slight crust formation.	Pronounced crust formation.
Duration,	Short; 1 week to 10 days.	Long; 3 to 4 weeks.
Type,	Mild.	Severe.
Temperature	Irregular; not high.	Rises suddenly; remains high until papules are developed, when it falls considerably; rises again during development of the pustules.

Prognosis.—The prognosis is invariably good, except when the disease occurs in weak and debilitated children whose hygienic surroundings and care are faulty.

Treatment.—Isolation should be enforced in schools and institutions containing many young children. In homes, unless the younger children are delicate, quarantine is unnecessary. In most cases the constitutional symptoms are so mild as to require no treatment. It is best at the outset to place the child in bed for a few days and to sponge daily with warm, carbolized water, applying carbolized vaselin to the vesicles to allay the itching. Later, when the crusts have formed, the following ointment is useful:

Apply locally:

℞.	Carbolic acid,	♏ xv
	Boric acid,	ʒ jss
	Glycerin,	ʒ iij
	Rose-water,	ʒ j
	Water, enough to make	ʒ iv.

Apply to affected parts once daily.

Or:

℞.	Carbolic acid,	♏ v
	Ichthyol,	ʒ jss
	Vaselin, enough to make	ʒ j.

Apply on soft cloth once daily.

℞.	Ichthyol,	gr. x
	Zinc ointment,	ʒ j.

A light diet, of milk, soups, and eggs. If the tongue is coated, calomel (1/8 grain) may be given every 1 1/2 hours until 4 or 5 doses have been taken.

Care should be taken to keep the skin clean and to prevent scratching. In all cases the urine should invariably be examined several times during and following the attack. Quarantine should be instituted for 2 weeks.

VARICOCELE.—Dilated and varicose condition of the spermatic veins.

The causes of varicocele are not definitely known. It has been attributed to an abnormally lax state of the parts, induced by debility and general want of tone; to congestion from too early or continual excitement of the sexual organs; to occupations involving prolonged standing; and to certain anatomic peculiarities (all of which, however, are present in every healthy male) such as the great length of the spermatic veins, the dependent position of the testicle, the plexiform arrangement of the veins in the scrotum, etc. But it often occurs in men in good health, and in whom the parts are not lax. The reasons given for its much greater frequency on the left than on the right side are: (1) that the left vein is longer than the right; (2) that an obstacle is offered to the outlet of the left vein by its opening at right angles into the renal vein; (3) that the blood-pressure is less in the vena cava than in the renal vein; (4) that the left vein is crossed by the sigmoid flexure, and is hence liable to be pressed upon by fecal accumulations. Spencer believes that the presence of the large veins is due to a congenital variation from the normal process of development, whereby many of the veins of the wolffian body (from which the spermatic veins are formed) remain unobliterated, and capable of being dilated by anything obstructing the return of venous blood from the testicle. More of these veins, he says, are normally obliterated on the right than on the left side.

Symptoms and Diagnosis.—There may be merely a sense of weight and fulness in the scrotum, or dragging or even severe pain, worse after the day's work, but relieved by recumbency. The symptoms, however, are often more mental than physical, the patient fearing impotence or sterility, and sometimes becoming hypochondriacal in consequence. The varicose veins, which may sometimes be seen through the skin of the scrotum, form a soft, irregular, opaque, knotted, pyriform mass, in which there is a distinct expansile thrill or impulse on cough. The swelling is confined to the scrotum, and although it may be reduced on the patient's lying down, it does not go back with a gurgle or slip like a hernia, and

gradually returns when the patient rises, notwithstanding that the finger is placed over the external abdominal ring. The testicle, though perhaps, as a rule, a little smaller than natural, is seldom much atrophied.

Treatment.—In the vast majority radical measures are entirely out of place; varicocele seldom causes inconvenience after early manhood is past. A suspensory bandage should be worn, one that is not too warm or too complicated; the parts should be bathed with cold water night and morning; the bowels should be opened regularly; a fair amount of exercise should be taken; and stimulants, sexual excitement, etc., should be avoided. It is only when the health is impaired that the weight of the part is noticed. Occasionally, however, this is not sufficient; the patient may wish to enter the Government service; both sides may be involved; the varicocele may be serious from its size, the rapidity of its enlargement, or the danger of rupture or phlebitis (which is not uncommon in connection with gout); the testis may be irritable and tender, or the patient very much troubled about its condition. In those cases in which there is any reason to fear the development of hypochondriasis, every endeavor must be made to divert the patient's attention from the disorder; but too often the attempt ends in complete failure, and, though the prospect is not an inviting one, there is no alternative. Pearce Gould considers operation advisable in all cases in which varicocele develops before puberty.

Operation.—The older method, in which a ligature was passed around the veins subcutaneously in one or more places, is practically abandoned: the result is uncertain, and there is great risk of transfixing a vessel. Even the addition of subcutaneous section does not increase the security. The method ordinarily adopted is to expose the veins freely, so that the structures to be dealt with can be seen; isolate the vas deferens with the spermatic artery, ligate the vessels above and below, and excise the intermediate portion. Pearce Gould, however, considers subcutaneous section with the cautery preferable.

The patient is placed under an anesthetic, the parts are shaved and cleansed, and an incision of sufficient length is made along the cord, exposing the fascia that surrounds the veins. The vas is then carefully separ ted at the back, taking care not to isolate it, but to leave the fascia around it untouched; a catgut ligature is passed around the rest of the fascia and the veins above, a second ligature below, and the intervening portion is excised. Practically, if the separation is commenced above, all the veins are included but one or two little ones with the vas. The length to be excised depends, as Bennett has shown, upon the height to which it is wished to raise the testicle, and after excision the two cut ends should be sutured together, so that the shortening of the fascia may help to support the gland. No drainage tube is needed, unless there has been much handling. The swelling afterward is considerable, and the testis may be a little tender, but orchitis does not follow. An ice-bag may be applied for 48 hours as a precaution. The patient should remain in bed for 10 days or 2 weeks, by which time the induration will have disappeared, and should wear a suspensory bandage for some months (Moullin).

VARICOSE VEINS.—A vein is said to be varicose when it is permanently and unequally dilated, and when its coats have undergone certain degenerative changes. A varicose condition is most common in the veins of the lower extremities and in the veins of the rectum and testicle. See Hemorrhoids, Varicocele.

The causes may be considered under the heads of increased intravenous pressure and changes in the vein-walls.

Increased intravenous pressure may be due to: (1) Organic affections of the heart whereby the return of venous blood is impeded. (2) Obstruction to the circulation in the portal system, a cause chiefly affecting the hemorrhoidal veins. See Hemorrhoids. (3) Pressure upon the veins, such as may be exerted (*a*) by the gravid uterus or by a tumor of the uterus or of the ovaries on the iliac veins; (*b*) by an aneurysm of the abdominal aorta on the inferior vena cava; (*c*) by fecal accumulation on the hemorrhoidal veins; (*d*) by a tumor in the groin on the femoral vein; (*e*) by an ill-fitting truss on the spermatic veins (see Varicocele); or (*f*) by a tight garter on the saphenous veins. (4) Prolonged standing, which has a tendency to cause the accumulation of blood in the veins of the lower extremity. (5) Severe muscular exertion, whereby an increased amount of blood is driven by the contraction of the muscles from the deep into the superficial veins.

Some authors consider this last the chief, if not the only, cause of varicose veins of the lower extremities. They maintain that the pressure of the blood first produces a dilatation of the superficial veins where the intermuscular veins empty into them; that this dilatation, being frequently repeated, becomes permanent; that the valves, in consequence, are unable to close and protect the veins, and, being thrown out of use, gradually undergo atrophy, while the weight of the column of blood, from the inefficiency of the valves, becomes further increased and the veins are still further dilated.

Changes in the Vein-walls.—These consist principally of a hereditary weakness, a want of muscular tone, and an inflammatory softening of the walls. Varicose veins are more common in men than in women, owing to their more frequent exposure to the exciting causes. Women, however, are peculiarly liable to them during pregnancy.

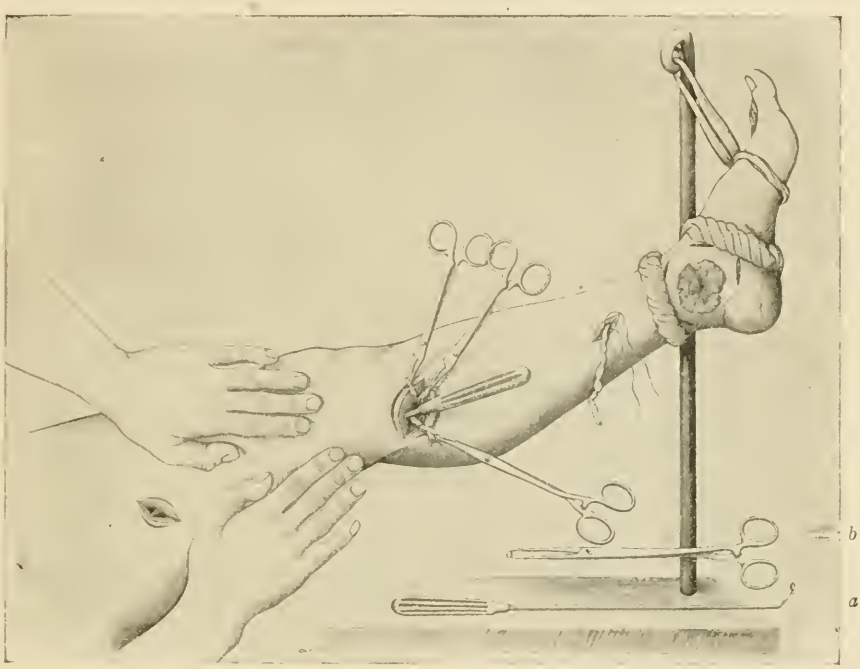
The symptoms usually complained of are fatigue and a sense of fulness of the limb after exercise or prolonged standing, and perhaps cramp, coldness of the feet, swelling and edema of the ankle, and numbness of the leg. Sometimes there is deep-seated pain. The tortuous vein or veins meandering up the leg is a characteristic sign, and cannot be mistaken. When the smaller radicals are affected, bluish clusters of minute veins are visible here and there, especially about the ankle and knee.

Treatment is palliative and radical.

Palliative.—All obstructions must be removed, as far as possible. Tight garters are exceedingly injurious. In pregnancy the patient must rest as much as possible, or as much as is consistent with health, and should wear a bandage or an elastic stocking both during and for some time afterward. The bowels must be kept well open, and prolonged standing and excessive walking should be avoided, although a reasonable amount of exercise, avoiding fatigue, is decidedly beneficial.

If the varix has made its appearance suddenly after exertion, the walls of the vein must be carefully protected from strain for some considerable time. The limb should be kept at rest in the horizontal position, for 2 or 3 weeks, according to the size of the vein, and then carefully supported.

In the majority of cases all that can be done is to caution the patient against the evil effects of standing, etc.; to maintain the general health by means of tonics, combined with good food, fresh air, and a fair amount of exercise; and to supply some kind of support. Silk anklets, elastic stockings, and the appliances generally in use serve the purpose for which they are intended very ill; they produce the maximum of constriction when first applied, and then each week relax more and more until replaced; they are usually much too tight, and generally cause considerable wasting of the muscles. If worn once, the limb becomes so used to their pressure that the patient can hardly be induced to leave them off. Bandages of thin flannel, domet, or perforated rubber are much better, as they can be put on with just sufficient pressure and no more, instead of an iron rule being followed in all cases alike. Upward friction and massage should be practised every night when the appliance is removed. If bleeding threatens, the part should be well bandaged and kept at rest; if it breaks out (the usual situation is the lower third of the leg), the limb must be raised at once. The hemorrhage is exceedingly profuse, but it comes from the proximal or cardiac end, and raising the limb stops it instantly. If inflammation sets in and the veins become hard and painful, showing that they are filled with clots, the patient should be confined to bed and the limb should be placed in a slanting position on a leg-rest and covered with lead lotion.



Mayo's Operation.

Radical.—In a certain number of cases the radical cure may be tried. As a rule, it is only advisable when the superficial veins are concerned, and when the part involved is limited in extent. Sometimes, however, it is beneficial in cases of varicose ulcer, in which the persistence of the sore appears to be dependent upon the vein. The choice lies between acupressure (with or without subcutaneous division), ligation, and excision.

Acupressure.—This is performed by passing a flat needle beneath the vein, while it is pinched up with the finger and thumb, and then twisting a figure-of-eight suture over the ends, protecting the skin beneath by means of a piece of bougie or quill. The needles should be about 3/4 of an inch apart, and the vein may be divided subcutaneously between them with a tenotomy knife. They should not be left in for more than a week, and if any

inflammation occurs, the time should be shortened. Failure is not infrequent, and there is always the risk of transfixing the vein.

Ligation.—A small incision is made over the vessel and an aneurysm needle is passed around it and threaded with catgut. The ligature left when the needle is withdrawn is tied and the ends cut short. This method may be combined with the former, ligatures being placed in the intervals between the pins. Subcutaneous ligation may be tried in suitable cases.

Excision.—This is by far the most effective method. The skin over the vein is reflected, the incision being as far as possible longitudinal; the vessel is carefully isolated from the surrounding tissue, a double ligature (catgut) is placed around it at each end and around each branch, and the whole intervening portion is excised.

C. H. Mayo excises the long saphenous vein in the following manner: the vein exposed and isolated near the saphenous opening and divided between ligatures and the peripheral portion grasped with a hemostat. The vein is passed through the loop of Mayo's dissector. Guided by the vein the dissector is pushed under the skin down to a point near the knee. The skin is incised over the end of the dissector. The vein clamped, pulled out through the wound, ligated and the loose portion excised. If the dissector is obstructed in its work by adhesions around the vein, the closed forceps is passed alongside it and when the adhesions are reached the blades of the forceps are slightly opened. In the same manner as many other veins are removed as may be necessary. The dissection is made from above downward to avoid the danger of detaching thrombi and throwing them into the circulation.

Schede's operation consists in making an incision completely around the leg down to the deep fascia and doubly ligating all the divided veins.

VARIOLA.—See SMALL-POX.

VARIOLOID.—See SMALL-POX.

VASELIN.—See PETROLATUM.

VASOCONSTRICTORS.—Drugs that increase the contractile power of the vessels, lessening the circulation therein and raising the blood-pressure; hence they are used to check hemorrhage and cut short inflammations. The principal agents are: Adrenal extract, adrenalin, antipyrin, cotarnin, hydrastinin, strychnin, hamamelis, atropin (small doses), opium (small doses), cocain, ergot, digitalis, squill, strophanthus, iron, camphor, sulphuric acid, barium salts, lead salts, silver salts, zinc salts, cold (locally).

These agents act upon the local vasomotor mechanism in the walls of the vessels, hamamelis affecting the venous system especially. Cold is one of the most powerful agents of this class, and is also a cardiac sedative. Adrenal extract produces an enormous rise of the blood-pressure, due to its extraordinary contractile power over the muscular fibers in the walls of the arterioles. Adrenalin is said to be 625 times more powerful in this respect than the extract. Digitalis, squill, and strophanthus, in small doses contract the vessels, but in large doses dilate them.

VASODILATORS.—Drugs that produce dilatation of the peripheral vessels, and increase the rapidity of the circulation, thus equalizing the blood-pressure and relieving internal congestions. The most useful are alcohol and ether, as they stimulate the action of the heart simultaneously with the vascular relaxation. The chief are: Alcohol, ether, nitrous ether, nitroglycerin, amyl nitrite, potassium nitrite, sodium nitrite, erythrol tetranitrate, belladonna (at last), stramonium (at last), hyoscyamus (at last), opium (full doses), ipecacuanha, Dover's powder, thyroid extract, chloral, chloroform, ammonium acetate, tartar emetic, hydrocyanic acid, aconite (?), heat (at first).

The nitrites are our most certain, in fact almost our only certain remedies to dilate the blood-vessels (Wood). The dilating action of amyl nitrite and other nitrites is due either to weakening of the muscular walls of the arterioles or to paralysis of the vasomotor terminals therein. Alcohol, ether and opium probably depress the vasomotor center. Aconite does not affect the vaso-motor center of the vasomotor nerves, hence the lessened arterial tension induced by it is due to its depressant action on the heart alone (Ringer). Atropin and its congeners act on the vessels differently in different doses, and at different stages in its action.

Vasodilators are often called vascular stimulants or stimulants of the circulation; but there is this difficulty of speaking of stimulants or sedatives of the circulation, that if both the heart and the vessels are stimulated at the same time, the action of the one tends to counteract that of the other. On the other hand, a drug which weakens the heart may increase the circulation by dilating the vessels, thus acting as a vascular stimulant (Brunton).

VEINS, INFLAMMATION (Phlebitis).—Phlebitis, or inflammation of veins, may be divided into the simple and the septic or spreading.

Simple phlebitis, formerly known as **adhesive phlebitis,** is a simple local inflammation of the vein-wall, and may terminate in resolution, in obliteration of the vein, or, more rarely in the formation of a localized abscess.

Causes.—(1) Injury of the vein-walls; (2) simple inflammation of the surrounding tissues; (3) the formation of a noninfective thrombus in a vein; (4) gout or the gouty diathesis; (5) certain conditions of the system the exact nature of which is not known, the phlebitis being then spoken of as idiopathic.

Symptoms.—When the vein is superficial, it can be felt as a hard, knotted cord, standing out under the skin and surrounded by inflamed cellular tissue. It is exceedingly tender to the touch, but, unless the periphlebitis is very acute, and the vein is quite under the surface (as in the case of a varicose internal saphena), the skin is seldom much reddened. There is often a very considerable degree of pain and stiffness, especially on movement, or when the limb is allowed to hang down; and sometimes there is profound constitutional disturbance. In the case of the deeper

veins the diagnosis chiefly rests upon the deep-seated hardness and tenderness, the peculiarly clumsy appearance of the part, the sense of weight and pain when the limb is allowed to hang down, the relief as soon as it is raised, and the evident distention of the more superficial vessels. Generally, a certain amount of superficial edema can be detected on the distal side of the obstruction: around the malleoli, for example, in cases of phlebitis of the deep veins of the leg.

Gouty, rheumatic, and syphilitic phlebitis can only be distinguished by the other symptoms that accompany these disorders; they have no certain distinctive character of their own, although the gouty variety is occasionally metastatic. They all have a decided tendency to symmetry, they affect the superficial veins rather than the deep ones and the lower limbs much more frequently than the upper. Recurrence is exceedingly common in the gouty variety, and may continue in the syphilitic form all through the secondary period, but it is seldom that permanent obliteration is caused by either gout or syphilis.

Treatment.—Rest is absolutely essential until at least all trace of inflammation and tenderness has disappeared. Serious extension of the thrombus and detachment of outlying fragments, causing embolism, are rare accidents, considering the very large number of cases of phlebitis of varicose veins of the leg; but they do happen occasionally, and every precaution must be taken to avoid them.

Elevation is no less essential, for the sake of the return circulation and to relieve tension. Cold lead lotion, as a rule, causes the inflammation to subside within a few days; but in cases of gout, and when the arteries are atheromatous, belladonna (equal parts of the extract and glycerin) and warmth should be used instead. The bowels should be kept well open; the diet should be light, without stimulants, and if there is any evidence of gout, rheumatism, or syphilis, appropriate remedies should be employed. Afterward, when all the inflammation has subsided, the patient may be allowed to go about with a support; if the leg is much wasted, or has a tendency to remain cold or edematous, massage may be used to improve the circulation.

Suppurative Phlebitis.—This, too, may originate either as a periphlebitis or in the interior. Examples of the former are often seen in diffuse inflammation of the cellular tissue; the pyogenic organisms rapidly destroy the coats of the veins, spreading along the loose cellular tissue around them, and causing them to slough or to melt away into the purulent fluid that fills up every interstice. As the endothelium is approached coagulation takes place, and although the thrombus shares the fate of all the rest of the structures, fortunately, in the vast majority of cases, the coagulation extends sufficiently far and with enough rapidity to act as a barrier and to prevent the poison from spreading far and wide in the circulation. If it fails, or if it is broken down, general pyemia is almost certain. This is of common occurrence in acute suppurative osteomyelitis and in otitis media, infective inflammation, with thrombosis, spreading along the coats of the veins into larger and larger trunks, until at length the puriform clot that fills the vessel gives way and is scattered all over the body, causing metastatic abscesses wherever it enters.

