Symptoms and Diagnosis of Acute Synovitis.—The superficial position of most of the joints facilitates the recognition of a simple synovitis. Except in the joints deeply seated, like the shoulder and the hip, the four cardinal symptoms of inflammation can be easily recognized. In the latter joints only are we called upon to look to other than the characteristic symptoms for recognition of the condition. As is noted in the symptomatology of joint injuries, the patient first complains of pain, which, as a rule, is proportionate to the rapidity of the joint distention with fluid. Generally the pain is complained of in the joint itself. Only in exceptional cases, as in the hip, is it felt in a part far removed. With the pain there is associated more or less tenderness, often felt at one or more points along the articular line rather than over the entire area. In cases of traumatic origin the reason for this is apparent. In other cases Volkmann has ascribed these special points of tenderness to the deposit beneath them of fibrinous material. It is more probable, however, that these special points of tenderness correspond to the attachment of ligaments or duplicatures of the synovial membrane, which are stretched by unequal tension of the effusion in the joint when pressure is made over them. When pain is not complained of when the limb is at rest, it will often be found to be very severe when any effort at motion, voluntary or passive, is made. The swelling is the most marked feature of a simple synovitis. Often within 24 or 48 hours it is sufficiently developed to have effaced all the normal outlines of the joint.

The development of an acute synovitis is very frequently, although not always, associated with definite change in the position of the limb. For the most part one midway between flexion and extension is assumed, and maintained throughout the entire course of the disease. The knee becomes flexed upon the thigh, the foot becomes

placed in the position of talipes equinus, the hip becomes flexed and abducted. When the shoulder is involved, the arm is held close to the side of the body; in disease of the elbow the forearm is extended at an angle of 140 degrees; in disease of the wrist there is a slight drop, the fingers are maintained almost in extension, and the hand somewhat flexed on the forearm. The assumption of these positions has been accounted for through the fact that by them an equal pressure on different parts of the joint surface is secured, since they are positions taken by the joints when injected experimentally. This explanation does not obtain in cases of synovitis, since in some of great distention with serous fluid no faulty position is assumed. In every case of purulent synovitis this tendency to contracture makes itself apparent early, as it does also in cases of tubercular disease, to be hereafter considered. It is exceedingly probable, therefore, that the contracture is a fixed phenomenon, manifested only when, from the nature of the disease, prolonged fixation in the position in which extensors and flexors are equally favored is to be maintained for a long time.

The symptoms heretofore considered are far more important than the remaining cardinal symptoms of redness and heat. In simple serous synovitis redness, as a rule, is altogether absent. In the purulent form it is present only when preparations are making toward spontaneous perforation. When synovitis is the result of joint contusion, the reaction following periarticular injury is often causative of a redness far in excess of that which follows the synovitis alone. In joints superficially placed, like the elbow, the knee, and the wrist, a local elevation of temperature of from 1 to 2 degrees may usually be recognized.

In cases of suppurative synovitis the general symptoms reflect the greater gravity of the local condition. With the systemic absorption of the products of inflammation, the usual accompaniments of toxemia, chills and continuous fever, coating of the tongue, and anorexia are found.

In the dry form of synovitis many of the local symptoms of the serous and purulent varieties are absent. Pain and tenderness are often very marked, and out of all proportion to the swelling, which, as a rule, is slight. In these cases the tendency to faulty position is very early developed. When efforts at motion are made, crepitus is felt. Movements of the patella upon the front of the femoral condyles may likewise cause such joint crepitus. When the latter is insufficient to be felt, it is distinctly audible when the ear is placed over the joint and the articular surfaces are moved upon each other. Passive movements are more painful than in the synovitis with effusion, and the pain associated therewith increases with the tendency to the formation of adhesions. The latter may form as early as the first week, and be firm enough to demand the anesthetizing of the patient for their severance and the correction of the concomitant deformity. The general symptoms in cases of acute dry synovitis are often out of proportion to the severity of the local condition.

Arthritis is inflammation not only of the synovial membrane, but of all the structures of a joint. It may be acute or chronic and is due to traumatism, extension by contiguity of tissue, nervous influence, or injection by way of the blood as, for instance, infectious fevers (scarlet fever, variola, measles, typhoid fever, pneumonia, erysipelas), gonorrhea, syphilis, gout, tuberculosis, pyemia.

Acute infective arthritis is due to pathogenic organisms. If suppuration occurs, in addition to the synovial lining, the cartilages participate in the morbid process. They lose their pearly hue and assume a reddish or even blue tinge. Blood-vessels appear within them, and absorption, often in patches, takes place, the subjacent bone thereby becoming exposed. Shreds of cartilage are often raised in areas, become necrotic, and are thrown off into the joint cavity. The ligaments become softened and permeated by small purulent foci; the joint becomes loosened and devoid of function.

Displacements of the articular ends of the bones are therefore of early and frequent occurrence. Caries of the articular ends, extending for a greater or less distance into the epiphyses, results. The periarticular structures, bursæ, and tendon sheaths take part in the suppurative process. Abscesses communicating with the joint occur and develop in different places. They are often far removed from the part primarily involved. Unless adequate treatment is instituted, the destruction of the joint invariably follows. If the limb is saved, the suppuration gradually subsides through the drainage given by fistulous formations or by surgical treatment. The joint cavity is almost always obliterated. Ankylosis, fibrous or bony, is an almost inevitable result.

The general symptoms of acute suppurative arthritis are proportionate to the severity of the local condition. Almost from the beginning the temperature rises from 3 to 5 degrees, and continues, with morning remissions, until vent is given to the inflammatory products or until death ensues from exhaustion. The fatality of this condition will be referred to in the section on penetrating wounds of the joints. See JOINTS (Injuries).

Gouty arthritis is but a manifestation of the general condition. It is serous, limited usually to the metatarsophalangeal joint of the left foot, associated with extensive periarticular swelling and redness. Through the soft parts, after the subsidence of the acute disease, nodules of calcareous deposit can often be felt within and about the joint structures, more or less defacing the joint outline and limiting motion to a varying degree. The subjective symptoms of pain and of tenderness are in excess of the local underlying conditions. Both rheumatic and gouty synovitis are further characterized by their tendency to become subacute, and even chronic. The structural changes involve the cartilage, ligaments, and periarticular structures. Both of these forms of synovitis, but particularly the gouty, are characterized further by their tendency to recur.

Gonorrheal arthritis is due to infection from the urethra or rarely from the conjunctiva in gonorrheal ophthalmia. Generally it arises during the subsiding stages of the primary gonorrheal urethritis or in chronic cases. According to symptoms it may be divided into seven varieties, as suggested by R. P. Howard of Montreal:

1. The simple *arthralgic* form, in which there is pain, without fever, with a tendency to travel from joint to joint.

2. *Rheumatoid gonorrheal arthritis*, very similar to acute inflammatory rheumatism. In addition to the local symptoms of rheumatism, fever is present and frequently polyarthritic involvement out of proportion to the severity of other symptoms (maximum 102° F.).

3. *Acute gonorrheal monarthritis*, in one joint only, characterized by severe pain and swelling and moderate fever. The knee-joint is most commonly attacked. Next in order follow the ankle, shoulder, elbow and wrist. Suppuration is rare.

4. *Chronic gonorrheal arthritis*, without or with effusion (chronic hydroarthrosis). Rarely suppuration takes place and pus is found in the joint cavity. There is generally slight rise of temperature.

5. The *periarthritic* variety, characterized by involvement of the periarthritic tissues, including the periosteum, capsule, ligaments, tendons, and adjacent fibrous structures, without the joint cavity itself being attacked

6. A variety that attacks *fibrous tissue not connected with joints*, as the plantar fascia, the sclerotic coat of the eye and iris, the pericardium and endocardium.

7. The *septicemic form*, characterized, in addition to the arthritis, by symptoms of general sepsis and endocarditis.

The diagnosis of gonorrheal arthritis is not difficult when the presence of the primary disease is known. From ordinary rheumatism it may be differentiated by its being monoarticular as a rule, the ankle, knee, and wrist being most frequently involved; by the low range of temperature, the absence of the profuse sweating and heavily loaded urine characteristic of rheumatic disease. Gonorrheal rheumatism, as it is too often misnamed, as a rule retrogrades slowly toward recovery. Often, however, the effusion becomes permanent. In other cases the plastic material thrown out tends toward the formation of fibrous ankylosis. Most ankyloses of the knee that are not the result of tuberculosis or trauma in young male subjects owe their origin to gonorrheal infection. Complications of general infection, such as endocarditis, may occur. Syphilis very rarely produces primary acute articular disease. Occasionally during the eruptive stage joint pains are complained of. Serous effusions do not occur frequently, and are almost altogether limited to the knee. Ordinarily, the joint complications of syphilis are secondary to gummatous deposits in the epiphyses. In the hereditary syphilis of early life multiple joint lesions of this nature are often seen. In doubtful cases aspiration should be resorted to and a study made of the fluid secured.

Treatment.—The treatment of acute *arthritis* has a fourfold object: (1) The limitation of inflammatory process; (2) the removal of the products of inflammation; (3) the prevention of deformity; (4) the restoration of full physiologic function.

Position and rest are important elements of treatment of inflammation of the larger joints. The patient should be put to bed and the limb suspended at nearly a right angle. Suspension alone often cuts short an attack of synovitis. When possible, a proper splint should be applied, and circulation controlled by an elastic bandage. Applications of ice or astringent lotions of acetate of lead and tincture of opium or the chlorid of ammonium will be of service.

To remove the products of inflammation preparations of iodin, of mercury, and of lead may be used. Blisters are often very efficacious, after the acute stage has passed off. Fixation of the joint in plaster-of-Paris, starch, or liquid glass is often very serviceable. Such fixation should not be continued for more than 2 weeks at a time. Massage and elastic compression will likewise prove efficient in removing joint effusions. When the latter resist these measures, aspiration of the joint should be practised. While all of the fluid cannot be removed by aspiration, the removal of only a part will relieve the intraarticular tension sufficiently to permit the function of absorption by the synovial membranes. When one or two aspirations have failed, a permanent cure can be generally secured by injecting into the joint cavity 2 or 3 drams of a 5 percent solution of carbolic acid. Bier's hyperemic treatment (*q. v.*) has been applied with benefit especially in acute gonorrheal arthritis.

In suppurative arthritis efficient drainage must be secured at the earliest possible moment. Without it, joint function cannot be saved. Arthrotomy—*i. e.*, the removal of the entire synovial membrane—often proves a conservative measure.

Deformity is to be prevented by giving the limb a proper position from the onset of the disease, and one, which, in the event of ankylosis, would leave it most useful.

Restoration of function is the most difficult achievement in the treatment of acute joint-diseases. It can be met only by properly conducted passive movements instituted as soon as the height of inflammation has been thoroughly passed.

In gonorrheal arthritis in addition to combating the urethritis, absolute rest of the joints involved, and inunctions of colloidal silver ointment (1/2 ounce into each joint involved three times a day) are recommended, ichthyol ointment (10 percent) being advised in the interval between the inunctions. Reports of the use of antigonococcus serum and vaccine therapy (*q. v.*) are encouraging. Antistreptococcus serum has been used with good results. See SERUM THERAPY.

Chronic Joint-diseases

Hydrarthrosis.—This term is used to designate a serous effusion into a joint with a tendency to chronicity. Strictly speaking, it is not a disease,

but a result common to many conditions in and about the joints.

Often in its inception it follows an irritation or an inflammation, the acute synovitis becoming chronic. On the other hand, effusion is often the result of changes in the vicinity of joints.

A tubercular or gummatous nodule and sarcoma of the epiphysis will often be associated with hydrarthrosis. Chronic articular rheumatism and osteoarthritis, or a retarded circulation, such as occurs in phlegmasia alba dolens, may be followed by hydrarthrosis. In very rare cases the hydrarthrosis is intermittent. It occurs at fixed intervals, and usually in both knees. The knee is more frequently the seat of hydrarthrosis than all the rest of the joints together. The effusion is generally serous. Even after long-continued distention of the joints the important ligaments do not, as a rule, become relaxed, so that pathologic displacements are rarely seen; usually there is some muscular atrophy, but contractures do not take place. The diagnosis of hydrarthrosis of the knee, elbow, wrist, and ankle is easily made.

Effusions into the shoulder and hip can only be recognized when they are quite large. The wave of fluctuation in extensive effusion is distinct. The articular outlines are effaced, and in the knee the ballottement of the patella can be easily demonstrated. The chronicity of the condition, its slow development, the absence of fever and pain, confirm the diagnosis.

Treatment.—In comparatively recent cases of hydrarthrosis absorption may frequently be secured by the treatment advocated for acute synovitis with serous effusion. Friction, methodic massage, repeated blisters, and the continuous application of an elastic bandage will often effect a permanent cure. In the failure of these measures recourse may be had to immobilization, from which the danger of ankylosis is not so great as in the cases of acute disease. In the majority of old standing cases, however, recourse must be had to aspiration of the joint, to be followed by irrigation with a 5 percent solution of carbolic acid, of which from 5 to 10 c.c. may be allowed to remain within the joint. To make the injections painless, a 0.5 percent solution of cocain may be injected before introducing the carbolized water. In cases when even this has failed, the draining of the joint may be resorted to.

Chronic Articular Rheumatism.—This is a condition of advanced life, and often found in the lower social strata. Individuals who have always been well nourished are not often subject to this disease. It occurs oftener in men who have led exposed lives; the earlier decades of life are, as a rule, exempt. The disease may follow in the wake of an acute rheumatic attack; generally it is subacute or chronic from its inception. Like its acute prototype, it is polyarticular. The pathologic changes of chronic articular rheumatism vary with its severity and duration. Joint effusions are ordinarily limited in amount, if at all present. Primarily, the synovial membrane, the capsule, and the periarticular structures are involved. The synovial membrane becomes thickened, the ligaments indurated, and the periarticular fasciæ show a tendency to become fixed.

The symptoms and course of chronic articular rheumatism correspond to the morbid conditions described. Mild or severe pain in one or more joints will be complained of. This is associated with restricted movement in the respective joints. There is usually an absence of redness over and about the joint, and tenderness is never excessive.

Joint-motion is very often associated with a distinct crepitus. With the continuance of the process, restriction of motion and faulty position will often eventuate in the disability of an entire limb. It is in this way that, by the multiplicity of the joints involved, the subject of chronic articular rheumatism is often permanently invalided. Acute exacerbations of the chronic disease are of frequent occurrence.

The diagnosis is ordinarily easily made. The conditions with which it may be confounded are arthritis deformans and the articular affections consequent on diseases of the spinal cord.

The treatment of this condition is chiefly general. During the acute exacerbation sodium salicylate or aspirin is as serviceable as in the typical acute articular disease. During the intervals alkaline waters, particularly those containing lithia, have been found efficient. Sulphur and mud-baths, when long continued, seem also to have proved serviceable. Methodic massage may accomplish much in overcoming joint-fixation, hastening the absorption of effused fluids, and reducing the thickened capsule and periarticular structures. Injections, subcutaneously, of fibrolysin are recommended conjointly with baths, massage, etc. The injections are made twice a week into the arm, leg, or loins, but not near a joint.

Arthritis Deformans

This is also known as osteoarthritis, chronic arthritis, rheumatoid arthritis, arthritis sicca, trophic arthritis. It is a condition of degeneration and proliferation of the structures entering into a joint, the morbid anatomy of which forms a distinct entity. The causes which bring about the changes are far from being clearly apprehended. For this reason the disease has been variously named according to the views entertained concerning its nature. For the most part it develops by predilection in individuals past middle life, many of whom present evidences of arteriosclerosis. Occasionally it develops in young subjects, especially in girls after the appearance of menstruation.

As the immediate cause, trauma plays a most important rôle, particularly about the hip, rapid changes of an osteoarthritis nature following contusions of and about the trochanter. Within 3 or 4 weeks most extensive changes may occur which simulate the conditions following a fracture. Medicolegally, the knowledge of a trauma as the exciting cause is of signal importance.

Since recent studies have shown infectious processes in various cavities and structures as the nose, ear, tonsils, etc., and excessive intestinal putrefaction, the belief in the infectious origin of

the disease is gaining ground, while a chronic toxemia due to perverted metabolism is regarded as the cause by some observers.

Symptoms and Diagnosis.—In its clinical manifestations osteoarthritis, except in the rarest cases, is characterized by its chronicity and the tendency to joint-fixation, not by obliteration of the joint cavity, but by the development of osteophytic processes which mechanically impede motion. Pain is one of the chief symptoms of this disease. The joint, as a rule, shows early the deformation of its contour. The ligaments are thickened, prominent, and indurated; often bony deposits can be felt within them and continued into the periarticular fasciæ and tendons. In the early stages joint distention by fluid can occasionally be made out, although, as a rule, the process is one in which synovial fluid is rather reduced than increased in quantity. In accordance with this, the patient often experiences a distinct creaking or grating when he makes an attempt at motion, and, therefore, stiffness and pain in the part will be complained of in the morning until the joint has been considerably used after a night's rest. Acute exacerbations following a trauma, for example, or a breaking off of one of the osteophytic growths, may be followed by hemorrhage or serous effusion into the joint. This condition usually subsides more readily in cases of this character than in joints that are otherwise normal.

The beginning of arthritis deformans, except when it follows a trauma, is ordinarily insidious. Pains varying in their intensity, but often severe, and associated with creaking of the joints and moderate joint effusion, are among the earliest clinical manifestations. Very frequently the pains are of neuralgic character. In the hip, for example, they are referred to the sciatic nerve. The joint deformity, however, usually manifests itself early. Irregular nodules appear, grow slowly, and show no tendency toward absorption. With the temporary joint effusion and the pain, muscular contraction often manifests itself early, fixing the joint in an abnormal position. The course of the disease is ordinarily chronic, continuing at times for from 3 to 10 years or more. Exacerbations consequent on trauma are frequently shown; severer injuries may produce fracture or dislocation.

Treatment.—The treatment of osteoarthritis is extremely unsatisfactory. Hydrotherapy, spa treatment, and hot-air baths, are recommended. Injections of fibrolysin are advocated by Bannatyne and others. Marked improvement has resulted from the use of Bier's stasis hyperemia (*q. v.*).

In every feasible way joint-movement should be maintained by active and passive movements. Vibration and massage may also be advantageous. Fixation by immobilizing dressing is to be strenuously avoided.

Benefit has resulted from the following treatment: Cod-liver oil, carefully and thoroughly rubbed into the affected joints 3 times a day, with the internal use of effervescent citrate of lithium, 1 dram 3 times a day, and the following tonic mixture:

℞.	Mass of iron carbonate,	gr. v
	Fowler's solution.	♏ v
	Sherry wine, } each,	ʒ j.
	Water, }	

After meals, well diluted.

Sodium salicylate or preferably aspirin, is recommended early in the disease. Complete recoveries are reported from the long-continued administration in small doses of Fowler's solution.

Attention to diet and hygiene are also necessary. Removal of infection from any portion of the body, correction of digestive disturbances and the internal administration of tincture of iodin in increasing doses in plenty of water one hour before or two hours after meals and increasing to point of tolerance will be found valuable in many cases.

Cataphoresis combined with radiant heat is recommended highly. The patient, nude, rests within a cabinet entirely exposed except his head to the radiant heat from incandescent lamps. After a 20 minute sitting, cataphoresis with iodin ions is employed, the constant current being applied to the part after it has been painted with iodin liniment, or surrounded by compresses containing a solution of potassium iodid. See CATAPHORESIS. When structural changes have destroyed portions of the joint, palliative treatment is the only indication. Thorough blistering or the actual cautery will often remove local tenderness and afford much relief. See RHEUMATISM.

Neuropathic Joint-diseases

Joint affections may follow any injury of the peripheral nerves or of the spinal cord. For the most part they are associated with either locomotor ataxia or syringomyelia. Neuropathic arthritis appears clinically under two forms—the benign and the malignant. The former begins as an acute or subacute swelling of the joint and the periarticular structures. There is a serous effusion into the joint which is unattended by fever, pain, or redness. It may become rapidly absorbed. The malignant type is found exclusively in tabetic subjects. With or without absorption of the serous effusion the joint capsule remains relaxed and weakened, the ligaments show a tendency to undergo softening, and the ends of the bones are rapidly destroyed by absorption.

In very rare forms of the disease there is a hypertrophy of the articular ends. In the atrophic form the head of the femur may be absorbed, with or without leaving a trace. When the knee is affected, the entire condylar end of the femur and the head of the tibia may disappear. The joint becomes flailed, and there is a tendency to displacement. In over half the cases the knee is affected, the hip, shoulder, elbow, and foot being involved in the order named.

In very rare cases, either spontaneously or through trauma, the joint has been opened. Such a condition is very apt to be followed by very serious consequences as traumatism is decidedly injurious to these cases. Not infrequently these joints recover entirely from the

softening and absorption processes and become again useful, though deformed.

Treatment.—This is palliative. When the effusion is extreme, temporary benefit may be obtained by tapping and the injection of carbolic acid. Joint-fixation by retentive dressing aids locomotion. Operative interference is contraindicated in these cases as the traumatism of opening these joints will cause very serious and frequently fatal results.

Hysteric Joints

As a result of slight trauma, of overexertion—as, for example, in dancing—and very frequently without any exciting cause, there develops in hysteric subjects a train of symptoms which, to casual observation, may closely simulate organic joint-disease. From the time of Brodie the joints thus apparently affected have been designated hysteric joints. The individuals afflicted are usually girls and young women, sometimes pregnant, otherwise well nourished, and generally in the higher walks of life. They may or may not display other phenomena of hysteria or allied neuroses. The joints most frequently involved are the hip, the knee, and the ankle. Clinically characteristic of a hysteric joint is the disparity between the intensity of pain complained of and the local manifestations.

Another clinical characteristic of the condition is the variability of the position assumed by the limb. The variations often follow each other at short intervals. A sign to which Brodie called particular attention is the intense hyperesthesia of the joint and the overlying integument. This is more marked even than the tenderness of the joint in organic disease, in acute articular rheumatism, or in an acute periarticular abscess about to rupture. The pain of hysteric joints manifests itself only during the waking hours. The starting-pains complained of at night, so characteristic of some forms of organic disease, may be complicated by the exaggerated suffering of hysteria, but here the permanency of muscular contractures, joint-fixation in one position, and the test by anesthesia will make the diagnosis clear.

The progress of a hysteric joint keeps pace with that of other manifestations of hysteria. As a rule, under proper treatment it disappears rapidly, although in exceptional instances it continues for months and even years. A hysteric hip has been known to withstand all forms of treatment during 4 years, to become finally dissipated in a single night through imagination.

The treatment of a hysteric joint should be directed toward the psychic condition of the patient. When once thoroughly assured that there is no serious disease present, applications of electricity and massage will ordinarily speedily cause the symptoms to disappear. Too much attention should not, however, be given to local treatment, and retentive appliances and dressings should be strenuously avoided.

Loose Bodies in Joints

In previously healthy joints or joints that have been diseased there are frequently found bodies varying in size, number, and histologic construction, either loose and contained within the joint cavity, or adherent at some point by a pedicle of varying length and thickness. The joints oftenest the site of loose bodies are the knee and elbow. The former is involved in nearly 86 percent of all cases. In joints that have been free of disease these loose bodies—or floating cartilages, as they are often termed—are invariably the result of a trauma.

Allied to this class is that known as the internal derangement of the knee, in which, in consequence of a violent wrench, one of the semilunar cartilages, usually the internal, has been loosened from its moorings to the tibia and the coronary ligament, and is deflected toward the joint-interior. Primary laceration of the synovial fringe, or its infiltration with blood and consequent exfoliation, may likewise be the source of a foreign body in a hitherto normal joint. In diseased joints foreign bodies may develop as a consequence of fibrinous deposits on the joint surfaces. By organizations and long-continued attrition the deposits are broken up, as a rule, into large numbers of minute bodies varying in size from a grain of mustard to a bean. They compress each other into ovoid biconvex forms, and occasionally fill the joint cavity.

These *corpora oryzoidæ*, or rice bodies, have been so called from their shape, size, and pearly appearance.

The hyperplastic synovial fringes observed in many of the diseases of the joints form another common source of these loose bodies, many of them floating freely within the joint, others fixed by more or less attenuated pedicles to the joint-wall. These synovial fringes may present all the histologic variations of the connective-tissue types found in the make-up of the joint; therefore, these foreign bodies may be cartilaginous, contain true bone, consist of a mass of fat, present a cyst within their interior, and, in very rare cases, a mass of mucoid connective tissue.

Symptoms.—The symptoms of loose bodies vary with their size, situation, mobility, and the conditions under which they were developed. When they are small and numerous, as in cases of hydrarthrosis, tubercular disease, and arthritis deformans, they produce few symptoms, and rarely of themselves require attention. When the bodies are larger, the symptoms are far more pronounced. Frequently their existence does not make itself manifest until the immediate results of the accident to the joint have largely disappeared. Thus, after a fall upon the knee, for example, a loose cartilage will occasionally be discovered a week or ten days after the injury, and after a partial subsidence of the articular distention with serum and blood. In other cases months and years may pass after an accident before the loose body is discovered. In the largest number of cases the symptoms manifest themselves in consequence of the locking of the foreign body between the articular surfaces and the consequent violent stretching of the joint ligaments. An individual makes a misstep or an awkward movement, and suddenly feels an excruciating pain, which compels him to stand

where he is or possibly to sink to the ground. The limb itself usually remains fixed nearly in extension in the knee; in the elbow, at an angle of 130 degrees or 140 degrees. By a little manipulation the patient, or some one assisting him, brings the joint surfaces again into position, and, except for some tenderness of the part and temporary effusion into the joint, a return to an approximately normal condition follows. This incarceration of the foreign body occurs at intervals varying between a few weeks and as many years. Between the attacks the joint function, however, is rarely normal. Limitation of motion is very common. In the knee—the foreign body being usually in the anterior portion of the joint or in the subquadricipital pouch—complete extension is not easily accomplished. In the elbow—the foreign body lodging more frequently in the anterior pouch—flexion to a right angle cannot be made. In cases of partial detachment of the semilunar body it can often be felt in its abnormal position, and is but slightly movable.

A positive **diagnosis** of a loose body can only be made when it is subject to palpation. When felt, it appears as a hard, round body under the soft parts, usually over the interarticular line or in relation with the condyle of the femur. Its position can ordinarily be shifted, and, as a rule, it disappears from observation, often for long periods. Through long experience the patient himself is often more successful than the surgeon in bringing it to the surface. As to the nature of the foreign body, preoperative diagnosis cannot be made.

Treatment.—The multiple bodies which belong to the graver joint-diseases, like tuberculosis and osteoarthritis, very rarely require surgical intervention. In the larger bodies, which are the important factors in a diseased condition of the joint, the treatment is palliative or radical. The former consists in the wearing of an elastic bandage, which will, in a measure, keep the foreign body from lodging between the joint surfaces. The radical measure applicable to-day is extirpation. To transfix them by needles and bury them without the joint by subcutaneous measures should not now be practised. The excision, as a rule, should be made by an ample incision directly over the foreign body, which is held by an assistant, or, for the time being, transfixed by a needle. When, after the incision is made, the foreign body is not visible, manipulation of the joint surfaces will either bring it to the surface or expose it somewhere in the interior. In the latter event it can readily be drawn into the wound by means of forceps or blunt hook. If there is a pedicle, this should be cut off as close as possible, and preferably without previous ligation. It is always wise as far as possible to explore the interior of the joint for other foreign bodies, one of which might be readily overlooked in its more hidden recesses.

Tuberculous Arthritis

Synonyms.—Among the numerous names which have been given this disease are: Tumor albus, or white swelling; scrofulous or strumous disease; fungous disease of the joint; caries; and spina ventosa. Since the important investigations of Friedlander and the discoveries of Koch and the causative relation of the specific bacillus to tuberculosis, the term properly reserved for this destructive disease is tuberculous arthritis. This disease may attack individuals at any time of life, but is most frequently seen before the period of puberty. It may develop in infants; 84 percent of cases occur in children under 14. In them the hip, the knee, and the ankle are most frequently affected. In adults the wrist, the elbow, and the shoulder are often involved. Usually the disease is limited to one joint. In 5 percent of all cases it is polyarticular. Heredity plays a predisposing rôle.

An injury *per se* produces tuberculosis only through the infection of a blood-clot or the formation of an infective thrombus in the epiphyseal end of the bone. In children the source of tuberculosis is, as a rule, a latent tuberculosis of the bronchial lymph-nodes.

Pathology.—In advanced cases tuberculous arthritis includes in its destruction all the joint structures. In its inception, however, it begins in the epiphyseal end of the bone, when it is called osteopathic, or in the synovial membrane, when it is known as arthropathic. In children the disease is almost always of osseous origin, whereas in adults the synovial type predominates.

1. *Osteopathic Arthritis.*—This begins, as a rule, as a small nodule of reddish-gray or yellowish color in the epiphysis. It is situated near the epiphyseal cartilage or directly underneath the articular line. Whereas the tuberculous nodule is usually single, there may be many. The bone about the nodule is distinctly hyperemic. The bone trabeculæ are thickened, the cancellous spaces are devoid of fat-cells, and within them are often found miliary tubercles. They are often the means of extension of the disease. As the central focus increases in its dimensions it becomes yellowish in spots, both from deficient nutrition and fat necrosis. Thus there are found nodules varying in size from a pea to a nut, consisting of soft, cheesy material, containing spicules of bone that have resisted absorption. This material has been erroneously called tuberculous pus. The tuberculous nodule becomes surrounded by a layer of granulation tissue, which in turn becomes invaded with tubercles, and it is through the growth of this granulation tissue that bone absorption takes place. Through the growth of the primary focus in the direction of the incrusting cartilage the joint itself sooner or later becomes involved.

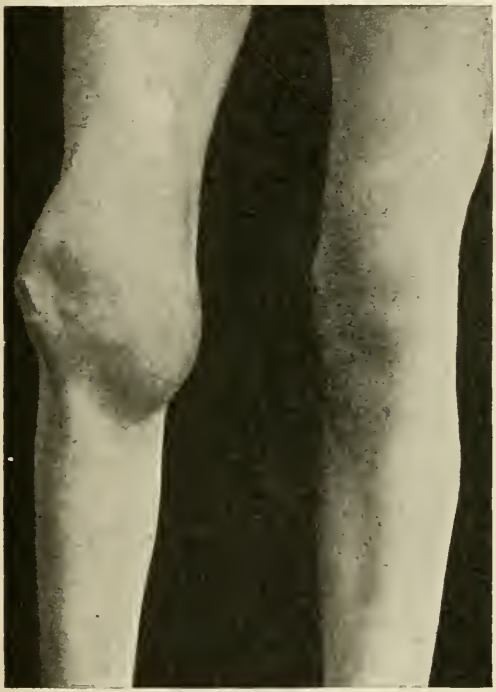
With the penetration of the disease into the joint a panarthritis is speedily developed. The synovial membrane loses its smooth appearance and becomes covered with fungous granulations. Within the joint there is found, as a rule, some fluid which is not strictly fluid, but is the product of the liquefaction of the cheesy foci and the cellular output of the fungous granulations.