Acute spreading phlebitis of the same character, and ending in embolic pyemia in the same way, may begin in the interior of a vein as well as around it. This, of course, unless pyemia has already developed, can only take place after the cavity of the vein has been opened. Usually, under these circumstances, the vessel either collapses at once or a coagulum forms and extends up to the next set of valves or to the next larger branch. If, however, septic decomposition sets in before organization has taken place, and lends its aid to the micrococci of suppuration, the clot melts away at once into an infective puriform fluid, and there is every chance of a wide-spread distribution of infective emboli all over the body, even before the rest of the tissues succumb or before the diffuse cellulitis assumes alarming proportions (Moullin).

VEINS, INJURIES.—Rupture or subcutaneous laceration of a vein occasionally occurs from causes similar to those producing rupture of an artery—an accident, moreover, with which it is frequently associated. When the vein is of large size, much blood may be extravasated into the tissues, and may produce gangrene by pressure on the vessels carrying on the collateral circulation, though such a result is much less common than after rupture of an artery. The blood, except when the extravasation is large, is usually absorbed, but it may break down and suppuration ensue.

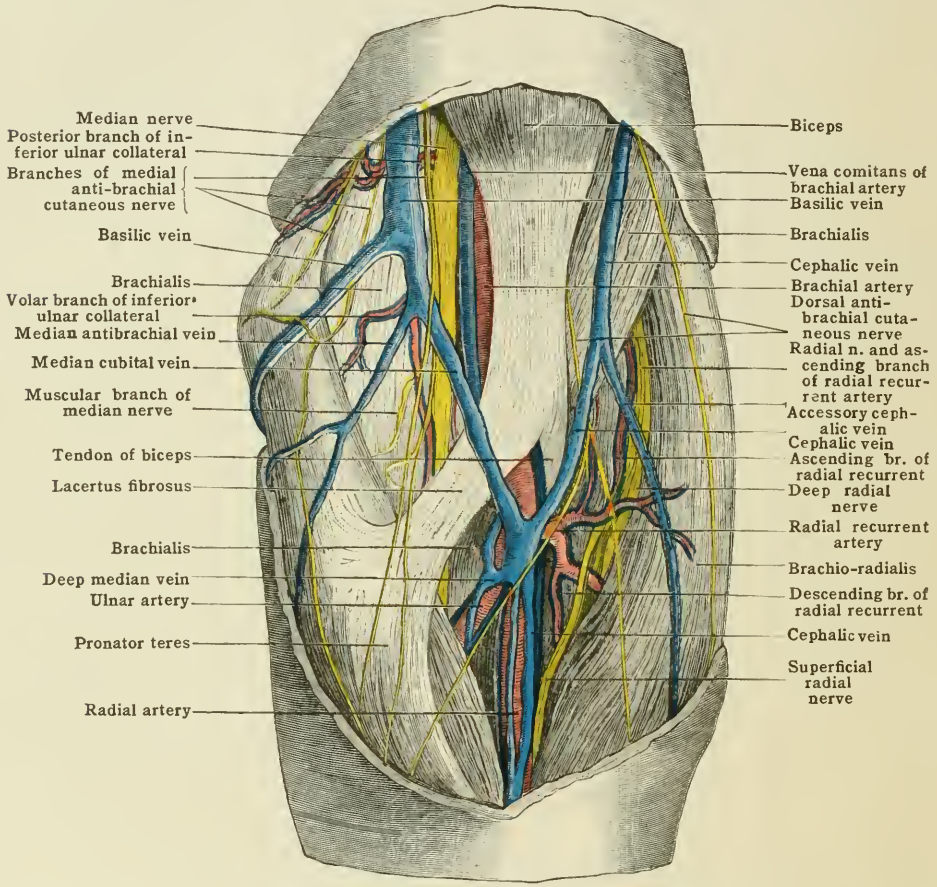
Wounds.—Punctured and incised wounds, when small and parallel to the long axis of even large veins, readily heal by adhesive inflammation without obliteration of the lumen of the vessel. At times, however, a clot may form in the wound, and successive layers may be deposited upon it until ultimately the vein is occluded. When a vein is completely cut across, as in amputation, it usually collapses as far as the next pair of valves, a clot forms as high as the first collateral branch, and the vein becomes permanently occluded. In consequence, however, of the vein-wall containing less elastic and muscular tissue than an artery, bleeding sometimes continues unless stopped artificially.

Treatment.—When the wound is a mere puncture in the continuity of the vein, unless it is found that pressure will control the hemorrhage, the coats should be nipped up by forceps and a lateral ligature applied. If a vein continues to bleed during an amputation, it should be tied like an artery. A large wound, or one made in the longitudinal axis of a large vein, necessitates ligation of the vein in two places, and the division of the vessel between the two ligatures. See Arteries (Injuries).

The dangers of wounds of veins are: (1) Hemorrhage; (2) inflammation of a septic character, and the attendant risks of blood-poisoning from the

detachment of the infected clots; (3) entrance of air.

Entrance of air into veins is fortunately a rare accident. It sometimes happens in operations about the root of the neck, where the disposition of the cervical fascia prevents the veins collapsing and thus allows air to be sucked in during inspiration. Air is known to have entered a vein by the hissing sound during inspiration, the escape of frothy blood from the vein on expiration, the urgent dyspnea, and the state of collapse into



THE BEND OF THE ELBOW WITH THE SUPERFICIAL VEINS.
(From a dissection by Dr. Alder Smith in the Museum of St. Bartholomew's Hospital.)—(*Morris' Anatomy.*)

which the patient immediately falls. On listening over the heart a peculiar churning sound can be heard. Death in fatal cases usually occurs in a few minutes, and is due to the admixture of blood and air preventing the circulation through the capillaries of the lungs, and so causing distention and paralysis of the right side of the heart.

Treatment.—The finger should at once be placed over the hole in the vein to prevent more air entering, and a clamp or ligature should be applied as soon as practicable. Pouring water into the wound has been suggested both as a means of preventing the further entrance of air during inspiration, and of allowing that which is already in to bubble out during expiration. The patient should be placed with his head low to insure a sufficient supply of blood to the brain, and for the same purpose the arteries of the extremities should be compressed, while injections of ether or of brandy should be given subcutaneously to stimulate the heart. Artificial respiration should not be performed until the vein is secured, lest more air be sucked in. To guard against the accident the veins should be clamped before division, and in removing a tumor traction should not be made at the moment the vein is severed (Walsham).

VEINS, VARICOSE.—See VARICOSE VEINS.

VENEREAL DISEASES.—See SYPHILIS, CHANCROID, GONORRHEA.

VENESECTION (Phlebotomy).—Venesection, though not so often employed in modern surgery as in ancient days, has been considerably discussed lately, and is again coming into use. It is at times most beneficial in very acute inflammations in young and plethoric subjects.

The blood may be taken from one of the veins of the arm—usually from the median basilic vein,

as that is the larger vessel—or from the external jugular vein. In bleeding from a vein of the arm, a bandage or tape is carried twice around the arm a little above the elbow, to obstruct the vein, and is tied in a bow. Grasping the arm with the left hand, with the thumb steadying the vein, the surgeon makes an incision into the vessel, holding the lancet with the blade between his forefinger and thumb, about 1/2 of an inch from the point, to prevent it penetrating too deeply. The blood is directed into a graduated bleeding-bowl, the flow, if necessary, being increased by having the patient firmly grasp a stick. When sufficient blood has been taken (usually about 10 ounces) the constricting tape is untied, a pad is placed over the incision, and the ends of the tape are carried across the pad to below the joint, then around the arm, and again over the pad, where they are tied.

Uses.—Sanquirico has established that within certain limits venesection never produces functional alterations or disturbances in the nutrition in animals. Maragliano has reported a number of tests and experiments demonstrating that impoverishing the blood has no injurious effect upon the evolution of infective diseases, but is even directly beneficial when the lungs are not working properly and are unable to eliminate the excess of carbonic acid formed in a blood particularly rich in red corpuscles. Traube expressed this fact when he stated that persons whose blood contains fewer red corpuscles than the average are less affected by pulmonary disturbances than others, and that even a small amount of lung surface is sufficient to eliminate their carbonic acid. This fact explains the manifest improvement after venesection in pneumonia, which he has observed again and again in his own practice; the dyspnea and cyanosis decrease, while the elimination of carbonic acid increases. On the other hand, in cases of circumscribed pulmonary lesions the elimination of carbonic acid decreases after venesection, showing that the elimination had been practically normal. Recent research (Robin) has proved that venesection promotes oxidation processes in pneumonia, and everything tends to the assumption that when the corpuscles are inert, they are useless. Maragliano agrees with Zakharine that venesection is especially beneficial in active congestions with hemorrhage, especially hemorrhage of the respiratory apparatus and brain. The amount necessary to obtain the mechanic effect required in these cases is from 200 to 400 c.c. Zakharine even ascribes a revulsive action to phlebotomy, claiming that the congestion may be drawn to a remote vascular region; and Calabrese adds two corroboratory observations of severe, rebellious hemoptysis in tuberculosis, arrested by a few leeches applied to the base of the thorax.

Maragliano has dwelt upon the advantages of venesection in eliminating the toxins circulating in the blood, especially in renal or pulmonary insufficiency, or when there is some obstacle to the passage of bile into the intestines, and also in the autointoxications resulting, usually, from the suppression or functional alteration of the organs designed for the defense of the organism against the poisons it manufactures spontaneously. Bouchard has demonstrated that 500 grams of blood taken from a uremic subject contain 8 grams of extractive matters: *i. e.*, about the same amount as is eliminated normally by the kidneys during 24 hours. The attempt has been made in cerebrospinal meningitis to clear the blood by venesection of all the toxic substances accumulating in it; and favorable results have been obtained with venesection, combined with the injection of salt solution, in diplococcic toxemia, especially in regard to the complicating hyposystolic phenomena, although these facts are not yet fully established. In uremic intoxication, an amount varying from 500 to 1000 c.c. is withdrawn. The simultaneous injection of salt solution allows greater quantitites of blood to be withdrawn. See Infusion of Saline Solutions.

Baccelli reports that he has seen most remarkable results follow venesection, especially in capillary bronchitis and acute nephritis. He explains its action in the latter case by the fact that the peripheral pressure of the effusion in inflammation of Bowman's capsule compresses the small blood-vessels and retards the circulation through the delicate apparatus of the glomerulus, from which the entire functional economy of the kidney suffers; the epithelium undergoes fatty degeneration, and the urine diminishes in quantity, with symptoms of progressively increasing toxemia. He has saved and even secured complete regeneration of the kidney in many cases of this nature by opening a vein in the foot.

VENOM.—See Bites and Stings (Snake-bites).

VENOUS INFUSION.—See Infusion of Saline Solutions.

VENOUS INJECTION.—See Intravenous Injection.

VENTILATION.—The dilution and removal of all impurities that collect in the air of inhabited rooms, the most common of which is CO_2, the presence of which may be tested for by Lange's method. It consists of shaking, in a bottle full of the air to be tested, 1/2 of an ounce of clear fresh lime-water. If the air contains 7 parts to 1000 of CO_2, a turbidity of the fluid will occur.

In hospitals the fundamental principle of ventilation observed is that each adult person confined in a space of 1000 cubic feet requires 3000 cubic feet of fresh air an hour in order to prevent the proportion of carbon dioxid in the room from rising above 0.06 percent. This estimate is based on the fact that each adult expires, on the average, 0.6 of a cubic foot of carbon dioxid an hour.

Ventilation may be *natural*, due to the forces constantly acting in nature, or *artificial*, the result of measures introduced by man. The former is brought about by the agency of the wind and by diffusion, or the power that gases of different densities possess of mixing with one another.

Artificial ventilation is brought about either by extracting the foul air from the room, or by forcing pure air into the room, and is affected by means of fans, heat, gas, or steam.

Natural ventilation is aided by means of tubes or shafts employed as inlets and outlets. The out-

lets are guarded by cowls, which prevent the entrance of rain, increase the extracting effect of the wind, and check the tendency to down-draft. A most valuable agent in this ventilation is the chimney. Windows also may be utilized for the same purpose.

The estimation of CO_2 in the air may be made by the following methods:

1. *Minimetric method*, when the proportion of CO_2 is not less than 1 part to 1000. The analysis is made by the use of a solution of sodium carbonate with phenolphthalein as an indicator.

2. *Pettenkofer's method* has for its basis the fact that if air containing CO_2 is brought into contact with barium hydroxid in solution, a combination takes place between the barium and CO_2 immediately, and insoluble barium carbonate is precipitated.

3. *Szydlowski's method* consists in comparing a given volume of the air to be tested with a sample of air from which CO_2 has been removed; the difference of pressure is recorded by means of a mercurial column.

4. *Reiset's method* calculates the amount of CO_2 in the air from the difference found between the titration of a given volume of barium water before and after the passage of the air through it.

Methods of Ventilation.—There are various methods of securing ventilation, some of which are as follows:

In the *Auburn* or *Pentonville system* of ventilating prisons the cells are arranged in blocks of several tiers in height, and each block is surrounded by an outer building, between the walls of which and the doors of the tiers of cells on each side there is an open corridor, not divided by floors corresponding to the floors of the several tiers. The air is drawn from this corridor into the cells.

Boyle's ventilator is an arrangement of mica valves allowing air to pass out, but allowing no back-draft.

Cooper's ventilator is a series of apertures in the glass of a window-pane arranged in a circle so as to be more or less completely closed by a circular disc having corresponding apertures and moving upon a central pivot.

Ellison's ventilating bricks are bricks perforated with conic holes, and fixed in the walls, with the apices of the cone on the outside. They are not likely to produce a draft.

Hinckes-Bird's method consists in placing a movable block of wood under the entire length of the lower window-sash.

Louvred panes are a form of window-ventilation by which an upward direction is imparted to the incoming air. These panes take the place of one or more of the squares of glass, and may be either opened or closed.

McKinnell's ventilator is a combined outlet and inlet ventilator, which is applicable in the case of upper rooms or rooms in single-story houses. It consists of two tubes, the one encircling the other, the inner acting as the outlet, and being fitted with a cowl.

The *Sheringham valve* is a common form of inlet in windows or walls for the purposes of ventilation. The entrance to the opening in the wall is guarded by a strainer to keep out dust, while on the inside is a valved iron plate with closed sides and hinged at the bottom. This opening is usually placed near the ceiling.

The *Smead-Dowd system of ventilation* is an artificial system of ventilation in which the outlets are at the bottom of the sheeting along the floor-line, and open into spaces beneath the floor. These spaces are connected with flues, down which the air is drawn by the powerful action of the furnace-chimney.

Tobin's tube is another means of ventilation, the air from without entering through a hole in the wall and being conducted by an upright tube into the upper portion of the room.

VERATRIN.—A mixture of alkaloids obtained from the seeds of *Asagræa officinalis*. See VERATRUM. It is an exceedingly poisonous local irritant, and is used mainly as an external application for neuralgia, gout, and rheumatism. Dose, 1/50 to 1/10 grain. Two preparations for external use are official—**Oleatum Veratrinæ** (containing 2 parts of veratrin dissolved in 50 parts of oleic acid and olive oil to 100) and the **Unguentum Veratrinæ** (containing 4 parts of veratrin and 6 parts expressed oil of almond incorporated with 90 parts of benzoinated lard). In practice, more than 6 parts of alcohol are necessary to dissolve the veratrin; chloroform and acetic acid are better solvents than alcohol. Veratrin is revulsant and parasiticide. When brought in contact with cutaneous surfaces, it is exceedingly irritating, producing a feeling of warmth, followed by a sense of tingling.

In neuralgia, especially in tic douloureux, the ointment of veratrin, rubbed into the affected part until it causes a sense of tingling, is often productive of great relief.

℞. Ver trin,	gr. xxv
Alcohol,	ʒ vj
Glycerin,	ʒ ij.

Paint along the course of the affected nerve with a camel's-hair brush twice daily.

This should not be applied if inflammatory symptoms are present. Veratrin has been highly commended by some ophthalmic surgeons as a remedy in orbital neuralgia. It is applied to the temple and brow in the form of ointment, containing from 1 to 4 grains to the dram, according to the degree of irritation desired and the sensitiveness of the skin. The proportion in the official ointment is 1 part in 26.5. Great care is necessary to keep it out of the eye, as it causes a violent and persistent conjunctivitis. The oleate (1 : 50, U. S. P.) is an excellent preparation. It is doubtful whether, as an external application, this drug has any therapeutic effect that cannot be attributed to the counterirritation it produces.

VERATRUM VIRIDE (Hellebore).—The dried rhizome and roots of *Veratrum viride*, American hellebore, or *veratrum album*, white hellebore. They contain the alkaloids *jervin*, *pseudojervin*, and *rubijervin;* but veratrum viride contains also *veratrin* (*cevadin*), and veratrum album contains

also *protoveratrin*, *protoveratridin* and other alkaloids. Dose, 1 to 3 grains.

Asagræa officinalis, *veratrum sabadilla*, *cevadilla*, is the source of the official veratrin, and is a mixture of alkaloids. It contains the alkaloids *veratrin* (*cevadin*), *cevadillin*, *sabadin*, *sabadinin*, and another base known as *Wright's veratrin*. It is a violent emetic and cathartic, and is actively poisonous; it is now little used, except as an insect powder. For this use it is highly valued, as it destroys many insects which the ordinary buhach does not affect. Veratrum viride is a powerful depressant of the heart and a paralyzant of the spinal cord. Its action is similar to that of aconite, but is regarded as inferior. The chief use is as a circulatory sedative in acute, sthenic, or dynamic inflammations. It is highly esteemed in puerperal fevers, pneumonia, pleurisy, hepatitis, peritonitis, cerebritis, and aneurysm. It is contraindicated in conditions of exhaustion or depression, or if vomiting is feared.

In *poisoning* by veratrum viride cardiac stimulants, atropin, strychnin, and external heat are indicated. **V., Flext.** Dose, 1 to 4 minims. **V., Tinct.**, 10 percent. Dose, 10 to 30 minims.

VERMIFORM APPENDIX.—See Appendicitis.

VERMIFUGE.—See Anthelmintics, Worms.

VERONAL.—Diethyl Malonylurea.—It is a very efficient and rapid hypnotic in doses of 8 to 10 grains, given in some hot liquid. It induces a practically normal sleep, does not affect the heart, circulation or kidneys, and is free from after-effects. It is particularly efficient when mixed with sulphonethylmethane (trional) in the proportion of two parts of the former to one of the latter (*e. g.*, gr. viii with gr. iv).

VERONAL-SODIUM.—Sodium diethyl-barbiturate. Its action and dosage are the same as veronal, but it is said to act more rapidly by reason of its greater solubility.

VERRUCA.—See Warts.

VERSION.—See Fetus (Positions and Presentations).

VERTIGO (Dizziness).—A subjective state in which the individual affected, or the objects about him, seem to be in rapid motion, either of a rotatory, circular, or to-and-fro character.

The etiology of an attack of vertigo depends upon the particular variety.

Ocular vertigo results from the paresis of one or more of the ocular muscles, or from eye-strain.

Aural or auditory vertigo, or Ménière's disease, results from disease of the semicircular canals and cochlea. Ménière's Disease (*q. v.*), properly so called, is a sudden severe vertigo, the result either of a hemorrhage or of a serous or purulent exudation into the semicircular canals.

Gastric vertigo is the most common variety, and results either from stomachic or intestinal dyspepsia, disordered hepatic function or constipation. The mechanism of the vertigo is complex. There are two factors; one consists in the toxic effect of the imperfectly oxidized materials that accumulate in the blood; the other is reflex. An impression made on the end-organs of the pneumogastric nerve in the stomach is reflected over the sympathetic ganglia.

Nervous vertigo is associated with migraine and with sick or nervous headache, and is also caused by physical or nervous excesses and by the immoderate use of tea, coffee, alcohol, and tobacco. It is also a result of many of the organic diseases of the brain.

Senile vertigo is the result of the disordered cerebral circulation resulting from changes in the heart and vessels.

Symptoms.—In all varieties of vertigo the symptom of a sensation of objects moving around the patient, or of the patient moving around objects that remain stationary, is present in some degree. The attack of giddiness comes on suddenly, with indistinctness of vision and slight confusion of the thoughts. The patient may fall, unless he grasps something to steady himself. Nausea and vomiting, and cardiac palpitation with tinnitus aurium, are often associated with the vertiginous sensations. There is no loss of consciousness.

In ocular vertigo the attack is usually the result of reading, writing, sewing, or other close application of the eyes, the ordinary symptoms of vertigo being preceded by headache, nausea, specks before the eyes, and pain in the eyeballs.

The prognosis is favorable in ocular and gastric vertigo. Unless the result of organic disease, the prognosis is favorable in nervous vertigo. In auricular vertigo the prognosis is fair, but in genuine Ménière's disease the prognosis is unfavorable, as it is also in senile vertigo.

Treatment.—For ocular vertigo rest for the eyes is necessary and properly adjusted glasses are required. For cases of Ménière's disease rest in the recumbent position and the use of full doses of quinin, 10 to 15 grains daily for a long period, as suggested by Charcot.

For gastric vertigo a careful regulation of the diet is indicated. At the beginning of the treatment it is often of great advantage to place the patient on an exclusively milk diet, gradually widening the variety of food as improvement occurs. If these cases a course of arsenic is often serviceable. If the digestion is torpid, the use of tincture of nux vomica is indicated. If the bowels are constipated, benefit is obtained from fluid-extract of cascara sagrada.

For nervous vertigo the removal of the exciting cause and the use of such remedies as iron, quinin, and strychnin, either alone or variously combined, are demanded. For senile vertigo a highly nutritious but easily digested diet, the use of pure stimulants, and a course of mercuric chlorid, or arsenic with tincture of nux vomica, are advisable.

In all varieties of vertigo the habits of the patient must be most abstemious, excluding tobacco, tea, coffee, highly seasoned foods, malt liquors, and alcohol unless particularly indicated.

VESICAL CALCULUS.—See Bladder (Stone).

VESICANTS.—See Counterirritation.

VIABILITY.—Ability to live; applied to a child at the time of birth. The term indicates the capacity for independent existence. Viability has

chiefly to be determined by the age of the fetus and by its condition as regards formation, health, and strength. It also depends in some measure upon the season of the year and upon the climate in which the child is born.

The earliest period at which a child can be born, in temperate climates, and be capable of living and of reaching maturity, is usually regarded as about 7 months, or 210 days. Cases are on record of children born at the sixth month who were reared.

Signs of maturity are: Strong movements and cries directly after birth; the body is of a clear pink or red color, and is covered with sebaceous matter; the mouth, nostrils, eyelids, and ears are open; the nails reach, if not extend beyond, the finger-tips; the hair and eyebrows are completely developed, the hair of the head being about an inch long; the skull is somewhat firm, the fontanels are not far apart; the four portions of the occipital bone are distinct, and the external auditory meatus is cartilaginous; the testicles have passed the inguinal ring; there is meconium at the end of the large intestine or it is freely discharged and urine is passed; there is a point of ossification in the center of the cartilage at the lower end of the femur. The power of suction has developed, as evidenced by placing a nipple or the finger in the mouth. The ordinary length of the child is from 16 to 20 inches and the weight is from 4 to 7 pounds.

Between the sixth and seventh months the length of the fetus is from 10 to 14 inches. The skin is of a dusky red color and is covered with down and sebaceous matter; the pupillary membranes are disappearing and the nails do not reach to the ends of the fingers. Meconium may be found at the upper end of the large intestine and the testicles are situated near the kidneys. Points of ossification may be found in four divisions of the sternum and in the astragalus. The center of the body at the sixth month is at the lower end of the sternum, while at the seventh month it is a little below the sternum. The length of the child at eight months is from 14 to 18 inches; its weight is from 3 to 5 1/2 pounds. The skin is rosy and is covered with fine short hairs, with distinct sebaceous envelope; the nails reach to the ends of the fingers, and the pupillary membranes have entirely disappeared; the testicles have descended into the inguinal ring, and there is a point of ossification in the last vertebra of the sacrum. The middle of the body is nearer to the umbilicus than to the sternum.

The signs of immaturity are: The head is out of proportion to the body; the body center is high up; the pupillary membranes are present; the testicles are undescended and the genital organs are of a deep red color; the skin is intensely red, mottled, and coated by a downy covering, sebaceous matter being absent; the nails are imperfectly formed. Movements are feeble; there is inability to suck; artificial heat is necessary; sleep is almost unbroken; the discharges of meconium and of urine are infrequent and imperfect; and the mouth, nostrils, and eyelids are closed.

The tests of live birth are appended:

Breslau Test.—If the intestines and stomach of the infant were found to float in water on removal from the body it was thought to be proof that the child was born alive. This test is of no value.

Hydrostatic Test.—Suggested by Raygat. It consists in placing the lungs in water and noting their specific gravity. If inflation has occurred, they will float. This test is valuable.

Ploucquet's Test.—This consists in estimating the ratio of the weight of the lungs to the weight of the body of the child. Ploucquet laid down this rule; that *before respiration* the weight of the lungs compared to the weight of the body was in the ratio of 1 : 70, and that *after respiration* it was in the ratio of 1 : 35. The test is of but slight value.

Static Test.—Also called *Foderé's* or *Schmidt's test*. This consists in ascertaining the absolute weight of the lungs, and comparing this weight with the average lung weights of still-born children and of children who have died soon after birth. Foderé fixes the weight of the lungs of still-born children born at term at 480 grains (1 ounce), and 960 grains (2 ounces) as the weight of the lungs soon after breathing has been established. This test is also of but slight value.

VIBURNUM.—**V., opulus,** cramp bark. Dose, 10 to 45 grains. Dose of the fluidextract, 10 to 45 minims. This drug is valued as a remedy for uterine and abdominal pains. **V. prunifolium,** black haw, is also derived from the bark of a shrub of the same natural order. It contains tannic, oxalic, citric, and malic acids, and sulphates and chlorids. It also contains 2 resins, viburnin and viburnic acid, the latter of which is identical with valeric acid.

The fluidextract (dose, 10 to 45 minims) is the only preparation. The drug is considered a nervine, and is antispasmodic, astringent, diuretic,

Spirillum of Vincent and the Fusiform Bacillus; Other Organisms are also Present.—(*Rosenberger and Coplin.*)

and tonic; it is especially useful in preventing abortion, in the nervous diseases of pregnancy, and in spasmodic dysmenorrhea. It may be administered with cannabis indica, with morphin and other nerve sedatives, and with aromatics. Nausea and vomiting are often excited by it. There is no exact observation concerning its physiologic action.

Liquor sedans is a utero-ovarian sedative and anodyne. Each fluidounce contains of black haw and golden-seal, each 60 grains; Jamaica dogwood, 30 grains; aromatics, a sufficient quantity.

VINCENT'S ANGINA.—A form of sore throat due to two organisms, the *fusiform bacillus* and the *spirochæta darticola*. It occurs chiefly in children and young adults; the eruption of the wisdom teeth is said to be a predisposing factor. Bad hygiene, and the use of alcohol and tobacco are favoring conditions.

Symptoms.—Two forms are recognized: (1) The *ulceromembranous* variety, which is the most common (occurring in about 98 percent of the cases) and in which both the bacillus and spirochete (or spirillum) are found. In this form there are malaise, sore throat, headache, fever, dysphagia, and fetid breath; later ulceration of one or both tonsils occurs. (2) The *diphtheroid* variety, which occurs in about 2 percent of cases only. This form is due to the fusiform bacillus alone, and is characterized by a distinct false membrane or an inflamed base. Otherwise the symptoms are the same as those found in the ulceromembranous variety.

Diagnosis.—A smear and culture will decide whether the case is one of diphtheria or not.

Treatment.—An antiseptic mouth wash, and the application of tincture of iodin twice a day are indicated. The disease is not amenable to antitoxin. On account of the presence of a spirillum, salvarsan has been tried and (it is claimed) with satisfactory results.

VINEGAR (Acetum).—An impure, dilute acetic acid produced by acetous fermentation of wine, cider, or other fruit-juice. In pharmacy a solution of the active principles of certain drugs in dilute acetic acid. There are two official vinegars: **Acetum Opii** (vinegar of opium) (black drop); containing opium, 10 percent; nutmeg, 3 percent; sugar, 20 percent. It is used as a sedative. Dose, 2 to 15 minims. **Acetum Scillæ** (vinegar of squill), containing 10 percent squill. It is used as an expectorant. Dose, 15 to 45 minims. See ACETIC ACID.

VINUM (Wine).—The fermented juice of fruits, especially that of grapes. White wines are made from the pulp; red wines from the pulp and skins, the latter yielding the coloring-matter.

When medicated, wines (vina) are practically the same as tinctures. The menstruum directed to be used is the official white wine (vinum album), which should contain from 7 to 12 percent by weight of absolute alcohol. It is, however, reinforced by the addition of alcohol to the amount of 5 to 17 1/2 percent in all the medicated wines. In the two ferric wines the alcoholic reinforcement is in the shape of the tincture of sweet orange peel. The wine of coca is made with red wine. The official wines are 10 in number, 2 of which are not medicated, namely white wine and red wine.

Vinum Album (White Wine).—An alcoholic liquid, made by fermenting the juice of fresh grapes, the fruit of *Vitus vinifera* freed from seeds, stems, and skins, and subjected to the usual cellar-treatment for fining and aging. A pale, amber-colored or straw-colored liquid, having a pleasant odor free from yeastiness, and a fruity, agreeable, slightly spirituous taste, without excessive sweetness or acidity.

Vinum Rubrum (Red Wine).—An alcoholic liquid, made by fermenting the juice of fresh, red-colored grapes, the fruit of *Vitus vinifera*, in presence of their skins, and subjected to the usual cellar-treatment for fining and aging. A deep red liquid, having a pleasant odor free from yeastiness, and a fruity, moderately astringent, pleasant and slightly acidulous taste, without excessive sweetness or acidity.

There are eight medicated wines official in the U. S. P., as follows:

TITLE.	ACTIVE CONSTITUENTS.	PROPERTIES AND DOSE.
VINUM:		
Antimonii.....	Tartar-emetic, 0.4 percent.	Expectorant (15 minims).
Cocæ.....	Coca, 6.5 percent.	Stimulant (4 drams).
Colchici seminis..	Colchicum seed, 10 percent.	Diuretic (30 minims).
Ergotæ.....	Ergot, 20 percent.	Emmenagogue, parturient (2 drams).
Ferri.....	Cit. iron and ammon., 4 percent.	Tonic, (4 drams).
Ferri amarum....	Cit. iron and quinin, 5 percent.	Tonic (2 drams).
Ipecacuanhæ....	Fldext. ipecac, 10 percent.	Expectorant (15 minims).
Opii.....	Granulated opium, 10 percent.	Sedative (8 minims).

See WINE.

VIOFORM.—Iodochloroxyquinolin. Nioform. Antiseptic and hemostatic in action, it is recommended as an ideal substitute for iodoform.

VIRUS, VACCINE.—See VACCINATION.

VISCEROPTOSIS. (Glénard's Disease, Enteroptosis, Gastroptosis, Splanchnoptosis).—By reason of relaxation of the ligaments, the organs in the abdomen are found below their normal position. Loss of elasticity of the abdominal muscles is a predisposing cause. This may result from gastro-intestinal autointoxication, from repeated pregnancies, from pressure of clothing, from hemorrhages. In some cases only one organ may be displaced.

Symptoms.—Nervous dyspepsia, anorexia, constipation or diarrhea may be found, although some cases present no symptoms. There may be abdominal distention, eructations, pains after eating, nervous symptoms such as headache, vertigo, insomnia, emaciation, or chlorosis is frequently found.

Treatment.—If symptoms exist, they may be relieved by a wide bandage or other appliances (such as pads, springs, trusses, or corsets). Lavage is useful in gastroptosis. For permanent relief operation is necessary.

VISION, DEFECTS.—See AMBLYOPIA, BLINDNESS, FIELD OF VISION.

VISION, TESTS. Test-cards.—It has been discovered that the smallest retinal image that can be perceived at the macula corresponds to a visual angle of 1′. The visual angle is the angle included

between two lines drawn from two opposite edges of the object through the nodal point. Following this principle, test-types have been constructed in such a manner that every letter is so made that when at its proper distance it subtends an angle of 5′. It is well to have two series of letters, to avoid doubtful results from the patient learning the positions of the letters on a single card.

The mode of procedure in determining the acuity of distant vision with test-types is as follows: The patient is placed with his back to the light in front of the test-cards, which should be hung at a distance of 5 or 6 meters, and should be well illuminated by artificial light from a reflector, about 2 feet away and to one side. The eye not under examination is then covered, and the patient is asked to read the lowest line possible. If, seated at 6 meters' distance, he reads the line marked 6 meters, his visual acuity is expressed by the fraction 6/6; if he reads the line marked 4 meters, he has remarkable acuteness of vision, and we express it by the fraction 6/4; if he is amblyopic, or ametropic he will not be able to read the 6-meter letters, and may possibly read only the line marked 15 meters, when his visual acuity is expressed by the fraction 6/15. Some surgeons prefer to use feet instead of meters in their estimations, and to seat their patients at about 20 feet from the card, expressing the visual acuity by using 20 for the numerator and the foot-number of the card seen as the denominator. It sometimes happens that the patient is not able to read any letter on the card at 6 meters' distance. In such a case he should gradually approach the card or the card should be brought toward him, until the top letter is distinguished. This distance is noted, and serves as the numerator in the fraction of visual acuity.

With illiterates it is best to use a regular illiterate card, consisting of lines shaped like the plain capital letter **E**. The patient is asked to tell which way the prongs of the **E** point—upward, downward, to the right, or to the left. More difficult are the Burchardt dots for counting. These cards are constructed on the Snellen principle. For foreigners special cards have been constructed. The German and Hebrew letters are often of value in hospital work.

Testing Near Vision.—The test-cards usually employed to estimate the accommodation are after the model of Jaeger, and are merely printers' types of various sizes. These cards have the advantage of closely resembling the work ordinarily done by the eye in reading, but have the disadvantage that they are not arranged on any scientific plan. It is possibly better to use cards in which each word is composed of several letters constructed in strict conformity with the Snellen basis of letter-formation.

The mode of procedure with the near type is to find the furthest and nearest point at which the smallest recognizable type is readable. In presbyopes it is necessary to use a convex lens of a strength varying with the age of the patient. Each eye should be examined separately. See also Blindness (Tests).

VITILIGO (Leukoderma).—An acquired pigmentary affection, characterized by variously sized and shaped whitish patches with hyperpigmented borders.

Symptoms.—The condition manifests itself as rounded, oval or irregular, milk-white or pinkish-white spots, which tend to spread slowly or rapidly, at times coalescing and producing large patches. These are smooth, soft, sharply defined, and neither elevated nor depressed. The surrounding skin shows increased pigmentation, being usually brownish-yellow in color. The hairs upon the affected areas may or may not turn white. The disease progresses slowly, becoming conspicuous only after a duration of years. In rare cases the affection may involve the greater part or, indeed, the whole of the body. Vitiligo lasts throughout life. The eruption may occur upon any portion of the cutaneous surface, although it is prone to elect the backs of the hands and the trunk. There are no subjective symptoms. Disfigurement is the sole inconvenience. The affection is frequent in negroes, in whom it produces a most striking appearance.

Etiology.—Vitiligo occurs in adult life. In many cases there is no ascertainable cause. It is due, in all probability, to a disturbance of innervation. It is occasionally associated with morphea, alopecia areata, and exophthalmic goiter.

Pathology.—The skin is normal, with the exception of an unequal distribution of coloring-matter. In the white spots there is total absence of pigment whereas in the darkened borders the pigment is abnormally increased.

Diagnosis.—Vitiligo is to be distinguished from chloasma, tinea versicolor, morphea, and leprosy.

In both chloasma and tinea versicolor the patches are brown, whereas in vitiligo they are white. Furthermore, tinea versicolor is scaly, and the fungus is found in the scales. Morphea shows structural alteration of the skin, and the patches in leprosy are anesthetic.

Prognosis.—In rare cases spontaneous recovery has been observed, but the affection may be said to be practically incurable.

Treatment is highly unsatisfactory. Duhring advises the long-continued administration of arsenic. Locally, lotions of corrosive sublimate or acetic acid, as recommended in chloasma, may be applied to the pigmented borders, with a view to dissipating the color and lessening the contrast.

VITREOUS, DISEASES.—The corpus vitreum forms the principal part of the globe of the eye. It consists of 98.6 percent of water. The remainder is composed of transparent fibers extending in all directions. Between these fibers are the compartments in which the nearly pure water, or vitreous humor, is contained. The vitreous is pierced in an irregular sagittal direction by the central canal, about 2 mm. in diameter. In the embryonic state the hyaloid artery traverses this canal, and sometimes persists after birth. The vitreous is contained in a delicate membrane, called the hyaloid membrane.

Hyalitis, or inflammation of the vitreous, is not an independent disease, but is generally associated

with inflammation of the uveal tract, particularly of the ciliary body, which causes disturbances of nutrition. It is characterized by change in consistency and by partial disorganization. Opacities, in the form of threads, clouds, or separate flocculi, are seen and cause subjective visual disturbance; and, provided the medium is sufficiently clear, are detected by the ophthalmoscope.

The treatment is constitutional, and under all circumstances should be directed to the cause. It consists chiefly of mercurials and iodids and of leeches to the temple.

VITRIOL.—See SULPHURIC ACID.

VOICE IN DIAGNOSIS.—The voice is the sound produced by the vibration of the vocal bands, modified by the resonance organs. It is of great value in diagnosis.

The Voice in Health.—If the ear is applied over the larynx or trachea of a healthy person, and he is directed to count "twenty-one, twenty-two, twenty-three," in a uniform tone and with moderate force, there is perceived a strong resonance with a sensation of concussion or shock, and a sense of vibration, thrill, or fremitus, the voice seeming to be concentrated and near the ear. Often the articulated words are distinctly transmitted (laryngophony). The sounds thus heard are termed **the normal laryngeal resonance.**

If the ear or stethoscope is applied over the third rib anteriorly on either side of the chest of a healthy person, and he is directed to count "twenty one, twenty-two, twenty-three," in a uniform tone, with moderate force, a confused distant hum is perceived, of variable intensity, accompanied by more or less vibration, thrill, or fremitus, most distinct in adults, but notably weaker in women than in men. This sound is termed the **normal vocal resonance.**

If the ear or stethoscope is applied over the third rib anteriorly of a healthy person, and he is directed to whisper, in a uniform manner, the words "twenty-one, twenty-two, twenty-three," there is heard a sound corresponding closely in character to the sound of expiration over the same region during the act of forced respiration; or, in other words, a feeble, low-pitched, blowing sound. This sound is termed the **normal bronchial whisper,** and is produced by the air in the bronchial tubes during the act of respiration.

The Voice in Respiratory Diseases.—The normal vocal resonance, as heard over the third rib of the chest anteriorly on either side, may be altered in intensity:

1. *Diminished or absent.*
2. *Increased or exaggerated.*

Or its resonance may be of the character of:

3. *Bronchophony.*
4. *Pectoriloquy.*
5. *Egophony.*
6. *Amphoric voice.*

The vocal resonance may be diminished or feeble in bronchitis with free secretion, in pleurisy with effusion, or in complete consolidation of the lung structure and the bronchial tubes.

The vocal resonance is absent in pneumothorax and in pleurisy with effusion.

Exaggerated vocal resonance differs from the normal resonance in a slight increase of its density. It denotes a slight degree of solidification of lung tissue, and is chiefly of value in the diagnosis of tubercle.

Bronchophony, or the voice concentrated near the ear, raised in pitch and in intensity, denotes complete consolidation of the pulmonary tissue in those parts in which the sound is abnormally present.

Pectoriloquy is complete transmission of the voice to the ear, the articulated words being distinctly recognized. It has a close resemblance to the resonance heard over the larynx in health. Its presence indicates either a pulmonary cavity or more complete consolidation—in other words, an exaggerated bronchophony.

Egophony is a modification of bronchophony, consisting in tremulousness of the voice, its character being nasal or bleating, somewhat suggestive of the cry of a goat. When heard, it may be considered a sign of pleurisy with slight effusion or of pleuropneumonia.

Amphoric voice, or "the echo," as it is sometimes called, is a musical sound, of a somewhat hollow, metallic character, like that produced by blowing into an empty bottle. It is sometimes produced in large cavities within the lung, but is especially incident to pneumothorax.

Increased bronchial whisper is a sound in which the whispered words are abnormally intense and are higher in pitch than in the normal bronchial whisper. It has the same significance as exaggerated vocal resonance. See CHEST (Examination).

The Voice in Other Morbid Conditions.—There are many other changes of the voice that may occur in different conditions, and that may be of value as indicating morbid states. There are differences in the cry of infants—the normal cry, indicating hunger; the cry of irritability or pain (see INFANTILE SYMPTOMS); the changes with respiratory disorders. Skene notices the morbid state of the voice, indicating circulatory disturbances, cases of heart disorder, and Bright's disease, including hyperemia of the vocal cords, lowering and modifying the tone and quality. Anemia raises the pitch of the voice, and a concealed hemorrhage may be detected by one whose attention has been called to this point. He refers to the importance of noticing the condition of the voice as indicating the nervous state before performing major operations, and also to its testimony as showing the amount of shock after an operation. The voice is also of value as indicating the reaction from this condition, and sometimes is the first and only symptom. The voice as an indication of apathetic conditions is also of importance, and frequently is of very valuable prognostic significance. There is a liability to take this apathetic tone as an indication of contentment, a wrong diagnosis resulting. Skene speaks of the expression of the voice after abdominal operations, and of the peculiar voices of the insane. The last, however, he does not venture

to remark on extensively. He says that it is necessary, in order thoroughly to utilize this feature in diagnosis, to have had considerable experience, and to possess a normal sense of hearing and ready appreciation of the varieties of quantity and characteristics of sound; but especial refinement of the sense is not necessary.