The symptoms of this condition are a manifest enlargement of the joint, which is early emphasized by the wasting of the muscles, above and

below. Usually spindle-shaped, covered by an anemic, often glistening and adherent skin, underneath which a few of the larger veins will be seen, the joint now presents the typical appearance of tumor albus, or white swelling. In the majority of cases the capsule itself is softened at one or more places, whereby the granulation process becomes extraarticular. Sooner or later the skin is broken through, and the products of the tuberculous disease escape. Before the rupture of such abscesses they are sometimes designated cold abscesses.

As in other abscesses that have discharged, contraction usually takes place until a fistulous opening is left. In long-standing cases many sinuses are often found undermining the periarticular tissues. With the breaking of the abscess secondary infection takes place, and the destruction of the joint is more rapid than before.

2. *Arthropathic Arthritis.*—When the synovial membrane is primarily attacked, the tuberculosis may be diffusely disseminated over more or less



Tuberculous Hydrops of Knee.

of the entire area or be limited to one portion thereof, preferably one of its reflections or a synovial fringe. In the diffuse form there may be deposited a large number of miliary tubercles, without much change in the intervening tissue. The joint itself is not much altered. It is occasionally found in general miliary tuberculosis, of which it is only one of the many manifestations of infection. In other cases the diffuse tuberculosis of the synovial membrane is associated with increased vascularity, as a product of which an extensive serous or serofibrinous exudation is found within the joint. This latter, which is known as hydrops tuberculosis, must always be taken into consideration in the etiology of chronic articular effusions. The capsule itself is very often thickened by excessive vascularization, and as a product of this a more or less extensive deposit of fibrin will be found covering the synovial membrane and the articular cartilages. This may be extensive enough to cover completely the tuberculous nodules. The partial organization of fibrinous deposit from proliferation of endothelial layers underneath will often give rise to the development of rice bodies in large numbers, to which consideration has already been given. In the majority of cases the synovial membrane is very much thickened and softened, and within it there are disseminated tuberculous foci of larger size, which also invade the subsynovial tissues. Commonly, there is only a slight increase of the synovial fluid, which soon becomes turbid and pyoid. As in the osteal form of tuberculosis, granulation tissue develops from the surface of the synovial membrane, and soon occupies the joint-interior. From it are invaded the incrusting cartilages. Ordinarily, these present a distinctly worm-eaten appearance, and it is from the periphery toward the center that the process of invasion takes place.

Repair in tuberculous arthritis follows the paths by which recovery takes place in tuberculosis elsewhere. Its first evidences are found in the granulation tissue, which loses its succulence from decreased vascularity, and shows a tendency toward conversion into fibrous tissue. In this process small caseous masses are often left for years, and account for the tendency to recurrence of the disease. While it is certain that the bacilli do not live throughout such long periods, it is probable that their spores live and develop actively after a slight trauma, sustained sometimes years after an apparent cure has been effected. (Although this explanation is hypothetical, it best accords with the clinical facts as often seen.)

Symptoms.—The early stages of tuberculous arthritis are, as a rule, vaguely indicated by symptoms. With its progress the symptoms become more pronounced. Those to which attention is earliest directed are defective movements, swelling, deformity, and muscular wasting. The first of these is among the most valuable aids in diagnosis. There is early seen a limitation of movement, which is most marked in the shoulder and in the hip, almost always present in the knee, and to a less extent in the wrist and ankle. Tuberculous hydrops, which is oftenest found in the knee, may exist without limitation of joint-movement. Swelling and deformity are seen early in all cases of tuberculous arthritis, except in cases of the hip and shoulder. Though seemingly the deformity may be due to an enlargement of the bones, this, in reality, rarely takes place, and then only as an excessive repair. In very exceptional cases there is an absolute elongation of bone in consequence of tuberculous arthritis. The deformity is very frequently enhanced by partial or total luxation

In the knee there is a tendency toward subluxation backward of the tibia on the femoral condyles, the latter becoming abnormally prominent. In the hip what is left of the femoral head often leaves the deformed acetabulum, thereby producing great deformity, with shortening. The deformity is almost always enhanced by vicious joint-fixation.

Reflex contractures, invariably of the stronger flexor muscles, and angular deformity speedily ensue. The knee is flexed upon the thigh; the elbow becomes flexed at an angle of 120 degrees to 130 degrees; the wrist drops; the hip is flexed upon the abdomen; and the foot assumes the talipes equinus position by the contracture of the stronger muscles which act upon the joints named respectively. The contracted muscles can always be felt early as well-defined ridges in close proximity to the angle in which the limb is fixed. With the contracture there is often associated an atrophy of the muscles as an early evidence of the disease. Although the degree of atrophy may not at first be measurable, the flabby condition of the muscles is significant of its presence.

Pain varies materially at different periods of the disease and in the various types. It is most marked in the osteopathic form of the disease. In the synovial type, even when associated with large effusion, it may be slight or altogether absent. Whereas, as a rule, the pain is experienced in the joint involved, it may be reflected, as is the case notably in the hip, to parts far removed. Through fixation of the limb by muscular contracture motion does not necessarily increase pain. Children with advanced disease of the hip or of the knee often do not suffer at all, even from violent exercise. By substituting the functions of other joints for that of the one diseased, motion in the latter is involuntarily reduced to a minimum.

The constitutional complications of tuberculous arthritis are rarely marked in the early stages. Adults and children are seemingly in perfect health, except for the local condition. In proportion as this extends the general condition suffers.

The diagnosis of tuberculous disease is, as a rule, easy. In fully 90 percent of the cases it is almost self-evident. Far more difficult is it to distinguish the individual types of the disease. The fungous variety of the superficial joints, like the knee, elbow, wrist, and ankle, is very easily recognized by the swelling, the deformity, and the sense of false fluctuation. More difficulty attaches to the recognition of a deep-seated tuberculous nodule within the epiphysis. The condition with which this is most easily comfounded is the epiphyseal gumma of late inherited syphilis. The presence of corroborating evidences of syphilis, rapidity of development, and, above all, the therapeutic test, will, as a rule, make the diagnosis clear. The perfection of the X-ray now renders possible the very early discovery of a focus of disease in a bone end or joint and readily differentiates it from the possible complications.

From arthritis deformans tuberculous disease is easily distinguished by the chronicity of the former, the enlargement of the articular ends of the bones, and the tendency to osteophytic growth.

Prognosis.—The prognosis of tuberculous arthritis depends very largely upon the treatment instituted and upon the degree of local disease when it first comes under observation. With proper treatment the disease may be arrested in its incipiency, and it is possible for complete restitution to occur. In the great majority of cases, however, the best that can be hoped for is a limitation of joint-function, either from the partial obliteration of the joint cavity or from the development of fibrous adhesions.

Treatment.—The treatment of tuberculous arthritis must be based on the natural tendency of the disease toward recovery. With or without deformity such recovery ensues—in disease of the spine, for example, when operative influence cannot be resorted to early. Conservatism, therefore, must be the rule of treatment, and only after failure should there be resort to active interference.

Since tuberculous arthritis is but the local expression of an infectious disease, *general measures* are not to be overlooked. An abundance of fresh air, a suitable diet, and attention to cleanliness are of first importance. The internal administration of guaiacol and of creosote has been found beneficial. In the hands of very many Continental surgeons the modified tuberculin treatment has also been followed by excellent results. See TUBERCULOSIS.

The local treatment of tuberculous arthritis should, in the first place, be directed toward securing absolute rest for the joint. A prolonged rest in bed will often at once relieve pain and swelling, and even if prolonged through many months, will not interfere with the nutrition of the patient. Local rest is best obtained by the use of a retentive dressing of plaster-of-Paris, of starch, or of silicate of sodium, applied with sufficient snugness to distinctly compress the distended joint. In the joints of the lower extremity, except the hip, and of the upper limb, except the shoulder, and in tuberculosis of the spine, such retentive dressings are often the most serviceable of the methods of treatment.

In the inception of the disease traction (extension) is also very serviceable, particularly in overcoming the tendency toward the contracture of the flexor muscles. During the acute stages such traction can be best maintained with the patient in the recumbent posture, whereas later some form of traction splints can be successfully used. In tuberculous arthritis of the upper extremity the use of extension is far less valuable. When the contractures are firm enough to resist traction, an open division of the contracted parts should be made.

In very many cases it is advisable to attack the tuberculous disease directly by agents which distinctly destroy the bacillus or unfit its soil for necessary sustenance. Such agents are zinc chlorid, balsam of Peru, and particularly iodoform. The direct injection of either of these agents into a tubercular focus at intervals varying from 4 to 5 days to as many weeks will often obviate the necessity of a more or less crippling operation. The zinc chlorid may be used in the saturated or

50 percent solution, and from 4 to 5 minims injected. The balsam of Peru is injected undiluted. Iodoform may be employed in 10 to 20 percent solutions in sterilized glycerin or olive oil, and injected in quantities varying from 1 dram to 2 ounces. To avoid iodoform intoxication it is best to begin with a smaller quantity. While the injections are being made the urine should be carefully examined, since the gravest result of intoxication has been found to be parenchymatous nephritis. The iodoform solution should always be sterilized by submersion of the iodoform during 4 days in a 1 : 1000 solution of corrosive sublimate; it should then be thoroughly washed in sterilized water. The glycerin, and particularly the oil, should be sterilized by boiling.

Bier's hyperemic treatment (*q. v.*) and open air are valuable adjuncts to the iodoform injections. The suction cup is especially beneficial in open lesions.

When many fibrinous shreds come away through the cannula, it is advisable to incise the joint freely, with proper aseptic precautions, and thoroughly irrigate it with a saturated boric solution before making the iodoform injection. If necessary the incision may be sufficiently enlarged to make the operation exploratory, the incision being closed immediately after the injection has been completed. For a cure of tuberculous arthritis from 3 to 20 injections may be necessary, and the time required to effect a cure varies from 2 months to 1 year.

Hydrops tuberculosis will often disappear under rest and compression. In the failure of this, aspiration should be resorted to, to be followed by the injection of carbolic acid or iodoform. The so-called cold abscesses require special attention in many cases although when they are limited in size, they may be allowed to take care of themselves. Through defective operative treatment, septic infection, which may rapidly be destructive to joint and life, has often been induced in the past.

If conservative and mechanic measures fail, *operative treatment* must be resorted to. A free incision of the joint (arthrotomy) is the simplest measure. By arthrectomy, or joint erasion, the removal of fungous masses from the synovial membrane and the incrusting cartilages is made possible. If necessary the entire synovial membrane may be removed, and with the chisel or sharp spoon tubercular foci can be taken from the epiphysis. This operation is an atypical resection. The wound may be entirely closed or provision made for drainage by a strand of silkworm-gut.

Resection for tuberculous arthritis, formerly very extensively practised, is for good reasons less and less employed. If done before puberty, a great shortening of the limb will often result. Resection is indicated in children and young adults only after arthrectomy has failed. In persons beyond the age of puberty excisions are more often called for. Excision for tuberculosis of the larger joints is often reserved for the correction of deformity after the tuberculous process has healed spontaneously or through the methods of treatment, operative and otherwise, already mentioned. In tuberculosis of the wrist and of the foot total excision of the bones involved is to be resorted to, rather than the excision of the focus and its evacuation by curette or chisel. It is particularly in these cases that operative infection of contiguous joints and of overlying tendon sheaths is likely to occur.

In the absence of such infection the shell of bone which is left after the operation is filled with a clot which readily becomes infected, and in the contrary event is difficult of organization.

In severer cases of tuberculosis of the wrist or tarsus amputation will often afford the patient the quickest and safest road to recovery. Amputation must likewise be resorted to at times in children in whom the tuberculous and secondary suppurative processes have left the region of the joint riddled with sinuses and the bones destroyed over extensive areas. In the lower extremity such amputations must be made oftener than in the upper, but in both, with the improved surgical technic of recent years, the mortality following them has been reduced to a minimum. See Hip-joint (Disease).

JOINTS, EXCISION.—See Excision of Joints.

JOINTS, INJURIES. Contusion.—This is the simplest injury to which a joint is liable. It usually results from direct violence, such as a blow or fall. Occasionally it is the result of indirect violence. This is generally the case in contusion of the small joints of the hand and foot. When severe, a contusion makes itself manifest by hemorrhage into the periarticular tissues. Within 24 hours or more the blood permeates the subcutaneous layer and appears in the form of ecchymoses of greater or less extent. In the severe forms of contusion considerable hemorrhage into the interior of the joint takes place. Swelling of greater or less extent, with loss of the normal joint outline, will make easy the recognition of this condition. Pain, as a rule, is never very severe, the inconvenience of the joint-movement and tenderness on pressure being the only subjective symptoms. In exceptional cases, however, pain is often severe enough to produce faintness. Even in these cases its duration is short. When there is an extensive hemorrhage into the joint, a slight rise of temperature may result during the first 24 or 48 hours.

The treatment of contusion consists of rest, evenly applied bandages, and elastic compression. If much pain is complained of, applications of ice during the first 24 hours will often give great relief. After the lapse of 2 or 3 days, passive movements should be made and systematic massage of the joint practised.

Sprains of joints are considered under Sprains (*q. v.*).

Penetrating Wounds.—The injuries of joints hitherto considered may prove serious to the function of the limb, but being subcutaneous, they never, *per se*, jeopardize either limb or life. In strong contrast to these, therefore, are the wounds in which communication is established between the external air and the joint-interior. Penetrating wounds, particularly of the larger joints, like the knee, the hip, the shoulder, and the ankle, may, and often do, become among the gravest of the

injuries to which the body is subject that are not immediately fatal.

A joint wound becomes dangerous only through infection. That mere opening into a joint is free of danger is displayed daily in the operating-room. Aspiration, puncturing with a trocar, free incision for the removal of foreign bodies, with the proper precautions as to asepticism, involve no danger. A wound of the synovial membrane heals by primary union, as does a wound of the skin. The great danger of infection of a joint from a penetrating wound lies in the complicated construction of many of the joints, the difficulty in securing adequate drainage, the communication normally present between the joint and surrounding bursæ, and the ease with which the connective-tissue planes about the joint are involved in the diseased process.

Penetrating wounds of the joint may be divided into the incised, the punctured, the lacerated, and the gunshot injuries. In very many instances the wound is complicated with more or less extensive injury to the surrounding structures, particularly the bones, the larger blood-vessels, and the nerve-trunk. For practical purposes simple incised wounds may be differentiated from the complicated forms, for in the latter the opening of the serous cavity is less significant than the concomitant injury to bone, blood-vessel, or nerve. In civil practice the injuries most frequently seen are of the punctured or incised variety. The shoemaker thrusts an awl into his knee, or the woodman sinks his ax into ankle or knee; the mechanic occasionally thrusts a pointed instrument into the wrist-joint. The wound of communication, it will therefore be seen, varies in its size, being often so small as to be just perceptible, or large enough, on the other hand, to afford a view of the joint-interior. In the latter instance the diagnosis is, of course, simple; in the former, on the other hand, it may be difficult to recognize the penetrating nature of the injury, and often it is impossible.

Symptoms.—Cardinal signs indicative of penetrating joint-injury have been said to be the outflow of synovial fluid, pure or mixed with blood, and, in the absence of this, the rapid filling up of the joint cavity with blood. Neither of these signs is pathognomonic. The opening of a periarticular bursa or of a tendon sheath will permit the outflow of a fluid closely allied to the synovial. When the perforation is small, the opening in the joint closes, and will allow no permeation of fluid through the wound tract. The accumulation of fluid within the joint, on the other hand, will often attend contusion of the joint without perforation. It is not uncommon, for example, to find, in consequence of falls upon the knee, a contused and lacerated wound of the periarticular structures, followed by hemarthrosis, without penetration of the joint.

In compound fractures of the epiphyses joint-penetration may often be suspected, but is rarely subject to demonstration until, in neglected or badly treated cases, the joint reacts to septic infection. When the diagnosis cannot be otherwise established, the careful use of a sterilized probe may bring certainty. In small, punctured wounds the displacement of the tract between muscles and tendon sheaths will often render the search futile. If indications arise demanding a positive diagnosis, an enlargement of the wound under anesthesia and exploration of its course must be made as the preliminary step of the proper operative treatment.

Punctured and small incised wounds of even the largest joints are not, as a rule, attended by severe constitutional disturbance. A man with a punctured knee may follow his vocation for a day or two without any marked local or general disturbance. In the lacerated wounds, on the other hand, there is, as a rule, very great depression. Being often associated with fracture or dislocation, and accompanied by profuse bleeding, the shock manifested is often extreme.

The clinical course of these injuries depends wholly on the presence or absence of primary wound-infection. In the latter even large wounds heal by first intention without local or general reaction. The continued outflow of synovia for several days, while it jeopardizes so fortunate a result, does not annul it.

In the presence of infection the course will be determined, to a large degree, by the nature of the infection, the facility for drainage, and the treatment instituted. The introduction of the less virulent pus-microbes into punctured wounds may be followed by a period of quiescence varying from 2 days to a week. The vascularization of the synovial tunic is then made evident by a serous articular effusion, which speedily becomes turbid and contains flakes of lymph. The joint and periarticular tissues become reddened, disfigured, painful, and tender. Often a chill announces the inception of the suppurative process. In evidence of systematic toxemia there is a continuous fever with morning remissions, which continues while intraarticular pus-retention exists. In these milder forms of traumatic synovitis, if ample opportunity for drainage is afforded, the integrity of the joint may still, to a large extent, be maintained. The outflow of the pus through one or more openings reduces the intraarticular tension, the discharge in the course of a few weeks becomes reduced to a minimum, the cartilaginous covering may even be left intact, and the joint saved with a fair degree of function.

In the cases of grave infection with insufficient drainage, the joint structures soon undergo changes that place them beyond repair. The synovial membrane becomes greatly thickened, the surrounding ligaments become softened, the cartilage covering the bones raised at first in areas, then separated altogether from the underlying bone. The joint structures thus become almost altogether unrecognizable. Communications are established between the pus-cavity into which the joint has been converted and the bursæ originally communicating with the joint tendon sheaths overlying them. In this way a joint-abscess finds its way to the surface, often in as many as from 3 to 6 places, removed from each other by considerable distances. While this process in and about the joint is going on, the limb becomes often enor-

mously swollen, the general septic manifestations are very marked, and, unless relief is afforded, death may sooner or later occur. But even in such unfortunate cases life and limb are often preserved after protracted suppuration, lasting at times for many months.

As in wounds of the soft part, those of joints that are primarily infected with the more malignant pus-formers (the streptococcus infection), if left to themselves, often run a more rapidly fatal course. From the very beginning the general manifestations of sepsis are graver. Within 24 hours of the injury the joint is already enormously tumefied. Within 48 hours the discharges are slightly putrid, and often an examination of the joint reveals free gases in the interior. In these cases ascending phlebitis of the deeper veins often leads to rapidly spreading gangrene of the extremity. In one case of a wound of the knee with such grave primary infection gangrene had developed within 24 hours; within 30 hours the gangrene had spread to the hip, ending fatally within 33 hours from the infliction of the injury. Between these extremes in the clinical course of penetrating wounds of the larger joints there are all degrees of rapidity and virulence of symptoms consequent on infection.

In penetrating wounds of the smaller joints, particularly of the hand and foot, owing to their greater simplicity, the local and general manifestations are proportionate to the size of the joint injured. Whereas, as a rule, the function of the joint involved is permanently restricted, the infection remains localized and limited, and life is rarely threatened. But even in this regard caution in prognostication is essential, since the extension of disease to parts far removed from the primary injury occasionally ensues.

The treatment of penetrating wounds of the joint must have for its objects: First, the securing of primary union through the prevention of infection; and, second, the treatment of the traumatic arthritis when the infection has already taken place. To meet the first condition is simple when the diagnosis is clear. Like wounds in other parts, joint wounds must be thoroughly cleansed. Unevenness of the surface and contused edges must be removed by clean incisions, and the joint should be thoroughly explored for parts of the vulnerating body which have possibly remained embedded in it. To accomplish this, the wound into the joint may, without fear, be very much enlarged. The joint cavity is then to be thoroughly irrigated with a sublimate solution of 1 to 4000. If there has been much oozing, a silkworm-gut strand may be left for drainage. The wound is closed by sutures, and the joint, being aseptically dressed, kept at rest.

When the diagnosis of joint-penetration is in doubt, the treatment should depend largely upon the facilities for aseptic exploration at the command of the surgeon. Without such facilities it is probably wiser to await the development of symptoms indicative of infection before resorting to operative interference. When the surgeon has control of his surroundings, it is advisable, as in cases of doubt pertaining to penetrating wounds of the abdomen, to enlarge the punctured or incised wound, to trace it to the joint capsule, and, if this is found to be penetrated, to treat it as in the cases just considered. With the first evidences of septic infection, in either class of cases, the treatment must consist of the antiseptic management of the joint-interior. By this is meant a free incision for the removal, through drainage, of the contents of the diseased joint and antiseptic irrigation of the joint-interior. In proportion as these objects are sought early or late, the integrity of the joint will be more or less maintained or entirely lost.

In the management of traumatic suppurative arthritis the position of the limb should be kept in mind, with a view to probable future ankylosis. Left to itself, a suppurative arthritis of the knee will invariably leave the limb much flexed; of the elbow, the arm slightly so. An early regard for the position to be attained is therefore an essential element of treatment.

When the penetrating wound of a joint is only one feature of a complicated trauma, the question of primary excision, or even of amputation, may arise. For uncomplicated wounds of the joint neither of these operations is primarily indicated. In cases of compound dislocation, with fracture into the epiphysis, particularly in the upper extremity, a primary excision will often save a useful limb. The same is ture of compound dislocations of the ankle. In a compound dislocation of the knee the force producing it is necessarily so great as to make the joint injury of secondary importance. In such a case primary amputation must, as a rule, be resorted to.

Gunshot Injuries.—Gunshot wounds of the joints are always lacerated and contused, and for this reason alone afford a better soil for infection. In the wounds made by larger missiles there is always added considerable injury to the epiphyseal ends of one or both of the contiguous bones. In these wounds the epiphyses are often shattered beyond repair, and the larger vascular or nerve-trunks are often involved to a degree calling for immediate amputation. A gunshot wound of a larger joint by a ball of larger caliber, when left to itself, often pursues a rapidly fatal course. Of 271 joint injuries in the Russo-Turkish war (tabulated by Reyher), 146 proved fatal; mortality, 54 percent. From the very first day the joint becomes tender, the slightest movement giving rise to excruciating pain. The integuments become discolored, the veins distended, and gas-formation in and about the joint rapidly takes place. The constitutional symptoms accord with the degree of the local infection: the temperature ranges between 103° and 105° F., the sensorium becomes obtunded, delirium develops, and the patient, if unrelieved, often dies, in from 3 to 5 days, of acute septicemia. In the gunshot wounds of joints made by small arms, as seen in civil practice, the symptoms are far less pronounced. They accord with those described of the milder infected wounds that are penetrating from other sources; but even in these, owing to the damage done to contiguous bones and the presence

of foreign substances, the symptoms develop more rapidly. In wounds produced by the larger missiles fired from modern arms there is usually perforation, under which circumstances, as in gunshot injuries elsewhere, the wound of entrance is smaller than that of exit, and has a tendency to contract. The wound of exit is larger, often gaping, and on exploration presents detached spicules of bone. In wounds made by missiles of small caliber, perforation of the larger joints is not common. The missile may rarely be found loose between the joint surfaces. Often it is found firmly embedded in the epiphysis, after having produced more or less splintering.

The diagnosis of gunshot injuries of the joints by larger missiles is always simple. The probe, or preferably the finger, thoroughly sterilized, can be made to freely enter the joint cavity and detect the damage done. In the injuries produced by balls of small caliber the diagnosis is likewise, as a rule, easily made. The outflow of synovia mixed with blood, the rapid filling of the joint with fluid, the crepitus detected by manipulation, the impairment of joint-motion due to the presence of the missile or fragments of bone, make the diagnosis clear. There are, however, cases in which doubt must remain, as in the cases of other than gunshot wounds in the cavity of joints. In these cases, the X-ray will entirely clear up any possible doubt and should be used whenever possible. Wounds made by the smallest caliber revolvers or rifles ordinarily do little damage, the propelling force being slight, and they rarely carry before them particles of infected clothing. If left to themselves, primary union or healing under a blood-clot ensues, as in similar wounds of the soft parts. In wounds by larger missiles, even those from large revolvers, the source of wound contamination is chiefly in particles of clothing penetrating with the ball. The ball, as it comes from the manufacturer, has been shown to be almost sterile; the temperature to which it is raised in its course and by impact is insufficient to sterilize the foreign substance which it carries into the wound before it. In 3 out of 5 pistol-shot wounds of the knee recently recorded, particles of clothing were found in the track of the wound.

In joints with subtendinous pouches, like the elbow and the knee, penetration not infrequently occurs without injury to the bone. A similar penetration may occur, for example, from a wound in the anteroposterior axis of the knee without injury to the bone when the leg is flexed at an angle of about 140 degrees.

Treatment.—The course of healing is greatly influenced by the initial treatment. This is particularly true of gunshot wounds of joints. Except when profuse hemorrhage calls for immediate care, the first attention should be limited to the application of an antiseptic dressing. More should not be done until the best possible facilities are afforded for antiseptic and aseptic manipulations. Above all things, probing with finger or instrument can only be harmful unless every precaution toward surgical cleanliness is observed. Conservatism in the sense of antisepsis and immobilization is indicated in cases of smaller wounds, such as are seen in civil practice. In all other gunshot injuries of joints conservatism is probably most favored by primary operative treatment. Delay until the manifestations of infection compel a tardy interference entails disaster to life and limb more often than in joint wounds from other causes. This has been established beyond a reasonable doubt.

According to the varying conditions found, recourse must be had to exploration and lavage of the joint, atypical excision, or amputation. In civil practice the latter will rarely be demanded; even in military practice it will probably be reserved for the complicated injuries, of which the joint-penetration is only one element. Extensive injury to the soft parts, communication of both epiphyses and fracture extending into the diaphysis, injury to larger nerves and vascular trunks, are the conditions demanding primary amputation. As for severe injuries from other causes, amputations of the lower extremity, other things being equal, will be more often demanded than those of the upper. In the smaller wounds seen in civil life, when the diagnosis is clear, the facilities for asepticism should determine the course; without them, an expectant treatment limited to thorough cleansing of the wound and immobilization should be trusted to, rather than exploration.

With facilities for aseptic work at hand even the smaller wounds seen in civil life should be subjected to immediate exploration. The wound should be enlarged and the site of joint-penetration thoroughly exposed. When it is required for further manipulation, a free incision into the capsule must be made. With the parts so exposed the course of the ball can ordinarily be easily followed. If it has plowed its way into an epiphysis, the canal should be enlarged with chisel and sharp spoon until it is found and dislodged. Loose spicules of bone are to be removed with the forceps and uneven projections chiseled away. An atypical resection may thus be made. Particular care must be given to the removal of foreign substances carried in with the missile. If, in perforating wounds the manipulations have brought the operator near the distal side of the joint, a counter-opening should there be made. Ample facility for drainage is the condition on which success depends. After such atypical resection fair joint-motion is often retained. If both epiphyses are injured, it is probably wiser to make a formal excision, in order to obtain ankylosis. See GUNSHOT WOUNDS.

JUGULAR VEINS, SURGERY.—The physical signs of importance in connection with the jugular veins are distention, pulsation, and venous hum.

Venesection of the external jugular vein is performed in cases in which congestion of the brain, asphyxia, or similar indication exists, and is done at the root of the neck. The patient usually is reclining, a pillow beneath the shoulders and the head turned to the opposite side. A small cork or pad of lint (hard) is placed over the vein as it dips under the clavicle at the outer border of the sternomastoid muscle and held by the thumb or a

bandage passing beneath the opposite axilla. The vein is to be opened as it lies on the surface of the sternomastoid, the incision in the same direction as the fibers of the muscle. To arrest the bleeding, a compress is placed on the wound and held by the thumb until the pad has been removed. It is important to avoid the possibility of air passing down the vein.

Wounds of the external jugular are usually quickly fatal, owing to the great loss of blood or to the entrance of air into the circulation. The direction of the wound is important, as a transverse wound is held wide open by the action of the deep cervical fascia, and a longitudinal wound will not gape. If the internal jugular is wounded near its entrance into the skull, septic infection, venous and sinus thrombosis are additional dangers to the loss of blood and entrance of air. See NECK (Injuries).

JUNIPER.—The fruit of *Juniperus communis;* its properties are mainly due to a volatile oil, and it is a stomachic tonic, diaphoretic, diuretic, and aphrodisiac. The oil is eliminated by the kidneys. It is valuable in chronic pyelitis and cystitis; but is contraindicated when acute nephritis is present. **J., Olo.,** the volatile oil. Dose, 1 to 5 minims. **J., Spt.,** 5 parts of the oil in 95 parts of alcohol. Dose, 1 to 4 drams. **J., Spt., Comp.,** the gin of commerce; oil of juniper 8, oil of caraway 1, oil of fennel 1, alcohol 1400, water sufficient to make 5000 parts. Dose, 1 to 4 drams. *J. oxycedrus* affords oil of cade. **Oil of Cade,** a tar-like substance obtained by the distillation of juniper wood; it is sometimes used externally in eczema and psoriasis.

JUNKET.—Curds and whey; a delicacy for invalids, prepared by taking 1/2 pint of fresh milk heated to an agreeable temperature, adding 1 teaspoonful of rennet or essence of pepsin and stirring well. Let the mixture stand until curdled, and serve with sugar and nutmeg.

SAYRE'S JURY-MAST.—(*Stewart.*)

JURY-MAST.—An appliance devised to produce fixation of the spine, when the disease is above the middorsal region of the back, supporting the head and neck. The jury-mast consists of a vertical steel bar shaped to the curves of the head and neck, and attached to this steel bar is a sling which supports the chin and occiput. The lower end of the bar may be incorporated with a plaster jacket or riveted to a leather or poroplastic jacket. See SPINE (Caries).

K

KAKKÉ.—See Beri-Beri.

KALA-AZAR. A chronic infectious disease widely distributed in certain parts of the tropics and characterized by persistent remittent fever, great splenic as well as hepatic enlargement, anemia, emaciation, and dysenteric symptoms. Hemorrhages into the skin and mucosa may be observed. Ulcers may appear on the skin or mucosa. The disease is probably caused by the Leishman-Donovan parasite, a form of trypanosome. The organism is obtained by splenic or hepatic puncture. This procedure should be resorted to for accurate diagnosis after the possibility of leukemia has been eliminated. The parasites are also found in ulcerations, bone marrow, and lymph glands near lesions and rarely in the peripheral blood. These bodies are round or oval, sharply outlined when stained, usually grouped in rosettes. Concurrent with this disease, malaria or hookworm disease may be found. The disease is fatal, death ensuing sooner or later from exhaustion or intercurrent disease. Isolation and quarantine should be insisted upon. Quinin is indicated for the fever; atoxyl and other organic preparations of arsenic, and salvarsan have been suggested, but little has been accomplished in the way of checking the disease.