VOICE, LOSS.—See APHONIA, DYSPHONIA, LARYNGITIS.

VOLVULUS.—See INTESTINAL OBSTRUCTION.

VOMITING.—Vomiting is produced: (1) By local causes, such as irritation of the stomach from disease of the organ (cancer, ulcer, dyspepsia, gastritis), or from the ingestion of certain varieties of food or drugs; (2) by reflex causes, such as cerebral diseases, disease of the spinal cord, heart-, lung-, or kidney-disease, abdominal tumors, pregnancy, intestinal obstruction, peritonitis, general nervousness, and constipation; (3) by infectious diseases, such as scarlet fever, typhoid fever, cholera, small-pox, yellow fever, malarial fever, and tuberculosis.

Character of Vomitus. Solid or Liquid Food.—Solid food may be ejected from the stomach immediately after it has been taken, as in certain varieties of dyspepsia, and after the ingestion of partly decomposed food.

Acid Vomiting.—This variety usually occurs in cases of dyspepsia with hyperacidity attended by constipation. The fluid is generally thin and highly acid, giving rise to pyrosis, or "water-brash." Excessive flatulence is usually present, attended by heartburn. In many cases the condition is relieved by correcting constipation. See FLATULENCE, CONSTIPATION, GASTRIC NEUROSES.

Mucous Vomiting.—In this variety the vomitus is, for the most part, composed of thick, glairy mucus; it occurs in acute and chronic gastritis.

Bilious Vomiting.—Bile may find its way into the stomach when reversed peristalsis occurs, as in obstruction of the bowels in the early stages, in impaction of a gall-stone, and in malarial fever or yellow fever.

Fecal vomiting occurs in the later stages of intestinal obstruction.

Bloody vomit (hematemesis) is seen in gastric cancer, in ulceration of the stomach, in yellow fever, and in some cases of cirrhosis of the liver.

Purulent vomit is due to rupture of an abscess into the stomach or esophagus.

Profuse Vomiting.—Profuse vomiting is generally due to gastric dilatation, as seen in cases of gluttony, prolonged debauch, and gastric cancer. In most instances it occurs a long time after eating. The material usually contains sarcinæ ventriculi if due to cancer, and sometimes if due to ulcer of the stomach.

Vomiting due to Cerebral Causes.—Vomiting due to intracr nial disease generally occurs soon after the food has been taken, and is usually unattended by premonitory feelings of nausea or discomfort. Gowers states that when this variety of vomiting is accompanied by persistent pain in the head, and when it occurs with increased frequency, it should always give rise to suspicion of cerebral disease. In such cases optic neuritis would point directly to intracranial disturbance.

Vomiting in Infectious Diseases.—Vomiting occurs during the onset of most of the infectious diseases, especially in children.

Treatment of Vomiting.—No well-defined rule can be laid down that would apply to all varieties of vomiting. Persistent effort must therefore be made to find the exciting cause of the act of vomiting, and it should be treated upon general principles. Cold applications and ice by the mouth will allay the irritability of the stomach. In cases of collapse heat may be used locally. Cocain may be administered in severe cases. The usual treatment of the vomiting of indigestion or debauch is the administration of calomel in small doses (1/10 grain every hour), followed by a purgative. Bismuth subnitrate, cerium oxalate and validol have been recommended. The immediate diet must be very scant and should be chiefly liquid. See EMETICS, ANTIEMETICS.

VOMITING OF PREGNANCY.—There is a physiologic, an exaggerated, and a pernicious vomiting in pregnancy. The first two forms are of minor importance; the last is a serious affection, requiring active treatment. See PREGNANCY (Pernicious Vomiting).

VULVA, DISEASES.—**Inflammation** of the vulva, or vulvitis, is usually the result of gonorrhea. It may be due to irritating discharges from other conditions, such as cancer of the cervix, corporeal endometritis, or a vesicovaginal fistula. In children it is seen not infrequently as the result of uncleanliness.

The symptoms are pain and burning of the vulva with more or less discharge. The parts are inflamed and somewhat edematous.

Treatment consists in rest in bed and in frequent cleansing of the vulva with boric acid solution (1 dram to 1 pint). As the acute symptoms subside the inflamed areas may be painted with a 2 percent solution of nitrate of silver. This should be repeated daily until all evidence of the disease has subsided.

Should the inflammation become localized in the mucous or sebaceous glands of the vulva, the affected glands should be punctured and cauterized with pure carbolic acid.

Hematoma of the vulva is usually a complication of labor, and is the result of subcutaneous rupture of a vein. It generally occurs as the result of other forms of traumatism.

Treatment consists in thorough cleanliness of the parts and in slight compression of the tumor, which will cause its rapid absorption. Should infection occur, the tumor should be incised and the blood-clot turned out, and the cavity should be irrigated and packed with gauze.

Papilloma of the vulva is usually the result of venereal disease. It is sometimes caused by uncleanliness, and may exist as a complication of pregnancy. Papillomata occur usually in two forms—as small, isolated, warty growths, or as distinct cauliflower-like tumors.

The treatment is excision. The small warts may be snipped off with scissors, after which their

bases should be cauterized. The larger growths should be excised and the wounds should be closed with interrupted sutures.

Pruritus.—Itching of the vulva may be due to a variety of causes. It not infrequently occurs as the result of irritating discharges, or it may be due to tubal or ovarian disease or to uncleanliness. Diabetic urine may cause this disease, or it may exist without any ascertainable cause, when it is called idiopathic pruritus. The intense itching of the vulva causes scratching and rubbing, which are finally followed by irritation, inflammation, and discharge.

Treatment consists in relieving the cause. If it is due to discharge from the uterus, measures should be taken to prevent this. A vaginal tampon should be worn and perfect cleanliness should be practised. Diabetic urine should be prevented from coming in contact with the vulva, and the patient should exercise care in thoroughly drying herself after urination. Local applications will sometimes be of value. One of the best is:

℞. Tincture of opium,
Tincture of iodin,
Tincture of aconite, } each, ʒ v
Carbolic acid, ʒj.

This may be applied to the parts 2 or 3 times daily.

The following ointment may be employed:

℞. Menthol, ʒ j
Lanolin, ʒ ij.

In some cases cauterization with pure carbolic acid may give relief.

W

WAHOO.—See Euonymus.

WALCHER'S POSITION.—See Gynecologic Examination (Table of Postures and Positions).

WARBURG'S TINCTURE.—See Quinin.

WAR SURGERY.—The great war has brought about many modifications in surgical practice and has given rise to much literature. A clearing house for both the "modifications" and the "literature" is much to be desired, but at present it seems far away. The first step in the treatment of wounds is to check the hemorrhage, combat the shock, alleviate pain, apply a simple antiseptic such as tincture of iodin, and then add a gauze dressing and bandage. The patients must be put in such a condition that they may be forwarded with as little harm and suffering as possible. A tourniquet should not be applied if there is a likelihood of its having to remain on for a long time. On arrival at the main dressing station, the first dressing is removed, the wound cleaned, thoroughly dressed and (when necessary) immobilization provided for. Successful treatment depends on the early removal of septic matter, and the bearing in mind that the "keynote of military surgery is time." It is a continual endeavor to obtain treatment of the wound within the precious first 24 hours. If the surgery in the Casualty Clearing Station is well carried out, the method of antiseptic treatment employed is of minor importance. It is desirable to adopt a method which will not interfere with subsequent methods at the base, and which will not require attention during transport. During transport, water, food, blankets and morphine are among the main requirements; and there should always be some one at hand who is competent to pack a bleeding wound. Numerous antiseptics have been recommended, and, later on, modified or discarded in favor of something newer. The *Carrel-Dakin Method* will be found described under that heading. Infected wounds are treated (wherever possible) by excision. With regard to the choice of method of wound treatment, the following summary is given by Hull (*Surgery in War*): "Amidst the bewildering mass of methods and treatments which have been advocated and used, one surgical principle alone stands impregnable, and that is the surgical removal of the septic tissues. Provided the surgical treatment is correctly carried out at the proper time, it is immaterial what particular treatment is adopted. . . . It is very difficult to compare various treatments, methods, and antiseptics in connection with gunshot wounds. There will always be a certain number of bad results, whatever treatment is adopted, and there will always be a still larger number of good results. So many factors are operative in the production of results that fallacies in judgment are almost inevitable. . . . The bismuth-iodoform-paraffin and particularly other antiseptic pastes composed of flavine, brilliant green, chloramine-T, and other similar antiseptics, appear to deserve a place in military surgery. The simplicity of the treatment, the facilities which such measures offer during transport, and the absence of frequent dressing give the paste treatment a certain preference, but it postulates the wounds are fit for closure. In spite of the scientific excellence of the Carrel-Dakin treatment, it is unsuited for transport except under elaborate special organization. Special Carrel-Dakin trains, with adequate fixed apparatus and specially trained and supervised staffs, would be necessary. Otherwise the setback which these cases will experience during evacuation will entirely negative the excellence of the results. These remarks apply equally to any form of irrigation treatment and, to a lesser degree, to all forms of treatment which entail dressing during transport. During the early stages of treatment in casualty clearing stations we are limited to a choice of a few methods, all of which offer great advantages from the point of view of transport—antiseptic pastes, salt sac drains, and flavine dressings. Provided the wounds are receiving treatment within the first twenty-four hours, and they are not of an extensive nature involving comminution of bone, Hull recommends a paste treatment and delayed primary suture. If the wounds are extensive and heavily infected, and cancellous tissue is involved, with extreme comminution of bone, the use of B. I. P. or any paste is contraindicated. If wounds cannot be completely excised, removing all infected tissue, paste treatment of any kind is negatived, and even more strongly so if foreign bodies cannot be removed. The expectation of gas gangrene or severe infection, owing to the nature of the fighting, will again make the use of any antiseptic paste treatment dangerous and unsuitable. In the case of wounds for which direct closure or paste treatment is unsuitable, Hull recommends dressing the wound with salt sac drains, soaked with flavine or other non-irritating reagent, inhibiting the growth of micro-organisms, before transport. The advantage of this method is that it does not interfere with subsequent treatment. The wound may be sutured when the patient arrives at the base, or treated by Carrel's instillation method if sepsis has occurred. The treatment of wounds at the base resolves itself into the treatment of lightly infected wounds with saline solution or flavine solution 1:3000 in 3 per-cent salt solution until the wounds are ready for suture. Moderately infected wounds should be treated with gauze soaked in flavine or some non-irritating antiseptic, and the more heavily infected wounds by the application of the Carrel technic. Acutely suppurating heavily infected wounds are little influenced by any antiseptic. Free drainage and the preventing of pocketing and loculation are

of the utmost importance. Counter-incisions are desirable. The removal of the tryptic pus and the determination of a large blood supply and its attendant exudation of serum are the factors to be obtained. Heat in the form of fomentations is still the best method of obtaining a rich supply of blood fluids; the addition of a hypertonic solution of salt is an advantage, and salt sac drains. Hot fomentations of salt solution with suitable surgical treatment forms one of the most satisfactory treatments for this type of wound. In some cases marine or rubber sponges may be packed in a wound to rapidly remove by capillary attraction the tryptic pus and to supply the necessary heat. These sponges require changing hourly, and the conservation of heat by an electric heating apparatus."

Gas Gangrene.—This is an acute infection caused by the *Bacillus perfringens* in the presence of necrotic tissue. It is believed to be carried into the wound by the missile and the clothing. "Once the wound is infected, the occurrence of gangrene is favored by several conditions: (1) delay in cleansing the wound and removing the cloth and foreign body; (2) excessive damage to the tissues and the presence of necrosed tissue and blood clot; (3) extensive comminution of bone; (4) interference with the blood supply; (5) the presence of sepsis; (6) unsuitable treatment, *e.g.*, the injudicious use of B. I. P. and antiseptic pastes in infected wounds without efficient surgical treatment" (Hull).

The condition is to be *prevented* by early excision of the wound, removal of all foreign material, and thorough cleansing and drainage. Tourniquets, tight bandages, and strong antiseptics must be avoided.

Treatment consists, at first, in wide excision of the wound, and dressing with saline or Dakin's solution; transportation is harmful, and if the condition spreads amputation may be necessary. If the condition spreads, and localized gangrene extends to the muscles, resection of the muscles or amputation of the limb will be imperative. The following *indications* are given by Hull (*Surgery of War*): "*Indications for resection:* (1) When gas gangrene has not gone beyond the stage of anerobic infection, the infection is limited to superficial and necrotic tissue. A simple wide excision of the wound is indicated. (2) When the skin is tense and distended, and the blanching is giving place to a gray cream color, gangrene is established. If at this stage upon exploration the gangrene is found to be limited to a single muscle, resect. (3) If crepitation be limited to an area of a few inches and the color has not progressed beyond the dirty gray stage, and the gangrene be found to be limited to a group of muscles, resect. (4) When amputation is impossible on account of the clinical condition of the patient, resection may be performed irrespective of the future usefulness of the limb. *Indications for amputation:* (1) When purple areas or blebs in the skin have already appeared; (2) when crepitation is extensive, evidencing extensive infection of underlying muscle; (3) when complicating a compound fracture; (4) when important vessels and nerves are injured; (5) when a joint is involved; (6) when resection of the infected area would result in a useless limb; (7) when the distal pulse in the limb cannot be felt."

Trench Feet.—This condition is due to cold, damp, fatigue, interference with the circulation in the limbs, and inactivity. Cold alone is probably not the cause; one or more of the other factors must be present. Humidity and the wearing of tight leg gear are potent predisposing agents. In the mild stages of the condition the foot is white, swollen, numb, and painful; red or purple blotches appear, and the patient may experience pain or anesthesia in the foot; the skin of the foot is not ulcerated. In the next stage the foot shows blisters, ulcers, and gangrenous patches, but only the superficial tissues are affected. Later on the deeper structures are involved, and gangrene of the toes or whole foot results.

Prevention of the condition depends on a removal of the predisposing causes. Particular attention should be given to the avoidance of constriction by tight boots and puttees. Massage of the feet, dryness, cleanliness, and warmth are all beneficial.

Treatment consists in massage of the feet with warm oil, and in the use of the "paraffin bath." "Commercial paraffin with a melting point of about 45° C. is heated and placed in metal foot-baths. The feet are placed in the paraffin, heated to about 60° C., for half an hour daily. At the conclusion of the paraffin bath the feet are painted over with hot liquefied paraffin and a layer of wool applied." This hastens recovery and relieves the pain.

The literature of *War Surgery* is very extensive, and readers in search of more information are advised to consult Hull's "*Surgery in War*," from which much of the above has been derived. See Wounds, Carrel-Dakin Method.

WARTS (Verrucæ).—Pinhead-sized to bean-sized circumscribed elevations of the skin due to epidermal and papillary hypertrophy.

Symptoms.—Various forms of warts are distinguished:

Verruca Vulgaris.—This is the common wart seen upon the hands. It is a pea-sized, rounded, rough or smooth, broad-based elevation, yellow or brownish in color. It may occur singly or in numbers.

Verruca Plana.—This is distinguished from the ordinary wart by being flat and broad. Flat warts are pea-sized or fingernail-sized, but slightly elevated, and of a brownish or blackish color. They occur in numbers, usually upon the backs of elderly individuals (**verruca senilis**). Occasionally, numerous small flat warts occur upon the face.

Verruca Filiformis.—These warts are slender, thread-like outgrowths, about 1/8 of an inch in length, occurring chiefly upon the face, eyelids, and neck.

Verruca Digitata.—These are slightly elevated pea-sized to fingernail-sized excrescences, with numerous digitations branching out from the base. The scalp is the most common site.

Verruca Acuminata (Pointed Condyloma, Venereal Warts).—These are pinkish or reddish, sessile or pedunculated, pointed vegetations occurring about the mucocutaneous surfaces (penis, labia, anus, mouth, etc.) of young individuals. Occurring upon the genitals, they are bathed in an offensive puriform secretion. These warts grow rapidly, not infrequently attaining the size of an egg. They bear at times a strong resemblance to a raspberry, to cauliflower, or to a cockscomb.

Etiology.—It is probable that at least some forms of warts are due to microorganisms, and that they are autoinoculable and contagious. Venereal warts are caused by contact with irritating secretions containing, in all probability, the causal microorganisms.

Pathology.—Warts consist of a hyperplasia of the papillæ of the corium and the overlying layers of the epidermis. A vascular loop is found in the center of each wart. In the acuminate variety the connective tissue and vascular hypertrophy is marked, while the horny layer is but slightly hyperplastic.

Treatment.—Warts may be removed by caustics, excision, erasion, or electrolysis. The best caustics to be employed are nitric acid, caustic potash, chromic acid, or glacial acetic acid. These should be cautiously applied from time to time until the disappearance of the wart. An excellent method is to scrape away the wart with a curette and to apply the stick of nitrate of silver to the base.

Salicylic acid in collodion or alcohol is often successful in causing the disappearance of warts.

℞. Salicylic acid, ʒ j
Alcohol, ʒ j.
Apply 2 or 3 times a day.

Or—

℞. Salicylic acid, ʒ j
Collodion, ʒ j.
Apply twice a day.

The use of a 1:500 corrosive sublimate solution is sometimes efficacious, as is also an alcoholic solution of resorcin, 30 grains to the ounce.

Filiform or digitate warts may be snipped off with curved scissors, the base being subsequently cauterized. Venereal warts may be washed with solutions of alum, tannin, or chlorinated soda, and then dusted with calomel, or they may be cauterized with nitric, carbolic, or chromic acid. Cleanliness should be strictly enjoined.

It has been claimed recently that chrysarobin is a specific for warts. The surface of the warts is carefully thinned with a sharp, fine glass-paper which gives better results than paring with a knife, as the patient is less afraid of injuring himself and can more conveniently handle the paper. Chrysarobin may be applied either in a 10 percent solution of the ordinary gutta-percha solution or in a 10 percent ether solution. It is best to apply the chrysarobin at night, and to advise the patient to put on an old stocking, to prevent soiling the bedclothing. Application once a day in this way seems ordinarily to be sufficient, but in obstinate cases it should be applied both night and morning.

The influence of chrysarobin is not only upon the keratinized portion of the skin, but also upon the proliferated blood-vessels in the papillary central part, for both disappear and true skin is formed over the surface.

WASSERMANN REACTION.—See Syphilis.

WATER (Aqua). H_2O.—Natural water in its purest attainable state is a colorless, limpid liquid, devoid of odor or taste, and neutral in reaction. Besides entering into the composition of most of the official extracts, fluidextracts, and many other pharmaceutic preparations, from it are prepared the official waters Aquæ (see Aqua), and also the following: **Aqua Destillata** (distilled water), H_2O: 1000 parts of water are distilled, the first 100 parts obtained being thrown away and 800 parts preserved. It is as near chemically pure water as can be obtained.

Uses of Water in the Human Body.—Water constitutes between 60 and 66 percent of the human body. Its uses have been well summarized by W. G. Thompson as follows: "(1) It enters into the chemical composition of the tissues. (2) It forms the chief ingredient of all the fluids of the body and maintains their proper degree of dilution. (3) By moistening various surfaces of the body, such as the mucous and the serous membranes, it prevents friction and the uncomfortable symptoms which might result from their drying. (4) It furnishes in the blood and lymph a fluid medium by which food may be taken to remote parts of the body and the waste matter removed, thus promoting rapid tissue changes. (5) It serves as a distributor of body heat. (6) It regulates the body temperature by the physical processes of absorption and evaporation."

Nomenclature of Water.—See Aqua.

Therapeutics.—Cold water or ice has many external applications of value in the treatment of disease. As a wet pack it is used in tonsillitis, diphtheria, and croup. Cold baths are the most effective antipyretic in the high temperature of fevers, and the cold wet pack is used for the same purpose. Ice or cold water is applied to the head in acute cerebral congestion, and to the spine in chorea, etc.; also locally in hemorrhoids, bubo, orchitis, and to the uterus in postpartum hemorrhage. Cold effusion to the body is employed as a preventive of spasmodic croup, as well as to lessen the tendency to taking cold. See Bath.