KATATONIA (Alternating Insanity).—A mental disease characterized by irregular cyclic symptoms, ranging from melancholia to mania, followed by stupidity and confusion, with cataleptoid phenomena, and by lucidity for a time, recovery, or passing to a dementia. There may be a hereditary predisposition. The exciting causes are usually the result of some excess. It is rarely associated with organic brain-disease. No characteristic lesions have been found associated with katatonia.

A typical case begins with melancholia, the mental depression, uneasiness, and distress followed after a variable period by mania, associated with hallucinations and delusions. This period is followed in turn by a condition of attonita, or rigidity and immobility, or a cataleptoid paroxysm. Any of the stages may be succeeded by confusional symptoms, or a true dementia may develop. During the maniacal stage there is a tendency in many cases to histrionic and sermon-like declamation, or the speech may be of the verbigeration character—that noisy, incoherent, and meaningless speech seen in many manias, composed largely of the constant repetition of a few words or phrases. During the stage of attonita the presence of the so-called mutism, or mutacismus, "a pathologic tendency to be silent," may continue for days, weeks, or months, or it may be interrupted by periods of verbigeration. The immobility or rigidity so characteristic of a period of katatonia is frequently alternated with automatic, incessant, and monotonous movements—the stereotyped movements.

Patients suffering from katatonia often refuse food for days at a time, and then suddenly present symptoms of bulimia. Vasomotor and trophic changes are frequent, one of the most constant being cyanosis of the hands and other peripheral parts. Hematoma of the ear, insane ear or perichondritis of the auricle, is frequent. Epileptiform attacks may usher in the disease or occur during any of its stages. Katatonia differs from circular insanity in the absence of a genuine lucid interval, and the presence of the stage of attonita and catalepsy. The disease may continue for a number of years and recovery follow, but, as a rule, the prognosis is unfavorable.

Treatment consists in attention to the general condition, and combating the various symptoms as they arise. In cases associated with anemia, arsenic and strychnin seem to be valuable. Two cases were rapidly improved with small doses of hyoscin hydrobromid, 1/300 to 1/200 of a grain, morning and evening.

KÉFIR.—A fermented drink prepared from the milk of a cow or mare by the addition of a mushroom-like ferment found in the Caucasian Mountains. It is used by the natives of the Asiatic plains as a remedy for struma, anemia, lung and stomach diseases. Kéfir is richer in albuminoids than Kumyss, is less alcoholic and less acid.

The following table shows the average composition of Milk, Kumyss and Kéfir:—

	Cow's milk.	Kumyss.	Kéfir.
Albuminoids (casein, etc.)	4	1	4
Butter,	4	2	2
Sugar of milk,	5	2½	2
Lactic Acid,	—	1	1
Alcohol,	—	1½	1
Water and salt,	87	92	90

KELENE.—See Ethyl Chlorid.

KELOID (Cheloid).—A tumor of the skin resulting from overgrowth of connective tissue within the corium, arising from preexisting scar tissue or inflammatory exudation. The scars from lupus, burns, and syphilis are especially prone to it, and it may arise from the scars of boils. Colored races are more affected than the white, brunettes more than blonds. It is most common in the middle-aged. It is more frequent over the sternum and about the shoulders and neck.

Keloid seldom gives rise to much inconvenience, and when left to itself, progresses slowly or remains stationary for life or years, and may disappear spontaneously. It has no tendency to desquamation or ulceration.

Keloid formed in scar tissue should never be removed by the knife or caustics, since it always returns quickly. Left to itself, it has a tendency

to undergo slow atrophic changes. Mercurial or lead plaster will sometimes check a keloid growth. Belladonna plaster is useful in alleviating pain, and occasionally recourse must be had to morphin. Linear scarification and electrolytic puncture have been advised.

KERATITIS.—See CORNEA (Diseases).

KERATOGLOBUS.—Distention and protrusion of the cornea. The sclerotic may also become distended in severe cases. When so extensive as to prevent closure of the lids, it has been called **buphthalmos.** When the distention is transparent, regular, and cone-shaped, the apex of the cone being the center of the cornea, it is called **keratoconus,** or **conic cornea.** When the protrusion is opaque or connected with synechia of the iris, it is called **staphyloma** of the cornea, or anterior staphyloma. When due to increase in the fluids of the eye, with increased tension and uniform ectasia, it is called **hydrophthalmos.** Enlargement of the cornea is also called **megalocornea.**

KERATOSIS PILARIS.—A cutaneous affection characterized by pin-head sized papules situated at the mouths of the follicles, and resulting from epidermal accumulations or hypertrophy. The lesions are grayish, whitish, or blackish in color and are found most frequently on the extensor surfaces of the extremities. The skin is dry and rough, but there is no itching. Infrequent bathing is believed to be the most common cause. Bathing with soft soap and alkaline water, followed by vigorous friction, and inunctions of petrolatum constitute the treatment.

KERNIG'S SIGN.—See CEREBROSPINAL MENINGITIS.

KIDNEY, CONGESTION. Varieties.—(1) Acute congestion; (2) chronic congestion.

Acute Congestion of the Kidney

Synonyms.—Active hyperemia; active congestion.

Etiology.—(1) Irritant poisons; (2) surgical operations; (3) exposure to the cold and wet; (4) pregnancy; (5) eruptive fevers.

Pathology.—The kidney is slightly enlarged in size from an excessive amount of blood, and of a dark red color. The renal epithelium shows evidence of parenchymatous degeneration.

Symptoms and Clinical Course.—There is dull pain over the lumbar region, and pressure over the abdominal wall in the region of the kidney may occasion pain. The urine is diminished in amount, sometimes suppressed, darker in color, of high specific gravity, containing albumin, often blood and epithelial casts.

Prognosis depends upon the cause. In most cases it is favorable.

Treatment demands rest in bed and a liquid diet. The bowels should be kept active with Rochelle or Epsom salts (4 drams). Water may be given in abundance to aid in eliminating the effete products in the kidney.

Hot baths or vapor baths, by opening the pores of the skin, aid the affected renal organs in this work. The baths should not be prolonged over 10 minutes.

The following may be given:

℞. Sweet spirit of niter, ℥ vj
Solution of potassium citrate, ℥ ijss
Simple elixir, ℥ iij
Water, enough to make ℥ iv.

Or—

℞. Citrated caffein, ℥ ss
Water, ℥ ij.

Two teaspoonfuls every 3 or 4 hours.

Chronic Congestion of the Kidney

Synonyms.—Passive hyperemia; enlargement of kidney; passive congestion.

Etiology.—It is often the result of (1) venous stasis, as from disease of the heart, lungs, or liver; (2) of pressure of tumor on the renal veins or in the region of the kidney.

Pathology.—The kidney is swollen and of a dark brown or purple color. Hemorrhages occur in the cortex and beneath the capsule, and often in Bowman's capsules. The tubules may be distended with blood. In cases of long standing the kidney may become fatty, necrotic, or there may be an overgrowth of the connective tissue, and the affected organ will become smaller in size and very hard. This change is called *cyanotic induration.* Many of the epithelial cells of the tubules are fatty and contain oil droplets.

Symptoms and Clinical Course.—There is dull pain or feeling of weight over the loins. The urine is dark in color, scanty, and of high specific gravity (over 1020). Uric acid is increased; urea is normal or slightly increased. In the early stages albumin may be detected at certain intervals; later, it is found constantly. Hyaline casts and red blood-corpuscles are often present. There may be edema and anasarca.

The condition may terminate in true nephritis.

Diagnosis.—

CHRONIC CONGESTION OF THE KIDNEY.	NEPHRITIS.
1. Congestion in other organs.	1. Kidney often first affected.
2. Urine high specific gravity.	2. Urine high specific gravity at first, then gradually falling.
3. Transient albuminuria.	3. Albumin nearly always present,
4. Hyaline casts.	4. All varieties of casts, especially granular casts.
5. Urates and uric acid increased.	5. Diminished.

The prognosis and **treatment** are the same as in acute congestion of the kidney. See NEPHRITIS.

KIDNEY, EXAMINATION. Normal Position of the Kidneys.—The kidneys are situated in the right and left lumbar regions respectively. The right is somewhat lower than the left, on account of being pushed downward by the liver. The left is immediately adjoining the spleen.

The kidneys extend from the upper border of the twelfth dorsal vertebra to the third lumbar vertebra. Posteriorly, they rest upon the lower portion

of the diaphragm and the fascia covering the quadratus lumborum and the psoas magnus muscles. Anteriorly, the right is covered by the right lobe of the liver, the descending portion of the duodenum, and the ascending colon; the left one has in front the fundus of the stomach, the tail of the pancreas, and the descending colon. Both kidneys descend about 1/2 of an inch during inspiration.

Physical Examination. Palpation.—The abdominal walls should be relaxed by drawing up the knees when the patient is in the dorsal position. Bimanual examination is the best. One hand should be placed, posteriorly, over the region of the kidney, while the other, anteriorly, makes firm pressure downward upon the organ, and by a rotatory pressing movement the correct outline is determined.

At times it may be necessary to have the patient turn from one side to the other, or even upon the abdomen, in making the examination.

Percussion.—In persons with very thin abdominal walls percussion may be made anteriorly. Usually, however, this method of diagnosis must be applied posteriorly, by having the patient lie face downward and placing a cushion across the abdominal region. The cushion should be of sufficient height to press the kidneys against the muscles of the back. Strong percussion should be made, beginning from below upward, to find the lower border of the kidney. To find the external border, begin at a point farthest away from the organ, gradually moving toward it. It is practically impossible to detect the upper margin of each kidney, owing to the close relation to liver on the right and to spleen on the left. See Kidney (Surgery).

KIDNEY, INFLAMMATION.—See Nephritis, Pyelitis.

KIDNEY, INJURIES.—The kidney may be wounded, either through the loin or the abdomen; in the latter case the peritoneal cavity is opened, and probably other organs injured as well. In one or two cases prolapse has occurred, the whole organ being squeezed out through a wound in the loins.

The symptoms are the same as in contusion of the kidney, with, in addition, those due to the wound.

The prognosis depends upon the nature of the injury; incised wounds heal readily; gunshot injuries, on the other hand, are very likely to be followed by suppuration and sloughing; but extensive urinary infiltration is not common. The lumbar plexus may be torn, the colon opened, and even the peritoneal cavity traversed by a bullet, without the result being fatal. Fistula, however, and serious bladder troubles, phosphatic calculus and cystitis, not infrequently make their appearance afterward.

Treatment.—Hemorrhage should be checked as soon as possible, and any foreign bodies that can be found removed at once; but prolonged exploration with a probe in order to find a bullet is not advisable. The wound should be left open; and, as there is always a tendency for it to become valvular, a large tube should be introduced down to the bottom. Later on, if suppuration occurs, free incisions are necessary. In prolapse of the kidney, if it is much injured, a ligature should be placed around the pedicle and the organ removed; in other cases an attempt may be made to return it. See Kidney (Surgery).

KIDNEY IN PREGNANCY.—See Nephritis of Pregnancy, Eclampsia.

KIDNEY, MOVABLE. Synonyms.—Floating kidney; wandering kidney; ectopia renis; nephroptosis.

Definition.—A condition of the kidney, either congenital or acquired, in which the tissues around the organ are so lax and the renal vessels so elongated as to permit the kidney to be moved in certain directions, causing a movable tumor in the abdomen.

Etiology.—The kidney is normally held in position by the layer of peritoneum attached to the anterior surface of its adipose capsule. In movable kidney the adipose tissue in which the normal kidney is embedded partly or wholly disappears. The renal vessels are in many cases abnormally long. Relaxation of the abdominal walls from pregnancy or other causes; the use of tight corsets or girdles about the waist; violence; increased weight of the organ from disease; the pressure of tumors growing in the neighborhood of the kidney; and the traction of hernias, are all causes. The condition may be congenital or acquired; more frequently the latter. It is far more frequent in women than in men.

Recent anatomic studies have shown that the perirenal fascia contributes materially to the fixation of the kidneys. This fascia is a specialized portion of the retroperitoneal connective tissue, which descending from the lower part of the diaphragm, splits into two layers above the superior pole of the kidney, one passing in front and the other behind. The anterior layers blend with one another over the lumbar vertebræ. The posterior layer on each becomes attached to the vertebræ along the inner border of the psoas magnus muscle. Excessive development or acquired relaxation of this fascia, is now considered by many to be the sole cause of movable kidney.

Symptoms.—Floating kidney may and often does exist without any noticeable symptoms, the condition being unknown until accidentally discovered by the physician while making a physical examination of the abdomen. As a rule, however, patients experience a heavy, dragging pain in the abdomen, aggravated when walking or standing. There are also present gastrointestinal symptoms, more or less constant, with melancholia, aggravated by the mental anxiety over the presence of a tumor in the abdomen.

At times, from some unknown or unrecognized cause, the movable kidney swells and becomes very sensitive to the touch, and migrates a considerable distance from its normal position. Such an occurrence aggravates all the symptoms mentioned. This condition has been ascribed to a twisting of the ureter and consequent retention of the urine in the pelvis of the kidney, or to localized peritonitis, or to a partial strangulation of the kidney from compression or twisting of its

blood-vessels. Hysteric symptoms are frequently observed in women suffering from wandering kidney.

Diagnosis.—The possibility of dislocation of the kidney is to be borne in mind in determining the nature of obscure tumors within the abdomen. Flint based the recognition of this variety of abdominal tumor on the following diagnostic points: "It is situated in the hypochondriac region. It has the size and shape of the normal kidney, and this may be determinable by palpation, which is most advantageously employed by placing one hand over the lumbar region and the other in front on the abdominal walls, and then making counter-pressure from one hand to the other. It is generally movable, and in some cases the organ can be restored to its proper situation." Other tumors are to be excluded by the absence of their diagnostic characters.

It is a rare occurrence to have a fatal termination from movable kidney *per se*.

Treatment is symptomatic. Some of the inconvenience, and sometimes the suffering, attending movable kidney may be lessened by means of an abdominal bandage, belt, or supporter. Stengel proposes two plans of treatment: (1) Overfeeding, to restore the necessary perirenal fat—which, however, was not successful; (2) artificial support by an abdominal belt and kidney-shaped pad so constructed as to exert pressure upward, backward, and to the right, instead of directly upward, as is usual. If attacks of pain and swelling occur, the patient should be placed in bed, have hot applications over the abdomen, opiates ordered, and attempts made to replace the organ. Extirpation of a movable kidney has been successfully performed a number of times. Nephrorrhaphy is an operation for fixation of the kidney to the parietes by means of sutures. See KIDNEY (Surgery).

KIDNEY, PAIN.—There is great disposition among the laity to attribute any pain in the loins to kidney-disease. Very often **lumbar neuralgia, lumbago,** or **muscular rheumatism** is the source of the trouble. **Chronic nephritis** is not generally associated with localized pain. **Acute nephritis** may be accompanied by severe pain in the region of the kidney. **Chronic renal congestion** is accompanied by dull pain and a feeling of weight over the loin. **Movable kidney** may produce similar symptoms.

Renal colic, due to the passage of a calculus from the pelvis of the kidney through the ureter, is the most common cause of pains in the kidney. The history of previous attacks of a similar character, the radiation of the pain downward into the groin and testicle, or to the end of the penis, aid in deciding the diagnosis; while the presence of blood in the urine, the irritable bladder, and the intense agony in the paroxysm, in contrast to the remissions, and the sudden onset, still further point to this condition. These symptoms are not, however, always present in sufficient degree or in association to make the diagnosis easy, and the absence of one prominent sign may seriously impair its certainty. **Somewhat similar pains** arise from pyelitis with possible nephritic abscess, from neuralgia of the kidney or the tissues near by, from nerve pains due to spinal caries or irritation, and, more rarely, from tumors adjacent to or in the gland, or from aneurysm of vessels: as, for example, aneurysm of one of the branches of the mesenteric artery. A calculus embedded in the kidney may be found, or excessive deposits of oxalic acid or other crystals, manifesting themselves in gouty kidney, or, finally, aortic valvular disease. Chronic pain in the kidney is ascribed to slight injury, and is said to be commonly met with in young women who endeavor while wearing corsets to take violent physical exercise.

The presence of **pyelitis** rarely produces great pain, and the appearances of the urine point clearly to the cause of the discomfort, though if the attacks are sudden in onset, the cause may be calculus in the pelvis of the kidney, surrounded by septic changes. The failure of health and the possible febrile movements and chills still further point to pyelitis. So, too, nephritic abscess is accompanied by so much systemic disturbance in many cases as to make the diagnosis clear.

The presence of spinal tenderness on pressure or motion in the dorsal or lumbar regions, and the history of **spinal irritation** or **disease,** decides this as the cause of the pain. The discovery of **aneurysm** of any of the abdominal vessels may be impossible, unless it is large enough to manifest itself through the viscera or abdominal wall on palpation.

The diagnosis of **stone embedded in the kidney** is very difficult and uncertain, but the onset of an attack of renal pain arising from oxaluria or an attack of gout is usually bilateral, and is associated with a scanty urine of high specific gravity, and with much lumbar soreness. A gouty history or that of having eaten large amounts of oxalic-acid bearing foods, such as pears, tomatoes, and cabbage, may be recognized as the predisposing causes of attack.

Fenwick asserts that there are two great groups of renal stones, and that in each class characteristic pain may be felt. In the cortical stones the pain is fixed and continuous, and is liable to exacerbation on movement, but does not depend so much upon changes in the diet. On the other hand, pelvic stones cause obstruction and colic, the pain radiating down into the groin and testicle, while the urine becomes bloody, purulent, or scanty. Fenwick also believes that the posture of the patient in bed is typical. In 9 out of 12 cases his patients could sleep only on the affected side. Cortical stones, in his opinion, never cease to give discomfort, but pelvic stones may become embedded, and the patient go for long periods of time free from any discomfort.

Many years ago attention was called to the fact that **aortic valvular disease** often caused pain to be radiated into the hypochondrium. Ralfe thinks that aching kidney is often due to **unrecognized trauma.** He has known of cases of young women who, by wearing tight corsets while playing tennis or other violent games, have so bruised the right kidney by some sudden and violent movement as

to suffer seriously for days afterward. Again, Ralfe asserts that sharp renal pain sometimes arises in cases of obstinate **constipation,** in which are accumulated in the colon hard scybalous masses which, by their pressure, produce reflex irritation and pain.

KIDNEY, STONE (Nephrolithiasis; Renal Calculus).—A condition in which concretions or calculi form in the kidney structure, pelvis of kidney, or ureter.

Etiology.—(1) Early infancy; (2) gout; (3) old age; (4) lithemia.

Pathology.—Renal calculi may be composed principally of uric acid, oxalate of lime, or phosphates of calcium, magnesium, and potassium.

They may be of different sizes and shapes, some having pointed edges, giving rise to excruciating pain as they pass into the ureter. If the stone forms in the pelvis of the kidney or the ureter, some foreign body, such as a blood-clot, generally acts as a nucleus.

Phosphatic stones are whitish or grayish-white, and soft in consistence. They are the largest variety. The uric acid stones are dark red or reddish-brown in color, very hard, and often pyramidal in shape.

Symptoms and Clinical Course.—In some cases no symptoms arise. The most common symptom is pain in the region of the kidney, aggravated by exercise or sudden jarring of the body. If the ureter is totally occluded, hydronephrosis occurs. When the calculus passes into the ureter, true renal colic ensues.

This begins with a distinct chill, blueness of the extremities, and agonizing pains in the lumbar region, radiating toward the umbilicus, down the ureters, and into the testicles, which may become retracted. Nausea and vomiting come on, accompanied by increased micturition, a feeble pulse, and symptoms of collapse. Occasionally after the paroxysm has ended, blood may be detected in the urine, and in some cases the stone is passed by the urethra.

Diagnosis.—(See also Colic.)

Renal Colic.	Intestinal Colic.	Biliary Colic.
1. Sudden onset....	1. Premonitory symptoms, such as nausea, borborygmi.	1. Sudden onset.
2. Chill, subnormal temperature, collapse.	2. No chill.....	2. Chill and collapse, followed by jaundice.
3. Pain begins in region of affected kidney, radiating down thigh and testicle, which may retract.	3. Pain begins in abdominal region, radiating toward umbilicus.	3. Pain begins in region of stomach on right side, radiating toward umbilicus.
4. Micturition frequent.	4. Micturition normal.	4. Micturition normal: urine contains bile.
5. Blood in urine....	5. No blood in urine.	5. No blood in urine.
6. Presence of stone in urine.	6. No stone in urine.	6. Stone often passed in feces; stools devoid of bile.
7. Pain continues for a day or two in affected ureter.	7. Pain uniform over abdomen.	7. Pain uniform over abdomen.

Prognosis is guardedly favorable.

Treatment.—For the acute attack of renal colic morphin (1/4 of a grain) and atropin (1/125 of a grain) should be given at once, and repeated in 2 hours, if necessary, to relieve the extreme agony of the patient. Hot flannel cloths, stupes, or poultices should then be placed over the affected area, and may aid in rendering the patient comfortable.

In the constantly recurring attacks, in which the symptoms are not so violent, much may be done by means of dieting. Meats, tea, and coffee should be greatly restricted; alcohol and tobacco should be avoided. Milk, soups, fruits, vegetables, eggs, and an easily assimilable diet is best.

Bathing in lukewarm water 2 or 3 times a week, followed by massage, will stimulate the skin and keep the circulation active.

The bowels should never be allowed to become constipated, and saline purgatives, such as Rochelle salts (4 drams), Epsom salts (4 drams), and Carlsbad salts (1 to 2 drams), may be given.

Alkaline diuretics may be valuable.

℞. Potassium acetate,
Potassium bicarbonate, } each, ʒ ij
Potassium citrate,
Fluidextract of triticum, ʒ iv
Water, enough to make, ʒ iv.

One teaspoonful every 3 or 4 hours.

Failing to secure relief by medicinal measures, surgical interference should be effected and the stone removed. See Kidney (Surgery).

KIDNEY, SURGERY.—Although the kidney had occasionally been the subject of surgical operation in early times, premeditated kidney surgery may be said to have begun with Gustav Simon's successful extirpation of the one kidney for ureterouterine abdominal fistula in 1869. He did this operation after a demonstration of the healthy condition of the other kidney, and after a series of experiments on dogs showing that the removal of one kidney was a practicable procedure. Two years later Simon removed another kidney for calculi and suppurative pyelitis. The patient unfortunately died of pyemia on the twenty-first day after the operation. At that time surgeons were unacquainted with antiseptic methods. Since the publication of Simon's work on the surgery of the kidney, in 1871 ("Chirurgie der Nieren" Erlangen), the methods of diagnosis have been so much improved in scope and precision by the ureter cystoscope, by the X-ray photographs, and by the study of clinical and pathologic material that the radical operations of 20 years ago have given way to partial nephrectomies, nephrotomies, and various reparative operations on the ureter and pelvis of the kidney.

Location.—The kidneys are located in the back in such a position that a little more than one-half of each is exposed below the last rib. The hilus or root of the kidney, into which pass the renal arteries and out of which pass the renal veins and the ureters, is directed toward the vertebræ and a little downward, so that a line passing longi-

tudinally through the middle of one kidney from pole to pole would meet a similar line, passing in the same way through the opposite kidney, somewhere in the region of the body of the sixth dorsal vertebra.

The ureters are small tubes, 30 cm. long, the wall composed of 2 layers of muscle and a thick layer of mucous membrane. They are supplied with blood-vessels from the kidney and bladder and from the adjoining connective tissue. The ureters are not of uniform caliber throughout their length, but are funnel-shaped at the kidney, and meet with a constriction as they pass over the brim of the pelvis, and another upon entering the bladder. The pelvis of the kidney is continuous with the ureter, and is connected with the several calices by infundibula. The relation of these parts is not uniform.

The kidney may be approached through an incision 4 to 6 inches long along the outer border of the quadratus lumborum muscle, or it may be reached through a laparotomy wound. The lower 3 cm. of the ureter may be approached in women by way of the vagina, and the rest of the ureter can be easily examined, both in men and women, through a laparotomy wound.

Operations.—Aspiration of the kidney may be performed either for the purpose of diagnosing a renal swelling, or for the relief of such affections as hydronephrosis, pyonephrosis, or hydatid or blood cysts. It should be done with the ordinary precautions, any prominent or fluctuating spot being chosen for the puncture.

Nephrotomy consists in making an incision into the kidney for the purpose of evacuating and draining the fluid or pus in the case of hydronephrosis, pyonephrosis, hydatid cyst, abscess, etc. The tumor may be exposed by the lumbar or lateral incision, as described in nephrectomy. An incision is made into the kidney, the fluid allowed to run out, the wound thoroughly irrigated with some antiseptic solution and insufflated with iodoform, a large-sized drainage-tube inserted into it, and voluminous dressings of absorbent cotton and the like applied to receive the subsequent discharges.

Nephrolithotomy consists in cutting into a kidney for the purpose of extracting a calculus. The kidney may be exposed either by the lumbar or lateral incision, as described in nephrectomy. If a stone is felt, an incision should be carefully made over it, the finger or forceps introduced, and the stone extracted. If one cannot be felt, a needle should be thrust into the kidney at several situations, and, this failing, an incision should be made into it, and the finger and a probe introduced to search for stone. A drainage-tube should be placed in the wound, and an antiseptic and absorbent dressing applied. The urine will at first escape through the wound, but will cease to do so, as a rule, after a longer or shorter interval.

Nephrectomy, or removal of the kidney, may be done without opening the peritoneum, either by a lumbar or lateral incision, or through the peritoneal cavity, the incision being then made either in the linea alba or linea semilunaris.

The Extraperitoneal Operation.—If the incision is made in the lumbar region, it may be vertical, T-shaped, or oblique, like that of colotomy. If the lateral incision is chosen, it should be made obliquely from near the tip of the last rib toward the anterior superior spine of the ilium. Its advantages are that it combines the facilities of the intraperitoneal and the greater safety of the lumbar incision, as it does not involve opening the peritoneal cavity. The kidney having been exposed by any of these incisions, the capsule should be opened, the finger introduced, and the kidney enucleated from its capsule; the renal artery and vein should then be securely tied with a silk ligature passed round them by an aneurysm needle, and the ureter separated in a similar way. The kidney is removed by cutting through the pedicle with scissors, and the wound drained and dressed antiseptically.

The Intraperitoneal Operation.—This consists in opening the peritoneal cavity by one of the incisions mentioned above, drawing the intestines aside, and then exposing the kidney by cutting through the peritoneum in front of it, external to the colon. The vessels are then tied separately, the kidney removed, and the peritoneum united, the same precautions being adopted as after an ovariotomy. A drainage-tube is passed by some surgeons through a counter opening in the loin, and the end of the ureter brought out of the wound.

The dangers of nephrectomy are: (1) Severe shock; (2) excessive hemorrhage; (3) suppression of urine from disease or absence of the opposite kidney; (4) peritonitis from wounding the peritoneum; (5) laceration of the colon; (6) inclusion of the vena cava in the ligature of the pedicle and injury of the duodenum in operating on the right side.

Nephrorrhaphy is an operation for fixing a floating or movable kidney by exposing the kidney in the loin and attaching it with sutures to the parietes. It should only be done when there is intense pain and constant suffering which palliatives have failed to relieve.

Surgery of the kidney may be necessary for (1) Congenital malformation, (2) for injury of the kidney, (3) for disease of the kidney, or (4) for deformity of the kidney or ureter, the result of injury or disease.

When a kidney is found abnormally placed in the pelvis of a woman likely to bear children, it must be removed to make parturition possible. When a congenitally cystic kidney grows after birth so as to interfere with the development of the child, it must be removed. When a ureter congenitally misplaced discharges urine into the vagina or urethra, the ureter must be implanted into its proper place, or the kidney tributary to it must be removed. When there is a congenital deformity of the ureter or kidney which results in complete or partial hydronephrosis, the deformity must be corrected or the whole kidney or part of it must be removed.

There are two sorts of **injury of the kidney** requiring surgical treatment. The kidney is sometimes driven out of place by a blow, a fall, or a slow

compression, as between two freight cars. A suddenly displaced kidney without rupture has gives rise to: (1) No symptom except pain; (2) to pain and obstruction of the ureter by torsion or kinking, and the rise of temperature attendant; and (3) to pain, tumor, and bloody urine, or these symptoms with a perirenal or abdominal hematoma.

The kidney is sometimes ruptured by the direct action of a blow, a fall, or a broken twelfth rib. The result is a hemorrhage either outward into the perirenal tissues or inward into the pelvis of the kidney or one of the calices; in the latter case there is bloody urine. Sometimes the rupture extends entirely through the cortex, and both blood and urine are then found in the perirenal tissue. In children the perirenal peritoneum is often ruptured by the same insult that ruptures the kidney. Then the blood and urine are extravasated into the general peritoneal cavity. The perirenal hematoma, especially if mixed with urine, is almost sure to become infected and produce a perirenal abscess if the patient lives so long. The patient is likely, however, to die of hemorrhage. This is sure to be the case when the renal vein itself or one of its larger branches is ruptured. Death comes on in the course of 24 or 48 hours.

When the kidney has been displaced, either slowly (floating kidney) or suddenly, and great pain persists, either with or without rise of temperature, indicating pyonephrosis, the kidney should be approached by an incision beginning on the outer margin of the overlying quadratus lumborum muscle just below the edge of the last rib, and extending downward to the crest of the ilium and then curved outward for about half a finger's length. Through this opening the kidney should be carefully reached (by dividing the perirenal fat with dull instruments or with the fingers) and carefully drawn out through the fat, and even out of the depressed edges of the wound. It will stay in the wound if it is slightly twisted like a button. Here it can be examined. The ureter should be found on the lower side. There should be no blood. The kidney is then allowed to sink back under the skin, but should be held within the muscular wound by a strip of gauze passed under the upper pole. The skin and muscle should then be partially coapted with sterile silk or silver wire. The gauze should be carefully and slowly removed about the fourth day, when the sutures are removed, and the resulting wound allowed to close slowly, with a diminishing iodoform gauze tampon.

When an injury of the kidney results in a large **hematoma,** without bloody urine, without symptoms of severe hemorrhage, and without any rise of temperature indicative of sepsis, it is enough to keep the patient in bed, apply cold, and wait.

When, however, a perirenal hematoma is accompanied by symptoms of gradually increasing anemia, rapid pulse, thirst, low temperature, pallor, and delirium, the kidney must be approached at once by the method mentioned and the ruptured kidney tamponed, or the bleeding vein compressed by a forceps left on for 24 or 48 hours. When the ruptured kidney cortex is tamponed with iodoform gauze, it may sometimes be necessary to pass one or two large silk sutures through the kidney from side to side to hold the tampon in the rupture. In such a case it is necessary to drain the perirenal space for a week or more.

When the cortex of the kidney is completely ruptured and the hematoma contains urine as well as blood, the treatment mentioned is imperative, but the drainage must be continued much longer.

When a large or small hematoma becomes infected after weeks or months, it gives rise to sepsis and abscess formation—the so-called perirenal abscess—and it must be opened and drained. The incision need not be quite so extensive as that described, but should be in the same line, and 3 inches or more in length. Perirenal abscess often occurs without the history of injury; the treatment is the same.

The diseases of the kidney for which surgical treatment is necessary may be grouped under three heads: (1) Pus-diseases; (2) tubercular diseases; (3) tumors.

Pus microbes may reach the pelvis of the kidney by way of the urethra, bladder, and ureter, and, having injured the ureter by forming granulations and obstructing the outflow of urine, **pyonephrosis** results. The pus, which had probably been noticed in the urine, stops; chills and fever come on; a large tumor, at last, after weeks or months, appears in the lumbar and outer abdominal region. In such a case the cortex of the kidney becomes very much thinned out, and its secretion stopped. The heart is usually hypertrophied. The treatment is obvious. The dilated kidney should be at once carefully opened, as in the case of, and in the same place as, rupture, even though it seems to "point" in front. Drainage must be kept up, and, if necessary, a subsequent operation done to remedy any defect in the ureter.

Pus infection sometimes reaches the kidney, especially in the course of typhoid or other infectious diseases, by way of the circulating blood, producing an infarct, and afterward an abscess, which may rupture outwardly and result in a perirenal abscess, or into one of the calices and produce a pyonephrosis. Multiple abscess of the kidney with pyonephrosis follows infection of the urethra, bladder, and ureter, especially in certain cases of gonorrhea and in catheterization during confinement, and as a part of a general pyemia. In the former case nothing avails except the complete and prompt removal of the whole kidney, while in the latter case we are hopeless to offer any relief at all.

In some persons, in certain conditions of digestion and elimination, and in certain locations the crystallizable matter of the urine in precipitated in the renal tubules, in the calices, or in the pelvis of the kidney. When these crystals are small, they pass off in the urine without being noticed. Sometimes they remain behind and furnish centers about which, according to well-known principles of crystallization, further deposits take place.

Such masses of crystals are called **renal calculi** when they are found in the calices or pelvis of the kidney, ureteral calculi when they are found in the ureter, and vesical calculi when they are found in the bladder. They often remain unrecognized for years, and grow to a large size (2 to 5 ounces). They make themselves known by terrible pain whenever they pass down the urinary tract or obstruct the flow of urine. Small stones less than a centimeter in diameter pass down the ureter in the course of 10 to 40 hours of great agony, and are then passed out of the bladder through the urethra with relative ease, especially if the urethra is cocainized and dilated with a large sound. The patient should take such a position as to bring the stone into the urethra at the beginning of emptying a full bladder. When a larger or smaller stone is retained in the bladder, it grows, and sooner or later gives rise to the symptoms of vesical calculi.

Even a very small stone passing down the ureter may give rise to unendurable pain, coming on in paroxysms at intervals of a few minutes, or it may pass off after many paroxysms weeks or months apart. Sometimes the passage of quite a large stone through the ureter is unnoticed or produces only a dull pain in the side and back. The pain is, however, usually worse at the beginning of the ureter, at the constriction at the brim of the pelvis, and at the perforation of the bladder. The pain is often referred to the inside of the thigh, to the testicle, or to the labia, but as it grows severe it settles in the side and is accompanied by tenderness over the ureter and kidney. The treatment is warm baths, hot applications, and large doses of morphin. Vigorous catharsis and a liberal liquid diet, with rest in bed, must be prescribed. If the pain continues longer than 2 days, and the temperature rises more than a degree or two, the region of the stone has probably become the site of infection.

One of the most serious consequences of calculi in the urinary tract is the almost inevitable microbic pus infection which sooner or later surrounds the stone. Suppuration about the stone produces pyonephrosis, either complete or partial. When the pus stops discharging itself through the bladder, either because the stone acts as a valve in the ureter or because the ureter has been deformed and obstructed, the kidney becomes distended and the patient has all the symptoms of sepsis. Then the kidney must be approached as described above, the stone or stones removed, and the pelvis of the kidney drained. A subsequent operation may be required to repair any remaining obstruction of the ureter.

The removal of a stone in the ureter requires unusual operative procedure, which can be undertaken only on very exact diagnosis and under most favorable circumstances. At the bladder end of the ureter in women the stone may sometimes be easily helped into the bladder by simple digital manipulation through the vagina or rectum.

Tubercular infection reaches the kidney through the circulation, when it produces a double-sided and inoperable miliary tuberculosis or a tubercular disease confined to a single focus of infection, primarily through the external génitals, the urethra, prostate, bladder, and ureter. Primary renal tuberculosis, the so-called renal phthisis, is a little less frequent than renal tuberculosis, going on after tubercular epididymitis, tubercular prostatitis, and tubercular cystitis. This condition is slow in its onset, insidious in its progress, and, after both kidneys are attacked, absolutely unfavorable in prognosis. The diagnosis is made by discovering tubercular nodules in the epididymis, seminal vessels, and prostate, by recognizing tubercular bacilli in the semen or urine, by discovering tubercular ulcers of the bladder, and by finding the ureter from the tubercular kidney enlarged. The crucial test is made by catheterizing the ureters and finding tubercle bacilli on the one side, with diminished urine, and healthy and increased urine on the other side. The treatment for tuberculosis of the kidney is removal of the tubercular kidney and ureter and all peripheral tubercular tissue, the seminal vesicles, the prostate, the testicle, and the cord.

Hydronephrosis.—Complete hydronephrosis is due to partial obstruction of the ureter. Its treatment is repair of the ureter, a difficult and complex operation. Partial hydronephrosis is due to partial obstruction of one or more of the infundibula. It may be treated by exposing the kidney, as described before, and cutting away with the scissors the wall of the cyst and destroying the remaining mucous membrane with a solution of zinc chlorid 1 : 40.

The adrenal tumors of the kidney usually grow in adults from remnant of adrenal tissue left between the lobules of the kidney. They do not, as a rule, invade the kidney substance, but displace it. They can generally be enucleated, and after such removal they show no tendency to recur. When they are of large size, they are likely to break down, and extensive hemorrhages occur in the tumor substance, sometimes invading the surrounding tissues. If one of these adrenal tumors growing near the pelvis of the kidney breaks through into the pelvis itself, bloody urine follows immediately. These tumors sometimes produce the normal secretion of the adrenal gland in too great a quantity. Then the patient's heart is slowed, his capillaries contracted, and his skin blanched. He has severe headaches. His arteries rapidly undergo sclerosis, and apoplexy is apt to occur even in the young. Some adrenal tumors show a tendency to metastasis in which the lungs and bones are usually conspicuous.

These tumors should be enucleated from the kidney when possible; when this procedure is impossible, a part of the kidney should be removed.

Malignant tumors in the adult are usually hypernephromas, or carcinomas. The former are the more common. Many tumors formerly supposed to be carcinomas were undoubtedly hypernephromas. Sarcomas are rare. In children they may attain a very large size in a short time. Secondary or metastatic carcinomas of the kidney are not fit for surgical treatment. In primary carcinoma the right kidney is a little more frequently at-

tacked than the left. Men are more often affected than women. Carcinoma sometimes follows long-neglected stone in the kidney and pyonephrosis. Primary carcinoma appears about the age of 50 to 60. Less than 1 percent of all primary carcinomas appear in the kidney. The diagnosis is made by the appearance of blood in the urine, pain in one side, tenderness and tumor in the region of the kidney, loss of weight for several months, and slight cachexia. Some latent cases show no blood in the urine and no tumor: say, one-third of all. Some cases show no tumor, but exhibit more or less frequent hematuria: say, one-tenth. Perhaps one-third of all cases exhibit both bloody urine and palpable tumor (these are the ideal cases for diagnosis), while the remainder show palpable tumor but no hematuria. The crucial test is the discovery of shreds of carcinoma tissue in the bloody urine. The tumor is usually nodular, attached to the kidney, moving with respiration. When obstruction results from clots in the ureter, the symptoms are like those in the passage of small renal stones. The blood-clot then resembles a black earthworm of enormous length.

Every case of hypernephroma and primary carcinoma of the kidney should be treated by complete removal of the affected kidney after the health and competency of the opposite kidney have been demonstrated.

The diagnosis of disease of the kidney is made by palpation, which in thin persons will discover the normal kidney and any tumor of considerable size; by percussion, which will sometimes discover the normal and always the greatly enlarged kidney; by urinary examination; by exploratory puncture; by photography or fluoroscopy with the X-rays, which will often discover stone; and by incision and direct palpation.

Summary.—The following adages should be considered in all cases requiring operations on the kidney.

1. One healthy kidney should be demonstrated by catheterizing the ureters before any considerable operation is undertaken on the opposite organ.

2. The kidney should be extirpated only for malignant disease, for tuberculosis, for rupture of the renal artery or vein, for irreparable loss of the ureter and for pyonephrosis when the kidney is riddled with multiple foci of suppuration, for the removal of which a nephrotomy has proved inadequate. Even a small portion of cortical substance should be left, as it shows great reproductive power.

3. In pyonephrosis the abscess should be freely opened and drained, and all reparative procedures on the obstructed ureter should be left to a subsequent operation.

4. An operation on a healthy kidney is more likely to precipitate an acute nephritis in the opposite kidney than a much more severe operation on a sick kidney.

5. The emergency operations on the kidney are for hemorrhage about the kidney in rupture of the kidney or rupture of the renal vein, torsion of the ureter in wandering kidney, and pyonephrosis.

6. Chloroform is the best anesthetic for kidney operations, but a pyonephrosis may be opened with Schleich's local anesthesia or with the use of ethyl chlorid spray.

7. Hypertrophy of the heart is usually observed in any disease impairing the function of the kidney.

8. Renal hematuria from an apparently healthy kidney has been repeatedly observed.

9. Operations on the kidney by the abdominal way are much more dangerous to the patient than similar operations by the lumbar incision.

10. Hydronephrosis is the result of partial obstruction of the ureter. Complete obstruction without infection results in atrophy and disappearance of the kidney.

11. Percussion is of little use in diagnosis.

12. Only in thin people can the lower pole of the normal kidney be palpated, and then only on inspiration and expiration.

13. Auscultatory percussion is of much value. See KIDNEY (Stone, Movable), NEPHRITIS, PYELITIS, etc.

KINO.—The inspissated juice of *Pterocarpus marsupium*, found in India, and similar in action to tannic acid. It contains 75 percent of a variety of tannin named *kinotannic acid*, which gives a greenish precipitate with persalts of iron; also a crystalline, neutral substance, *kinoin*, and *kino-red*, gum, pectin, etc. Dose, 5 to 10 grains. It is used mainly as a constituent of gargles and diarrhea mixtures. The tincture in dram doses is one of the best remedies for the diarrhea which results from the disuse of opium or morphin. K., Tinct., 5 percent of the drug. Dose, 1/2 to 2 drams.

KNEE-JERK. See JERK, REFLEXES, NERVOUS DISEASES (Examination), LOCOMOTOR ATAXIA.

KNEE-JOINT, DISEASE.—See JOINTS (Diseases), EXCISION OF JOINTS.

KNEE-JOINT, INJURIES.—**Fracture of the patella** is a frequent injury due to direct violence, producing an oblique or stellar fracture or to indirect violence, sudden muscular traction of the quadriceps, producing transverse fracture (traction fracture).

TRANSVERSE AND VERTICAL FRACTURE OF THE PATELLA. —(*Spencer and Gask.*)

Fracture the result of direct violence is seldom accompanied by the same degree of diastasis of fragments as fracture the result of muscular contraction, in which there frequently occurs an extensive laceration of the aponeurotic layers passing alongside the patella; without this laceration wide separation of the fragments cannot occur.

The patella is fully inclosed in the capsule of the joint, and hemorrhage is into the joint. Excep-

tionally, this may be excessive and distend the capsule.

When only a small piece at the edge of the patella is separated, and if the periosteal covering remains intact, the diagnosis may be difficult and doubtful. But when the fracture is transverse and is accompanied by some diastasis of the fragments, the diagnosis lies immediately at hand. This fracture is peculiar in that there may result a very good and useful limb, with comparatively wide separation of the fragments and fibrous union entirely, while sometimes well-placed fragments united by bony union occasion a permanent impairment functionally.

Ununited Fracture of the Patella.—(*Spencer and Gask.*)

Treatment.—In fractures from direct violence, when there is likely to be little or no separation, treatment is comparatively easy, consisting in fixation by means of a posterior splint and roller bandage. The danger here is not nonunion, but ankylosis. If a distending hemorrhage has occurred into the joint, it should be removed by aspiration. Massage of the quadriceps should be practised almost daily, and passive motion begun as early as the third week. At the end of 6 weeks dressings can be discarded and the patient permitted to go about.

It is in the transverse fracture, the result of muscular traction, that the serious difficulty occurs. Here the fragments are likely to be widely separated, owing to the tearing of the lateral aponeurotic layers along the sides of the patella. The aponeurosis covering the patella becomes first very much stretched, and when it finally tears, a retracted fringe projects between the fragments. This fringe sometimes prevents an osseous union, even when the fragments can be closely apposed.

Above all, it is the condition of the quadriceps extensor muscle which most demands attention. Even when comparatively good union is attained, a useless limb may result because of the atrophic condition of the muscle which has occurred as the direct result of the treatment that brought the fragments close together and permitted a good union. To effect apposition of the fragments it is necessary to practically paralyze the muscle with the roller bandage. The nutritive disturbance thus brought about, together with the atrophy resulting from the prolonged inactivity of the muscle, leaves the muscle in a crippled condition, from which it does not recover. This fact has led to the treatment of this condition by daily massage alone (kneading and tapotement), the effort being made at the same time to bring the fragments nearer together. Very good functional results are reported as a result of this treatment. A better plan of conservative treatment is to combine this valuable method with the effort to approximate the fragments directly. This is accomplished by means of a posterior splint, applied with the leg extended and the thigh flexed, so relaxing the quadriceps. Straps of adhesive plaster now catch the upper and lower fragments, cross each other, and are stuck fast over the posterior aspect of the splint, so pulling the lower fragment up and the upper fragment down. A circular strip over the fragments may be found necessary to keep them from tipping. A figure-of-eight bandage may reinforce these straps. The quadriceps is now to be massaged daily, chiefly from above downward, seeking thus to bring down the upper fragment. Complete failure of union and adhesion of the upper fragment to the anterior surface of the thigh are rare and, of course, very unfavorable occurrences.

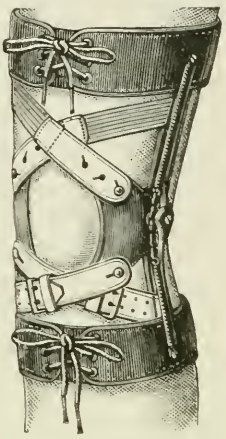
Subcutaneous suture by means of wire, tendon, or silk is recommended; but of operative measures only the open **bone suture** is to be advised. Chromicized catgut answers this purpose well. The sutures need not penetrate the fragments of bone; by being passed through the aponeurotic layers over and to the sides of the patella, they are able to bring the fragments in apposition. This procedure is only to be attempted by a skilled surgeon, as the knee-joint is necessarily opened, and the occurrence of sepsis here may be fatal either to the usefulness of the joint or to the life of the patient. When this operation is undertaken, it is advisable to use rubber gloves, as thereby the chances of infection are undoubtedly diminished. Taking into account the danger of this operation, and the comparatively useful limbs which result from intelligent and careful conservative treatment, the conclusion is clear that conservative treatment is best for the large majority of cases. In special cases, as in robust young men who are dependent on strong legs for their daily bread, the direct suture in competent hands is certainly advisable.

To perform this operation, a longitudinal incision is made over the center of the joint, which is opened, and the fragments of the patella are exposed; any blood-clot which is present in the joint or between the fragments is turned out, and the fragments themselves are cleared of any aponeurotic and fibrous tissue which may be found lying between and over their broken surfaces. Each fragment is then bored obliquely with a drill, taking care not to reach its cartilaginous surface. Sutures of silver wire or of heavy catgut are then passed through the drilled holes, and the fragments having been drawn together, the ends of the wire are twisted, cut short, and then hammered down on the bone, where they may be allowed to remain permanently, without causing any irritation.

Kocher's method of treating fractured patella

consists in passing a stout silver wire completely around the bone. A needle in a handle is passed through the ligament of the patella, through the tendon of the quadriceps, and out through the skin. It is then threaded and drawn back again; the broken fragments are drawn together, the wire twisted up over something, to protect the skin, and the openings dusted with iodoform. The limb is then placed upon a back splint, bandaged, and kept in this position for 3 weeks; at the end of this time the wire is cut, drawn out of the wound, and the sore points that are left dusted with iodoform until the parts are healed.

Knee-joint dislocations are very rare, though displacement of the semilunar cartilages, especially following violent rotatory movements with flexed knee, are more frequent.



Brace for Dislocated Semilunar Cartilage. The mechanism permits flexion and extension, but prevents rotation.—(*Walsham.*)

Dislocation of the semilunar cartilages of the knee joint (*subluxation, internal derangement of the knee*) follows a twist of the partly flexed knee. The cartilages are torn from the tibia by rotation of the leg; the internal cartilage being the one usually affected. Any of its attachments or even the cartilage itself may be ruptured.

The **symptoms** are severe pain in the knee and effusion into the joint which is locked in flexion; extension being impossible. This locking may not be present; such cases are sometimes diagnosed as sprains. In the latter tenderness is more generalized and extension may relieve rather than increase the pain. The displaced cartilage may be felt, but more often palpation will reveal nothing but marked tenderness along the front of the upper surface of the tibia. Recurrences are frequent.

The **treatment** is reduction by increasing the flexion, rotating the leg, making firm pressure over the situation of the displaced cartilage, and extending the leg. Often spontaneous reduction occurs before the surgeon is called. The synovitis should be treated and the knee immobilized for five or six weeks. In order to prevent recurrence an elastic knee-cap should be worn for several months. If relapses are frequent a brace may be applied, or the joint may be opened by a curved incision along the upper edge of the tibia, and the cartilages stitched to the periosteum with catgut, or excised if they are ruptured.

Complete displacements may occur **forward, backward,** and **laterally;** they are combined with tearing of the lateral and crucial ligaments, result from the direct application of great force, and hence are usually complicated injuries. Such an injury is, of course, easily manifest. Reduction is by direct pressure and traction. **Rotatory dislocation,** from twisting, also occurs. In all dislocations of the knee the patient should wear an elastic knee-cap or a brace for several months after restitution of the joint.

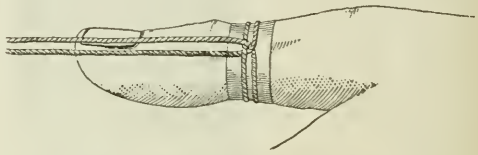
Dislocation of the patella may be outward, inward, and vertical (rotated about the long axis, this embracing also its complete reversal). The outward displacement is more frequent. These conditions are easily recognized, except the completely reversed form, which is the greatest rarity. Complete extention of the leg with flexion of the hip will usually permit reduction.

The fibula may be dislocated from the tibia at its upper (and lower) extremities. The head may be dislocated forward and backward. This injury may be associated with isolated fracture of the upper tibia. There is inability to bear weight with mobility of the head. After reduction a molded splint should be applied to fix the head.

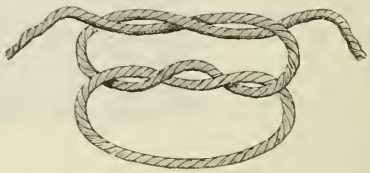
For further discussion of injuries of the knee-joint, see Joints (Injuries).

KNOCK-KNEE.—See Genu Valgum.

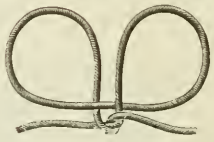
KNOT.—An interlacement of ends or parts of one or more cords or threads so that they cannot be readily separated. **K., Clove-hitch,** a knot



Clove-hitch Knot.



Combined Surgeon's and Reef Knot.



Staffordshire or Tait's Knot.

Granny Knot

Surgeon's Knot.

Reef Knot.

consisting of two single, contiguous loops, the free ends toward each other. It is used for making extension in the reduction of dislocations. **K., Double.** Same as K., Friction. **K., False.** Same as K., Granny. **K., Friction,** one in which the ends are wound twice around each other before they are tied. **K., Gerdy's Extension,** resembles the clove-hitch; it is employed in making extension of

the leg at the ankle. **K., Granny,** a tie of a cord in which in the second loop the end of one cord is over, and the other under, its fellow, so that the two loops do not lie in the same line. This knot may easily be converted into a slip-knot. **K., Reef,** a knot so formed that the ends come out alongside of the standing parts and the knot does not jam. It is also called square knot. **K., Sailor's.** Same as K., Reef. **K., Square.** Same as K., Reef. **K., Staffordshire,** a knot used in ligating the pedicle in ovariotomy. The ligature is passed through the pedicle, and withdrawn so as to leave a loop, which is passed over the tumor and one of the free ends is then drawn through the loop; both ends are then passed through the pedicle, tightened, and tied. It is also called Tait's knot. **K., Stay,** a term applied by Ballance and Edmunds to a knot formed by two or more ligatures in the following way: On each ligature separately is made the first hitch of a reef knot, which is tightened so that the loop lies in contact with the vessel, without constricting it; then, taking the two ends on one side together in one hand, and the two ends on the other side in the other hand, the vessel is constricted sufficiently to occlude it, after which the reef knot is completed. The simplest method of completing the knot is to treat the two ends in each hand as a single thread, and to tie them as if completing a single reef knot. **K., Surgical,** a double knot made by passing the thread twice through the same loop. **K., Tait's.** See K. Staffordshire.

KOCH'S POSTULATES.—See Bacteriology.

KOLA.—The nut or seed of *Cola acuminata,* used in parts of central Africa as a substitute for tea and coffee. It contains both *caffein* and *theobromin, tannic acid* and a glucosid substance named *kolanin,* which, in the presence of a ferment, splits up into free caffein and glucose. The Kola nut is said to be stimulant and aphrodisiac. It improves the appetite and the digestion, and is useful in gastric catarrh and in the dyspepsia of alcoholic subjects, as an adjunct to other treatment; also in asthma of both the nervous and cardiac forms. It is especially efficient in atonic diarrhea; and in gastrointestinal irritation with looseness of the bowels, a restricted diet and Kola-wine are frequently all that is needed.

KOOMISS.—See Kumyss.

KOUSSO.—See Cusso.

KOPLIK'S SPOTS.—See Measles.

KRAMERIA (Rhatany).—The dried root of *Krameria triandra.* It contains 20 to 45 percent of *rhatania-tannic acid,* also *rhatantin,* an alkaloid, and wax, gum, etc. Dose, 10 to 20 grains.

It may be employed for the same purpose as tannic acid except as an antidote to antimony. It has been used as an injection for fissure of the anus, as a local application to spongy gums, as a tonic for debilitated subjects, in chronic diarrhea, also in passive hemorrhages and mucous discharges, as menorrhagia and leukorrhea.

Preparations.—**Extractum K.,** aqueous. Dose, 5 to 10 grains. **Fluidextractum K.** Dose, 5 to 20 minims. **Tinctura K.,** 20 percent. Dose, 1/2 to 2 drams. **Syrupus K.,** has of the fluidextract 45 parts, with syrup 55. Dose, 1/2 to 4 drams. **Trochisci K.,** each troche contains nearly 1 grain of the extract, with tragacanth, sugar and orange-flower water.

KYPHOSIS.—See Spine (Curvature).

KUMYSS (Koomiss).—An effervescing fermented liquor originally prepared by the Tartars from mare's milk, but now imitated with cow's milk by adding sugar of milk, fermenting in open tanks, skimming off the casein and butter, then bottling during active fermentation. Its successful preparation depends on its undergoing slow fermentation for 5 to 10 days in a cold room, at 40° F. If the temperature be higher than 50° the fermentation will be of the acetous variety, and will result in sour milk with heavy curd, feeble effervescence and repulsive taste. Kumyss has an acidulous and peculiar taste. It is a powerful diuretic, especially in cold weather, and in warm weather it causes free perspiration. It is stimulant and tonic, increases the nutrition of the body and produces considerable somnolence. The stomach tolerates it well, even when it rejects all other food. It is easily assimilated and very nutritious.

Kumyss is an invaluable article of diet in many wasting diseases, especially phthisis. It is of great benefit in dyspepsia, the diarrheas of children, convalescence from acute maladies, chronic affections of the kidneys, and other cachexiæ. In cases of feeble digestive power an ounce every hour is sufficient, but as its digestion and assimilation increase it may be given almost *ad libitum,* and when used with other food a half-pint may be taken after each meal. Each quart is estimated to contain four ounces of solid food, besides from 1 to 3 percent of alcohol. See Kefir.

L

LABARRAQUE'S SOLUTION.—Solution of chlorinated soda; an aqueous solution of several chlorin compounds of sodium, containing at least 2.4 percent by weight of available chlorin prepared by adding together aqueous solutions of monohydrated sodium carbonate 65, and chlorinated lime 90, then adding water to 1000. Dose, 10 to 30 minims (average, 15 minims) in 20 parts of water. See DISINFECTION.

LABIA, DISEASES.—There is a type of inflammation of the labia that resembles erysipelas in its extensive swelling and redness, but differs from it in the fact that it does not spread. It subsides in a few days, but if severe, it may produce sloughing. It is seen in typhus and small-pox, and after delivery. A wound may be found, or no history of any violence is to be elicited, without pregnancy or previous illness. The affection is usually bilateral. Treatment requires separation and support of the labia, and the application of an evaporating lotion like the following:

℞. Solution of lead acetate, } each, ʒ ss
Rectified spirit of wine, }
Water, O j.

If a tendency to gangrene is seen, the actual cautery is needed to separate the slough, followed by cleansing by frequent antiseptic lotions.

Erysipelas may attack the labia, as any other part of the body.

Herpes of the labia runs its usual course, requiring drying and sedative applications, such as bismuth, lead ointment, or an ointment containing bismuth, 30 grains; morphin, 10 grains; and vaselin, 1 ounce.

Abscess of the labia is usually unilateral, generally in Bartholin's gland, and is due to gonorrhea or traumatism. It forms a tender, fluctuating, and nonreducible swelling which, if left alone, will burst and refill, and thus continue indefinitely. The gland must be dissected out to obtain effectual cure. See BARTHOLIN'S GLANDS.

Eczema of the labia is often found in elderly, plethoric, and gouty women and in the subjects of diabetes. Antacid remedies and purgatives are given, combined with rest, the avoidance of alcohol, and a restricted diet.

℞. Magnesium sulphate, ʒ j
Magnesium carbonate, gr. x
Aromatic spirit of ammonia, ♏ xx
Water, ʒ j.
Give twice daily.

For local application, lead ointment, zinc ointment, and an ointment of the nitrate of mercury and zinc ointment in equal parts may be used, the last being used in chronic and indolent conditions, the first when the parts are very sore. Silver nitrate, 20 grains to 1 ounce of water, may be applied once or twice a week.

Warts on the labia, when nonsyphilitic, are acuminate, and not flat and overhanging. They are associated with uncleanliness and unchastity, but are not proof of the latter. A powder of calomel and zinc oxid may be used; they may be cut off if large, the hemorrhage being controlled by pressure, styptics, or the Paquelin cautery.

Syphilitic warts, mucous tubercles, or condylomata are moist, broad, overhanging, white patches. Locally, black wash should be applied, and mercury given by the mouth.

Epithelioma of the labia occurs as a warty growth, accompanied by ulceration, which shows no tendency to healing.

The treatment of epithelioma is removal of the growth—best by the knife or Paquelin cautery—together with a good margin of healthy tissue. The inguinal glands on the corresponding side should be removed also if the growth is at all advanced.

Innocent growths, as lipomata, are met with in the labia; and **elephantiasis** of the labia is occasionally encountered. These growths are to be treated by removal, if their bulk causes inconvenience. The labia may also be the seat of lupus and swelling or of hematoma. Boils sometimes are found here, and are distressing because of pain and the suspicion they suggest. Hydrocele of the labia must be carefully differentiated from hernia, and probably the safest practice is to cut down on the tumor, open it, and remove the sac. See VULVA.

LABOR.—That natural process by which the fetus and its appendages are expelled from the uterus and vagina at the normal expiration of pregnancy. This should be about 280 days after appearance of the last menstruation.

Causes.—Just why labor should occur at this particular time is unknown. It has been thought to be due to: (1) *Periodicity*, the muscular action of the uterus being particularly strong at the tenth period; (2) *overdistention of the uterus*, which is followed by retraction of the uterine muscle and expulsion of the fetus; (3) *maturity of the ovum*, the decidual cells undergoing fatty degeneration toward the end of pregnancy, thus causing a "loosening" of the ovum; (4) *nervous impulse*, reflected from the central nervous system through the sympathetic to the uterus; (5) when the uterus is incapable of further distention the fetus becomes practically a *foreign body*, and as such is expelled.

Signs. 1. Subsidence of the Uterus.—This occurs about 4 weeks before term in primiparæ, 2 weeks before term in multiparæ. It is due to retraction of the abdominal muscles, which forces

the presenting part and lower uterine segment into the pelvic cavity. The size of the abdomen is decreased, the pressure-symptoms above, such as irritability of the stomach and difficult breathing, are relieved; and the pressure-symptoms below, as edema and excessive vaginal secretion, are increased. Should subsidence of the uterus not occur, it usually indicates a malposition of the child or some obstruction, as a contracted pelvis or oversized head.

2. **Pains.**—These are felt over the sacrum and lower part of the abdomen. They are intermittent in character, occurring at first about every 15 minutes, and lasting about 1/2 to 1 minute. They should not be confounded with pains due to intestinal colic or to rheumatism of the uterine muscle.

3. **Show.**—This is a small plug of blood-tinged mucus which has occluded the cervical canal during pregnancy, and which is now expelled with the first few pains.

4. **Dilatation of the Os.**—This is by far the most important sign, and when accompanied by effacement of the cervical canal, is a positive indication of labor.

Stages.—Normal labor may be divided into 3 stages:

1. **The Stage of Dilatation and Effacement.**—This begins with the first pain and lasts until full dilatation of the os is accomplished. The average time required for the completion of the first stage is, in primiparæ, 10 to 12 hours; in multiparæ, 6 to 8 hours.