Hot water externally—as fomentations, hot wet pack, hot baths, etc.—is most effective in reducing local congestion and in setting up resolution of local inflammation. Hot fomentations to the renal region are useful in functional inactivity of the kidneys. The hot spinal douche is used in affections of the spinal cord and meninges, and in the backache of women. The hot wet pack is highly esteemed in inflammation of the chest organs, and hot injections are useful in chronic inflammation of the uterus. Hot-water dressings

for wounds are strongly favored by many surgeons. Vapor and Turkish baths are used as diaphoretics in advanced kidney-disease, in acute and chronic rheumatism, in mineral poisoning, and in syphilis. Warm baths, with cold applications to the head, are of value in infantile convulsions and chorea. See BATH.

Internally, water is chiefly of value as a diuretic, and, if hot, as a diaphoretic. A glass of cold water before breakfast daily is often an effective means of overcoming constipation, while the drinking of hot water an hour before each meal has been of great benefit to many dyspeptics. The value of the popular teas in chronic diseases is almost entirely due to the diluent, diuretic, and diaphoretic actions of the hot water used.

In moderate quantity water is necessary to digestion, but large amounts weaken digestion by diluting the gastric juice. Ice-cold water, if freely used, suspends the action of pepsin and depresses the nerves of the stomach and lowers its blood supply. In some subjects the free use of water internally favors the deposition of fat.

WATER, EXAMINATION.—A potable water is one that is *apparently fit* to drink.

An unpotable water is one that is *obviously unfit* to drink.

Characteristics of a good drinking water are: (1) It should be clear and limpid. Cloudy and muddy waters should be avoided. (2) It should be colorless. A greenish or yellowish color is usually due to vegetable or animal matter in solution or to organisms. (3) It should be odorless; especially free from sulphuretted hydrogen or putrefactive animal matter. (4) It should not be too cold, but should have a temperature of from 46° F. to 60° F. (5) It should have an agreeable taste; neither flat, salty, nor sweetish. A certain amount of hardness and dissolved gases gives a sparkling taste. It should contain from 25 to 50 c.c. of gases per liter, of which 8 to 10 percent is carbon dioxid and the rest oxygen and nitrogen. (6) It should be as free as possible from dissolved organic matter, especially of animal origin. (7) It should not contain too great an amount of hardness. A certain quantity of saline matter is necessary, however, to give it a good taste. It should not contain over three or four parts of chlorin in 100,000 parts of water (Bartley).

Diseases Which may be Transmitted by Drinking Water.—Typhoid, cholera, dysentery, diarrhea, indigestion, goiter, vesical calculi, intestinal worms, lead poisoning.

At the present day the subject of drinking-water involves the interest, attention, and welfare of every civilized community. The question of health largely depends upon the water consumed, in which may reside the microorganisms of disease and death. In chemic examination the determination of chlorids, of nitrites, and of free and albuminoid ammonia gives an index as to contamination, yet the proof is not absolute.

When, however, an attempt is made to isolate the causative factors in such diseases as typhoid fever, cholera, etc., insurmountable difficulties may present themselves, from the fact that a few microorganisms are scattered throughout a large volume of water, and that the portion of water selected for examination may yield negative results. This condition was instanced in Philadelphia during an epidemic of typhoid fever the origin of which was traced to a burst sewer-pipe that discharged its contents into the water-supply of a certain reservoir. The disease was wide-spread among those who consumed this water, whereas persons in other sections of the city remained comparatively free. A thorough bacteriologic examination of the water failed to show the presence of the typhoid bacillus.

Again, all varieties of potable water contain bacteria, most of which do not seem to be detrimental to health, while water which may contain a few pathogenic bacteria gives rise to epidemic diseases. It is important, therefore, to determine a "standard" in this respect. After the definite number of colonies have been found in a given quantity of water, a sudden fluctuation of this number may indicate contamination.

Qualitative Bacteriologic Analysis of Water.—By this is meant the isolation and study of different species of bacteria in drinking-water.

In collecting the sample extreme care should be exercised to avoid its contamination. If water is to be collected from a hydrant or spigot, it should be allowed to run for from 15 to 20 minutes; if from a spring or lake, it should be taken from about a foot beneath the surface. The specimen should be examined near the region where the sample is procured, and as soon as possible after its collection.

Abbott states that: "In the qualitative analysis it is necessary that a small portion of water—one, two, three, five drops—should first be employed, from which plates are to be made in order to determine the *approximate* number of organisms; also the amount of water necessary to use for each set of plates. Duplicate plates are always to be made—one set upon agar-agar, which should be kept in the incubator at the temperature of the body, and one set upon gelatin, to be kept at from 18° to 20° C." As soon as the colonies have developed, the plates are to be carefully studied and the results compared with subsequent inoculations into animals.

Quantitative Estimation of Bacteria in Water.—The results of the quantitative estimation of bacteria in water are expressed in terms of the number of individual organisms to a definite volume. The water should be examined in the spot where it is collected.

Collection of the Water.—For this purpose a glass bulb drawn out into a pointed extremity and sealed while hot should be used. The stem should be broken off under water, when, owing to negative pressure, the bulb fills with water.

The number of organisms in a fixed volume is approximately determined by the plate or tube method, at first selecting 1 or 2 drops, and finally 1 c.c. of water. If the original drop of water contained too many colonies to be counted, it should

be diluted with 10, 25, or 100 volumes of water, the results being expressed in terms of the number of bacteria to a cubic centimeter of water.

It is always essential to make duplicate plates.

Method of Counting the Colonies on Plates.—For this purpose the Wolffhügel's counting apparatus is used. When the colonies are quite small, an ordinary hand lens may be used. Esmarch also has devised an apparatus for counting the number of colonies of bacteria in water.

Chemic Analysis of Water.—In order to determine the fitness of a water for potable purposes both chemic and bacteriologic examinations are necessary. While the value of drinking-water may be judged by the chemic method alone, the evidence is not absolutely conclusive, because it is desired most frequently to determine whether or not there is pollution from sewage, and this information cannot always be derived from a chemic examination. Unfortunately, the bacteriologic examination does not always tell this, because it is hard to obtain a standard of water in which a certain number of colonies of bacteria can be allowed to a cubic centimeter; and also on account of the fact that the typhoid bacillus or other pathogenic organism is seldom found, because so few bacteria exist in comparatively large quantities of water, and thus erroneous results may be derived from the examination.

A method of analysis, though seemingly primitive, may and does frequently present such evidence as to prevent the use of contaminated water; this method may be called "examination by the senses," and, according to Blyth, "water that is evidently turbid, that possesses an odor and an unpleasant taste, requires no analytic processes to condemn it entirely; such water is unsuitable for drinking purposes."

Another simple water test is as follows: Into a stoppered, ground-glass, perfectly clean bottle put 5 ounces of the water to be tested. To the water add 10 grains of pure, granulated, white sugar. Cork tightly, and set in a window exposed freely to light, but not to the direct rays of the sun. Do not disturb the bottle, and keep the temperature as near 70° F. as possible. If the water contains organic matter, within 48 hours an abundance of whitish specks will be seen floating about; and the more organic matter, the more specks. In a week or 10 days, if the water is very bad, the odor of rancid butter will be noticed on removing the stopper. The little specks will settle to the bottom, where they appear as white, flocculent masses. Such water should not be used for potable purposes.

Drinking-water should be free from such elements as lead, copper, barium, zinc, manganese, chromium, and arsenic. After eliminating these elements, the chemic analysis of drinking-water resolves itself into the estimation of (1) the total amount of solids; (2) amount of chlorids; (3) amount of free and albuminoid ammonia; (4) amount of nitrates; (5) presence or absence of nitrites; (6) amount of hardness; (7) organic matter.

Percentage of Elements Allowed in Potable Water.

Total solids,	30	parts to	100,000
Chlorids (NaCl),	2 or 3	parts to	100,000 (suspicious).
Free and albuminoid ammonia,	0.15	parts to	1,000,000
Nitrates,	3 or 4	parts to	1,000,000
Nitrites,	none		
Hardness ($CaCO_3$),	20 grains	to	100,000
Organic matter,	——		

The total solids are determined by evaporating a given quantity of water and weighing the residue.

The chlorids are usually estimated as NaCl, and are determined by a standard solution (not a normal solution) of nitrate of silver. In this way the molecular weight of $AgNO_3$ is expressed in milligrams (170 being the molecular weight of $AgNO_3$ when dissolved in 1000 c.c.):

1000 c.c. equals 170.0 grams
100 c.c. equals 1.70 grams
1 c.c. equals 0.0170 grams. (170 milligrams)

Free and Albuminoid Ammonia.—For the estimation of free and albuminoid ammonia the most delicate apparatus must be used and exceedingly careful methods must be exercised. The requisites are (1) Nessler's solution; (2) solution of ammonium sulphate; (3) solution of sodium carbonate; (4) solution of potassium permanganate; (5) distilled water free from ammonia.

Nessler's solution is prepared by dissolving 50 grains of potassium iodid in a small quantity of hot water and adding, while the solution is hot, a strong aqueous solution of mercuric chlorid (40 grams to 300 c.c. of water) until the red precipitate just redissolves; filter, add to the filtrate a strong solution of 200 grams of patassium hydrate, filter, dilute to 1000 c.c., add 5 c.c. of a saturated solution of mercuric chlorid, allow the precipitate formed to settle, decant the clear fluid, and preserve it in a glass-stoppered vial.

To determine the amount of *free ammonia*, the water to be examined is placed in a retort with a small quantity of solution of sodium carbonate and distilled. The amount is determined by the Nessler solution, and a known quantity of ammonium sulphate is used as an indicator.

To determine the amount of *combined or albuminoid ammonia*, the distillate is freed from ammonia, potassium permanganate is added, and successive portions are tested until less than 0.01 milligram of NH_3 is obtained, deduct ammonia due to potassium permanganate and the result gives albuminoid (free) ammonia.

The nitrates are determined by evaporating 2 of 3 liters of water, adding caustic lime, heating, transferring to a Liebig condenser, and introducing a thin sheet of zinc plated with copper. The distillate is then evaporated with platinum tetrachlorid and the amount of nitrates is calculated from the spongy platinum in terms of nitric acid.

Nitrites.—The following method is sometimes used. It consists in placing the water to be

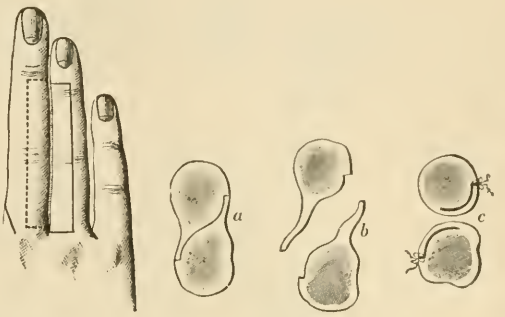
tested in a narrow glass cylinder and adding 1 c.c. of a solution of sulphuric acid (35 percent), and afterward a solution of metaphenylenediamin, with a solution of argentic nitrate of known strength as an indicator, similar comparisons are made with the metaphenylenediamin until the two colors are identical, when the amount of nitrites in the given sample can be calculated.

Hardness is mainly due to the bicarbonates of calcium and magnesium. To determine the hardness of water a solution of soap is made by dissolving 10 grams of soda soap in 1 liter of 90 percent alcohol; filter this and add 100 c.c. of the filtrate to 100 c.c. of distilled water and 33 c.c. of alcohol. Then prepare a solution of calcium chlorid by adding a small quantity of dilute hydrochloric acid to calcium carbonate, dissolving the residue in 1000 c.c. of water; dilute 10 c.c. of this with 100 c.c. of water, and add soda soap, shaking gently until a lather forms that remains unbroken for 5 minutes. From this as an indicator the amount of hardness is determined in a given sample of water.

Organic Matter.—Evaporate 250 c.c. of water to dryness in a platinum dish, first in a water-bath, then in an air-bath, and reweigh. Heat again to a low red heat until all the organic matter is destroyed, add water saturated with CO_2, evaporate, dry, and weigh. Repeat the process with CO_2. The difference between this weight and the first expresses the amount of organic and volatile matter. Organic matter of animal origin—such as sewage—during oxidation first changes into nitrous acid and nitrites, then into nitric acid and nitrates. The presence of nitrites is always a cause for suspicion. Any increased amount of nitrates should be carefully watched. The presence of nitrites, with an unduly large proportion of chlorid and of free and albuminoid ammonia, indicates the presence of sewage. In fresh sewage nitrites and nitrates may be diminished or absent.

WEANING.—See INFANT (Care), MILK (Mother's).

WEBBED FINGERS (Syndactylism).—This condition is treated by incising the web in such a way as to form a flap which is used to cover the raw surface between the roots of the fingers, or by raising two flaps of skin by an incision along the middle of the palmar surface of one finger, and another along the dorsal surface of the other finger; the flaps are then separated and wrapped around the fingers.



OPERATION FOR WEBBED FINGERS.—(*Stimson.*)

WEIGHTS AND MEASURES.

TROY WEIGHT

Grains.
24 = 1 dwt.
480 = 20 dwt. = 1 oz.
5760 = 240 dwt. = 12 oz. = 1 lb. = 22.816 cu. in. of distilled water at 62° F.

AVOIRDUPOIS WEIGHT

Drams.	*Ounces.*	
16 =	1 =	437.5 grains troy.
256 =	16 =	1 lb. = 1.2153 lb. troy.
6400 =	400 =	25 lb. = 1 quarter.
25,600 =	1,600 =	100 lb. = 4 quarters = 1 cwt.
512,000 =	32,000 =	2000 lb. = 80 quarters = 20 cwt. = 1 ton.

APOTHECARIES' WEIGHT

Grains.
20 = 1 scruple.
60 = 3 scruples = 1 dram.
480 = 24 scruples = 8 drams = 1 oz.
5760 = 288 scruples = 96 drams = 12 oz. = 1 lb.

APOTHECARIES' MEASURE

60 minims = 1 fluidram.
8 fluidrams = 1 fluidounce.
16 fluidounces = 1 pint.
2 pints = 1 quart.
4 quarts = 1 gallon.

Forty-five drops of water, or a common tablespoonful, make about 1 fluidram; 2 tablespoonfuls, about 1 fluidounce, a wine glassful is about 1 1/2 fluidounces; and a teacupful, about 4 fluidounces.

Liquid or Wine Measure

Gills.
1 = 7.2187 cu. in.
4 = 1 pint 28.875 cu. in.
8 = 2 pints = 1 quart = 55.75 cu. in.
32 = 8 pints = 4 quarts = 1 gallon.
2016 = 504 pints = 252 quarts = 63 gallons = 1 hogshead.
4032 = 1008 pints = 504 quarts = 126 gallons = 2 hogshead = 1 pipe.
8064 = 2016 pints = 1008 quarts = 252 gallons = 4 hogsheads = 2 pipes = 1 tun.

Long Measure

Inches.								
12	= 1	foot.						
36	= 3	feet	= 1	yard.				
72	= 6	feet	= 2	yards	= 1	fathom.		
198	= 16.5	feet	= 5.5	yards	= 2.75	fathoms	= 1	perch.
7920	= 660	feet	= 220	yards	= 110	fathoms	= 40	perches = 1 furlong.
63,360	= 5280	feet	= 1760	yards	= 880	fathoms	= 320	perches = 8 furlongs = 1 mile.

Square Measure

Sq. Inches.	*Sq. Feet.*						
144	= 1						
1296	= 9	= 1	sq. yard.				
39,204	= 272.25	= 30.25	sq. yards	= 1	perch.		
1,568,160	= 10,890	= 1210	sq. yards	= 40	perches	= 1	rood.
6,272,640	= 43,560	= 4840	sq. yards	= 160	perches	= 4	roods = 1 acre.

An acre is 69.5701 square yards; or, 208.710321 square feet.

A township is 6 miles square = 36 sections.
A section is 1 mile square = 640 acres.
½ section is ½ mile square = 160 acres.
1/16 section is ¼ mile square = 40 acres.

The standard United States bushel is the Winchester bushel (cylinder form, 18½ in. diameter, and 8 in. deep). = 2150.42 cubic inches.

The English Imperial bushel = 2218.192 cubic inches. = 1.03152 U. S. bushels.

The English quarter = 8 Imperial bushels. = 8¼ (nearly) U. S. bushels. = 10.2694 cubic feet.

Solid Measure

Cu. In.
1728 = 1 cubic foot.
46,656 = 27 cubic feet = 1 cubic yard.

Dry Measure

Pints.
1 = 33.6 cubic inches.
2 = 1 quart = 67.2 cubic in.
8 = 4 quarts = 1 gallon = 268.8 cubic in.
16 = 8 quarts = 2 gallons = 1 peck = 537.6 cubic in.
64 = 32 quarts = 8 gallons = 4 pecks = 1 bushel.

WEIL'S DISEASE (Acute Febrile Jaundice, Infectious Jaundice, Bilious Typhoid).—An acute infectious disease, characterized by fever, jaundice, muscular pain, and enlarged liver and spleen.

Etiology.—Unknown. The latest view is that the disease is caused by a spirochete—the *Spirochæta nodosa*. It occurs in the summer months, and attacks men in preference to women; butchers, brewers, and alcoholics are particularly liable to the disease.

Symptoms.—The illness begins suddenly with a chill, fever (102° to 104° F.), and epigastric pain; jaundice, headache, and muscular pains soon follow; the stools are apt to be clay-colored; a rapid pulse is quite common, and herpes is frequently noted; the liver and spleen are enlarged. The urine is dark and contains bile pigment, sometimes albumin and casts and blood. Fever lasts from 8 to 14 days and is remittent in character.

Diagnosis.—Bilious malarial fever may be excluded by the absence of plasmodia in the blood. The presence of fever, muscular, joint and epigastric pain distinguish it from catarrhal jaundice. Acute yellow atrophy of the liver and phosphorous poisoning are excluded by the mild course and favorable outcome.

Prognosis is generally good.

Treatment.—General symptomatic treatment is indicated: calomel, salines, and cold water enemata are beneficial; heat and massage with chloroform liniment may help the muscular pains.

WERNICKE'S SIGN (Hemiopic Pupillary Inaction).—If a bright light is thrown into the eye and the pupil reacts, the integrity of the reflex arc is demonstrated. It is possible, in cases of lateral hemianopsia, to throw the light into the eye so that it falls upon the blind half of the retina. If when this is done, the pupil contracts, the indication is that the reflex arc referred to is perfect, by which is meant that the optic nerve-fibers from the retinal expansion to the center, the center itself, and the third nerve are uninvolved. In such a case the conclusion would be justified that the cause of the hemianopsia was central; that is, situated behind the geniculate bodies, either in the fibers of the optic radiation or in the visual cortical centers. If, on the other hand, when the light is carefully thrown on the hemiopic half of the retina, the pupil remains inactive, the conclusions are justifiable that there is interruption in the path between the retina and the geniculate bodies, and that the hemianopsia is not central, but is dependent upon a lesion situated in the tract. See Hemianopsia.

WET PACK.—See Pack.

WHEY.—The liquid part of milk separating from the curd in coagulation. **Alum whey** is separated by stirring milk with a lump of alum; a popular remedy for sore eyes.

Wine whey is prepared by adding Rhine wine, 1 part, to hot milk, 4 parts, and straining. See Infant Feeding. **Whey cure**, a cure for chronic catarrh of the respiratory organs. This consists in drinking warm whey, either alone or mixed with a mineral water, in definite quantities at set times. About 20 ounces are taken daily. This is regarded by many as in all respects similar to the use of skimmed milk. Sometimes the method is combined with baths of whey.

WHISKY.—See Alcohol; Spirits.

WHITE SWELLING.—See Joints (Diseases) (Tubercular Arthritis).

WHITES.—See Leukorrhea.

WHITLOW.—See Paronychia.

WHOOPING-COUGH (Pertussis).—A highly contagious disease, characterized by inflammation of the respiratory tract, associated with a peculiar spasmodic cough ending in a whooping inspiration.

Etiology.—A bacillus described by Bordet and Gengou, similar to that of influenza, is the cause of whooping cough; this bacillus is discharged in the sputum and nasal secretions. This disease is directly very contagious, next to measles probably the most so of any of the infectious diseases, and it is possible for it to be carried by a third person. One attack usually protects from a second. It is most likely to occur before the tenth year; and although infants are not so susceptible as older children, it frequently does occur at that period of life, and is then a fatal disease.

Pathology.—There are no characteristic pathologic lesions due to whooping-cough, but post-

mortem there are found—besides the catarrhal condition, which is always present to some extent —lesions due to complications.

Symptoms.—The period of incubation is from 4 to 14 days, during which time there are no symptoms to indicate the onset of the disease. In the clinical course three stages are usually noticed: viz., the catarrhal stage, the paroxysmal stage, and the stage of decline. The first symptoms are those of a slight bronchial catarrh, which is worse at night. The cough is of a laryngeal type, and has a peculiar ring.

The child at this time has some fever, the appetite is poor, and the sleep is restless. The cough gradually increases, and after a few days is out of proportion to the physical signs, only a few dry râles being found on examining the chest. The physiognomy changes, the face becomes swollen, the eyes are suffused and the under lids are swollen and pink in color. This characteristic of the under lids may be recognized before the whoop appears, and is a valuable diagnostic sign. During the paroxysmal stage, which begins about the second week, the cough becomes spasmodic. The child often has a premonition of the onset of a spasm, and will run to its mother or nurse or grasp a chair in its efforts to be relieved.

The paroxysm consists of a number of short, spasmodic expiratory coughs, succeeded by a long-drawn inspiration and the peculiar whoop. Drinking, eating, crying, or any excitement will often bring on an attack. There may be 3 or 4 paroxysms in rapid succession, followed by a period of several hours when the child apparently feeds as well as usual.

The attacks of coughing are frequently followed by eructations of stringy mucus, which may be streaked with blood, and vomiting of mucus and of the food which has been eaten is quite common.

Nose-bleed is not unusual during this stage, and there may be ecchymoses, giving the skin a livid appearance. Extravasation of blood under the conjunctiva may occur, and the pink color and swollen appearance of the lower lids are more characteristic than during the catarrhal stage.

The physical signs of the chest are not characteristic. Between the attacks of coughing the child may play about and may seem as well as usual. The patients, however, as a rule, suffer more or less from malnutrition and weakness, and young infants frequently from gastrointestinal disturbances, which may prove a dangerous complication.

The number of paroxysms vary; usually, one occurs about every hour, or there may be as many as 30 or 40 in the course of the 24 hours. In young children the whoop may be absent. This is also noticed when pneumonia occurs as a complication, but the whoop appears again as the lungs clear. Long after an attack of whooping-cough is over the paroxysms may occur again and again, being brought on by a slight cold or by catarrh of the respiratory tract. The paroxysmal stage continues for a period of 3 or 4 weeks or longer.

The third stage, or stage of decline, begins when the cough grows less in intensity. The sputum is then not so tenacious, but becomes purulent. The cough is less violent, and occurs at less frequent intervals. This stage continues for 2 or 3 weeks.

Complications.—In infants convulsions are common when the cough is most severe; they are apt to be general and severe, and often prove fatal. At times vomiting becomes a serious complication, and it may reduce the child's strength to such a point as to endanger life. Severe bronchitis and bronchopneumonia occur quite frequently, and are dangerous complications. Adenoids greatly increase the dangers.

Diagnosis.—Until the whoop appears it is frequently impossible to make a diagnosis; but the troublesome cough, especially at night, and the absence of physical signs to account for it, with the peculiar puffy appearance of the face and the swollen and pink under eyelids, previously mentioned, are quite positive signs. A simple catarrhal laryngitis may sometimes simulate pertussis, but there is no distinct whoop, and the symptoms do not progressively increase and continue for a long period, as in the latter disease. Vomiting at the end of a paroxysm is a most suspicious symptom of whooping-cough.

Prognosis.—The older the child, the more favorable the prognosis. As stated, pertussis in infants is a very serious affection, the mortality being 25 percent in the first year. Children who are debilitated and poorly cared for also suffer severely from this disease. If between the paroxysms the child is well, the prognosis is very favorable; but if fever, accelerated breathing, somnolence, and persistent intestinal catarrh are present, the outlook is unfavorable. As a rule, whooping-cough is not a fatal disease, but the tendency to complications and the appearance of sequels affecting the lungs make it necessary to watch every case with care.

Treatment.—The child should be isolated during the whole course of the disease. The hygienic treatment of pertussis is very important, and all cases should receive careful treatment, as the attack may thus be shortened, and the danger of serious complications may be rendered much less.

The patient should be surrounded constantly by fresh air, to accomplish which it is of advantage to have two rooms, airing one while the others is being occupied. The room should be kept at a uniform temperature of about 65° F., and the child should be protected from drafts while sleeping by placing mosquito netting over the bed or crib. On pleasant days that are not windy it is an advantage to keep the child in the open air as much as possible.

Careful attention should be paid to feeding, especially in infants, whose nutrition is so easily interfered with. They should be nursed regularly if at the breast, and if fed by the bottle, should receive a properly modified milk diet. When vomiting follows a paroxysm of coughing and causes the food to be ejected, another feeding should be given at once. Small quantities at frequent intervals are more likely to be retained than the usual amount every 1 1/2 or 3 hours.

In the treatment of this disease it is important that it be recognized early.

During the catarrhal stage it is a local affection, and treatment locally at this time will in many cases shorten the duration. For this purpose the following formula is valuable to sterilize the throat and nose:

℞. Hydrogen dioxid, Glycerin, } each, ℥ ss
Water, ℥ iij.

Spray thoroughly through the nares every 4 hours.

When the cough is fully established and is accompanied by eructations of stringy mucus, mixture of asafetida, in 1/2 teaspoonful doses every 2 hours, should be given. Belladonna is a very useful remedy, and should be given in doses sufficient to cause flushing of the face. The tincture of belladonna may be given every 3 or 4 hours, in doses of one drop for each month of the child's age, gradually increasing the dose until toxic effects are produced. The dose of atropin may be more easily regulated, and it may be given instead of belladonna, giving from 1 to 5 drops of the following every 3 or 4 hours:

℞. Atropin sulphate, gr. j
Water, ℥ j.

In young infants a belladonna plaster placed between the scapulæ will often give good results.

Antipyrin combined with belladonna seems to have a more favorable action than either drug alone:

℞. Antipyrin, ℥ j
Tincture of belladonna, ℥ iv
Brandy, ℥ iv
Water, ℥ iij.

Give 1/2 to 1 teaspoonful every 4 hours to a child 3 or 4 years of age.

Bromoform may be given to quiet the cough:

℞. Bromoform, gr. x
Alcohol, ℥ j
Simple syrup, ℥ iv
Water, ℥ ijss.

To a child 2 or 3 years old give 1 teaspoonful every hour until quiet.

Inhalations of quinin solution or of oxygen or of ethyl iodid are recommended.

During convalescence, if the indications seem to demand tonics, cod-liver oil, syrup of iodid of iron, syrup of hydriodic acid, etc., should be given, and the child should be as much as possible in the open air, preferably at the seashore.

Serum or vaccine therapy has proved valuable in the hands of several observers.

WIDAL REACTION.—See Typhoid Fever.

WILD CHERRY.—See Prunus Virginiana.

WINE.—The fermented juice of various species of *Vitis*. A sweet wine is one in which a notable portion of the original grape-sugar of the must has escaped fermentation, or to which an addition of sugar has been made subsequent to the main fermentation. A dry wine is one in which the sugar, whether originally present or subsequently added, has almost all undergone change in the processes of fermentation. A sparkling wine is one in which a supplementary fermentation is purposely developed subsequent to the bottling, whereby quantities of carbon dioxid are developed and held dissolved under pressure. See Vinum. **W., Barley,** beer. **W.-blue,** the coloring-matter of red wines, a blue substance similar to litmus, possessing the property of turning red in the presence of acids. **W., Burgundy,** a heavy red or white wine from Burgundy, France. **W., High,** commercial ethyl-alcohol. **W., Low,** the products of the first distillation. **W., Maderia,** a heavy wine from the island of Maderia, having a nutty flavor. **W., Malaga,** a sweet wine from Malaga, in Spain; it contains between 13 and 14 percent of alcohol. **W., Milk,** fermented milk. **W., Moselle,** a light wine from the valley of the Moselle, in Germany. **W., Mulled,** a preparation made by adding eggs and spices to wine and then heating it. **W., Oil of.** See **W., Heavy Oil of.** **W., Heavy Oil of,** ethereal oil. **W., Light Oil of,** etherol, a yellowish liquid of a peculiar odor obtained from ethereal oil. **W., Port,** a heavy wine from Oporto, Portugal. **W., Raisin,** wine consisting mainly of a fermented infusion of raisins; it contains also the fermented juice of fresh grapes, sugar, and tartaric acid. **W., Red.** See Vinum Rubrum. **W., Sherry,** a heavy wine from the region of Xeres, in Spain; it is white or brown in color. The sherry wine often marketed seldom contains any wine, but consists of alcohol, water, and flavoring ingredients. **W., Spirit of,** ethyl-alcohol. **W., Whey,** a nutritious and slightly stimulating preparation used in adynamic states. It is made of white wine and milk, from 2 to 8 ounces of the former being added to a pint of the latter at the boiling temperature; the whey is then strained off and sweetened. **W., White.** See Vinum Album.

Heavy wines are wines containing more than 12 percent by weight of alcohol. **Light wines** are wines containing less than 12 percent by weight of alcohol, as claret, Sauterne, or Moselle.

WINGED SCAPULA.—See Sprengel's Shoulder.

WINKING.—See Nictitation.

WINTERGREEN.—See Gaultheria.

WITCH-HAZEL.—See Hamamelis.

WITNESSES, MEDICAL.—See Expert Testimony.

WOLF'S-BANE.—See Aconite.

WOMB.—See Uterus.

WOOL-SORTER'S DISEASE.—See Anthrax.

WORD-BLINDNESS.—See Aphasia.

WORMS.—The worms that are parasitic in man are the *flat worms*, and the *round worms*.

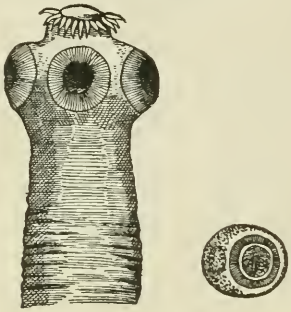
Flat worms (plathelminthes) are subdivided into the fluke-worms (trematodes) and the tape-worms (cestodes).

Fluke-worms (trematodes).—The chief worms of this order are: (1) The distomum hepaticum (liver fluke). See Distomiasis. (2) The distomum heterophyes (Egyptian intestinal fluke). (3) The Schistosomum hematobium (African blood fluke). (4) The schistosomum Japonicum (Asiatic blood fluke). See Schistosomiasis.

Tape-worms or Cestodes

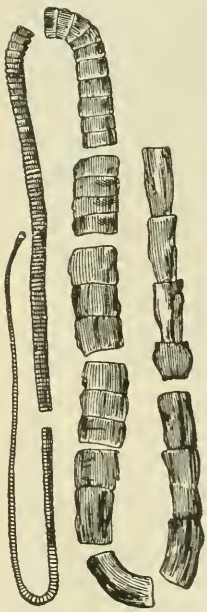
To this order belong (1) the tænia solium; (2) the tænia saginata; (3) the bothriocephalus latus; (4) the tænia echinococcus, the larval stage of which forms the hydatid cyst. See Liver; Hydatid Cyst; (5) the tænia nana (dwarf tape-worm) of southern Europe.

The tænia solium, the "armed tape-worm," is the most common in this country. It is derived from the embryos contained in pork, known as the cysticercus cellulosæ. It is from 6 to 30 feet in length, and has a globular head, or scolex, and

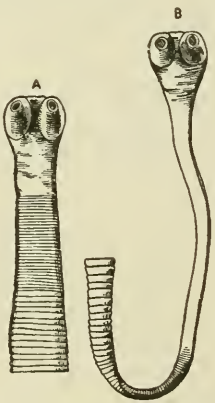


Head and Egg of Tænia Solium.

a slender neck, connecting its numerous flat segments or joints. The head, or scolex, measures about 1/40 inch, has a double circle of hooklets—whence the term "armed tape-worm"—and is provided with from 2 to 4 suckers. The segments or joints (strobila) are flat, and vary from 1/8 to 1/2 of an inch in length. Each segment contains both male and female sexual organs, the uterus being a long, numerously branched tube, in which the ova develop. The ovum measures about



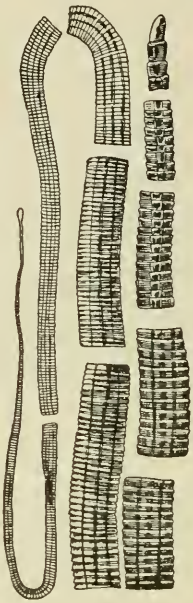
Tænia Saginata.



Cephalic End of Tænia Saginata; A. Retracted head. B. Extended head.

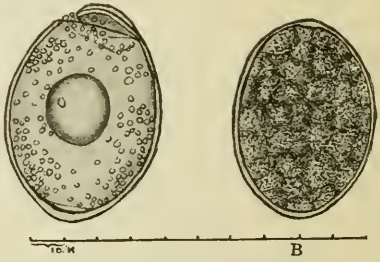
1/1700 inch in diameter. An ordinary tape-worm contains some 5, 000,000 ova. The parasite is firmly embedded in the mucous membrane of the upper third of the small intestines by its hooklets and suckers. The lower or terminal segments represent the adult and complete animal, and are termed the proglottides; these separate from the parasite and are discharged either alone or with the feces.

The tænia saginata, the "unarmed tape-worm"—a not uncommon variety—is derived from the embryos contained in beef, known as cysticercus bovis. This worm is from 10 to 40 feet in length, has a rounded or oval-shaped head that measures about 1/10 of an inch, and has 4 strong and prominent suckers, but no hooklets—whence the term "unarmed tape-worm;" the neck is short and thick and the segments are larger, stronger, and thicker than those of the tænia solium.



Bothriocephalus Latus.—(*Leuckart.*)

The bothriocephalus latus (fish tape-worm, tænia lata), also an "unarmed tape-worm," the largest parasite infesting man, is supposed to be derived from an embryo found in fish. The embryo, or ovum, is introduced into the intestinal canal with the food and drink. The parasite reaches its final growth after its entrance into the intestines. Those handling fresh meats or those eating uncooked animal food are most liable to be affected. Uncleanliness is also an important factor. This worm is larger than the tænia solium and the tænia saginata, the length ranging from 15 to 60 feet; the head is oval, measuring about 1/10 inch; the neck is short, and the segments or joints are nearly three times as broad as they are long. Its color is a dull, bluish-gray. Zoologically considered, this variety is not a true tape-worm.



Ova of Bothriocephalus Latus.

A, after treatment with sulphuric acid so as to render lid apparent; B, natural appearance in fecal matter.

Symptoms.—Not infrequently a tænia produces no symptoms whatever. Usually, however, there are colicky pains throughout the abdomen, inordinate appetite, disorders of digestion, emaciation, constipation, attacks of cardiac palpitation, faint-

ness, disorders of the special senses, and pruritus of the anus and nose. Any or all of these symptoms may be present. A large meal will often remove the majority of the symptoms. In a great many cases the discovery of the segments is the first intimation of the presence of the parasite.

Treatment.—Many remedies have been suggested for the tape-worm. Pomegranate, pepo, male-fern, creosote, glycerin (2 drams to 1 ounce), pelletierin tannate (10 to 20 grains), have all been used. The following is often successful:

℞. Chloroform, Fluidextract of male-fern, } each, ʒ j
Emulsion of castor oil, ʒ iij.

To be taken in the early morning with no food to follow until there has been thorough action of the bowels.

Another successful plan is to boil pomegranate seeds (2 ounces) in 1 pint of water down to 7 ounces; add pumpkin seeds (1 ounce), deprived of their outer coats and beaten to a paste with finely powdered sugar; to this add oleoresin of male-fern (30 grains) made into an emulsion with acacia, and flavored with syrup enough to make 9 ounces. One-third of this mixture is to be taken after a light diet in the morning, a laxative having preceded it the previous day. A second and a third portion are to be taken at intervals of 3 hours, if not previously successful. The worm should be passed while sitting in a warm sitz-bath, in order that the weight of the expelled portion may not break off before the expulsion of the head. It is important to remove the head. See ANTHELMINTICS.

Round-worms or Nematodes

1. Angiostomidæ to which species belong the tropical *strongyloides intestinalis*. This worm has been encountered in the Southern States. The presence of large numbers of this species may induce enteritis and anemia. They may be expelled by ethereal extract of male fern.

2. Filariidæ. See FILARIASIS, GUINEA-WORM DISEASE.

3. Trichotrachelidæ, which includes the *trichiuris trichiura* (trichocephalus dispar, whip-worm) one of the most common and least harmful of intestinal parasites, and the *trichina spiralis* the encysted larvæ of which lodge in the muscles. See TRICHINIASIS.

4. Strongylidæ, to which belong the *Uncinaria*, U. duodenalis (European hook-worm), U. Americana (American hook-worm). See HOOK-WORM DISEASE.

5. Ascaridæ, which includes the *ascaris lumbricodes* (the common round-worm of children) and the *oxyuris vermicularis* (pin-worm, thread-worm, seat-worm).

The ascaris lumbricoides is one of the most common parasites affecting the human body, and develops in the intestines, either after the entrance of the ova of the same or from the so-called "intermediate parasites." Their entrance is effected by means of food and drink. The ascaris is of a brown color, and has a cylindric body from 10 to 20 inches in length and 1/8 to 1/4 inch in circumference; the head terminates in 3 semilunar lips, each having about 200 teeth. The ova are oval-shaped, are produced in immense numbers—some 60,000,000 in a mature female—and have wonderful vitality, resisting extreme heat or cold. Round-worms inhabit principally the small intestines, although they often migrate to other parts. From one to several hundred worms may be found.

Symptoms.—The ascaris lumbricoides may be present in great numbers and yet produce no characteristic symptoms other than those of gastric and intestinal irritation, such as picking the nose, foul breath, colicky pains, nausea and vomiting, diarrhea, and disturbed sleep—tossing from side to side of the bed and grinding the teeth. Any or all of these symptoms may be present or absent; a positive diagnosis may be based upon the passage of the parasite, which is often the first thing to call attention to the condition. The presence of 1 or 2 round-worms may cause no symptoms *per se*. Round-worms have been discharged from abscesses in the abdominal wall, and have obstructed the bile-duct and found their way into the peritoneal cavity.

ASCARIS LUMBRICOIDES AND EGGS.—(*Coplin and Bevan.*)

Treatment.—The fluidextract of spigelia, the fluidextracts of spigelia and senna combined, the oil of chenopodium, the infusion of brayera or kousso, and santonin are the drugs usually employed against the ascaris. One dram of spigelia and from 2 or 3 drams of spigelia and senna, in divided doses, may be given to a child of 3 years. From 5 to 20 drops of the oil of chenopodium may be given on lumps of sugar.

℞. Powdered leaves of brayera, ʒ ss
Mucilage of acacia, Water, } each, ʒ viij.

To be taken at one dose, for an adult.

The fluidextract of brayera may be given in a dose of 1/2 ounce to an adult. Koussin may be given in 40-grain doses in capsule to adults, save to pregnant women.

When used alone, vermifuges should be followed by a full dose of castor oil, or by a saline purge.

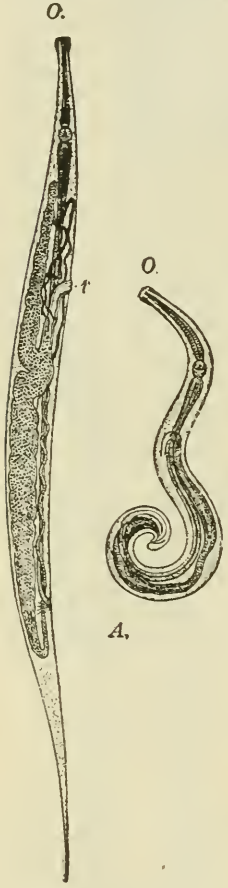
The usual remedy is santonin combined with calomel. The following prescription may be given overnight, and castor oil or citrate of magnesia or some saline purgative may be given the next morning before breakfast:

℞. Santonin, gr. j to iij
Calomel, gr. ss to j.

The santonin may be dissolved in 2 or 3 teaspoonfuls of castor oil and given before breakfast. It should not be repeated more than twice, until the physiologic effects have passed off. Smaller doses should be tried if ordinary santonin administration causes poisoning, or compound scammony powder may be substituted.

Whenever a round-worm is to be attacked, the patient should not be given solid food for from 12 to 24 hours before, so that no residue in the intestinal canal may protect the worm. A small quantity of milk may be taken, and the anthelmintic should be given in the morning, after a night of fasting. See ANTHELMINTICS.

The oxyuris vermicularis develops in the large intestines, either from its peculiar ova or from the so-called "intermediate parasites," these latter finding their way into the bowel with the food and drink or by direct contact. The oxyuris resembles an ordinary piece of white thread, measuring from 1/6 to 1/2 of an inch in length, the head terminating in a mouth with three lips, the tail terminating as a sharp point. The ova are oval, are produced in large numbers —each female containing about 10,000—and are surrounded by a stout envelope, which increases their vitality. The seat-worm, as its name indicates, inhabits the large intestines, especially the rectum, although it frequently migrates to the sexual organs. The worms vary in number, sometimes the parts infested being entirely covered.