2. **The Stage of Expulsion.**—This begins with full dilatation of the os, and lasts until the child is expelled from the vagina. Its average duration is, in primiparæ, 2 to 4 hours; in multiparæ, 1 to 2 hours.

3. **The Placental Stage.**—This covers the period which elapses between the birth of the child and the expulsion of the placenta and membranes. Its average duration is 15 minutes.

Management.—A call to an obstetric case should be answered immediately. The strict observance of this rule may prevent many complications, such as malpresentations, lacerations of the perineum, postpartum hemorrhage, and asphyxia of the new-born.

Certain articles are indispensable to the proper management of an obstetric case. **The patient should provide** the following: A half-pound can of ether, 2 ounces of brandy, 4 ounces of vinegar, 4 ounces of tincture of green soap, 1 dozen tablets of mercuric chlorid, a large new sponge, a skein of bobbin, a fountain syringe, a bed-pan, a new soft-rubber catheter, 4 ounces of absorbent cotton a bottle of carbolized vaselin, 2 yards of unbleached muslin, 1 pound of salicylated cotton, 5 yards of carbolized gauze, 8 yards of nursery cloth, and 2 dozen clean towels.

The physician's **obstetric bag** should contain 2 pairs of forceps, preferably the Simpson and the Tarnier axis-traction; a Sims speculum; perineal needles and needle-holder; half a dozen hemostats; a pair of blunt-pointed scissors; a set of Barnes' bags; a hypodermic syringe; iodoform gauze; fluidextract of ergot; tablets of nitroglycerin; and a 2 percent solution of silver nitrate.

The lying-in room should be large, sunny, and well ventilated, preferably by an open fireplace. It should not contain a stationary wash-stand, nor should it have any connection with a sewer, bath-room, or water-closet. If it is heated by a hot-air furnace, the intake for the air and the sanitary condition of the cellar may need investigation. No decomposing food, unemptied bed-pan or commode should be left in the room for any length of time.

The water used for douches or for washing off the vulva or perineum should be sterilized by boiling it for at least one-half hour.

The patient should receive a full bath before labor (special attention being given to the genital region), and be supplied with clean clothes. The mattress on which she lies should be clean and not soiled with discharges of previous labors or other putrescible material; it should be protected by a perfectly clean rubber cloth. The pads on which the buttocks rest during and after labor should be of nursery cloth, previously boiled and dried. The material used to wipe off the genital orifice, mouth of the urethra, and perineum should be absorbent cotton, soaked in mercuric chlorid solution (1 : 1000) for one-half hour. After labor an antiseptic vulvar pad, composed of salicylated cotton and carbolized gauze, should be worn during the continuance of the lochial discharge. These pads should be changed and the vulva cleansed 4 to 6 times in the 24 hours. If there is any pathologic discharge, the vagina should be thoroughly cleansed by scrubbing with tincture of green soap, hot water, and pledgets of cotton, followed by a mercuric chlorid douche (1 : 2000); this followed by a douche of sterile water.

The physician should not carry infectious germs upon his person or clothing. He should not attend an obstetric case after seeing a contagious disease without first taking a full bath and changing his clothing. The preparation of his hands should consist of 10 minutes' scrubbing with tincture of green soap, hot water, and a stiff nail-brush followed by scrubbing in alcohol, and immersion in mercuric chlorid solution (1 : 1000) for 2 minutes.

The instruments used about the patient should first be boiled for 10 minutes. If boiling injures them, they should be immersed in mercuric chlorid solution (1 : 1000) for one-half hour.

Examination of the patient must be made to determine the position and presentation of the child, its approximate size, the condition of the perineum, the dilatability of the vagina, the size of the pelvis, the amount of dilatation of the cervix, and the effectiveness of the pains. To ascertain the above facts an abdominal examination should first be made, the patient lying upon her back, with knees drawn up and shoulders slightly raised; followed by a vaginal examination, the patient lying in the Sims position. The vaginal examinations should be made as infrequently as possible, and always visually, so that the finger may not be contaminated by groping over the perineum or vulva before entering the vagina. By observing

these two precautions the dangers of sepsis are greatly reduced.

During the first stage of labor the patient should be allowed to occupy her time very much as she pleases. The lower bowel should be thoroughly emptied by an enema of a pint of warm soapsuds and a dram of turpentine. The vaginal examinations should be made only when necessary and when the os is dilated to the size of a silver dollar, she should be placed in bed, lying upon that side toward which the fetal back looks. If the patient is nervous, or if she complains very much of the severity of the pains, she may be given chloral hydrate, in 15 grain doses, every 20 or 30 minutes, until she has taken 45 grains. A cup of beef-tea or a glass of sherry or milk will oftentimes act beneficially.

During the second stage of labor the examinations should be made only when necessary.

If, in a multipara, the membranes have not ruptured, they should be perforated with the finger or with some aseptic instrument. Care should be exercised that the child's scalp or the lower uterine segment may not be injured.

If the pains are very severe and if the patient complains excessively, chloroform or ether may be given. The latter is probably the safer. It should be given only during the second stage, and never in sufficient quantity to produce complete anesthesia. See Anesthesia; Twilight Sleep.

During this stage the expulsive force of the abdominal muscles may be much increased by the use of a "puller." As the head advances toward the vulvar outlet, precaution must be taken to prevent laceration of the perineum. This is best avoided by making firm backward and upward pressure against the occiput during pains; by restraining voluntary expulsive efforts during pains; and by securing expulsion of the head between pains.

When the head is born, support it with the hand, wash the eyes carefully with warm sterile water, and if the cord is coiled about the neck, loosen it or slip it over the head. By this time the next pain, which secures delivery of the shoulders, will occur. Should this be delayed, stimulate the uterus by friction through the abdominal wall; or grasp the sides of the child's face with the two hands, make downward and forward traction until the anterior shoulder appears under the symphysis, then upward and forward traction, until the posterior shoulder appears, finally downward and forward traction, the anterior shoulder and remainder of the body being extracted in rapid succession. As the child is born one hand should grasp the fundus to secure and maintain firm contraction. The child should be placed by the mother's side, with its face turned away from the maternal discharges. As soon as the cord stops pulsating it should be ligated and cut.

During the third stage of labor the patient should be carefully guarded against hemorrhage. A dram of the fluidextract of ergot should be administered to aid firm contraction; and irritation of the uterus, by friction through the abdominal wall, should be persisted in for 10 or 15 minutes. If, at the expiration of this time, the placenta has not been voluntarily expelled, the fundus should be grasped firmly between the thumb and 4 fingers; as soon as the uterus is felt to harden the fundus is compressed tightly, and firm downward and backward pressure is made in the direction of the pelvic axis. Very slight traction is made on the cord with the other hand, to guide the placenta through the cervix and vagina. The placenta should be received in some sort of a receptacle as it emerges from the vulva, and should then be carefully inspected; if it and the membranes are intact, and if the womb is firm, an abdominal pad and binder should be applied, all blood and discharges cleaned away, and the patient fixed comfortably in bed.

For immediate care of the infant see New-born Infant.

LABOR, COMPLICATIONS AND SEQUELS.—See Eclampsia, Perineum (Injuries), Postpartum Hemorrhage, Puerperal Fever, Uterus, Vagina, etc.

LABOR, DIFFICULT.—See Dystocia, Fetus (Positions and Presentations), Pelvis (Contracted), etc.

LABOR, PREMATURE.—Expulsion of the fetus after it has become viable—after the sixth month of gestation.

The causes and clinical phenomena of premature labor have been discussed under Abortion (*q. v.*).

The treatment is the same as labor at term.

Induction of Premature Labor.—This becomes necessary at times for the preservation of the mother's life. Not infrequently, too, it offers to the child its best or only chance for safe delivery.

Indications for the Induction of Premature Labor.—Besides the indications which were mentioned for the induction of abortion, we have the following: (1) Certain degrees of contracted pelvis (8 to 9.5 cm.); (2) placenta prævia; (3) grave systemic disease, as phthisis and advanced heart-disease; (4) habitual death of fetus just before term.

Method of Inducing Premature Labor.—The most satisfactory method is by catheterization of the uterus. The steps of this method are as follows: (1) Disinfect the cervical canal, vagina, vulva, pubes, and inner part of thighs by scrubbing thoroughly with tincture of green soap and pledgets of cotton, followed by a vaginal douche of mercuric chlorid (1:4000); (2) two fingers of the left hand, previously sterilized and well lubricated with 5 percent carbolized oil, should now be introduced into the vagina, the middle finger pressed against the external os, which will gradually dilate until the tip of the finger is at or beyond the internal os; (3) an elastic silk bougie (No. 17 French), previously sterilized by soaking in cold mercuric chlorid solution (1:1000) for one hour, is now passed along the groove between the middle and index-fingers until it enters the uterine cavity and extends from 7 to 9 inches between the decidua vera and decidua reflexa; (4) finally, the bougie is kept in position by a vaginal tampon of iodoform gauze. The patient then lies quietly in bed, labor beginning after a variable period, the average being 12 hours. If, at the end of 12 hours, there are no

signs of beginning labor, a second and larger bougie may be inserted by the side of the first. If this fails, after the lapse of another 12 hours the cervix, which has become very much softened, may be easily dilated by means of Barnes' bags.

If there is any necessity for immediate delivery, the patient should be anesthetized, the cervix dilated with fingers or dilators, the membranes ruptured, and podalic version performed.

LABOR, TWIN.—See PREGNANCY (Multiple).

LACQUER POISONING.—Workers in lacquer, the base of which is the balsam of rhus vernicifera, are subject to a disease which resembles ivy poisoning, though the symptoms are more intense. It is met with especially in China and Japan. There is severe pruritus with edema and papules of the face and extremities and probable involvement of mucous membranes and conjunctivæ.

Treatment.—Soothing lotions such as lime water and sodium thiosulphate solution (1 to 8) or solution of aluminum acetate are indicated.

LACRIMAL DISEASE.

Diseases of the Lacrimal Gland

Abscess and inflammation of the lacrimal gland are very rare. The diagnosis depends on the presence of swelling or the signs of abscess in the region of the gland. An abscess should be incised, and any inflammation of the gland treated with a mercurial ointment or potassium iodid.

New growths are mostly **adenomata. A chloroma** is a malignant greenish tumor which sometimes attacks the lacrimal gland. **Sarcoma** and **carcinoma** are also occasionally found in this location. However, disease of the lacrimal gland is so rare an affection that many men of vast experience have never seen a case. The treatment of a tumor is prompt excision.

Dacryops is a condition in which a lacrimal duct becomes occluded and the lumen full of secretion, forming a bluish tumor on the outer upper fold of the conjunctival sac. It should be opened with a fine needle.

Fistula of the lacrimal gland is usually the result of injury or operation. The fistula should be connected with the conjunctival sac, after which the dermal opening soon heals.

Diseases of the Lacrimal Passages

The all-important sign of diseases of the lacrimal passages is the overflow of tears, or **epiphora.** The first purpose in treatment of such cases is to clear the passages so that the tears will run into the nose. However, we must remember that in oversecretion the tears will run over the cheeks. Thus, on a windy day or in emotional weeping there is not only extra secretion into the nose, causing sniveling, thus proving that the nasal duct is patulous, but, in addition, epiphora. Oversecretion of tears may be due to conjunctivitis, keratitis, an especially irritable trigeminus nerve, uncorrected ametropia, and a number of other causes.

Eversion of the puncta, or even of the lower punctum alone, will cause epiphora. We should immediately endeavor to correct any malposition, as the sequences of epiphora are very serious, eventually leading to ectropion. In cutting operations on the lids, or in the application of caustics, we must always be careful that the puncta are not involved, as eversion, with its annoying sequels, will result if this precaution is not taken.

Although it is always well to preserve the puncta, which have a physiologic function of importance in keeping solid, irritating bodies from the nasal duct and lacrimal sac, it is often necessary, for immediate drainage, to **slit the canaliculus** involved. This simple operation is performed as follows: The lower lid is drawn downward and outward, and slightly everted by the thumb of one hand, while the probe point of a canaliculus knife is introduced vertically with the other hand. When the knife is well inserted into the canal, its point is turned inward and slightly backward, reaching the inner wall of the lacrimal sac. During this maneuver the edge of the knife is turned toward the conjunctiva, and the whole length of the canaliculus is divided, close to the mucocutaneous junction by bringing the knife up boldly from the horizontal to the vertical position. In dividing the upper canaliculus the upper lid is made tense, and the knife is introduced into the upper punctum and passed into the sac in a direction downward and inward. If the canaliculus is very small, a fine-pointed conic probe should first be used to dilate it. There are various modifications of the operation—with a grooved director, fine scissors, etc. The wound should be examined at short intervals, and kept open with a probe.

Affections of the Canaliculus.—Obstruction of the canaliculus is often due to a foreign body, such as an eyelash, which not only occludes the canal, but scratches the cornea. The obstruction may be due to a stone in the canaliculus, called a **dacryolith.** Polypi of the canaliculi may grow so luxuriantly as to protrude from the puncta. The treatment in these cases is to remove the foreign body if it protrudes from the punctum; or, if the obstruction is due to a stone or polypus or there is absolute stenosis or obliteration of the canaliculus, it should promptly be slit to its full extent.

Affections of the Lacrimal Sac.—The lacrimal sac is lined with mucous membrane, which is subject to inflammation and catarrh like any other mucous membrane. Any condition which obstructs the free passage of the tears predisposes to disease of the sac, and particularly if the obstruction is in the nasal duct. The sac also becomes diseased by extension of any inflammatory process from the nose. **Inflammation** of the sac leads to **blennorrhea,** and this, in its turn, leads to **dacryocystitis,** or abscess of the lacrimal sac. The contents of a constantly suppurating tear-sac are very infectious, and although the patient may go on for many years with epiphora, conjunctivitis, and crusting of the lids in the morning, yet the infection may be so severe as to set up an inflammation which will eventually destroy the

eye. The slightest abrasion of the cornea may become infected and a dangerous ulcer result.

Dacryocystitis.—The initial symptoms are conjunctivitis, local pain, and redness of the skin. The distended sac soon appears as a tumor involving the tissues near the inner canthus of the eye. If left to itself, this tumor may ulcerate and the pus burrow through the skin, establishing what is known as a **lacrimal fistula**, which may remain a lifetime, and become in itself a safeguard against a new attack. Often the distended sac loses its elasticity and becomes a permanent tumor, called **hydrops sacci lachrymalis.**

The diagnosis of simple catarrh, blennorrhea, or *hydrops* is easily made by emptying the sac with pressure of the finger: in catarrh, a watery secretion appears at the punctum; in blennorrhea there is more or less pus; in hydrops, the sac may empty into the nose and no secretion appear. Dacryocystitis and fistula need only be seen to be recognized.

Treatment.—Any nasal affection should be corrected, and a free passage for tears into the nose established. The latter is generally effected by the passage of sounds. Bowman's sounds or probes are usually employed. The canaliculus should be slit, and the following day the passage of probes commenced. It is optional which canaliculus is used, but the upper is shorter and easier to sound.

To pass a lacrimal sound or probe, the point of the sound must be passed along the floor of the slit canaliculus to the nose, until it is felt to strike against bony resistance; the sound is then rotated until it points downward; keeping close to the inner wall of the sac, the sound is then firmly pushed along. Under ordinary circumstances, if the probe is in the right position, it will pass along the nasal duct with a moderate pressure; undue resistance to a small probe indicates stricture of the duct or a false passage; in either case the pressure should be used cautiously. If the sound has passed easily, it should be left in position several minutes; in fact, it may remain one-half hour often to advantage. If the passage has been tight, the sound should be immediately withdrawn. The sounding of the passage should be repeated every 3 or 5 days, and the size of the sounds progressively increased. In some cases it is well for the patient to wear a leaden stilet constantly for several days. Theobald and others advocate the use of very large lacrimal sounds. A special probe-pointed knife has been devised for slitting strictures of the nasal duct. In treatment of the lacrimal passages we should resort to frequent syringing, various astringent and antiseptic preparations being used. Weak solutions of silver nitrate are of benefit in blennorrhea.

Recently there has been a reaction against promiscuous probing in lacrimal disease. The results are generally unsatisfactory and the case is often protracted. As a substitute there has lately been advised copious syringing with a fountain syringe attached to a hollow No. 4 Bowman's probe. The canaliculus need only be split halfway, and in some cases not at all. Boric acid and weak antiseptic solutions are used in the irrigations.

A simpler treatment of lacrimal obstruction, which dispenses with mutilation of the puncta and canaliculus and probing, consists in the following manipulations:

First empty the sac and canaliculi by dexterous pressure, and cleanse the eye and palpebral pockets of the unhealthy material. Then cant the patient's head back and to one side, or have him lie so that a teaspoonful of liquid will be held in the depression formed by the nose, orbital border, and superior maxilla. Fill this space with a weakly antiseptic solution. A good solution is composed, to the ounce of distilled water, of boric acid, 10 grains; common salt, 3 grains; chlorid of zinc, 1 grain—all deeply tinted with pyoktanin-blue, and doubly filtered after long standing. With the little finger again slowly empty the sac and canaliculi by pressure, and then, as slowly lessening the pressure, allow these spaces to refill, by suction and capillary attraction, with the solution under which the puncta are submerged. Again, in half a minute, empty the canaliculi and sac by pressure, but this time beginning the pressure from the canthus toward the nose and downward, so as to force the antiseptic solution downward into the duct. These alternate emptyings and refillings of the sac may be repeated several times and as often as desirable to meet the indications of the case. It will usually be found that the sac will soon become healthy, and that pressure upon it will not cause regurgitation of morbid material through the puncta.

A certain number of cases, however, will not yield to this treatment. There is too great stenosis or spasmodic contraction of the muscular sphincter of the punctum, etc., so that the cleansing solution cannot be forced into the sac and duct. In such case it is well to insert one sharp point of the iris-scissors into the punctum, and snip it open about 1/8 of an inch, perpendicularly downward toward the conjunctival fold. This gives a larger opening for the indrawal of the solution.

Obliteration of the lacrimal sac is a questionable procedure. **The treatment of acute dacryocystitis** consists in voiding the pus, either through the canaliculus or by an incision through the skin. The fistula is treated like other fistulous passages, and will generally heal if the obstruction to the passage of tears is removed. Repeated irrigation, syringing, and probing are the important after-treatments of all these affections.

LACTATION.—See Breast, Infant Feeding, Milk (Mother's), New-born Infant.

LACTIC ACID.—A liquid composed of 75 per cent by weight of absolute lactic acid, and 25 percent of water; nearly colorless, syrupy, odorless, of acid taste and reaction, freely miscible with water, alcohol and ether, but nearly insoluble in chloroform. It is produced by the lactic fermentation of sugar of milk or grape sugar, and is difficult to obtain pure. It enters into syrupus calcii lactophosphatis. Dose, 20 minims to 1 dram (average, 30 minims), well diluted.

It aids digestion and promotes the appetite, but in large doses causes flatulence and much epigastric pain. It dissolves false membranes and also

calcium phosphate. Hypnotic properties have been ascribed to it.

Lactic acid is used with benefit in diabetes, atonic dyspepsia, oxaluria, and in the lithic and phosphatic diatheses, when due to imperfect digestion and assimilation. As a solvent of false membrane in diphtheria it is unquestionably of great service, but painful. In chronic cystitis it arrests the ammoniacal decomposition in the urine. As the acid found in the shops is generally of poor quality, disappointment in its use may be expected. It has been used in tuberculous ulceration of the tongue: lactic acid, 80 parts; water, 20 parts, brushed daily over the ulcerated surface with a camel's-hair brush.

LACTOPHENIN.—A phenetidin derivative containing a lactic acid radicle instead of the acetic acid one of acetphenetidin (phenacetin). Its action is analgesic, antipyretic, and hypnotic; and it has been recommended as a substitute for phenacetin because of its greater solubility. Dose, 8 grains to begin with (for adults); maximum daily dose, 45 to 75 grains in wafers.

LACTUCARIUM (Lettuce).—The concrete milk-juice of *lactuca virosa*. It is partly soluble in alcohol and in ether, and yields a turbid mixture when triturated with water. Lactucarium is a mixture of several substances, the most important being *lactocin*, which is thought to be the active principle. It occurs in white scales, is soluble in water, and is used as a sedative and hypnotic in doses of 1 to 5 grains. Lactucarium also contains three bitter principles, *lactucin*, *lactopicrin* and *lactucic acid;* also *lactucerin*, an inert, waxy substance, constituting nearly one-half of the drug. A minute quantity of a mydriatic alkaloid, believed to be *hyoscyamin*, has been found in the plant, but not in commercial lactucarium. Dose, 10 to 20 grains.

Lactucarium is feebly hypnotic, somewhat sedative and diuretic. It is supposed to act similarly to opium, but very feebly and without depressing after-symptoms. Its preparations are very uncertain in activity, and are chiefly used as placebos, to allay cough and quiet nervous irritability. The syrup is a good vehicle for expectorants and antispasmodics.

Tinctura L., 50 percent. Dose, 10 minims to 2 drams according to the activity of the drug. **Syrupus L.**, has of the tincture 10 percent. Dose, 1 to 8 drams.

LAGOPHTHALMOS.—A condition in which the eyeball is so extruded that the lids cannot be completely closed. The exposure of the eye following this condition is accompanied by the greatest danger to the cornea. Lagophthalmos may be due to staphyloma of the cornea, ocular or orbital tumor, exophthalmic goiter, or paralysis of the orbicularis muscle.

LA GRIPPE.—See Influenza.

LAMBERT'S TREATMENT FOR NARCOTIC ADDICTION.—This treatment, originated by Mr. C. B. Towns of New York, has been described by Dr. Alexander Lambert, of the same city, and is best known under his name. Previous to its publication, the usual treatment had been to deprive the patient slowly or quickly of his narcotic on the theory that deprivation from a narcotic would soon wear off the desire for it. But deprivation instead of obliterating the craving, intensified it. A patient deprived of his morphin or alcohol counts the days or hours until he can return to his narcotic, and this longing for it and looking forward to it has been known to last for weeks and months. After this treatment has been correctly given the desire for the narcotic is gone, and although the patient may feel weak and relaxed, he does not feel the craving. This treatment will take a morphinist from his drug without undue suffering, and will put him in a position in which he may be built up and given a chance to be free from his drug. It will do the same for the man who takes cocain. It has also been successfully used for tobacco, and the habits of the coal-tar hypnotics such as veronal and trional. This treatment will put an alcoholic on his feet, make him absolutely sober, and with all desire for his alcohol gone. It will give the man who wishes to be helped a chance to be free from his habit. After a man has been freed from the desire for his drug—the after treatment is of the greatest importance. The patient should be made to realize that he is mentally just unpoised, and his nervous system cannot as a rule stand the strain of worry and work. He must be built up physically into as perfect a condition as circumstances will permit, and this will take usually three weeks or a month, or longer. If this is done, the physical condition will not tempt the mind back into the seductive taking of little nibbles at his drug, which to his mind don't count, but which in reality are the beginning again of all the old habit. It is useless to compromise; the man who has taken alcohol to excess, or morphin or cocain to excess, cannot again touch these things without great danger of relapse to all their excesses. The first drink will start up all the old desires with the same inevitable results. To the man who has indulged excessively, his nervous system and alcohol are chemically incompatible. The alcohol forms a poisonous combination with the brain cells which perverts the normal reaction of these cells. There is no question that it poisons the higher functions of the brain and perverts them. It is useless for him to ever hope to drink again in moderation. Many alcoholics have the faint hope back in their minds, against everything that is told them, everything they have experienced, and everything which their own judgment dictates, that some day they may be able to drink without going to excess. This *summum bonum* of their desires is always being sought for and never attained, and the self deception goes on; they are always trying to see if the first few drinks cannot be taken with impunity. This is one of the reasons why so many men revert. It is useless to endeavor to help a man who does not want to be helped. It is useless to waste time giving a treatment to take away the craving for narcotics to an individual who has no intention of trying to stop. The Lambert treatment is distinctly contraindicated in those who are

not willing to help to stay sober. It is also contraindicated in pregnant women, as the very active cathartics may sometimes produce a miscarriage. The method of administering this treatment has been most recently described in the Journal of the American Medical Association of February 18, 1911, and is as follows:

The belladonna mixture of two parts 15 percent tincture of belladonna, and one part each of the fluidextracts of hyoscyamus and xanthoxylum, has proved itself an essential part of the treatment. When the 10 percent tincture of belladonna has been used, or when even a 12 percent tincture has been employed, the results obtained were not clear-cut, but left the patients with an indefinite nagging longing for their narcotic. It seems necessary to push this mixture to the physiologic tolerance of the belladonna. This tolerance, of course, varies with the individual, and some of the best results have been obtained with patients who could not tolerate as an hourly dose more than from 2 to 4 drops of this mixture, while others easily tolerated from 18 to 20. It would seem, judging from clinical results, that there are some properties in this mixture which are necessary to a successful carrying out of the treatment. The bottle containing this mixture must be kept well corked, and shaken before using. The method which Lambert pursues is as follows:

A patient addicted to morphin is given five compound cathartic pills and 5 grains of blue mass, and, six hours later, if these have not acted, they are followed by a saline; after three or four abundant movements of the bowels from these cathartics, the patient is given, in three divided doses at half-hour intervals, two-thirds of the total daily twenty-four-hour dose of morphin or opium to which he has been accustomed. Observe carefully after the second dose has been given, as the amount then equals four-ninths or nearly one-half the total twenty-four-hour dose. Some few patients cannot comfortably take more than this amount. At the same time with the morphin, 6 drops of the belladonna mixture are given in capsules. This belladonna mixture in doses of 6 drops (and by drops are not meant minims, but drops dropped from an ordinary medicine dropper, which is about half a minim dose) is given every hour for six hours. At the end of six hours the dosage is increased 2 drops. The belladonna mixture is continued every hour of the day and every hour of the night continuously throughout the treatment, increasing 2 drops every six hours until 16 drops are taken, when it is continued at this dosage; it is diminished or discontinued at any time if the patient shows belladonna symptoms such as dilated pupils, dry throat or redness of the skin, or the peculiar and incisive and insistent voice, and insistence on one or two ideas. It is begun again at reduced dosage after the above symptoms have subsided.

At the tenth hour after the initial dose of morphin is given, the patient is again given five compound cathartic pills, and 5 grains of blue mass. These should act in six or eight hours after they have been taken. If they do not act at this time some vigorous saline is given, and when they have acted thoroughly the second dose of morphin is given, which is usually about the eighteenth hour. This should be one-half the original dose; *i. e.*, one-third of the original twenty-four-hour daily dose. The belladonna mixture is still continued, and ten hours after the second dose of morphin has been given, that is about the twenty-eighth-hour, five compound cathartic pills are again given and 5 grains of blue mass, these again if necessary followed by a saline seven or eight hours later. At times when the C. C. pills are not acting well, or too slowly, five or six "B. B." pills are given from two to three hours after the C. C. pills. These "B. B." pills are the pilulæ catharticæ vegetabiles of the pharmacopeia with 1/10 grain of oleoresin of capsicum, 1/2 grain of ginger, and 1/25 minim of croton oil added to each pill. After these have thoroughly acted at about the thirty-sixth hour, the third dose of morphin is given, which is one-sixth of the original dose. This is usually the last dose of morphin that is necessary. Again, ten hours after this third dose of morphin, *i. e.*, the forty-sixth hour, the five C. C. pills and 5 grains of blue mass are again given, followed in seven or eight hours afterward by a saline, and one expects at this time to see the bilious green stool appear. When this appears, after the bowels have moved thoroughly, ten or twelve hours after the third dose of morphin, about the fifty-sixth hour, two ounces of castor oil are given to clear out thoroughly the intestinal tract. During this last period when the bowels are moving from the C. C. pills and before the oil is given, the patients have their most uncomfortable time. Their nervousness and discomfort can be controlled usually by codein, which can be given hypodermically in 5 grain doses and repeated if necessary, or some form of the valerianates may help them. About the thirtieth hour these patients should be stimulated with strychnin or digitalis, or both. After they are off their drug, the tonics which do them the most good are those which contain some form of phosphorus and arsenic; and here a warning must be given as to the danger of these patients overeating, and thus bringing back all their withdrawal symptoms due to the disturbance of digestion. They have been in the habit of referring all uncomfortable feelings to those of the withdrawal symptoms of morphin, and digestive disturbances feign these withdrawal symptoms. Sometimes about the thirty-sixth hour the stools become clay-colored. Some form of prepared ox-gall is most effective to stimulate further biliary secretion given in small doses every hour for five or six doses.

In treating an alcoholic, the belladonna mixture and the five C. C. pills and 5 grains of blue mass are given simultaneously at the first dose. The belladonna mixture is continued every hour of the day and every hour of the night the same as with the morphin patients, and twelve hours after the initial dose patients are again given from three to five C. C. pills, and at the twenty-fourth hour after the initial dose, they are again given the cathartics followed by salines if necessary, and again

at the thirty-sixth hour. After these cathartics, the bilious stools will appear, and by the forty-fourth or forty-fifth hour the castor oil is given. Sometimes it is necessary to carry on the treatment over another period, and the C. C. pills and blue mass are again given at the forty-eighth hour, which would bring the end of the treatment about the sixtieth hour.

Elderly or very nervous patients who have been on a prolonged debauch are tapered off with 2 ounces of whisky for four or five doses through the first twenty-four hours. If these patients are excessively nervous it is necessary also to see that they sleep, and the mixture of chloral hydrate, 20 grains; morphin, 1/8 grain; tincture of hyoscyamus 1/2 dram; ginger, 10 minims; and capsicum 5 minims; water 1/2 ounce; which was recommended before is the best hypnotic for them. These patients should also have cardiac stimulants such as strychnin and digitalis after the first twenty-four hours, sooner if they are weak. If the patient has an alcoholic gastritis and cannot retain medicine, it is wise to give him 5 grains of Tully's powder (pulvis morphinæ compositus) with 5 grains of sodium bicarbonate about every two hours for two or three doses, as this seems to be the most effective method of allaying the vomiting of an alcoholic gastritis.

The cocainist can be treated like the alcoholic, except that no cocain is given at any time, and strychnin or some such stimulant must be given from the beginning of the treatment.

The lasting effects of this treatment are of course greatly influenced by the environment in which the patient must live after he has had the treatment. As was said before, if he be in as fine physical condition as is possible, he stands the best chance of being able to resist. Except in the elderly, and those in whom there is danger from cardiac degeneration physical exercise is the very best after treatment. They should not be treated with a rest cure, but should be built up by physical exertion. As soon as they are in good physical trim they will do better if the responsibility of some occupation is given them, rather than distrust and idleness. It is a very noticeable feature in treating these patients, especially the alcoholics, that those who are addicted to a cigarette habit are much more prone to relapse than those who do not smoke at all, or even than those who smoke cigars or a pipe. It is the constant poisoning by an incessant accumulation of small doses of tobacco poison, which finally amounts to a chronic tobacco poisoning. This wears on their nerves, and their nerves must be quieted by some narcotic and they turn to the one to which they are most accustomed and moving in the line of least resistance drop back into their old habits. If a man who drinks to excess can be treated at the same time for his cigarette habit, it increases the probability of his remaining abstinent. This treatment must not be considered as a cure-all and a regenerator of the weak-minded and congenitally unfit members of the human race, but it will give those who desire to break away from narcotic addiction a chance to do so, and a chance to go on in life successfully where they might otherwise fail.