OXYURIS VERMICULARIS, to the left, female: to right, male (considerably enlarged). *A*, anus: *O*, mouth: *V*, vulva.—(*Braun, after Claus.*)

Symptoms.—The oxyuris produces intense itching about the anus, with a desire for stool, the passages often containing much mucus, the result of the irritation produced by its presence. Should the worms migrate to the sexual organs, intense itching of these parts results, which in children, unless speedily corrected, leads to masturbation.

OVUM OF OXYURIS VERMICULARIS.

Treatment.—Santonin and calomel, with the use of enemata of quassia, alum, sodium chlorid, or phenol (5 grains to 1 pint of water) according to the age, the injection not to be retained; or an enema of a weak solution of mercuric chlorid (1:10,000). All medicated enemata should be preceded by a large injection of water to unload and clear the rectum. Washing the anus and external genitals with a solution of carbolic acid should also be employed. For the pruritus ani a mercurial ointment is useful. See ANTHELMINTICS.

WOUNDS.—**An incised wound** is a division of the parts, more or less extensive according to the extent of the injury. The fibers have only been simply divided; there is no contusion or laceration; hence they are not likely to take on severe inflammation, nor are they likely to slough or suppurate. By the extent and color of the hemorrhage the surgeon is enabled to judge of the kind of vessel injured: if an artery is wounded, the blood flows rapidly in jets and is of a florid color; if a vein, the bleeding is slow and the blood is of a purple color.

Treatment.—In a recent incised wound the indications are to check the bleeding, to remove all extraneous matter, and to bring the parts in perfect apposition. To check the hemorrhage, steady, and continued pressure upon the surface with a sponge wet with hot corrosive sublimate solution will be sufficient, as a general rule. Should the hemorrhage proceed from a vessel of some size, a ligature should be applied. As soon as the bleeding ceases all clots are to be completely sponged away and all foreign bodies must be carefully removed; the edges are then to be brought together in their entire extent and retained in contact by means of sutures. The wound being dressed, the parts must be placed at rest, in a relaxed position.

The wound must not be entirely closed, lest the secretions be retained; if this is allowed to take place, erysipelas may follow, and there will be risk of septicemia. Drainage must be provided for by means of drainage-tubes; they should be placed in the wound before it is closed, care being taken not to let them remain in too long. When the bloody serum ceases to flow, the tube must be removed, unless there is prolonged suppuration. The ligatures may be cut off short. The wound must be dressed antiseptically.

Lacerated wounds are those in which the fibers, instead of being divided by a cutting instrument, have been torn asunder by violence. The edges of the wound are ragged and irregular; there is little pain or hemorrhage, and the surrounding parts, frequently bruised and discolored, are cold and numb. A lacerated wound differs from an incised one in the mildness of the pain and hemorrhage; in its tendency to suppurate and slough; and in its liability to be followed by erysipelas, septicemia, pyemia, tetanus, and various nervous symptoms. When the lesion is very extensive, the attendant shock being necessarily severe, local sensation is obliterated; but when reaction takes place, the pain is frequently intense.

The treatment of lacerated wounds does not differ greatly from that of incised wounds. All

foreign bodies must be removed, the torn vessels tied, and the edges of the wound gently approximated. Guard against secondary hemorrhage by applying, if possible, a provisional tourniquet to the part, to be tightened on the slightest appearance of blood. Great care must be taken to select a sound portion of the artery when the ligature is applied. Venous hemorrhage may generally be controlled by a compress and roller. All tension is to be carefully avoided, and the edges are to be trimmed with scissors and the wound closed with sutures, using drainage-tubes if necessary.

To moderate the inflammation, bichlorid irrigation is to be used, either warm or cold. Should suppuration present itself, spray the wound with peroxid of hydrogen, wash with corrosive sublimate solution, and dress antiseptically; and when the granulating process is established, apply a solution of 3 drops of nitric acid to 1 ounce of water; opium cerate or dilute ointment of nitrate of mercury may be employed. Should the inflammation run high and gangrene threaten, purgatives should be used and antiphlogistic regimen observed. Anodynes, to allay pain and produce sleep, must be freely given. Secondary hemorrhage may arise as soon as reaction takes place, or it may occur when the sloughs begin to separate; this will probably take place in 5 or 6 days from the date of the injury, and should be carefully guarded against, especially if a large artery is involved. Should tetanus set in, it should be promptly treated with anodynes, using opium, hyoscin, bromid of sodium, and chloral freely; blister the part, or paint it with tincture of iodin, or use cold bichlorid irrigation. See GANGRENE, SEPSIS, SUPPURATION, TETANUS, etc.

Contused wounds are usually produced by greater violence than produces lacerated wounds, and are accompanied by greater disorganization; blood is extravasated, cellular tissue is broken down, muscles are bruised, and the surrounding parts are apt to be disorganized. They bleed but little in consequence of the organization of the parts being destroyed. The pain that accompanies a wound of this kind is in inverse ratio to the extent of the injury. When there is a moderate contusion, the pain is generally severe; and when there is a violent degree of contusion, the patient scarcely suffers any pain until reaction sets in.

Treatment.—If there is hemorrhage, it is to be controlled in the usual manner—by compression, hot water, and ligatures. When an artery lies exposed in contused wounds, ligatures should be applied both above and below the point of lesion. The edges of the wound must be brought together gently, allowance being made for swelling and drainage. If it is necessary, sutures to bring the parts together may be used. The usual antiseptic dressings should be applied. When the inflammation is very active, leeches may be necessary. Pain and nervous symptoms are controlled by anodynes and antispasmodics. After the lapse of a few days, if the wound has healed, the part may be bathed with tincture of camphor, soap liniment, or dilute tincture of iodin.

Contusions producing subcutaneous injuries are caused by blows from a hard, blunt object or by violence applied to the injured part. The surface is not broken, but, as a rule, blood is extravasated under the skin. The injury is to the soft parts under the skin; the connective tissue with its delicate vessels primarily; then the muscles may be crushed or torn; next the lymphatics and arteries; the nerves show the most resistance, though they may be violently stretched.

Contusions vary in degree from a trivial bruise to absolute crushing of the part. In the slightest cases there is no perceptible bruise—mere redness and swelling, with local pain, which soon subsides; in those that are more severe there is ecchymosis, some of the capillaries being ruptured, and blood is effused into the skin or subcutaneous tissues, when swelling and discoloration make their appearance. In the worst cases the amount of extravasation may be enormous, as when a large vessel has been ruptured, or in persons in whom the tissue is easily torn. The scrotum or the loose cellular tissue of the female genitals may be swollen to an enormous size. The case may prove fatal almost at once from hemorrhage alone.

The changes that take place in the part depend upon the amount of extravasation, the tension, the nutrition of the surrounding tissues, and the treatment that the injured part has received. Absorption is the rule; but if the tension is great, as when a large artery is severed, or if the part is not kept at rest, or if the surrounding tissues are not sufficiently nourished, inflammation may ensue when suppuration is very likely to follow. The degree of swelling varies with the amount and situation of the extravasation and with the looseness of the tissues. As a rule, the pain depends upon the amount of tension. In some instances the shock is very severe, as when the testis is squeezed or the abdomen is struck. If a large vessel is torn, the loss of blood may at once prove fatal. When the bruise is superficial, the staining of the skin will soon show itself; when deep, it may not appear for weeks. Traumatic fever is a usual accompaniment, and in cases of large extravasations may be very severe, lasting for several days.

Treatment.—Slight contusions are best treated with cold or evaporating lotions. Lead-water and laudanum and acetate of lead in a decoction of powdered opium are especially useful. When the extravasation is considerable, uniform, gentle compression with many layers of cotton-wool checks the increase, limits the hyperemia, and promotes absorption. This treatment will be found efficacious even when bullæ are forming upon the skin. The fluid should be drawn off through a minute puncture, and absorbed with cotton-wool or thick blotting paper; the epidermis should then be carefully replaced and a little iodoform dusted on or collodion painted over, and then cotton-wool carefully applied. In very severe cases when there is risk of suppuration, the tension may be relieved by the aid of the aspirator. Only a small portion of the fluid need be removed—sufficient to relieve the tension; this will at once diminish the hyperemia, when absorption will proceed unchecked.

The contusion is sometimes so severe as to destroy the skin. If the injury is small, and the deep structures are not badly implicated, the slough should be allowed to separate itself; but when the skin has been stripped off from the subcutaneous tissue to some distance above the apparent seat of injury, and it is thought advisable to amputate, the line of incision must be carried well above, or the flaps will be sure to slough.

A punctured wound is one made with a narrow-pointed instrument, such as needles, nails, splinters, swords, bayonets, scissors, hooks, etc. These wounds are much more dangerous than cuts or incised wounds, from the effects they produce on the injured part.

A slight punctured wound through the skin into the cellular tissue will sometimes be followed by red lines along the course of the absorbent vessels, from the wound to the absorbent glands. If a tendinous structure is punctured, alarming symptoms will frequently follow. In punctured wounds their depth is usually much greater than their width, making it frequently difficult to determine the amount of injury inflicted. The pain is often very great, depending upon the injury sustained by the nerves. Punctured wounds are rarely attended with much hemorrhage, and sometimes with practically none. They are very liable to be followed by erysipelas, lymphangitis, abscess, and wasting of the muscles.

The treatment consists in the extraction of foreign substances, in checking hemorrhage, in moderating inflammation, and in preventing the development of nervous symptoms. All such articles as fish-hooks and similar barbed substances must be extracted by counter-openings or by pushing them through the part in which they may be embedded. If bleeding arises by reason of an artery having been laid open, it must be exposed and tied at both ends. An anodyne should be administered and the parts should be dressed antiseptically. Great care must be exerted to see that full and sufficient drainage is established. It is always safe, and frequently absolutely necessary, to change a punctured wound into an incised wound by free incisions.

Gunshot wounds are injuries caused by substances discharged from firearms, by fragments of stone or wood struck thereby, and by the bursting of firearms and shells. See Gunshot Wounds.

Dissection wounds are those contracted in the examination of dead human bodies. The first symptom that attracts attention is a stinging or burning sensation; upon examining the part a little whitish vesicle is observed, extremely sensitive on pressure. When the vesicle breaks, a small ulcer is exposed. The pain by this time is very great, the sore enlarges, the swelling increases, and the part is hot, tense, and numb. A red line is usually seen, extending from the point of inoculation along the arm to the axilla. As the disease spreads the whole limb becomes enormously enlarged, pitting on pressure and looking dusky and erysipelatous. Cases occur in which the symptoms begin at the axilla and extend thence up the neck and down the side. In the worst forms the disease soon reaches a crisis, the system rapidly falling into a typhoid state.

Treatment.—As soon as a wound of this kind is received, it should be thoroughly washed with warm water and soap; this should be followed by suction by the mouth. If the wound is small, it should be dilated; if it has bled, it should be thoroughly cauterized with acid nitrate of mercury, nitrate of silver or hydrochloric, nitric, or sulphuric acid. If a vesicle forms, it should be freely opened, and then thoroughly cauterized; antiseptic dressings should be applied, and, if necessary, a purgative should be administered. To relieve the severe pain and the restlessness, anodynes should be freely employed, and if the skin is hot and dry, aconite or veratrum viride should be administered. To meet the typhoid symptoms, milk-punch, quinin, iron, and such other treatment should be resorted to as will support and sustain the patient.

Wounds of the various members, regions, and organs are considered under their respective headings. See Abdomen (Injuries), Neck (Injuries), Kidney (Injuries), etc.

Listerian Methods of Dressing Wounds.—Carbolic acid was the first antiseptic, but from its volatility and slowness of action as a germicide it was replaced by corrosive sublimate. But this proved irritating, and was precipitated by the albumin of the blood-serum.

What might be called the **third method** was the antiseptic dressing called **serosublimate gauze**, consisting of a gauze charged wth a solution of corrosive sublimate in the serum of horses' blood. This was found difficult to manufacture, and was harsh and nonabsorbent.

The fourth method consisted in a combination of chlorid of ammonium and bichlorid of mercury, called **sal alembroth.** This was likewise objectionable because of its ready solubility in the blood-serum.

Fifth method, a gauze containing 3 or 4 percent by weight of the biniodid of mercury. This proved irritating to the skin.

A sixth method consists in the employment of gauze impregnated with a solution of a double cyanid of zinc and mercury colored with a dye. This is said to be nonvolatile, unirritating, insoluble in water, and only soluble in 3000 parts of blood-serum. It possesses but little germicidal power, while but 1 : 1200 keeps animal fluids free from putrefaction.

Lister's antiseptic dressing has a base solution of bichlorid of mercury, 1 : 4000, with small quantities of potassium cyanid, mercuric cyanid, and zinc sulphate added.

Dissolve the two cyanids in 2 ounces of distilled water and add the zinc sulphate dissolved in 6 ounces of distilled water; collect the precipitate (which will be thrown down) upon a filter, and wash thoroughly by pouring over it (while still in the filter) distilled water. While the precipitate is still moist, diffuse it in 8 ounces of distilled water Dissolve the hematoxylin in 1 1/2 drams of dis-

ing, in some forms of mental or emotional disturbance such as fear, and when much fluid has left the body as in case of excessive diarrhea. It often occurs in women over 50 years of age. The lips are dry and scaly, the tongue fissured like crocodile's skin, the cheeks and gums glazed and covered with crusts. The teeth are carious and slowly crumble away. The parotid glands become swollen and painful, and the skin dry and harsh. Frequently a similar condition is met with in the nose and conjunctiva. The patient, in addition to dryness of the mouth, may complain of loss of taste, only a strong solution of quinin being perceived, or of subjective sensations as a salt flavor in the mouth.

Treatment.—Tonics and mouth-washes with removal of carious stumps, and the fitting in of suitable dentures. Sialogogs, such as pilocarpin, are useless, perhaps harmful.

X-RAYS.—See ROENTGEN RAYS.

Y

YAWS.—Frambesia; pian; polypapilloma tropicum; amboyna button; parangi; coco; endemic verrugas. A tropical contagious disease of the skin, of long duration, characterized by dirty or bright red raspberry-like papules and nodules, tubercles, which undergo ulceration, appearing usually on the face, toes, and genital organs. It is most frequent in young colored people. It is believed to be caused by a slender spirochete, the *Spirochæta pallidula*. Treatment does not differ materially from that of other tubercles of the skin. Very satisfactory results are reported from the use of intramuscular injections of salvarsan.

YEASTS.—Blastomycetes or saccharomycetes are responsible for fermentation in many forms and are the cause of blastomycosis (*q. v.*) Cerevisin, the spores of the saccharomyces cerevisiæ, is claimed to be beneficial in furunculosis.

YELLOW FEVER.—An acute, specific infectious disease, remarkably limited in its geographic distribution. It is prevalent chiefly in tropical and semitropical regions. Upon the western hemisphere it occurs along the shores of the Gulf of Mexico and of the Caribbean Sea and in adjacent islands, and along the Southern Atlantic coast of the United States, extending into the interior of the Southern States along railway lines and navigable rivers. In South America it appears on the Atlantic coast as far south as Montevideo and on the Pacific coast in Peru. In Africa it is limited to the west coast and contiguous islands; in Europe, almost exclusively to the Iberian peninsula. So far, the continents of Asia, Australia, and Polynesia have been exempt. Endemic foci exist now principally upon the island of Cuba, at Rio de Janeiro, and upon the Senegambian coast.

Yellow fever is characterized by a fever of sudden onset, of short duration (3 to 5 days), and of one paroxysm.

Etiology.—Recent experiments carried on in Cuba under the auspices of the medical department of the United States army demonstrate the rôle of the mosquito in disseminating yellow fever infection.

The specific organism that is the cause of this disease has not yet been demonstrated. The bacillus icteroides of Sanarelli, and the bacillus of Sternberg, have both been rejected. The *Stegomyia fasciata* serves as the intermediate host for the unknown parasite. See Mosquitos. The disease is not conveyed by fomites. About 12 days or more must elapse before the contaminated mosquito is capable of infecting. In the absence of the *Stegomyia fasciata*, as has been demonstrated, yellow fever is not contagious. The disease can also be transmitted by the injection of blood taken from a yellow fever patient.

Classification and Symptomatology.—Like most other acute infectious diseases, yellow fever occurs in different grades of severity. It is sufficient to mention the following forms: viz., mild, moderate, grave, and fulminating. Conditions of the individual likely to aggravate the attack are those having a similar effect in other fevers: viz., loss of sleep, severe and prolonged physical exertion, excessive sexual indulgence, mental depression—as from fear, anxiety, melancholy, excesses in eating and drinking, and complications from preexisting or intercurrent diseases. Conditions favoring severity of epidemics are not fully understood, but unhygienic influences—as overcrowding, filth from decomposing vegetable and animal products, imperfect drainage and sewerage, inadequate ventilation, lack of sunlight, excessive heat and humidity—undoubtedly play an important rôle. An epidemic moderate in the beginning may increase in virulence as it progresses.

The period of incubation is usually short: most frequently from 1 to 5 days, and rarely exceeding a week.

The onset is commonly sudden, the patient generally being able to state definitely the hour of the attack. Less frequently, the invasion is preceded by anorexia, malaise, headache, and mental and muscular debility. A well-pronounced rigor is mentioned as an initial symptom by many authors, but most patients will mention only a sense of chilliness and discomfort.

The fever rises rapidly, and often reaches its acme within a few hours from the onset. There are cutting pains through the forehead; the eyes ache; the muscles of the back, loins, thighs and calves are sore, and often ache severely even in mild cases. These symptoms continue during the febrile stage. It should be noted that the pains, except those in the head, involve the muscles rather than the joints. The face is turgid, not infrequently a dusky red; the upper lip is often swollen. The appearance resembles that of the early stages of typhus or the stage of measles before the eruption, with an addition of slight or well-marked jaundice. The conjunctivæ are congested and shiny, with a yellow tinge; the eyes are sometimes intensely red and sensitive to light. The jaundice becomes more distinct after the first or second day, the skin showing the same combination of capillary stasis with an icteroid hue as the eyes. Yellowness may be demonstrated by pressure or pinching when otherwise it would be unnoticed. As the case progresses jaundice may be intense and unmistakable.

The surface of the body may be hot and dry, but more frequently there is a tendency to diaphoresis, which is especially marked at the end of the febrile stage. In some fatal cases the skin remains dry until death; in others, with the stage of depression there is a cold, clammy sweat. Great significance has been attached to a peculiar musty odor given off from the body; this symptom is un-

doubtedly present in some instances, but more frequently it is absent. The mental condition is one of alertness and anxiety.

Gastrointestinal Symptoms.—The appetite is lost from the beginning, but returns at the expiration of the fever. The patient is likely to be thirsty throughout the attack. The tongue is whitish in the center, with red tip and edges, and is pointed. The gums are swollen and are disposed to bleed easily. There is marked tenderness and pain in the region of the stomach; nausea and vomiting are very common, the vomitus in the first stage being chiefly the ingested fluids with mucus. In the stage of depression the tendency to passive hemorrhages is manifested by vomiting of blood more or less discolored and disintegrated by the gastric secretions; this is the black or coffee-ground vomit to which such grave significance is attached. It is often ejected with great force and in large quantity; at other times it may be small in amount and mixed with mucus, or there may be an active hemorrhage and vomiting of pure blood. The bowels are nearly always constipated; hemorrhage from the intestines is not infrequent, and is also likely to occur from the nose, gums, kidneys, and uterus.

The urine is scanty; there is a decided diminution in the excretion of solids, and albumin is found so constantly as to be generally regarded as one of the pathognomonic symptoms. It usually appears within 72 hours; there may be only a trace found by careful testing of the evening urine. In the second stage, or stage of depression, the amount of albumin may be large, granular and other casts are found, and there is a decided tendency to suppression, with the consequent uremia. The early occurrence of an acute parenchymatous nephritis in a large proportion of cases is of the utmost importance, both from a diagnostic and a prognostic standpoint. This aspect of the subject will receive further notice under the heading of differential diagnosis.

Course of the Fever.—As previously observed, yellow fever is a disease of one short paroxysm, lasting usually from 2 to 5 days, but sometimes continuing longer and assuming an irregular or typhoid aspect. The temperature curve is characterized by a sudden sharp ascent, reaching the highest point most frequently on the first day; from this time the line ordinarily descends rapidly until the normal point is reached, which is the termination of the first stage. In mild cases the patient may rapidly become convalescent; in moderate or severe cases the second stage, or stage of depression, supervenes, when the temperature may be normal, slightly above normal, subnormal, or elevated, and the fever may run an irregular course. It is in this stage that the serious effects of the toxins upon the blood and upon the various organs are manifested by passive hemorrhages and uremia. Sternberg states that, out of 192 cases recorded by Faget, Jones, and himself, the highest temperature was reached on the first day in 102, on the second in 54, and on the third in 33. The initial temperature ranges from 101.6° to 104.5° F. The height of the fever is an index to the gravity of the case. Out of 10 cases approximating a temperature of 105° F., only 1 recovered. The typical febrile course is likely to be disturbed by complications of various kinds.