LAMINARIA (Sea-tangle).—A seaweed, *Laminaria digitata*, found upon the shores of Great Britain. It has a stem from 6 to 15 feet in length, and about 1 inch to 1 1/2 inches in diameter at its largest part. The stem shrinks to a marked degree in drying. The dried pieces, when again moistened, quickly regain their natural size. This property makes laminaria valuable for the manufacture of tents and bougies. The plant is one of the sources of iodin, which it contains in large proportion. When burned, it produces a superior, fine-grained charcoal. See TENT.

LAMINECTOMY.—See SPINE (Injuries).

LANDRY'S PARALYSIS.—See PARALYSIS (Acute Ascending).

LANOLIN (Adeps lanæ hydrosus).—The purified fat of the wool of sheep, mixed with not more than 30 percent of water. A yellowish-white, ointment-like mass of faint, peculiar odor, insoluble in water, but miscible with twice its weight thereof. It is a cholesterin fat, differing from other fatty substances chiefly in resisting saponification and the action of water, and having no tendency to become rancid. It readily passes through the integument, carrying with it any medicament with which it is charged. It is a neutral base, and not likely to decompose any substance. It is peculiarly useful in chronic skin-disease where there is infiltration. It is inferior to lard, vaselin, or cold cream when a simple protective action alone is desired.

LAPAROTOMY.—See ABDOMINAL SECTION.

LAPPA (Burdock).—The dried root of *Arctium Lappa*, and of other species of *Arctium*. It contains a bitter principle, traces of a volatile oil, also inulin, resin, tannin, mucilage, sugar, etc. Dose, 20 to 45 grains.

Lappa promotes all the secretions and is considered aperient, diuretic and diaphoretic, without irritating qualities. In decoction it has been a popular domestic remedy for many morbid conditions, especially rheumatism, gout, pulmonary catarrhs, and chronic cutaneous affections. It has been used as an alterative in constitutional diseases, as syphilis and scrofula, also as an external application to swellings, hemorrhoids and chronic sores.

Fluidextractum Lappæ, made with diluted alcohol. Dose, 20 to 45 minims.

LARD (Adeps).—The prepared internal fat of the abdomen of the hog, purified by washing, melting and straining. It occurs as a soft, white, unctuous solid, of bland taste and neutral reaction, entirely soluble in ether, benzin, and bisulphid of carbon; composed of 38 percent of stearin and margarin, and 62 percent of olein. Lard forms 50 percent of ceratum, and 80 percent of unguentum, and enters into the composition of several of the official cerates.

Preparations.—**Adeps benzoinatus,** *benzoinated lard*, has 2 percent of benzoin in powder, incorporated by stirring. **Oleum adipis,** *lard oil*, is a fixed oil expressed from lard at a low temperature.

LARGIN.—A silver-albumin compound, which

in the air-dried condition contains 11 percent of silver. It forms a gray powder, which is soluble in 10 parts of water. Largin is a powerful bactericide and astringent, like silver nitrate, but is nonirritant, and is not precipitated by sodium chlorid or albumin. It is chiefly used in gonorrhea in 1/4 to 1 1/2 percent solution.

LARYNGEAL MUSCLES, PARALYSIS. Etiology.—Central nervous lesions, as bulbar paralysis; perpiheral nervous lesions, affecting the recurrent laryngeal nerve (such as aortic aneurysm, tumor of mediastinum, diphtheritic paralysis); local lesions of the vocal cords (such as ulceration due to syphilis, or tuberculosis); and hysteria.

The nerves involved are the superior laryngeal and the recurrent laryngeal (both branches of the pneumogastric nerve).

The following oftquoted table from Gowers shows the symptoms, laryngoscopic picture, and lesions.

Treatment, is that of the cause; electricity and strychnin have also been employed.

Vocal Cords (Diagrammatic Mirror Picture). 1. Normal position in breathing and phonation respectively. 2. Adductor paralysis (left); 2′. bilateral adductor paralysis. Both in phonation. 3. Unilateral abductor (left) and 3′. Bilateral abductor paralysis both during breathing. 4. Left recurrent paralysis phonation. 4′. Same in respiration. 4″. Recurrent bilateral in both respiration and phonation. 5. Arytenoid paralysis phonation. 5′. Thyroarytenoid paralysis phonation. 5″. Arytenoid and thyroarytenoid paralysis.—*Greene.*)

Symptoms.	Signs.	Lesion.
(*a*) No voice; no cough; stridor only on deep inspiration.	Both cords moderately abducted and motionless.	Total bilateral palsy.
(*b*) Voice low-pitched and hoarse, no cough; stridor absent or slight on breathing.	One cord moderately abducted and motionless, the other moving freely and even beyond the middle line in phonation.	Total unilateral palsy.
(*c*) Voice little changed; cough normal; inspiration difficult and long, with loud stridor.	Both cords near together, and during inspiration not separated, but even drawn nearer together.	Total abductor palsy.
(*d*) Symptoms inconclusive; little affection of the voice or cough.	One cord near the middle line, not moving during inspiration; the other normal.	Unilateral abductor palsy.
(*e*) No voice; perfect cough; no stridor or dyspnea.	Cord normal in position and moving normally in respiration, but not brought together on an attempt at phonation.	Adductor palsy.

LARYNGISMUS STRIDULUS.—A peculiar form of laryngo-respiratory spasm, occurring almost exclusively in rickety children. There is no lesion of the larynx, it being usually a pure neurosis. The characteristic feature of the attack is a sudden "holding of the breath" for a few seconds; the glottis is then burst open, the air rushing in with a stridulous sound. In a severe attack not only the glottis, but the epiglottis, is closed, and the respiratory muscles are in a state of spasm. The exciting cause is most commonly some emotional disturbance, while dentition, irritation of the larynx or pharynx, nasal adenoids, or constipation may act as exciting causes.

The following table gives the chief points of diagnosis:

Laryngismus (Spasm of the Glottis).	Spasmodic Laryngitis.	Membranous Croup.
Occurs in rickety children 18 months of age.	Rarely occurs under 2 years of age; commonest 2 to 7 years.	Occurs at all ages during childhood.
No fever, no coryza and no laryngeal catarrh.	Slight fever, mostly coryza and laryngeal catarrh.	Variable amount of fever and perhaps some diphtheria of fauces.
Occurs at any period of the 24 hours, and often many times.	Attack occurs at night.	Mostly worse at night.
No cough; inspirations are stridulous.	Metallic cough, stridulous respirations, variable dyspnea.	Metallic cough, stridulous respiration, progressive dyspnea.
Contraction of the limbs or general convulsions not uncommon.	Convulsions rare.	Convulsions rare.
The attack lasts a few seconds and then recurs frequently.	Attack passes off in the course of an hour or two.	Becomes steadily worse, though variations occur in its progress.
Occasionally fatal...	Rarely fatal.....	Very often fatal.

Treatment.—During the spasmodic stage, while the breath is being held, attempts to excite the inspiratory center reflexly must be made. Cold water may be dashed in the face, the back may be patted, or a vigorous shake be given. Fanning the face vigorously during an attack is also useful. Hooking back the epiglottis with the forefinger is usually followed by an inspiration. A catheter may be passed into the larynx, or intubation performed, while quick tracheotomy is indicated if other means are not speedily followed by relief. The most useful medicines to check attacks are chloral, bromids, and minute doses of morphin. Potassium (or sodium) bromid, with chloral, may be given to an infant of 6 months, and repeated every 6 hours.

℞. Potassium bromid, ʒ ij
Chloral, gr. xxxij
Peppermint water, ʒ ij.
Teaspoonful every half hour.

The diet and surroundings are most important. Fresh air is imperative; and a steam tent and close,

hot room are the worst possible things. A change to the seaside works wonders, and medicines which assist and regulate the bowels, such as extract of malt, rhubarb and soda, acids and pepsin, and cod-liver oil, when it can be digested, are indicated.

LARYNGITIS, ACUTE.—Acute catarrhal laryngitis; mucous laryngitis.

Acute inflammation of the mucous membrane lining the larynx.

Etiology.—(1) Sudden changes in the atmosphere; (2) exposure to the cold and wet; (3) immoderate use of voice; (4) inhalation of dust or chemicals; (5) traumatism; (6) certain diseases act as predisposing causes, such as tuberculosis, rheumatic diathesis.

Pathology.—The mucous membrane is red and highly congested, the swollen capillaries being of larger volume, and traverse the surface of the membrane in all directions. Large quantities of mucus are secreted, and form a coating over the vocal bands. In some cases the serous material is retained within the cellular tissue, causing occlusion of the glottis (edema of the larynx). The latter condition is more common in tuberculosis or syphilis.

Symptoms.—There are, commonly, hoarseness, cough, expectoration of a viscid secretion, dryness of throat, and pain on deglutition. In children the respiration is frequently embarrassed, and paroxysms of croup may occur. Physical examination reveals a reddened condition of the mucous membrane lining the organ, and also affecting the vocal bands, which lose their characteristic shining appearance.

Diagnosis is determined by the subjective and objective symptoms.

Prognosis is favorable.

General Treatment.—Calomel should be given in fractional doses (1/4 of a grain), followed by a saline purge. The room should be at an equable temperature, not lower than 65° F.

℞. Tincture of aconite, ♏ xxx
Tincture of belladonna, ♏ xxx
Glycerin, ʒ ij
Solution of potassium citrate, enough to make ʒ ij.
Two teaspoonfuls every 3 hours.

Hot foot-baths taken at bedtime are of great benefit. The water should be as hot as can be borne, and applied by means of a towel as high up as the knees. From 10 to 15 minutes may be well spent in this manner. If necessary, it may be repeated again during the night, and for several successive nights. Diaphoresis may be encouraged by the use of hot drinks, with 5-grain doses of quinin and a Dover's powder. The diet at all times should be light and nourishing. Under no circumstances should constipation be allowed to exist.

Diuretics are also advisable; the solution of potassium citrate is particularly serviceable. It may be combined with 2-drop or 4-drop doses of tincture of aconite.

Local Treatment.—Small pieces of ice may be allowed slowly to dissolve in the mouth; externally, cold cloths. Leiter's coil or rubber tubing, through which cold water is allowed to run, may be applied.

Sedative inhalations are valuable:

℞. Menthol, gr. ij
Chloroform, ʒ ss
Compound tincture of benzoin, enough to make ʒ ij.
Two teaspoonfuls to a pint of hot water, and inhale every two hours.

For the first 2 or 3 days the throat may be swabbed out once daily with glycerite of tannin or boroglycerid.

Acute laryngitis in children is best relieved by the administration of syrup of ipecac (1/2 of a dram) every 15 minutes until vomiting occurs. Externally, the throat may be thoroughly lubricated with benzoinated lard, containing a small amount of oil of mustard. The parts may be covered with hot flannel cloths, frequently repeated. If there is a tendency to recur, the throat may be swabbed with glycerite of tannin.

LARYNGITIS, CHRONIC. Varieties.—Simple chronic catarrhal laryngitis; (2) tubercular laryngitis; (3) syphilitic laryngitis.

Simple Chronic Catarrhal Laryngitis

Synonym.—Chronic laryngeal catarrh.

The etiology is the same as acute laryngitis. It may follow acute attacks.

Pathology.—Cellular infiltration and hypertrophy of the mucous membrane, with permanent dilatation of the blood-vessels, is the distinct lesion. The glandular structure becomes involved, forming slight elevations (granulations), giving rise to what is termed follicular laryngitis. Generally the surface is red and swollen, and covered with thick mucus. Superficial erosions may occur. The vocal bands may contain small nodules.

Symptoms.—Tickling in the throat, hoarseness, persistent cough, and expectoration of thick, tenacious, whitish mucus are the most common symptoms. Physical examination reveals congestion of the larynx, with small granulations in certain portions of the mucous membrane. The vocal bands are usually reddened, frequently unilateral, or the cartilaginous portion alone may be affected.

Prognosis is guardedly favorable under prolonged treatment.

General Treatment.—Correct the indigestion, constipation, and restrict the use of tobacco and alcoholic drinks. Tonics, such as the syrup of hypophosphites with iron and strychnin, are valuable. Turkish baths are of benefit.

Local Treatment.—Erosions or enlarged follicles, after being cocainized, should be removed by means of molded silver nitrate or the galvanocautery. Stimulating inhalations are of service.

℞. Eucalyptol, gr. iij
Spirit of camphor, ʒ iv
Compound tincture of benzoin, enough to make ʒ ij.
Two teaspoonfuls to a pint of hot water. Inhale on rising and at bedtime.

After the morning inhalation it is best for the patient to remain indoors for an hour or two. Local applications of a solution of silver nitrate (10 to 20 grains to the ounce) may be applied twice a week. Glycerite of tannin, or boroglycerid (50 percent), may be substituted for the silver nitrate. Cleanse the throat at intervals by means of alkaline solutions, used in the form of a spray. Solutions made from any of the antiseptic nasal-douche tablets may be employed for this purpose. See RHINITIS (Chronic). Guaiac has been recommended. It is best administered in the form of a lozenge.

℞. Guaiac, ʒ ij
Oil of cloves, ♏ ij
Oil of lemon, ♏ v
Powdered acacia, ʒ ss
Powdered sugar, ʒ j
Confection of rose, enough to make 30 lozenges.
Allow one to dissolve in the mouth every 4 hours.

Tuberculous Laryngitis

This is usually secondary to pulmonary tuberculosis.

Symptoms.—Hoarseness, pain on deglutition, distressing cough, hemoptysis, and frequent attacks of aphonia.

Physical examination reveals a marked paleness of the mucous membrane of the larynx and vocal cords, ulceration, and distinct hypertrophy (excrescences) of the glandular structure in localized areas. Caries and necrosis may be present.

The ulcers are multiple in character and have a tendency to coalesce without much tendency to penetrate deeply.

Tuberculous laryngitis and syphilitic laryngitis may be differentiated as follows:

TUBERCULOUS LARYNGITIS.	SYPHILITIC LARYNGITIS.
Pain severe on deglutition.	Usually slight.
Ulcerates slowly.	Rapidly.
Usually first appears as small spots or nodules which are rapidly followed by great edema.	Is rarely seen in stage of induration, the first evidence being a clear-cut, deep ulcer.
Ulcers extend laterally, but not deeply.	Extend deeply, often involving cartilage.
Mucous membrane is usually pale.	Hyperemic, injected.
Health impaired previous to laryngeal involvement.	Unimpaired.
Previous or coincident pulmonary trouble common.	Frequently evidence of syphilitic disease in other tissues.
Iodids have no influence.	Readily improves under iodids.

Complication.—Edema of the larynx is very common.

Prognosis.—See TUBERCULOSIS.

General Treatment.—See TUBERCULOSIS.

Local Treatment.—Cleanse the parts once or twice a week with an alkaline spray, and subsequently dust over with aristol or iodoform. If the pain is intense, touch the ulcers with a solution of cocain (10 percent). Menthol may also be used for the same purpose.

To be inhaled:

℞. Menthol, gr. iij
Creosote (beechwood), ♏ xvj
Compound tincture of benzoin, ʒ ij.
Two teaspoonfuls to a pint of hot water. Inhale at bedtime.

Weak solutions of menthol in albolene used in a nebulizer give good results.

More profound and prolonged anesthesia may, however, be produced by the application of a 20 percent solution of quinin and urea hydrochlorid (*q. v.*); which has recently been highly praised.

Electric cataphoresis with guaiacol or oxychlorid of copper has proved of value. Submucous and intratracheal injections of guaiacol, 20 percent, are sometimes efficacious.

Edema of the larynx frequently occurs, and tracheotomy is occasionally advisable.

Syphilitic Laryngitis

Symptoms.—There is persistent huskiness of voice. The cough is less troublesome than in the tuberculous form, and pain is not great or may be entirely absent.

Physical Examination.—The larynx is ulcerated, the vocal cords congested, and mucous patches may appear on the tip of the epiglottis or on the ventricular bands. The latter are described by Gottstein as being "round or elongated grayish-white spots of thickened epithelium, slightly raised upon the congested tissue which surrounds them, and are either sharply circumscribed or shade gradually off into it." The secretion is scanty and very tenacious.

Complication.—Edema of the larynx is very common.

General Treatment.—See SYPHILIS.

Locally, the ulcers may be touched with the galvanocautery, a solution of zinc chlorid (30 grains to 1 ounce), or with a crystal of copper sulphate or silver nitrate. Stimulating inhalations may be used.

Should edema of larynx occur, tracheotomy may be necessary

LARYNGITIS, EDEMATOUS (Edema of the Glottis).—An acute inflammation of the mucous membrane of the larynx and that about the glottis, with an infiltration of the areolar tissues by a serous, seropurulent, or purulent fluid; it is characterized by obstructed or stridulous breathing and dysphonia or aphonia.

Etiology.—It may be the result of acute laryngitis; abscess in or about the throat or tonsils; erysipelas of the face; scarlatina; small-pox; Bright's

disease; syphilis of the larynx. It is rare in children, except when due to scalds.

Pathologic Anatomy.—There is infiltration of the loose connective tissue of the aryepiglottic folds, the glossoepiglottic ligament, the base of the epiglottis, and the interarytenoid space. If the true vocal bands are inflamed, their color changes, and instead of appearing white, glistening, and brilliant, they are dull, grayish-red, or violet-red in patches. If the swelling is the result of purulent infiltration, the parts affected present a deeply congested color, with here and there spots of a yellowish hue. Serous infiltration, sufficient to cause fatal edema, disappears with death, leaving but slight traces to account for the formidable symptoms.

Symptoms.—The onset is much the same as a simple catarrhal laryngitis with a gradually increasing impediment to the respiration. The patient experiences the sensation of a foreign body in the throat, and, after a short time, a difficulty of breathing, which ultimately threatens suffocation. The deglutition is rendered difficult owing to the swelling of the epiglottis. The voice, at first muffled, gradually becomes weaker and weaker, until finally it is almost extinct. The cough at first is dry and harsh, but as the infiltration increases it becomes stridulous and suppressed; there is no expectoration except that, after great effort to clear the throat, a little frothy mucus is raised. The difficulty of respiration, as the disease progresses, becomes greater and greater, and the paroxysms of impending suffocation more frequent. The inspiration is accompanied by a whistling sound characteristic of the narrow condition of the glottis; the patient sits up in bed, his mouth open, gasping for breath, his eyes protruding, the whole body trembling with intense convulsive movements; after a time a general cyanosis commences, the face assuming a bluish hue, all these symptoms continuing for a few moments, when slight relief occurs, to be again followed by another paroxysm, in one of which, if nature or art does not afford prompt relief, death occurs from asphyxia. A physical examination of the parts may be made by gently passing the finger into the throat, when the epiglottis may be felt very much thickened, and the aryepiglottic folds may have attained such tumefaction as to convey to the finger an impression similar to that which is given by touching the tonsils.

Laryngoscopic Appearance.—The mucous membrane has a bright-red appearance. The epiglottis has the appearance of a semitransparent, roll-like body, or it is often merely erect and tense. It is this condition of the epiglottis which explains the pain and difficulty in deglutition. Rarely the vocal bands are infiltrated.

Diagnosis.—Any disease which gives rise to dyspnea may simulate edematous laryngitis, but the history of the case, together with a laryngoscopic examination, will generally furnish conclusive evidence as to the real nature of the malady.

Prognosis is, as a rule, unfavorable. If early and vigorous treatment is instituted, recovery is possible; but without it death is the inevitable result, the patient dying asphyxiated. Even when local measures have removed the obstruction to free respiration, the patient is very likely to perish subsequently from exhaustion or blood-poisoning, or from pneumonia or other lung complication. The duration of infiltration of the larynx varies from a few hours to several days.

Treatment.—Prompt local treatment must be adopted in order to remove the laryngeal obstruction. A blister or leeches placed over the sides of the larynx in mild cases may effect so much reduction in the edema as to free the patient from danger.

If the infiltration has already occurred, and is slight in amount, scarification, guiding the instrument by the index-finger of the opposite hand, may afford relief, or the hypodermic injection of pilocarpin, 1/3 of a grain, repeated, may lessen the swelling.

The persistent use of small pellets of ice, swallowed or held far back in the mouth until dissolved, early in the attack and the application of ice to the neck; the administration of saline laxatives; the inhalation or spray of alum, adrenalin, or a strong solution of tannic acid; and the application, as near the seat of the disease as possible, of Monsel's solution, full or half strength, may be effective. Mackenzie says the patient should be kept constantly under the influence of potassium bromid.

If these means fail, tracheotomy or intubation is indicated; in those cases of sudden and rapid infiltration of the glottis or larynx occurring in Bright's disease, erysipelas, scarlatina, or syphilis of the larynx, and especially the former and the latter, tracheotomy or intubation should be performed at once.

In cases of infiltration of the larynx stimulants should be boldly administered by the rectum, if stomachic administration is impossible. If the infiltration is composed of pus, quinin sulphate, 5 grains every 4 hours, and stimulants are indicated. See Laryngitis, Tracheotomy, Intubation.

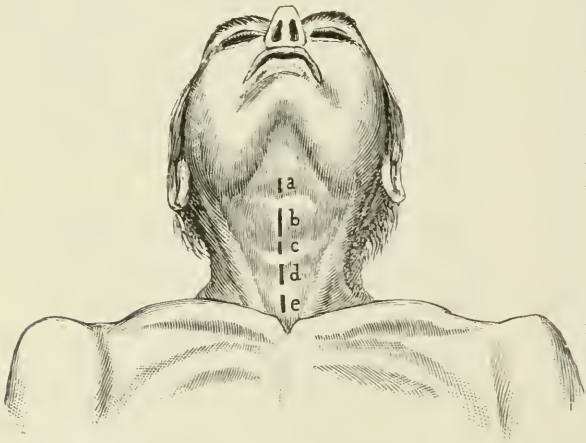
LARYNGOSCOPE.—See Larynx (Examination).

LARYNGOTOMY. Indications.—The operation of laryngotomy is now rarely performed by laryngologists, because of their skill in operating within the larynx through the mouth; yet with surgeons less skilled in laryngology, and, perhaps, more efficient in general operating, laryngotomy continues in favor. It must be remembered, however, that it is a serious operation, and especially dangerous in young children and the aged. It is indicated for the removal of neoplasms and foreign bodies in the larynx, provided there is danger to life from suffocation or dysphagia, and when they cannot be removed through the mouth; also, in some instances, for the relief of stenosis resulting from diphtheria, when other measures fail. In cases in which laryngeal tumors are very large or very numerous, or, when single, are attached in places difficult to reach, laryngotomy is probably easier than intralaryngeal operation, and sometimes it may be safer and more complete.

Impacted jagged foreign bodies often demand laryngotomy, and others usually require tracheotomy. In any case the operation to be preferred, provided the operator is competent, should only be decided upon after an accurate diagnosis, unless suffocation is imminent, and then tracheotomy should be done.

The history and symptoms can seldom be relied upon in making an accurate diagnosis of surgical affection of the larynx. In supposed cases of foreign bodies in the larynx due attention must be given to the statements and sensations of the patient; yet they are often very misleading, so that inspection is necessary in most cases. Laryngoscopy is difficult, and sometimes impossible, in nervous children and in some adults. When the throat is very irritable, the sensitiveness may generally be relieved by the use of a cocain spray. But in young children in order to inspect the larynx one will often be obliged to give an anesthetic and then employ Kerstein's autoscope. Even this will fail to reveal the parts in some cases, and then we must rely upon the symptoms and history for our diagnosis.

The symptoms of foreign bodies in the larynx vary greatly with the position, size, and shape of the object, ranging from a slight irritation, and including paroxysmal cough, dyspnea, dysphagia, and hemorrhage, to clonic spasms of the glottis and speedy death. The usual symptoms of a tumor in the larynx—varying, of course, with its size and shape—are cough, dyspnea, dysphonia or aphonia, and dysphagia. There is also slight pain in some cases.

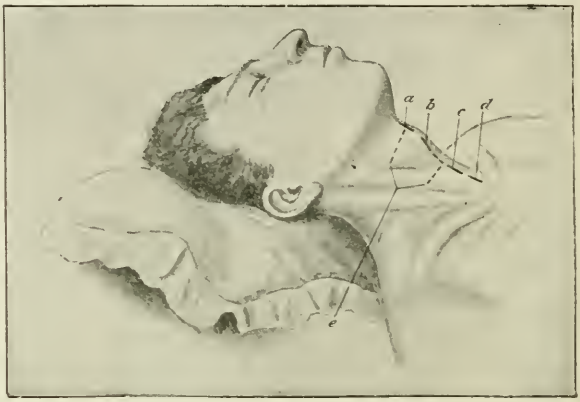


Situation for Incision in the Middle Line of the Neck.
a. Subhyoid pharyngotomy. b. Thyrotomy. c. Laryngotomy. d. Tracheotomy above isthmus. e. Tracheotomy below isthmus. The lines only show the relative situation of the incisions, not their correct length.—(*Spencer and Gask.*)

Operation.—Laryngotomy includes suprathyroid laryngotomy, thyrotomy, and infrathyroid laryngotomy.

Suprathyroid laryngotomy is performed by making a transverse incision through the superficial structures and the thyroid membrane. This incision gives but a limited exposure of the cavity of the larynx, and the operation is seldom employed, as by it no more can be accomplished than through the mouth.

The infrathyroid method is seldom resorted to unless combined with division of some of the upper rings of the trachea.



Laryngeal Incision.
a. Median subhyoid pharyngotomy. b. Thyrotomy, and, point below laryngotomy. c. High tracheotomy. d. Low tracheotomy e. The interrupted lines mark the incisions in laryngectomy.—(*Spencer and Gask.*)

Thyrotomy consists of the division of the thyroid cartilage in the median line, and is the operation commonly referred to as laryngotomy.

If there is great embarrassment of respiration or if much bleeding is feared from the operation within the larynx, a preliminary tracheotomy should be performed and a proper tube inserted and left in place. This insures free respiration and allows the upper part of the trachea or lower part of the larynx to be packed with gauze in case troublesome hemorrhage is encountered within the larynx. Several days, or, better, one or more weeks, should generally elapse before the more serious operation of thyrotomy is undertaken, though sometimes it is best to do both operations at the same time. In the interim the surgeon may endeavor from time to time to remove the growth or foreign bodies by endolaryngeal means or through the tracheal opening; or success may possibly be attained by the aid of Kerstein's autoscope.

For thyrotomy the patient should be anesthetized, and if tracheotomy has been previously performed, a rubber tube may be attached to the cannula within the trachea and the anesthetic administered through the tube, out of the operator's way. The patient should be in the dorsal recumbent position, with the head hanging over the end of the table, supported by an assistant or by the knees of the operator.

An incision is made exactly in the median line

from the hyoid bone to just below the cricoid cartilage, dividing everything down to the thyroid cartilage. The soft parts should be retracted and all hemorrhage arrested. The thyroid cartilage now remains to be divided. In children this can easily be done with a strong knife or scissors. In adults if ossification has taken place, a small circular saw revolved by a motor, a convex saw, or bone-forceps will be found satisfactory. Care must be taken to cut exactly in the median line, and thus avoid the vocal bands, which are attached on either side. It is advantageous to leave a little of the upper part of the thyroid cartilage intact, in order to avoid displacement of the vocal cords in suturing the edges of the wound. The greatest difficulties of the operation begin when the larynx is opened. Violent reflex action is set up from the introduction of the knife or blood into the larynx, which rises and falls rapidly and spasmodically. A sharp-pointed knife is therefore dangerous at this stage of the operation. When this reflex action interferes greatly with the progress of the operation, it may be checked, in a measure, at least, by spraying a 10 percent solution of cocain on the laryngeal mucous membrane. Hemorrhage is seldom marked, save in cancerous growths. Compression is usually sufficient to arrest what bleeding there is.

If operating for a tumor, the larynx may now be tamponed below the growth, as suggested for the prevention of the entrance of blood into the trachea.

The divided cartilages having been retracted, the growth or foreign body is removed. To remove neoplasms several differently shaped slender forceps, cutting forceps, sharp spoons, a snare, porte-caustique, and pointed cautery electrodes should be at hand. These must be used with great care, so as to preserve as much of the mucous membrane of the part as is compatible with thorough removal of the tumor. The base of the tumor should be cauterized with the galvanocautery or with solid nitrate of silver. Mackenzie prefers the latter, believing this practice less likely to be followed by laryngitis. The foreign body or tumor having been removed, the larynx should be gently sponged, to remove all foreign substance, and the divided cartilages carefully approximated and sutured, preferably with silver wire.

If tracheotomy has been performed, the tube should be left in the trachea until all danger of edematous laryngitis is past.

Removal of a papilloma is not infrequently followed by recurrence, but the operation may be repeated with a good hope of permanent cure. Malignant growths are, of course, liable to return, and the operation for their removal is useless, except when the growth is very small and distinctly circumscribed. See Neck (Injuries).

LARYNX, EXAMINATION.—The larynx is the organ of voice placed at the upper part of the air-passage. It is situated between the trachea and base of the tongue, at the upper and anterior region of the neck. On each side of it lie the great vessels of the neck; behind it forms part of the boundary of the pharynx, and is covered by the mucous membrane lining that cavity (Gray).

Physical Examination of the Larynx (Laryngoscopy).—For this is needed (1) sunlight or light from a student-lamp or an Argand or Welsbach gas-burner; (2) a head-mirror with an aperture in center; (3) two sizes of laryngeal mirrors; (4) a tongue-depressor; (5) a throat applicator; (6) a solution of cocain (5 percent or 10 percent).

The patient is seated facing the examiner, with the light behind or on either side of the head and on a level with the eye of the operator. After anesthetizing the posterior vault of the pharynx and soft palate with a solution of cocain (5 percent), the tongue is then grasped firmly between the folds of a napkin and withdrawn a sufficient distance so as to expose the vault of the pharynx, and the light is then reflected by means of the head-mirror. It is essential that the operator should always look through the central opening of the mirror, instead of from above or below.

The laryngoscopic mirror is then slightly heated (to prevent the image from becoming cloudy from the moisture given off during respiration), and slowly introduced until the posterior vault of the pharynx is reached. Care should be exercised not to touch any portion of the vault of the pharynx, tongue, or of soft palate not anesthetized, as it would cause retching, and often vomiting. The patient is then directed to slightly tilt the head backward and to phonate "ā" or "ee."

The first examination is often unsatisfactory, from the fact that the fear of the patient is aroused.

LARYNX, FOREIGN BODIES.—It not infrequently happens that children place various articles in their mouth, and then by aspiration draw them into the trachea, instead of swallowing them, as was purposed. Such accidents are not infrequent with beans, peas, cherry-pits, almonds, candies, pennies, tacks, corks, etc.

The symptoms are violent coughing and suffocation, with cyanosis, attending the entrance of a foreign body into the larynx, and if it remains, an irritating cough persists with subsequent inflammation and ulceration of the trachea. Should the substance be carried deeper, we may be able to perceive its irritating motion as an audible gurgling sound, to and fro with each respiration. Or if it is lodged fast, as might happen with a sharp bit of bone, it produces localized ulceration, indicated by a cough attended with bloody or purulent sputum. Should the body be drawn still lower down into the smaller bronchioles, it may lead either to atelecetasis of that portion of the lung or to pneumonia.

Some of these foreign bodies, as needles, may migrate to other parts of the body, or they may result in abscesses, or may, more rarely, become encapsulated. Small, soft bodies, like bits of meat, may be thrown out by violent coughing or, if soluble, like candy, may be dissolved.

The prognosis is generally unfavorable if the foreign body has passed within the local bands or if the body is too large to be coughed out or dissolved. An insoluble foreign body inspired into one of the lesser bronchioles leads almost inevit-

ably to death, as there is no operative or medicinal measure that can be safely used for its removal.

Treatment.—If the foreign body lies above the vocal bands, its extraction should be attempted as speedily as possible, with the aid of the appropriate instruments, or, if these are not at hand, by holding the child by its heels, head downward, and encouraging coughing by slapping its back or tickling its fauces. When the offending substance has gone deeper, we must resort, first, to forcible expiration following long-drawn inspirations (forced coughing) and emetics, the promptest of which is apomorphin (1/12 of a grain) or turpeth mineral (1 grain). Tracheotomy is called for when the object can be localized, and this operation is usually successful. Foreign bodies in the trachea or the bronchi should, whenever possible, be removed through a bronchoscope. The best bronchoscope is probably that devised by Jackson. It is a long, straight, slender speculum, with an electric lamp at the distal end. Under local anesthesia the glottis is exposed with Jackson's direct laryngoscope, the patient being in the dorsal position with the head fully extended, *i. e.*, the occiput is forced down toward the shoulders, thus elevating the anterior part of the neck. The bronchoscope is passed through the laryngoscope into the larynx, the laryngoscope is withdrawn, and a "bite-block inserted to prevent the patient biting the thin-walled bronchoscope. The bronchial tree is exceedingly elastic and flexible, and may be explored by following the lumen by sight." During the exploration the head and neck should be out in the air beyond the table and supported by an assistant, so that the head may be freely movable as needed. For instance it must be moved to the right for the bronchoscope to enter the left bronchus, and *vice versa* to enter the right bronchus; and it must be slightly lowered to enter the middle lobe bronchus of the right side, raised to enter the posterior branch bronchi" (Jackson). Secretions are removed by aspiration or by sponging. Foreign bodies are removed with suitable forceps. The sooner the bronchoscopic examination is made the greater the chances of success, as after 12 hours the foreign body may be concealed by swollen mucous membranes. Successful removal has been effected, however, even after years (Stewart). See Laryngotomy, Tracheotomy.

LARYNX, TUMORS.—The most frequent benign tumors observed are first, papillomata, second, fibromata. They should be removed under local anesthesia by the intralaryngeal method if possible, the laryngeal forceps, the cutting forceps, the cold wire or galvanocautery snare being used. In children, and for large growths tracheotomy may be demanded.

Malignant growths are usually epitheliomata. Rarely sarcoma occurs. In the case of a sarcoma the preliminary tracheotomy, which is desirable in every instance, generally reveals the necessity of a complete laryngectomy. Epithelioma usually originates in a vocal cord, in old and middle aged men and is of slow development. There may be a history of chronic inflammation or of overuse of the voice. The first symptom is hoarseness. Microscopic examination of a piece of the growth may not be feasible. In some cases, indeed, there is danger of metastasis and stimulation of the growth resulting from removal of a piece of tissue, and a negative report is often misleading. Tuberculosis and syphilis may be eliminated by the tuberculin test and large doses of potassium iodid. One or the other of these diseases, however, may coexist with the epithelioma.

Palliative treatment consists in relieving the pain with local anesthetics and, as a last resort, morphin. The frequent application of adrenalin and the ligature of the laryngeal arteries possibly may control the growth. Radical treatment includes thyrotomy, with a primary tracheotomy, followed by free excision of all the diseased tissue.

LATERAL SCLEROSIS, PRIMARY (Spastic Spinal Paralysis of the Adult, Primary Spastic Paraplegia, Spasmodic Tabes Dorsalis).—A chronic disease of the spinal cord characterized by paraplegia, contractures of the muscles, with exaggerated reflexes, but without sensory or vesical disturbances or atrophy. A disease of early adult life, generally between 20 and 40, occurring very rarely in children. The etiology is obscure. It has been traced to syphilis, trauma, lead-poisoning, acute infectious fevers, and the puerperium. The lesion is essentially in the pyramidal tracts. The onset is marked by a sense of heaviness and weakness in the legs.

Symptoms.—There is gradual loss of power in the muscles combined with rigidity. The spasms of the legs gradually increase in extent as the power lessens, until at last the legs, whenever extended, pass into a condition of strong extensor spasm, rigidly fixing them to the pelvis, so that the patient lies rigid; if one leg is lifted from the couch by the observer, the other leg is moved also. The spasm may be such that the knee cannot be passively flexed by any force that can be applied to it until the spasm has become less. When flexed, the limb is comparatively supple; but if it is then extended, the spasm instantly returns, making the limb rigid, and often completing the extension, just as the blade of a knife opens out under the influence of its spring—"clasp-knife rigidity." Occasionally there occur brief flexor spasms, drawing the legs up. The tendon and superficial reflexes are markedly exaggerated (Babinski's sign and ankle clonus are easily elicited). The spastic gait is characteristic, termed by Hammond "the waddle"; the legs drag behind and are moved forward as a rigid whole, the toes catching against the ground, the patient showing a tendency to fall forward. Sensation is unaffected. As the morbid process extends upward, the superior extremities suffer in the same manner as those of the lower. The reaction of degeneration is absent.

The disease may be long protracted, but is incurable. Treatment consists in rest, massage, warm baths. Treatment should be directed to the improvement of the general health. If syphilis is present, mercury and the iodids are indicated. Electricity may be tried.

Hysterical spastic paraplegia simulates the true

form, but some hysterical stigmata may appear on careful examination. Recovery may take place under proper treatment.

LATHYRISM.—See LUPINOSIS.

LATIN, MEDICAL.—**The verbs** used in prescription-writing are nearly all in the imperative mood; giving directions to the compounder, and having their object in the accusative case. Such are:

Adde, add.	*Fac*, make.	*Recipe*, take.
Cola, strain.	*Filtra*, filter.	*Signa*, write.
Divide, divide.	*Macera*, macerate	*Solve*, dissolve.
Extende, spread.	*Misce*, mix.	*Tere*, rub.

A few verbs are found in the subjunctive mood, taking their subject in the nominative case. The most usual are:

Fiat, let be made.	*Detur*, let be given.
Coletur, let be strained.	*Dividatur*, let be divided.
Coloretur, let be colored.	*Sit*, let it be.
Bulliat, let boil.	*Sumatur*, let be taken.
	Capiat, let take.

Participles or verbal adjectives are occasionally used, and should agree with their respective nouns in gender, number, and case. Such are:

Adhibendus, a, um, to be administered.
Dividendus, a, um, to be divided.
Sumendus, a, um, to be taken.

Prepositions.—The accusative case follows those in the first column, the ablative those in the second column:

Ad, to, up to.	*Cum*, with.
In, into.	*Pro*, for.
Supra, upon.	*Sine*, without.

Ana, of each, governs the genitive case.

Sundry Words and Phrases in Most Frequent Use.

Bis, twice.	*Numero*, to the number of.
Bene, well.	*Numerus*, number.
Dein, thereupon.	*Octarius*, a pint.
Et, and.	*Semel*, once.
Gradatim, gradually.	*Simul*, together.
Guttatim, by drops.	*Statim*, at once.
In dies, daily.	*Ter*, thrice.
Da, give.	*Quater*, four times.
Non, not.	*Ad saturandum*, to saturation.

Quantum sufficiat, as much as necessary.
Pro re nata, according to need.
In partes æquales, into equal parts.
Redactus in pulverem, let be pulverized.
Secundum artem, according to art.
Non repetatur, let it not be repeated.
See PRESCRIPTION-WRITING.

Genitive Case-Endings.—(*Potter.*)

NOM.	GEN.	EXCEPTIONS.
a	æ	Cataplasma, Enema, Physostigma, Aspidosperma, and Gargarysma all have the genitive in *-atis*. Folia is plural; gen., Foliorum.
us um os on	i	Rhus, Rhois; Flos, Floris; Bos, Bovis; Limon, Limonis; Erigeron, Erigerontis. Fructus, Cornus, Quercus, Spiritus, Haustus, Potus, do not change, being of fourth declension.
as	atis	Asclepias, Asclepiadis; Mas, Maris.
is	idis	Pulvis, Pulveris; Arsenis, Arsenitis; Phosphis, Phosphitis; Sulphis, Sulphitis; and all salts ending in *-is* have genitive in *-itis*.
o	onis	Mucilago, -inis; Ustilago, -inis; Solidago, -inis.
l	-lis	Fel, Fellis; Mel, Mellis; Sumbul, Sumbuli.

Words which do not change in the Genitive.

e	es	Azedarach	Ethyl[1]	Potus
en	inis	Buchu	Fructus	Quercus
ps	pis	Cannabis	Gambir	Sabal
rs	rtis	Caoutchouc	Haustus	Sago
r	ris	Catechu	Hydrastis	Sassafras
x	cis	Chloral[1]	Jaborandi	Sinapis
		Cundurango	Kino	Spiritus
		Curare	Matico	Sumbul
		Digitalis	Menthol[1]	Thymol[1]

LAUDANUM.—The tincture of opium, containing about 48 grains of opium to the ounce. The dose is from 5 to 30 minims, according to the effect desired. It is the form of opium mostly used in liniments, and for external applications, as with lead-water. See OPIUM.

LAUGHING GAS.—See NITROUS OXID, ANESTHETICS.

LAVAGE.—Irrigation or washing out of the stomach.

Uses.—Lavage is more valuable for diagnosis than for treatment. In cases of chronic indigestion and often in neurasthenia, constipation, insomnia, and especially in stubborn headaches, it is of value to make an analysis of the stomach-contents under varying conditions, to determine exactly what sort of work the organ is doing as to its secretory, absorptive, and motor functions. When such tests show a large amount of mucus, gastric catarrh may be suspected; and in most cases of chronic catarrhal inflammation of the stomach lavage will do good; in many of them it is almost indispensable. More often the mucus comes from the parts above, having been swallowed; and the diagnosis of chronic gastric catarrh, which many physicians attempt to make offhand, frequently presents difficulties, even with the help of chemic and microscopic examinations of the stomach-contents. See STOMACH.

The most imperative indication for lavage is gastrectasis, or aggravated dilatation of the stomach, whether resulting from narrowing of the pyloric orifice (cancer or other tumors, or the cicatrix of an ulcer), from a kink of the small intestines (which may follow displacement of the stomach, colon, or right kidney), or from atony of the muscular walls of the organ. Whatever the cause, dilatation, when neglected, tends to become a serious condition, and lavage judiciously done is an aid to the cure in the atonic cases, while it is a most

[1] In the B. P. Chloral, Ethyl, Menthol, and Thymol are Latin nominatives, and do not change in the genitive, (*e. g.*, Syrupus Chloral, Liquor Ethyl Nitritis, Emplastrum Menthol). In the U. S. P. the corresponding nominatives are Chloralum, Æthyl, Menthol, and Thymol; but the genitive of Æthyl is Æthylis, and that of Thymol is Thymolis, (*e. g.* Æthylis Carbamas, Thymolis Iodidum).

valuable palliative in the desperate ones until operative relief can be obtained. In bad cases of gastric catarrh and in patients not too reduced in strength, provided all the results are encouraging, it will be proper to wash out the stomach every day at first, until the amount of mucus is markedly lessened. This will be the more advisable if the microscope shows the presence of numerous yeast fungi or sarcinæ in the wash-water. As the conditions improve, or sooner if the patient should fall off in flesh, cardiac tone, or appetite, the intervals should be prolonged, until by the end of a month or two, once or twice a week may often be enough. When the treatment has been begun early and is properly carried out, one will often succeed in removing all the symptoms and signs of disease within 2 months; but in very advanced or debilitated cases, one will need to be guided by the effects, and sometimes, in such cases, a radical cure is scarcely practicable outside of a special institution. The best that can be accomplished then, under ordinary conditions, is palliation, and for this it is useful to cleanse away the accumulated mucus and bacteria at least once a week for long periods (Reed).

Time.—In nearly all cases the best time for lavage is before breakfast. Many good authorities advise that lavage should be done at bedtime when fermenting food in the stomach prevents sleep. Exceptionally this may be useful, especially in cases of gastralgia, but diseased stomachs are rarely empty at bedtime, and experience teaches that, as a continuous practice, washing away half-digested food is disastrous. When severe fermentation cannot be otherwise controlled, it would be better to feed less by the stomach and supplement by nutritive enemata.

Method.—The best and the simplest apparatus is a medium-sized tube, though the larger the better, provided the patient tolerates it well. It should be long enough to extend 3 feet from the mouth. A bulb in the course of it will be helpful in case of blocking; and a separate large glass funnel holding a pint is much better than the small soft-rubber ones that are found attached to many of the tubes in the shops. Warm water, sterilized by boiling, with or without bicarbonate of sodium dissolved in it to the extent of 1 or 2 teaspoonfuls to the quart, is used. If there is doubt as to the diagnosis, simple boiled water may be used.

When there is a marked deficiency of hydrochloric acid, the water may be hotter, and table salt, from a teaspoonful to a tablespoonful, may be added to each quart. Exceptionally, stronger antiseptics or astringents may be used—alum, one-half to a teaspoonful, and silver nitrate, 1 or 2 grains to the quart, but this should be followed with a salt solution after the silver nitrate. The patient's garments should be protected with towels or oilcloth. If the throat is very sensitive, it should be sprayed with a solution of cocain (3 or 4 percent) in liquid vaselin, to which has been added 1 grain of menthol.

It is not necessary to lubricate the tube with glycerin or vaselin, but it may be dipped in water. The process of introduction must be an educative one, and the first trial may fail.

The patient should sit in a low chair with his head thrown back; the mouth should be opened about two-thirds its full width, and the patient is instructed to breathe naturally. The index-finger of the operator is then inserted well back into the pharynx, and the tube is pushed along the side of the finger to the posterior wall of the pharynx and down into the entrance of the esophagus; the patient is then instructed to swallow, at the same time gradually pushing the tube onward until it has entered the stomach. The average distance from the incisor teeth to the lower border of the stomach is 22 inches. In gastric dilatation it is more than this.

The tube, with the funnel inserted in it, having been introduced, the solution, previously prepared and placed in a pitcher at hand, is poured in, a pint or quart at a time. Just before the last of the water has disappeared from the funnel the latter should be carried quickly down toward the floor and held in the inverted position over a pail. By siphonage the liquid now flows back into the inverted funnel, where it may be inspected before emptying. A piece of glass tubing inserted at some point of the tube outside the mouth, or between two sections of the tube, will enable one to see when the liquid is flowing through properly. One quart of water is quite as much as most patients will care to have used in the first washings, but later the quantity may be gradually increased, until finally several quarts, or enough to cleanse away all the mucus, may be introduced; but not more than 1 quart at a time, and in some very weak stomachs a pint at a time, will be more advisable. It has been found that to lessen considerably the time required to loosen and detach all the mucus in old gastric catarrhs it is advisable to have the patient drink a cup or two of warm water before taking the tube, and then, lying down on the back, make voluntary contractions of the abdominal muscles so as to splash the water around in the stomach for 3 to 5 minutes. When this is done, scarcely one-half the usual quantity of water is required in the washing out, which follows directly afterward. Delicate patients should be allowed to rest in the recumbent position half an hour at least after lavage, and in no case should a meal be eaten within that time after the procedure.

The tube should be withdrawn gradually while the patient is in a sitting posture.

Lavage in Infants.—Lavage is a very valuable therapeutic measure in infants. In children over 18 months or 2 years of age it is more difficult of application and not, as a rule, useful. The indications for stomach-washing are acute indigestion, either with or without persistent vomiting, when a single washing may be sufficient; and certain cases of chronic indigestion when daily washing is necessary, and in poisoning.

Apparatus and Method.—A soft-rubber catheter connected by a short glass tube to a piece of rubber tubing and a glass funnel, as described under GAVAGE (*q. v.*), are all the apparatus necessary.

The catheter should be as large as can be easily passed (about No. 24 French), and should have one or more large eyes. The child should be held in the sitting position and its body protected by a rubber sheet. The tongue is depressed with the forefinger of the left hand, and the catheter moistened and passed rapidly back into the pharynx and down the esophagus. About 10 inches of the catheter should be passed beyond the lips.

When the stomach is reached, the funnel is momentarily raised to allow the gas to escape, then lowered in order to siphon out any fluid which may be in the stomach. If nothing escapes, the funnel is raised and from 4 to 6 ounces of water poured into it, when the funnel is again lowered and the water siphoned out. This procedure is repeated from 4 to 10 times or until the water returns perfectly clear. Boiled water should be used at 100° to 110° F.—the higher temperature when there is great gastric irritation.

It is not often advisable to add anything to the water, but in some cases a weak solution of boric acid or a salt solution, a teaspoonful to the pint, may be used.

LAVENDER (Lavandula).—The fresh flowers of *Lavandula officinalis*. They have a fragrant odor, and an aromatic, camphoraceous taste; and contain resin and tannin, also a *volatile oil*.

Lavender is aromatic, stimulant and carminative, but is rarely used alone as a medicine. It is an agreeable flavoring and perfume, in the form of the official spirit, which is sold under the name of *lavender-water*, after the addition of oil of bergamot and essence of ambergris. The compound tincture is a very agreeable combination of spices, and is much used as a remedy for gastralgia, nausea, and flatulence, and as an adjuvant or corrigent of other medicines.

Preparations.—Oleum lavandulæ florum, a volatile oil distilled from fresh lavender, and having the fragrant odor of the flowers. It is soluble in alcohol in all proportions, in 3 times its volume of a mixture of alcohol 3 and water 1, and in glacial acetic acid. Dose, 1 to 5 minims. **Spiritus L.** has of the oil 5, in alcohol 95. A perfume and flavoring agent. Dose, 10 to 45 minims. **Tinctura L. Composita,** an aromatic stimulant, composed of the oil 8, oil of rosemary 2, saigon cinnamon 20, cloves 5, nutmeg 10, red saunders 10, alcohol 750, water to 1000. Is a constituent of Fowler's solution. Dose, 10 to 45 minims.

LAXATIVES.—See Cathartics.

LEAD (Plumbum).—Symbol, Pb. Atomic weight, 207; quantivalence, ii or iv. A bluish-white, soft, malleable metal, obtained from a native sulphid called galena, by roasting. Soluble salts of lead combine with albumin, forming albuminates. In large doses by the stomach they are irritant to the mucous membrane. Upon the intestines they act as powerful astringents. If absorbed into the circulation in small quantities for a considerable period of time, lead causes a very interesting and varied group of symptoms, which are described below. Lead is eliminated through the kidneys and the intestinal mucosa. It appears to check the elimination of uric acid, and is, especially in England, a factor in the causation of gout in lead-workers. In medicine lead is used locally as a sedative to inflamed parts, as an astringent to mucous surfaces, as in gonorrhea and leukorrhea.

Therapeutics.—Lead salts are chiefly used as astringents and hemostatics. The solution of the subacetate, diluted with 4 parts of glycerin and water, is locally employed in many skin-diseases, especially in eczema, lichen, impetigo, and erythema; also in catarrhal discharges of mucopurulent character from the ear, vagina, and urethra, particularly in gonorrhea and leukorrhea. Inflammations of external parts are constantly treated by the lotion of "lead-water and laudanum" (liquor plumbi subacetatis dilutus, 7 parts to 1 of tinctura opii).

Internally the acetate, in 2-grain doses every 3 hours, is used in various internal hemorrhages, particularly hemoptysis, hematemesis, and gastric ulcer. The same salt is used in smaller doses in bronchorrhea, and with powdered opium if there are choleraic symptoms, and still smaller doses for the summer complaint of children. In caseous pneumonia and in cardiac hypertrophy, and in whooping-cough with excessive bronchial secretion, and in humid asthma, the acetate is also useful.

The carbonate is useful in erythema, erysipelas, intertrigo, and as white paint, mixed with linseed oil, applied to burns or scalds only when the cuticle is unbroken.

The iodid is useful as an ointment for enlarged lymphatic glands and enlarged spleen, and in chronic eczema and psoriasis. The nitrate is serviceable when applied to fissured nipples, 10 grains to 1 ounce of glycerin. In solution it is deodorant to the fetor of gangrenous sores, ozena, and other offensive discharges.

Acute poisoning is rare, as the salts of lead are not often chosen by the intending suicide. It is treated by encouraging emesis and washing out the stomach. Dilute sulphuric acid, 30 minims in water, or the sulphate of magnesia or soda, 1/2 of an ounce, should at once be administered, all well diluted with water. Milk or the white of egg is to be freely given. Morphin given hypodermically and poultices may be employed. A subsequent course of potassium iodid is advisable.

Chronic poisoning is called **saturnism** or **plumbism.** It is most common in those whose occupation exposes them to contact with salts of the metal, such as painters, glaziers, workers in white-lead works, etc. Drinking-water and foods may also convey the poison to the system; so may cosmetics impregnated with lead; indeed, the sources of poisoning are manifold and often very curious.

The forms of chronic lead-poisoning may be grouped as follows: (1) *Lead colic*, the most frequent. The pain is centered about the umbilicus, the abdomen is retracted, constipation obstinate, the pulse corded. See Colic. (2) *Lead palsy*, wrist-drop or drop-wrist. This is a paralysis of the extensor muscles of both forearms; it may be associated with sensory disturbances. Paralysis

of the ocular and the laryngeal muscles has also been observed. (3) *Saturnine encephalopathy.* (4) *Saturnine arthralgia,* a painful affection of the joints, especially the knee, rarely the others. Objective signs are usually absent. The disease may resemble chronic gout. (5) *Chronic contracted kidney.* (5) *Amblyopia* due to atrophy of the optic nerve. The general symptoms of lead-poisoning are a marked anemia and cachexia, and a blue line at the edge of the gums.

Treatment.—Prophylaxis is of the first importance, and among workers absolute personal cleanliness, extending to the finger-nails, the use of a working suit, a daily warm bath after work, eating outside the works, and the use of respirators are the chief preventive measures. "Treacle beer" and sulphuric acid lemonade are beverages of service in preventing the effects of the metal. Constipation is to be relieved by occasional doses of magnesium sulphate.

Dry, hot fomentations to the abdomen are the best applications for the lead colic. Magnesium sulphate is an excellent purgative, and may be administered after the more acute symptoms have subsided, in combination with potassium iodid. Castor oil, with 5 to 10 minims of the tincture of opium added to each dose, is useful to clear the bowel.

Massage is the best treatment for the paralysis of lead poisoning, and the electric current may be applied daily for about 10 minutes. A long period of treatment is necessary.

Incompatible with *lead salts* are: Alkalies, mineral acids and their salts, albuminous solutions, opium, potassium iodid, vegetable acids, vegetable astringents, waters containing lime, sulphates, carbonates, and carbonic acid gas. With *lead acetate* are: Acids, acetamid, alkalies, bromids, carbonates, chloral hydrate, chlorids, chromates, cyanids, glucosids, gums, hydrochloric acid, iodids, opium, phenol, pyrocatechin, pyrogallol, resorcinol, salicylic acid, sodium phosphate, sodium salicylate, sulphates, sulphids, sulphites, tannic acid, urea, urethane, vegetable decoctions, infusions and tinctures. With *solution of lead subacetate* are: Acacia, acids (organic), albumin, alkaloids, antipyrin, glucosids, and otherwise like lead acetate.

Preparations.—**P. Acetas** (*sugar of lead*), colorless, shining, prismatic crystals or scales, efflorescent, of faintly acetous odor and acid reaction, and a sweetish, astringent and metallic taste. Soluble in 2.3 of water and in 21 of alcohol at 59° F., in 0.5 of boiling water and in 1 of boiling alcohol. Dose, 1/2 to 2 grains. **P. Iodidum,** a heavy, bright, citron-yellow powder, odorless and tasteless, fusible and volatilizable by heat; soluble in about 2000 of water at 59° F., and in about 200 of boiling water. Used externally as an ointment. May be given internally in doses of 1/5 grain twice daily. **P. Nitras,** colorless, opaque, octahedral crystals, odorless, of sweetish, astringent and metallic taste and acid reaction; soluble in 2 of water at 59° F., almost insoluble in alcohol. Used locally as an astringent and deodorizer in solutions up to 1 percent, also as an escharotic and a disinfectant. **P. Oxidum** (*litharge*), a heavy, yellowish, or reddish-yellow powder, odorless and tasteless; insoluble in water or alcohol, but almost wholly soluble with slight effervescence in dilute nitric acid. When heated in contact with charcoal it is reduced to metallic lead. Used as plaster and sometimes with oil as an external application. **Liquor P. Subacetatis** (*Goulard's extract*), an aqueous solution containing about 25 percent of the salt, prepared from acetate of lead 18, oxid of lead 11, and distilled water to 100. It is a clear, colorless liquid, of sweetish, astringent taste and alkaline reaction, and when added to a solution of acacia it produces a dense, white precipitate. Used locally as an astringent and cooling lotion, diluted usually with an equal quantity of water. **Liquor P. Subacetatis Dilutus** (*lead water*), has of the preceding 4, in distilled water to 100. Used locally as a mildly astringent and cooling lotion. **Ceratum P. Subacetatis** (*Goulard's cerate*) has of the solution of lead subacetate 20 percent, with camphor 2, wool fat 20, paraffin 20, white petrolatum 38. An astringent application. **Emplastrum P.,** has of lead acetate 60, soap 100, each dissolved in hot water, mixed, and the liquid decanted. It is pliable and tenacious, and forms the basis of other plasters. **Emplastrum Adhesivum,** has of rubber 2, petrolatum 2, lead plaster 96. **Unguentum Diachylon,** has of lead plaster 50, olive oil 49, oil of lavender flowers 1. Used locally in eczema and other cutaneous disorders.

LECITHIN.—A phosphorized fat found combined with proteids in nervous tissue, yolk of eggs and in almost all animal and vegetable cells. The lecithins are esters of the fatty acids and glycerophosphoric acid in combination with cholin. Lecithin stimulates nutrition, causing an increase in the number of erythrocytes and in the percentage of hemoglobin and in the amount of reserve proteids. It is believed to be efficient in malnutrition and is said to be especially valuable for bottle-fed infants. Dose, 1 1/2 to 8 grains before meals in pill form; for infants one-third as much.

LEECHING.—The use of leeches is indicated when it is desired to abstract blood from localities which, from their position or from excessive tenderness, are with difficulty operated upon by the knife. They are particularly valuable in inflammations of the eye and ear. In order to imitate as near as practicable the conditions under which these animals secure their food, the skin over the selected locality should be carefully cleansed, especially should all traces of soap be removed, and of such pungent medicaments as turpentine, liniments, etc., otherwise the animals will refuse to bite. A little blood or milk smeared upon the skin will often induce leeches to take hold. Medicinal leeches are of two kinds, the Swedish and American. The former are much the more powerful, and, at least in the treatment of adults, are, as a rule, preferred. Each abstracts from 1/2 an ounce to 1 ounce of blood. The American leech is one-sixth the strength of the European. When a number of leeches are to be applied, as over the abdomen in nervous persons, and each bite causes alarm, the leeches may be placed in a half glass of

cold water, and by an adroit movement the glass may be inverted on the part; the leeches will attach themselves rapidly; the water may be drained away and caught in a pledget of absorbent cotton. Leech-bites are likely to continue bleeding. The bleeding may be controlled by pressure, Monsel's solution on cotton, styptic cotton, or, if these fail, by the application of the actual cautery. Leeches should not be applied where the skin is delicate or loose, as on the eyelids or scrotum. To remove a leech easily, apply a small quantity of table salt to it.

The **Heurteloup's apparatus,** or **artificial leech,** is of great value when leeches cannot be obtained.

LEG, AMPUTATION.—Improvements in artificial limbs have rendered obsolete the rule that made the point of election for amputation of the leg three inches below the tubercle of the tibia. Amputations just above the ankle, are unsatisfactory but unfortunately the teaching of a past era still prevails in certain localities.

The operation is applicable to any portion of the leg below the knee-joint to a point within 3 inches of the ankle.

The Anteroposterior-flap Operation.—The 2 flaps are of the same length: that of the anterior being cut from without inward, and the posterior being procured by transfixion. The patient is brought well to the edge of the table; the limb to be removed is laid upon a pillow, supported at the heel by an assistant. The operator places the thumb of the left hand on a point just below the fibula, and the index-finger a little below the line of the internal border of the fibula; with these points as guides, a semilunar flap is cut, somewhat longer than half the diameter of the limb, through the skin and fascia; this is dissected back to the points where the index-finger and thumb of the left hand rest; a transfixion knife is then entered just below the fibula, and being carried through the tissues, is made to protrude on the other side, opposite the point of entrance, when a posterior flap is cut of the same length as that for the anterior. Any muscles which have not been divided are to be severed by a circular sweep of the knife; the interosseous space is divided, the periosteum pushed back, and the bones sawed through. After the limb has been removed, saw off the sharp edge of the tibia and cut off 1/2 of an inch of the fibula, which insures a better stump. Secure the vessels, apply necessary drainage, and close the wound in the usual manner.

Double-flap method, at the upper fourth of the leg. A stout bistoury, with blade 4 or 5 inches long, and a broad saw are the cutting instruments required. The flaps are made of integument only, by cutting from the surface without transfixion. The point of the knife is entered at the side, about 2 inches below the tibial tubercle, and carried across the front of the leg, describing an anterior curved flap, somewhat longer than, and of the exact width of, the half diameter of the limb. This is dissected up close to the bones and deep fascia. A similar flap is made on the posterior aspect, and the integument and fascia composing it are raised from the muscles. The latter, with the large vessels and nerves, are then divided transversely, direct to the bone. The point of the knife must be used to divide the intervening structures. The bones are then divided straight across.

The anterior tibial artery is often divided as it passes between the bones to the front of the leg, and it may be difficult to get it separated from the surrounding ligamentous structures.