The Pulse-rate.—The pulse of yellow fever is characterized by its abnormal slowness and by its want of correlation with the temperature. This latter phenomenon—known as Faget's law—possesses great diagnostic significance. It is exhibited best during the first 3 days. In other fevers the rule is that the rapidity of the pulse-rate increases with the temperature, while in yellow fever, though the thermometer may show a rise of from 1 to 4 degrees, the pulse continues to fall.

Diagnosis.—In order to aid physicians in the prompt recognition of yellow fever, and to assist in its prevention as far as possible, the following excellent presentation of the subject, made by Dr. Samuel L. Bemis, and adopted by the State Board of Health of Louisiana, is quoted.

The following group of symptoms is considered to be indicative of yellow fever:

Group First.—A person after (1) a sudden attack has (2) a fever of one paroxysm, attended with (3) marked congestion or blood stasis of capillaries of the surface, conjunctivæ, and gums, with (4) a history of probable exposure to infection and (5) no history of a previous attack of yellow fever.

Group Second.—A person after (1) a sudden attack has (2) fever of one paroxysm, followed by (3) unusual prostration, (4) albuminous urine, and (5) yellowness of the conjunctivæ or skin, and having (6) no positively authenticated history of a previous attack of yellow fever.

Group Third.—A person has (1) a fever of one paroxysm, (2) albuminous urine, (3) black vomit, (4) suppression of urine, or (5) general hemorrhagic tendency under (6) circumstances when exposure to infection is a possibility.

The following symptoms are held to be suspicious of yellow fever when associated with a fever of one paroxysm in a person who has never had the disease:

1. Suddenness of attack, either with violent pains in the back and head and injected eyes and face, or with marked congestion of the superficial capillaries.
2. Want of that correlation between pulse and temperature usual to other forms of fever.
3. Albuminous urine.
4. Black vomit.
5. General hemorrhagic tendency.
6. Yellowness of skin.
7. Any case respecting which reputable and experienced physicians disagree as to whether the disease is or is not yellow fever.
8. Any case respecting which efforts are made to conceal its existence, full history, and true nature, in violation of ordinances requiring a report of the same.

Differential Diagnosis.—The disease with which yellow fever is most likely to be confounded is dengue, not only from the remarkable resemblance of these fevers, but on account of a similar geographic distribution and because of their frequent concurrent prevalence. "In time of appearance,

and generally in geographic distribution, they seem related to each other. Dengue has, however, prevailed in Asia and Egypt, where yellow fever is unknown. Both diseases are arrested by severe frosts. Both dengue and yellow fever are diseases characterized by one febrile paroxysm," (Foster).

In view of the possibility of dengue and yellow fever coexisting, the following table (from Jackson) is appended:

	Yellow Fever.	Dengue.	Malarial Fevers.
Temperature	Fever of one paroxysm, as a rule. High temperature for 3 days.	Fever of two paroxysms and a remission, as a rule. Fever high in first period; low in second.	Fever of several paroxysms with remissions or intermissions. Moderate temperature, as a rule.
Duration of fever	3 to 7 days	5 to 8 days	Variable duration. May last weeks.
Incubation	Human incubation, 1 to 6 days. Mosquito incubation about 12 days.	Short incubation, 1 to 5 days; average less than 3 days.	Human incubation, 1 to several days. Mosquito incubation, about 10 days.
Vomiting	Very common symptom—both bilious and hemorrhagic (black vomit).	Not common. Bilious vomiting in some cases.	May or may not be present. Bilious in character.
Pulse	At first, rapid and bounding; later, abnormally slow and soft. Does not correspond with temperature.	Corresponds with febrile temperature.	Corresponds with febrile temperature.
Jaundice	Characteristic and constant	Rare	Subicteric jaundice rather common.
Eruptions	Rare and not characteristic	Common and distinctive	Rare and not characteristic.
Urine	Scanty; often completely suppressed, and albuminous from early stages.	Quantity ample. Rarely albuminous.	Not usually albuminous nor suppressed.
Mentality	Apathy common. Consciousness preserved as a rule.	Preserved	Delirium not uncommon.
Hemorrhagic symptoms.	Frequent and often fatal. (Gastric and intestinal chiefly.)	Of rare occurrence and of slight consequence.	Rare except in pernicious cases and in malarial hemoglobinuria.
Fatality	Average mortality 25 per cent	Non-fatal	Rarely fatal if treated properly.
Convalescence	Rapid and without sequels	Rather prompt but with arthralgic and myalgic sequels.	Slow, succeeded by anemia; and is apt to recur.
Immunity	One attack confers subsequent immunity.	Doubtful immunity	No immunity.
Response to treatment.	Abortive or curative treatment negative.	Symptomatic treatment alleviates.	Satisfactory, specific (quinine) treatment cures.
Blood condition	Incomplete coagulation and free hemoglobin in serum. Red cells not greatly altered. White corpuscles either increased or decreased.	Leukocytosis common. Decreased leukocytes claimed by some observers.	Malaria parasites and pigment present. Leukopenia with a relative increase of large mononuclear leukocytes, the rule.

The symptoms that have heretofore been relied upon to differentiate yellow fever and dengue are the occurrence in the former of albuminuria, the characteristic facies (inclusive of jaundice), the divergent pulse and temperature, and excessive irritability of the stomach and passive hemorrhages. The absence of such symptoms in the main, the presence of an eruption, and a want of mortality in connection with the ordinary febrile phenomena are considered as characteristic of dengue. The diagnostic significance of the foregoing symptoms requires modification: that is to say, a careful examination of the urine in cases of undoubted dengue may demonstrate a mild and evanescent albuminuria. A certain proportion of these cases may have slight jaundice, severe nausea, vomiting, and a disposition to passive hemorrhages from mucous membranes.

Aside from the increased mortality of yellow fever and the characteristic postmortem findings, the differential diagnosis between these two diseases can be made by the symptom-complex of an acute nephritis in yellow fever and its absence in dengue. In the latter disease simple parenchymatous changes may occur in the kidneys, manifested by a slight and temporary albuminuria; while in the former, in a series of cases many will afford incontestable evidence of a severe nephritis: viz., scanty urine, of high color and high specific gravity, intense and persistent albuminuria, hematuria, casts, a decided tendency to suppression, and the accompanying uremia. There is no

authority who will claim that a serious kidney involvement belongs to the pathology of dengue; on the contrary, it is universally conceded that the nephritic complications dominate the clinical picture in every severe case of yellow fever.

Prognosis.—Reference has been made to the fact that yellow fever is a protean disease, with a mortality varying in the extreme degrees from 85 percent, as in the epidemic of 1853, to 4 percent, as in that of 1897. Further illustrating this fact is the experience of Touatre, who states that in the epidemic of 1867 in New Orleans he lost an average of 1 patient in 3; in 1870, 1 in 14; in 1873, 1 in 13; in 1878, 1 adult in 29, 1 child in 52; in 1897 he treated 76 patients—33 adults and 43 children—without a death.

The death-rate will be affected: (1) By the comparative virulence or attenuation of the microorganism that produces the disease; (2) by idiosyncrasies, age, race, and acclimatization of the patients; (3) by intercurrent complications. The patient may be overwhelmed by the intensity of the toxins—suddenly struck down, with vertigo, stupor, coma, or convulsions; with weak, fluttering pulse; cold, clammy skin; involuntary discharges; and profuse hemorrhages, speedily terminating in death. In these fulminating cases the temperature is likely to be subnormal and the yellow discoloration of the skin is absent.

In individual cases three important prognostic indications are afforded: (1) by the height and range of the temperature; (2) the severity of the kidney complications; (3) the disposition to hemorrhage.

Touatre makes the following observations: "When the fever reaches its maximum at the outset, and defervescence is continuously noted at each visit, the disease is mild. When the fever ranges between 103° and 104.5° F., even during the first 3 days, with remissions of at least a degree in the morning, and the exacerbations are less and less pronounced each night, the patient always recovers. When the fever ranges between 104° and 105° F., still with remissions of at least 1 degree, but with exacerbations above the previous day, the disease is grave, but recoveries are more numerous than fatal results. When the fever reaches 105° F. or above within the first 12 hours, the attack is nearly always fatal, unless by heroic treatment the temperature can be reduced at least 2 degrees. When defervescence is not maintained after the temperature has reached 105° F. or above, and the fever rises to the same point again, death is almost certain. A temperature above 105° F. during the first 24 hours in adults gives slight hopes of recovery.

The extent of kidney involvement, and of consequent functional incapacity, is an important prognostic guide. The severe symptoms of the stage of depression, the vital prostration and the nausea, vomiting, headache, stupor, coma, and convulsions are chiefly of uremic origin.

If the urine is abundant in spite of a decided albuminuria, the chances for recovery are good. Scanty urine, with much albumin on the second day, indicates danger. Recovery rarely, if ever, ensues after complete suppression has lasted as long as 12 hours. The disposition to passive hemorrhages, as manifested by black vomit, and by bleeding from the gums, intestines, uterus, nose, and other mucous surfaces, is of serious import, but is not necessarily attended by a fatal result.

Prophylactic Treatment.—Yellow fever patients should be isolated and screened against the mosquito. Nonimmunes should be guarded against infection by the mosquito by screening houses, etc. Prophylaxis consists essentially in the destruction of the mosquito. The stegomyia fasciata is a house mosquito, biting mostly by day, disliking both sunlight and darkness. It is often carried long distances by railway or ship. The mosquitos should be destroyed by drainage and insecticides. Breeding places should be covered with petroleum, etc. Disinfection of their lurking places is best accomplished in the house or aboard ship by means of fumigation with sulphur or formaldehyd. See DISINFECTION.

Medicinal Treatment.—The important fact to be remembered in the treatment of yellow fever is that it is a self-limited disease of short duration, and one likely to be complicated by serious lesions of vital organs. There is no specific. Treatment should begin promptly, and while it should be energetic and careful, all doubtful, useless, and harmful medication should be avoided.

1. The first indication is absolute **rest** in the recumbent posture from the onset until convalescence is well advanced. There is no disease in which this rule is more imperative, or in which its disregard is so fraught with serious consequences. The action of the toxins upon the heart, kidneys, stomach, intestines, liver, brain, and muscular structures is aggravated by physical exertion. Hence the patient should be put to bed at once, should not be allowed any imprudent movements in bed, and should be rigidly kept there until well on the road to recovery.

2. The second indication is **ventilation, cleanliness, and disinfection** of the sick-room and of all its appurtenances. The popular idea that fresh air should be excluded by closure of windows and doors must be combated by the physician. In the intensification of the infection by overcrowding and inadequate ventilation, yellow fever resembles typhus. While drafts should be avoided and chills from uncovering should be prevented, there should be an abundant admission of fresh air, and, if possible, of sunlight. Scrupulous cleanliness of bedding and clothing and of the body of the patient should be maintained. All excretions should be disinfected and speedily removed.

3. The third indication is **prompt evacuation of the gastrointestinal canal.** If the stomach should contain food at the onset, a mild emetic, such as a dose of ipecac or a glass of warm water with mustard and common salt, should be given. The bowels should be emptied quickly. Castor oil, on account of the rapidity, mildness, and certainty of its action, is used by many; but its nauseous odor and taste are objectionable to most persons, hence the effervescent salines are to be preferred.

Calomel is excellent, not only for its purgative, but also for its antiseptic effect: from 3 to 4 grains in divided doses for adults, and proportionately smaller doses for children, is usually sufficient; it should be given during the first 24 hours. Afterward, 1 to 2 daily movements should be obtained by enemata of warm solutions of common salt, sulphate of magnesium, or sodium, to which glycerin, for its osmotic effect, is a useful addition. Purgatives are useful, not only to empty the intestines of irritant and undigested contents, but to prevent autoinfection, to relieve congested blood-vessels, to allay nausea, and to act vicariously on the kidneys.

4. The hot mustard foot-bath, for its diaphoretic and revulsive effect. It should be given under blankets, and as hot as the patient can bear, hot water being added from time to time. Properly given, the foot-bath produces free action upon the skin, attracts the blood from the upper to the lower parts of the body, relieves internal congestion, and allays pain.

5. **Attention to Diet.**—Contrary to the rule in treating other fevers, in yellow fever the patient should be starved. During the first 3 or 4 days, and longer in severe cases, no food whatever should be allowed, and then only the blandest and most digestible liquids, in small portions, as milk with lime-water, Vichy, or barley-water; buttermilk; wine whey; or corn, oatmeal, or barley gruel. Meat, eggs, beef-tea, or nitrogenous foods of any kind should not be given until the urine is abundant and free from albumin. Only those who have treated yellow fever can appreciate the necessity for such rigid rules of diet. It should be remembered that digestion is in abeyance, that the gastrointestinal mucous membrane is intensely congested, that nausea and vomiting are present, that hemorrhage is likely to ensue, that nature warns us to give the stomach rest, and that food now is poison. Probably more patients have been killed by indiscreet eating during convalescence than by almost any other cause. The physician should preceed carefully, gradually increasing the amount and changing the character of the food as the symptoms indicate restoration of the functions of the secretory and excretory organs.

6. **Diluents, Diaphoretics, and Diuretics.**—Alkaline carbonated waters, as Vichy or Apollinaris, should be freely used, and are beneficial in various ways: they allay nausea, correct excessive acidity, cleanse the stomach, and promote action of skin and kidneys. Ice may be added or not according to taste; the quantity taken may be regulated by the tolerance of the stomach. Warm drinks, as orange-leaf and watermelon-seed tea, serve a useful purpose in the same way, and are extensively used as domestic remedies. While it is important to promote activity of skin, sweltering the patient beneath heavy blankets and exhausting him by excessive sweating should be prohibited. Pilocarpin, on account of its depressing effect, should be very carefully prescribed, if at all. Stimulating diuretics should not be given; it is better to flush the kidneys by the free use of diluents than to run the risk of increasing congestion by the effects of turpentine and the like.

7. **Regulation of the Temperature**—Hyperpyrexia is best controlled by cold spongings and baths. Ordinarily, repeated spongings, as required, with water or with a mixture of water, vinegar, and alcohol, at a temperature varying according to the height and obstinacy of the fever, are preferable to the cold bath; lifting the patient in and out of the tub, with its attendant perturbations, is objectionable. Touatre, however, is an earnest advocate of the cold bath in cases where the temperature reaches 104°–105° F. He uses the bath boldly, and claims that the mortality in such cases can be reduced in this way only. Opinion is divided as to the use of the coal-tar antipyretics; if used at all, they should be prescribed only during the first 24 hours, and then in moderate doses. The effects produced by these remedies are undoubtedly pleasant in relief of the symptoms; but in a disease where cardiac depression is so marked a feature, care should be taken not to injure the patient for the sake of mere temporary relief.

8. **Treatment of Complications.** *Nausea, Vomiting, Black Vomit.*—Direct medication to meet these symptoms is not usually required. In addition to the general measures already recommended, such as rest, abstention from food, iced carbonated drinks, purgatives, and enemata, the following simple procedures are advisable: sinapisms to the epigastrium; ice-cold cloths to head, face, and neck; cocain tablets in 1/4-grain doses; a combination of creosote and subnitrate of bismuth. Rectal injections of chloral hydrate—from 15 to 20 grains for adults, and proportionately smaller doses for children—will not only often arrest the vomiting, but will allay nervous excitement and produce sleep. It should be remembered that the severe gastric symptoms are often of uremic origin, and that black vomit is due to profound blood and tissue changes, hence rational treatment should be directed to the underlying cause rather than to the symptom.

Uremia, Albuminuria, Scanty and Suppressed Urine.—In addition to the general measures indicated which are, largely beneficial, in actual or threatened kidney trouble we must consider additional resources needful in the presence of these grave complications: viz., intravenous, intracellular injections, or high rectal enemata of normal solution of chlorid of sodium in sterilized water and wet and dry cups over the region of the kidneys. These means will sometimes succeed when others have failed in impending anuria.

Restlessness and insomnia are best relieved by hydrated chloral administered by the rectum according to the necessities of the case.

Malaria.—When the case is thus complicated, quinin should be given. The routine treatment by this agent should be condemned.

Tendency to heart failure is to be treated by the moderate use of iced champagne or whisky, and by hypodermic injections of digitalis, strychnin, or caffein.

A nurse who will carry out the physician's instructions to the letter is indispensable. Many

patients with yellow fever are frightened to death. The conduct of attendants should be such as to quiet fear and excitement, instead of contributing to them. It is only by careful attention to details that success may be attained in severe cases. If possible, there should be an attendant who has had previous experience with the disease.

Sternberg's treatment, by means of which a death rate of only 7.3 percent was secured, consists in giving 7 1/2 grains of sodium bicarbonate and 1/60 grain of bichlorid of mercury every hour with a liberal amount of water. In addition, a hot mustard foot-bath is advised during the first day, no food being given for 3 days, and then stimulants and a milk diet are ordered. Cold sponging and cold applications to the head and sinapisms over the stomach and lumbar regions are recommended.

Serum treatment has not yet proved satisfactory.

YEO'S METHOD.—A method of treating obesity, consisting of a dietary that limits the amount of farinaceous food, prohibits sugar, limits the amount of liquids taken with the meals, but encourages the drinking of large amounts of hot or warm aromatic beverages between meals.

YERBA SANTA.—See ERIODICTYON.

Z

ZEA (Corn Silk; Maize; Indian Corn).—The fresh styles and stigmas of *Zea Mays*, the maize or Indian corn. It contains *maizenic acid*, a fixed oil, resins and salts. Dose, of a fluidextract, 1 to 2 drams; of an infusion (1 to 8), 4 to 8 ounces, almost *ad libitum*. There are no official preparations.

Zea is a certain but mild diuretic when given in full doses at short intervals. It has been used with success for incontinence of urine, uric and phosphatic gravel, gout, rheumatism, urethritis, pyelitis, acute and chronic cystitis, cardiac dropsy and obstructive valvular disease of the heart.

ZINC (Zincum). Zn = 64.9; quantivalence II.—A metallic element, with a lead-like luster. It is represented in medicine by several of its salts, all of which are more or less poisonous. In small doses it is tonic and astringent; in larger quantities, a strong emetic. It is used mainly in the form of lotions in conjunctivitis, in various catarrhs, and in certain skin-diseases.

Preparations.—**Z. Acetas**, soluble in 3 of water and in 36 of alcohol at 59° F., in 1/2 of boiling water and in 3 of boiling alcohol. Used locally as an astringent in solution of 1 or 2 grains to the ounce, or internally in doses of 1/2 to 3 grains. **Z. Carbonas Præcipitatus**, insoluble in water or alcohol, but soluble in acids with copious effervescence. Used locally as a protective. **Z. Chloridum**, very soluble in water and in alcohol; very deliquescent. Is tonic and escharotic. For internal use a solution in spirit of ether is the most convenient form, strength 1 dram to the ounce, of which 4 to 8 minims may be given twice daily in water. Strength of injections and collyria, 1 to 2 grains to the ounce. **Liquor Z. Chloridi** is an aqueous solution, containing about 50 percent of the salt. A clear, colorless, odorless liquid, of a very astringent, sweetish taste and an acid reaction. A powerful disinfectant for sinks, drains, etc. Used also as an injection in gonorrhea, leukorrhea, etc., in dilute solution, 1/2 to 1 percent. *Burnett's Disinfecting Fluid* is similar to the above, but slightly stronger. **Z. Iodidum**, very soluble in water and in alcohol. Dose, 1/2 to 2 grains in syrup. **Z. Oxidum**, insoluble in water or alcohol; soluble without effervescence in dilute acids; also in ammonia water. Dose, 1 to 10 grains in pill. **Unguentum Z. Oxidi** has of zinc oxid 20, benzoinated lard 80. **Z. Phenolsulphonas** (*Zinc Sulphocarbolate*), very soluble in water and in alcohol. Dose, 1 to 5 grains. **Z. Stearas.** Used locally as a dressing powder and a vehicle for dry antiseptics. **Unguentum Z. Stearatis**, strength 50 percent, made with white petrolatum. **Z. Sulphas**, soluble in 0.6 of water, insoluble in alcohol. Dose, as emetic, 10 to 20 grains; as a tonic and astringent, 1/10 to 2 grains in pill. **Z. Valeras**, soluble in about 50 of water and in about 35 of alcohol. Dose, 1/4 to 4 grains in pill.