Single-flap Operation.—The operator places the heel of the knife on the side of the limb furthest from him, then draws it across the front of the limb, cutting a semilunar flap of skin; when its point arrives at the opposite side, it is made to transfix the limb, and then the posterior flap is cut. Care must be taken not to get the knife between the bones when making the flap by transfixion. The muscles and ligamentous structures which are between the bones are then divided by the point of the knife. The fleshy mass of the gastrocnemius may require to be cut out to make the posterior flap thinner.

The circular operation is especially adapted to removal of the leg at the lower third of its length. One assistant supporting the foot and another holding the knee, and at the same time drawing up the skin, the surgeon makes a circular incision through the skin, 4 inches below the point where the bones are to be divided. The integument is then dissected up for 2 inches and turned back, and the muscles divided down to the bone by a second or third circular incision. A catling is then passed between the bones to divide the interosseous ligament and muscles, and both bones sawed through together, the flesh being protected by a three-tailed retractor, the middle tail passing between the bones; to prevent splintering, the division of the fibula should be completed before that of the tibia. The anterior and posterior tibial are the principal arteries requiring ligatures. The modified circular operation may also be satisfactorily performed at this part of the leg. See AMPUTATIONS.

LEG, BOW-. See GENU VARUM.

LEG, FRACTURES.—**Fracture of the tibia at its upper end** usually results from compression by the opposite condyle of the femur, as in falling from a height and landing on the feet. The symptoms are those of a severe contusion; joint-movements are painful, lateral movements usually possible, with distinct painful points at the upper end of the tibia. Generally the fracture is of only one-half of the articular surface, so varus and valgus positions are liable to result.

Treatment is by fixation by splint or weight with early massage and movements as in all articular fractures.

Traumatic separation of the upper epiphysis of the tibia is rare. It is to be suspected in cases of severe contusion at the upper end of the tibia. Abnormal mobility and cartilaginous crepitation can alone make the diagnosis positive.

Treatment is on general principles.

Separation of the tuberosity of the tibia rarely occurs. The traction of the quadriceps sometimes tears off the tuberosity instead of fracturing the

patella. The fragment is drawn upward, active extension at the knee is impossible, the fragment is felt under the skin movable in all directions, while the patella is found intact.

Treatment is very similar to that described for fractured patella. See KNEE. The joint need not be implicated; hence the best treatment is to secure the replaced fragment in place by open suture.

Fracture of the shaft of the tibia may occur isolated as a result of torsion or bending, being transverse, as a rule, in the upper part of the bone, and oblique in the lower.

The symptoms are clear and easily recognized. If the fibula remains unbroken and there is much longitudinal displacement, the head of the fibula must be dislocated upward. This is most likely to occur in fracture of the upper half of the shaft. If the fibula remains intact and is not luxated, marked displacement of the fragments cannot well occur.

Treatment.—If marked swelling has already occurred, it is best for a few days to elevate the limb in a fracture-box and make local sedative applications. The swelling having in a large degree subsided, a close-fitting plaster-of-Paris dressing is applied, fixing the knee and taking in the foot. This dressing should extend to the upper part of the thigh and be well padded under the tuberosity of the ischium, which is designed to rest upon it, a perineal crutch in this way being provided. A 2-inch cotton pad is placed on the sole of the foot before the plaster is applied. When the patient is on his feet, the splint catches the body weight on the tuberosity of the ischium, while the foot descends into the thick cotton pad mentioned. This constitutes the so-called **ambulatory splint.** If there is not great tendency to displacement, the patient may be placed on his feet by the end of the first week, or even at once, using crutches at first and then getting about by the aid of a stick alone. It will usually be found necessary to put a high sole on the shoe of the sound side. In 4 weeks the dressing can be removed and a lighter one supplied, which is worn for 2 or 3 weeks longer, when dressings can be discarded.

Isolated fracture of the fibula is somewhat rare, especially in its middle and upper portions, and it is due to direct violence. Fracture at the lower end may be due to violent eversion or inversion of the foot. There is little tendency to displacement.

Treatment.—Plaster-of-Paris is the best dressing. The knee need not be fixed. The foot should be placed in slight inversion, at a right angle to the leg, and fixed in the dressing.

Fracture of both bones of the leg in the region of the diaphysis is a frequent injury, the result of direct violence, both bones usually being fractured at the same level. Sometimes, the foot being fixed and the body twisted, a torsion fracture of the tibia results; the weight of the body then falls on the tibia, which is broken secondarily and frequently higher up on the shaft. Oblique fractures are, of course, more liable to considerable displacement, and are relatively less favorable than transverse. The lower fragment of the tibia is usually displaced upward behind the upper fragment, and rotated a little outward. This ascent is largely due to the action of the calf-muscles.

This fracture is easy of diagnosis, abnormal mobility, crepitation, and displacement being readily demonstrated. Palpation of the crest of the tibia in the two directions discloses the point of fracture, and also any rotation of the lower fragment. The exact point of fracture of the fibula is sometimes difficult of determination.

Treatment.—In fracture near the ankle-joint the pull of the calf-muscles tends sometimes to maintain deformity, and may even demand tenotomy of the Achilles tendon. For the first 3 weeks 1 posterior and 2 side splints should be used, or a fracture-box may be employed. The dressings should be removed and the fracture inspected and controlled at the end of each week. After this time plaster-of-Paris can be employed, and the treatment be made ambulatory, as already indicated for isolated fracture of the tibia. After healing, a painful bony prominence may persist on the crest of the tibia, which may require removal by the chisel. See KNEE, ANKLE (Fractures).

LEGITIMACY, LAWS.—The law assumes that every child born in wedlock is legitimate unless it can be shown that the man and wife had been separated for a longer time than that accepted as the average period of gestation, or unless it can be proved that the husband was impotent. The accepted period of gestation is from 268 to 313 days. A child is regarded as legitimate though not conceived in wedlock, if the mother afterward marries and her condition is recognized by the husband at the time of the marriage.

LEMON (Limon).—The fruit of *Citrus limonum*, official in two forms: (1) Orange, *Citrus vulgaris* and *C. aurantium*, and (2) Lime, *C. acris*. The rind contains an official volatile oil, and a glucosid. The pulp yields about 7 percent of citric acid, $C_6H_8O_7$, which has about the same properties as acetic acid, but has much value as a refrigerant and antiscorbutic. The expressed juice is largely employed as a refrigerant drink in fevers. **L., Ol.**, the volatile oil. Dose, 1 to 5 minims. **Tinct. Limonis Corticis**, a 50 percent tincture, made with alcohol. Dose, according to the amount of alcohol desired to be given, 1/2 to 4 drams. **Acidi Citrici, Syr.**, citric acid, water, tincture of lemon peel, each 1; syrup to 100.

LENIGALLOL.—Pyrogallol triacetate. A substitute for pyrogallol in psoriasis, lupus, etc. It is applied in 5 to 10 percent ointment with zinc oxid.

LENSES.—A lens is a transparent refracting medium, usually of glass or crystal, which is bounded by two curved surfaces or a curved surface and a plane surface.

Lenses may be considered as a juxtaposition of prisms with different refracting angles. Convex lenses are equivalent to prisms with their bases placed together; and concave lenses, to prisms with their apices placed together. Therefore, rays of light always being deflected toward the base of a prism, will be rendered convergent by convex lenses, in which the prismatic bases are central;

and will be rendered divergent by concave lenses, in which the prismatic bases are peripheral.

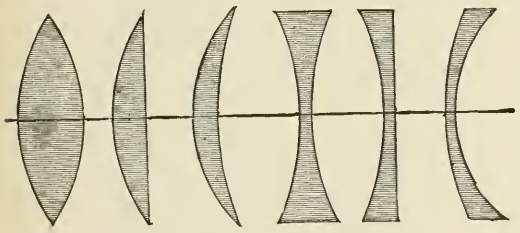
Spheric lenses are used in ophthalmology in 6 different forms:

1. Biconvex, segments of two spheres having two convex surfaces.
2. Planoconvex, the segment of one sphere, having a plane surface on one side and a convex surface on the reverse side.
3. Concavoconvex, or converging meniscus.
4. Biconcave, having two concave surfaces.
5. Planoconcave, having on one side a plane surface and on the reverse side a concave surface.
6. Convexoconcave, or diverging meniscus.

Numbers 3 and 6, having opposite sides at different surfaces, are called periscopic or meniscus lenses, and are used to avoid spheric aberration and to gain a greater field of clear vision.

The principal axis of a lens is a line passing through the optic center at right angles to the surfaces of the lens. Rays passing through this axis are not refracted. Rays passing through the optic center of a lens, but not passing through the principal axis, are slightly deviated, although in practical optics they may be considered as straight lines. The focal length of a lens is the distance from the lens to the point at which parallel rays, refracted by the lens, focus.

A cylindric lens is a lens with a plane surface in one axis, and a convex or a concave surface in the axis at right angles. This form of lens is really a segment of a cylinder. Examination of any cylinder—as, for instance, a bottle—will show there is curvature only in one direction, from side to side, and not in the axis. As the axis of a cylinder has a plane surface, the rays are only refracted at right angles to the axis, and the strength of the cylinder depends on the curvature possessed by the surface



DIFFERENT FORMS OF SPHERIC LENSES.

1. Biconvex lens. 2. Planoconvex lens. 3. Concavoconvex or convergent meniscus. 4. Biconcave. 5. Planoconcave. 6. Convexoconcave, or divergent meniscus.

at right angles to the axis. The axes of the cylinders in a test case are usually shown by grinding and making partially opaque portions of each side of the lens in the direction of the axis.

It must be remembered that a cylinder refracts rays of light only in the meridian at right angles to its axis, while a spheric lens refracts rays of light in every meridian.

Classification and Numbering of Lenses.—Lenses are numbered according to their focal distance, and the strength of the lens varies inversely as its focal distance. Formerly, lenses were numbered according to the **inch system,** the unit of which was a lens whose focal distance equaled 1 inch—a very strong lens. This system necessitated the use of large numbers or fractions; and, moreover, the denomination inch had different significations in different countries, the French inch, for example, varying from the English inch. The **metric or dioptric system** of numbering lenses is now in use, and the unit is a lens having a focal distance of 1 meter and is called a lens of 1 diopter strength—a comparatively weak lens; a 2-diopter lens is one having half the focal length of the 1-diopter lens, or 1/2 of a meter. Decimals, of course, are used instead of fractions; a lens of a focal length of 4 meters is called a 0.25-diopter lens.

Convex lenses form real images, and are called positive or plus lenses, and are designated by the sign +.

Concave lenses produce only virtual images, and are called negative or minus lenses, and are designated by the sign −.

To convert a prescription written in the old system of numbering lenses into the modern metric system of diopters, we can roughly consider the meter as equivalent to 40 inches. A 10-inch lens would be equivalent to a lens having a focal length of 1/4 of a meter, or 4 diopters.

The following table from Landolt gives the equivalents in both the old and new systems:

OLD SYSTEM.				NEW SYSTEM.			
No. of the Lens, Old System.	Focal Distance in English Inches.	Focal Distance in Millimeters.	Equivalent in Diopters.	No. of the Lens, New System.	Focal Distance in Millimeters.	Focal Distance in English inches.	No. Corresponding of the Old System.

Varieties of Lenses Used to Correct Refractive Errors.—1. The simple sphere may be either convex or concave, and is used to correct the uncomplicated forms of refractive errors.

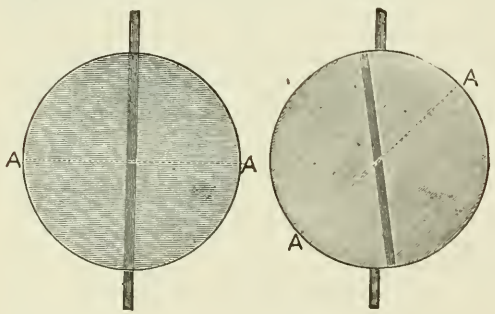
2. The simple cylinder is limited in refractive power to the direction of its curvature, and is used in cases of simple astigmatism in which there is an error of refraction in only one meridian of the eye.

3. The spherocylinder is a combination of a sphere with a cylinder, and is used in cases of compound or mixed astigmatism in which there is a different refractive error in the two principal meridians of the eye.

4. The cross-cylinder is a form of lens made up of two cylinders with their axes at right angles to each other. It is seldom prescribed, but is occasionally used in making tests.

For a further description of test-lenses, see REFRACTION.

Neutralization of Lenses.—The lens is held a few inches in front of the eye, and some object, such as the vertical and horizontal lines of a window-frame or the test-letters, is viewed through it. The lens is then moved to the right, and if it is convex, the object will move to the left; if it is concave, the object will move with the lens to the right. Having determined what sort of a spheric lens we have under examination, we proceed to neutralize it by holding successively a concave lens if convex, or a convex lens if concave, until no movement of the object is perceived through the lens; therefore, **to find the strength of spheric lens,** it is only necessary to combine it with successive lenses of the opposite sign, until one is found which neutralizes the apparent movement of objects seen through the lens under examination. The more rapid the apparent movement, the higher the power of the lens required to neutralize.



NEUTRALIZATION OF CYLINDRIC LENSES.

Cylindric lenses only show movement in the direction opposite to their axes; the movement is against in convex cylinders and with in concave cylinders. To find the axis, an object presenting a straight line, such as the vertical line of the window-sash or the edge of a frame, is viewed through the lens. As the lens is rotated about the visual axis the portion of the vertical line seen through the lens will appear to be oblique, as compared to that seen above and below the lens. This oblique displacement takes place in a direction contrary to the rotatory motion given a convex lens, and in the same direction as the rotatory motion giving a concave lens. To ascertain the position of the axis of a cylinder it is slowly rotated unt the line seen through it appears continuous abov and below. If motion from side to side produces apparent motion of the object, this line is the axis of the cylinder, and if no motion results, the line is at right angles to the axis of the cylinder. The axis being determined, the cylinder is neutralized by successive cylinders of opposite curvature applied in the same axis.

Spherocylindric lenses are neutralized the same way as two cylinders with their axes perpendicular to each other. Having neutralized the movement in one meridian, we note the result and neutralize the movement in the other meridian.

The phacometer is an instrument designed rapidly to discover the strength of lens under examination. It is operated by pressing the surface of a spheric lens squarely against three steel pins, the central one of which is movable. When the central one is depressed until all three points touch the glass, the curvature of the lens is indicated on the dial.

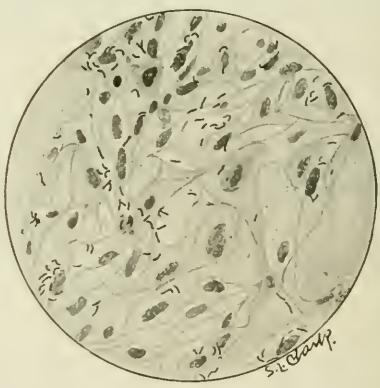
LENTIGO.—See FRECKLES.

LEONTIASIS OSSEA.—See BONE, (Diseases).

LEOPARD'S-BANE.—See ARNICA.

LEPROSY.—Lepra vera; elephantiasis Græcorum; black leprosy.

An endemic, chronic, constitutional disease, analogous to syphilis, and varying in its morbid manifestations according as the brunt of the disease falls on the skin, the nerves, or other tissues. It occurs in 3 forms: the tuberculous, the nontuberculous or anesthetic, and the mixed tuberculous.



BACILLUS LEPRÆ (EXTRACELLULAR).—(*Coplin.*)

The tuberculous or **nodular leprosy** is attended at the onset by debility, depression, dyspepsia, diarrhea, drowsiness, chilliness, and profuse perspiration, marked vertigo, recurrent epistaxis, fever up to 104° F.; after a variable period of days, or even months, coming first with edema of the eyelids, the leprous spots appear on the face and ears, and then on the anterior and external surfaces of the limbs. The exanthem is an erythema, varying from a bright-red to a purplish-red or mahogany-red tint, associated with the leprous deposit of well-defined, shiny, slightly raised patches of from one to several inches in diameter. Papules then form in crops, gradually reaching

the size of a hen's egg and of a yellowish to a dark-brown color. Tuberculation does not develop until from 3 to 6 months after the commencement of the disease. Nodules are most common on the face, limbs, breast, scrotum, and penis. There is also an involvement of the mucous membranes. When the disease is fully developed, the face assumes the characteristic leonine appearance, from thickening of the skin. Ulceration eventually sets in, and the patient dies of exhaustion or complications.

Nontuberculous leprosy is the most common tropical form. The prodromal symptoms are marked, and are associated at first with hyperesthesia of the skin. At the end of a year the special eruption breaks out, usually on the back, shoulders, posterior aspect of the arms, nails, thighs, and sometimes in the course of nerves. The spots are 1 or 2 inches in diameter, well defined, not raised, and of a pale yellow color. They spread peripherally, clearing in the center, which becomes dry, scaly, and anesthetic. Paralysis is usually a late symptom, and ulceration is common. Death results from ulceration, gangrene, marasmus, or general debility.

Mixed tuberculous leprosy is the least common form, and its symptoms are a combination of those of the other two varieties. Destruction of the cartilages of the nose and of the soft palate is common.

Etiology.—Leprosy is caused by the invasion of the organism by the bacillus lepræ. Heredity, climate, soil, and mode of living may act as predisposing causes.

The contagion is probably chiefly effected through direct or mediate inoculation.

Pathology.—The disease consists of a deposit of cells in the corium and subcutaneous tissue, similar to those seen in lupus and syphilis. The specific bacillus is found in the tubercles, infiltrations, lymphatic glands, nerves, etc.

Diagnosis.—Advanced cases of leprosy are easily recognized. The disease may be confounded with syphilis, morphea, vitiligo, and lupus. The occurrence of anesthesia and the history and course of the disease will usually enable one to make the diagnosis. In doubtful cases the microscope should be resorted to, with the view discovering the bacilli in the affected tissues. The Wassermann reaction seems as successful in leprosy as in syphilis.

Prognosis.—Always unfavorable. The disease progresses, with rare exceptions, to a fatal termination. The course is more rapid in the tubercular than in the anesthetic form.

Treatment.—Nutritious food, good hygiene, and removal to a healthful climate are important therapeutic measures.

The remedies which have proved most valuable in the treatment of leprosy are chaulmoogra oil (best in the form of antileprol, it is claimed) and gurjun oil, used both internally and externally in the tubercular variety, and strychnin in large doses in the anesthetic form. Nastin and eucalyptus are advised. X-ray treatment has apparently resulted in cures.

LEPTANDRA (Culver's-root).—The rhizome and rootlets of *Leptandra virginica*, now called *Veronica virginica*. Its properties are thought to be due to a glucosid, *leptandrin* (dose, 2 to 4 grains). It is a tonic, laxative, and cholagog, and is indicated in indigestion and chronic constipation. Dose of the extract, 1 to 6 grains; of the fluidextract, 10 to 20 minims.

LEPTOMENINGITIS.—Inflammation of the pia and arachnoid of the brain and the spinal cord, in contradistinction to pachymeningitis, though meningitis alone usually signifies the same as leptomeningitis. See MENINGITIS.

LEUKANEMIA.—A term applied by von Leube to an acute condition of leukemia combined with severe anemia. It is usually fatal in from a few days to three months. The onset may be sudden with fever and severe tonsillitis, prostration, hemorrhage, extreme pallor and rapid decline. There is often general glandular enlargement including the liver and spleen. The reduction of hemoglobin and erythrocytes with increase of plymhocytes (usually the large form) is conspicuous. The red cells may be as low as 1,500,000. The color index is high.

LEUKEMIA (Leukocythemia).—A chronic disease of the blood-making organs, characterized by great and persistent increase of the white blood-corpuscles; by a diminished number of red cells, which are altered in shape and size, and display nucleated and degenerate forms; by a lessened amount of hemoglobin; and by enlargement of the spleen, lymphatic glands, or medulla of bone (Musser).

Etiology.—The disease may occur at any period of life, but is seen mostly in adult males. Syphilis, splenic traumatism, pregnancy, heredity, malaria, bad hygiene, and repeated hemorrhages may act as predisposing causes. It has been held to be due to the absorption of toxic substances from the digestive tract. It seems probable that it is of infectious origin.

Pathology.—There may be great emaciation. The spleen is usually enlarged. The cervical, inguinal, and axillary glands may be the first to enlarge. The liver may be enormously enlarged.

There is extensive hyperplasia of the lymphatic tissues and reversion of the bone-marrow to the embryonal type.

Symptoms and Course.—By examining the blood we detect 2 varieties of leukemia: (1) Splenic myelogenous leukemia; (2) lymphatic leukemia. Mixed splenic and medullary leukemias are the most common—called splenomedullary (lienomedullary) or lienomyelogenic.

Splenic Myelogenous Leukemia.—The colorless corpuscles are greatly increased, but there may be only a small diminution in the number of the red cells, averaging slightly above 3,000,000, with a small decrease of the hemoglobin. Nucleated red cells are present in abundance. Eosinophiles and basophilic leukocytes are markedly increased.

Characteristic of this form of leukemia is the large corpuscle—the *myclocyte*, a large cell with a large, pale blue nucleus, and not ameboid. The great number of these myelocytes present is diag-

nostic of this form of leukemia. With the decided increase in the number of these myelocytes there is a corresponding diminution in the lymphocytes (youngest leukocytes).

Lymphatic Leukemia.—This is characterized by enlargement of the lymphatic glands and an absolute lymphocytosis. In this form (about 15 percent of all cases)there is a greater reduction in the number of red cells than in the splenic myelogenous form, but there is almost an absence of the nucleated red cells, in contrast with the splenic variety of leukemia. With this reduction of the red cells there is a greatly increased number of the leukocytes (though less so than in the splenomyelogenous form) especially the lymphocytes, which may constitute 90 percent of the white corpuscles. These lymphocytes are of all sizes.

The leading characteristics of leukemic blood are:

Splenomedullary leukemia	1. Red cells reduced to greator or less degree (at times below 1,000,000), numerous nucleated forms. 2. White cells about 400,000, of which— 3. Myelocytes form about 35 percent.
Lymphatic leukemia.	1. Red cells about 3,000,000 or lower, nucleated forms rare. 2. White cells 100,000 or lower, of which— 3. Lymphocytes form 90 percent, either large or small predominating. 4. Myelocytes and eosinophiles very scanty.

Symptoms.—At first the symptoms are those of the other anemias: Insidious onset, pallor, faintness, vertigo, dyspnea, weakness, anorexia, indigestion, headache, palpitation. Hemorrhages are common. Enlargement of the spleen or lymphatic glands or both are found. There may be moderate fever. The enlarged glands are free from active inflammation and give rise to pressure symptoms. There is a tendency to serous effusions in the later stages and emaciation appears. The pulse is rapid and easily compressible. Nausea and vomiting are common. The urine usually contains an increased amount of uric acid.

Diagnosis can only be made by the blood examination. See BLOOD, Diagnosis of Leukemia.

Prognosis is usually unfavorable. The lymphatic form may be fatal in from 6 weeks to 2 months.

Treatment.—The best hygienic surroundings possible should be given the patient, and good, nutritious food supplied. The patient should never exhaust himself by too active exercise. If there is a history of malaria, quinin in 3- or 4-grain doses should be given 3 times daily. Arsenic is highly recommended, and any prescription recommended for pernicious anemia may be given. Benefit has been derived, it is claimed, from X-ray treatment by the Pancoast method (exposure consecutively of the various bone-marrow regions of the body). In the splenomyelogenous type remarkable results have been obtained from the use of the X-rays. Some improvement is reported in cases of the myeloid type from the use of mixed toxins of streptococcus and B. prodigiosus. See ANEMIA (Pernicious); BLOOD (Examination).

LEUKOCYTE EXTRACT.—According to Hiss, an aqueous extract of washed leukocytes, obtained from healthy rabbits after an injection of aleuronat into the pleural cavity, has a curative action when injected in infectious diseases. Satisfactory results have been obtained in pneumonia, furunculosis, erysipelas and cerebrospinal meningitis.

LEUKOCYTOSIS.—See BLOOD (Examination).

LEUKODERMA.—Leukasmus; achroma cutis; leukopathy. A congenital pigment anomaly of the skin, in which, at the time of birth or soon after, whitish patches or bands, irregularly outlined and usually isolated, appear upon the skin of the child. See VITILIGO.

LEUKOMA.—An opacity of the cornea the result of an ulcer, wound, or inflammation, and presenting an appearance of ground glass. See CORNEA.

LEUKOMAIN.—The name applied by Gautier to the nitrogenous bases or alkaloids necessarily and normally developed by the vital functions or metabolic activity of living organisms, as distinguished from the alkaloids developed in dead bodies, and called by Selmi ptomains. See PTOMAIN, AUTOINTOXICATION. From their chemic affinities leukomains may be divided into two groups: The *xanthin group*, comprising xanthin, adenin, carnin, gerontin, guanin, heteroxanthin, hypoxanthin, paraxanthin, pseudoxanthin, spermin, and the *creatinin group*, in which are classed creatin, creatinin, amphicreatinin, crusocreatinin, xanthocreatinin, and some unnamed bases.

LEUKOPENIA (Hypoleukocytosis).—See BLOOD.

LEUKOPLAKIA.—See TONGUE.

LEUKORRHEA.—A whitish mucopurulent discharge from the female genital canal, popularly called "the whites." See CERVIX (Diseases), GONORRHEA, VAGINITIS, VULVA.

LICE.—See PEDICULOSIS.

LICHEN RUBER.—An inflammatory disease characterized by the appearance of small, flat, angular, and shining or discrete, acuminated and scaly, reddish papules, running a chronic course and attended by more or less itching.

Symptoms.—There are 2 varieties: Lichen ruber acuminatus and lichen ruber planus. Some authors regard these forms as distinct diseases.

Lichen Ruber Acuminatus (Lichen Ruber).—This is a very rare disease, particularly in America. It is characterized by discrete, millet-seed sized, acuminated, scaly, reddish papules, which are disseminated over the trunk with no disposition to grouping. After a duration of years the skin may become diffusely infiltrated, reddened, and scaly. There is mild or severe itching present. The disease is extremely chronic, usually compromising the general health, and tending ultimately to a fatal termination.

Lichen Ruber Planus (Lichen Planus).—Lichen planus is not an uncommon disease. It may develop gradually or rapidly, appearing as pinhead-sized to pea-sized flat, quadrangular, or polygonal, shining, slightly umbilicated papules of a violaceous or reddish color. The lesions may be disseminated, but are more commonly closely aggregated in patches, which assume frequently a linear form. The surface of the papule is at first glazed or shining, later covered with fine whitish scales. The favorite regions are the flexor surfaces of the forearm and wrist and the dorsal surfaces of the feet. When occurring upon the legs, the

papules are apt to become confluent, with the formation of elevated plaques of a purplish color. A brownish pigmentation often persists after the disappearance of the lesions.

Itching is, in the majority of cases, a prominent symptom. The general health remains unaffected.

Etiology.—The disease is of neurotic origin. The most common cause is nervous exhaustion resulting from worry, overwork, etc. It is most frequently observed in middle-aged individuals.

Pathology.—The pathologic process in the plane variety consists of a dilatation of the papillary blood-vessels, a dense, sharply circumscribed round-cell infiltration in the upper part of the corium, proliferation of the cells of the rete mucosum, with either flattening or elongation of the papillæ. The papules are claimed by some to develop at the sites of hair follicles; by others, around the sweatducts.

Diagnosis.—The characteristic features of the papules of lichen planus are their angularity, flatness, shining surface, violaceous color, and umbilication. These points will differentiate the disease from papular eczema, psoriasis, and the papular syphilid. The papules of eczema are rounded, somewhat acuminate, brighter red in color, and have a different history.

Prognosis.—The prognosis of the acuminate variety is extremely guarded; of the plane variety, favorable.

Treatment.—The treatment is both general and local. Attention to diet and hygiene should not be neglected. Cod-liver oil, iron, strychnin, etc., are often indicated. Arsenic is by far the most valuable remedy, exerting almost a specific influence upon the disease. In some cases, particularly when arsenic fails, mercury acts most favorably.

Locally, applications containing tar, phenol, menthol, salicylic acid, mercury, etc., are to be employed. The following formula, suggested by Unna, has been successfully used:

℞.	Carbolic acid,	gr. x to xx
	Mercuric chlorid,	gr. ij to iv
	Zinc oxid ointment,	℥ j.

Apply twice a day.

LICORICE.—See Glycyrrhiza.

LIFE ASSURANCE EXAMINATION. **General Remarks.**—Life assurance is a contract by which a corporation agrees to pay a stipulated sum, such as may be agreed upon between the parties, either on the death of the life assured or within a limited number of years, as the case may be, provided the applicant fulfils his part of the contract. The latter consists in the regular payment of fixed sums, known as premiums. Before a company will enter into such a contract it usually requires the recommendation of at least two medical officers of the company—the one the local examiner, to whom the applicant submits for medical examination as to his present state of health, and to whom also he must furnish a truthful report of his past ailments, as well as data with regard to his family history: the other, the medical director, or chief medical officer, whose duty it is to examine carefully this report and advise the company as to the desirability of accepting the risk.

Of late years the amount of money involved in these contracts has reached enormous dimensions. The financial standing and the success of all companies depend to so large an extent on the judicious report as to the past and present state of health of the applicant, as well also as the moral hazard of the risk, that it is necessary that the medical inspection and supervision of each individual risk should be made with great care.

The first important point it is desirable for the medical examiner to remember is that all assurance companies base their premiums on the assumption that their assured lives shall be healthy individuals of healthy families: *i. e.*, not only must the applicant for assurance be himself free from disease and of good habits, but he must also belong to a family of healthy brothers and sisters (if he has any), children of healthy parents.

With such a history, the average duration of life at all ages has been estimated by actuaries of several companies, who have varied but a few months as to its duration at the different ages; that is to say, as to the number of years longer which a healthy person, as above stated, of a certain age, is expected to live. This is what they call their "expectation." The rates of assurance for first-class lives are fixed accordingly. See Life (Expectation).

The "selection" of the risk is the duty of the medical board, which may consist of one or more "medical directors," so called because they direct the medical affairs of the company. Most English companies have but one such officer, whom they call the "medical referee" or "chief medical officer."

It is the duty of these officers to examine the medical reports of all examinations and to eliminate the objectionable risks. Many cases are rejected by medical directors because of features which their greater experience leads them to believe are hazardous, although recommended as first class by medical examiners.

In other cases, although they may consider the risk not a safe one on a cheap plan, they may think it assurable on some plan with large annual payments, and offer a policy on an endowment plan or some plan more favorable to the company than the one applied for. If the applicant will not accept this policy, the risk will be completely declined and placed on the black-list.

The medical examiner who has examined the applicant may consider him an unobjectionable risk because at the time of examination he is perfectly healthy, but the medical director, in reviewing the whole history of the case and acting upon the statistics furnished by the actuarial department, as well as his own observation in examining death claims, may, and very frequently does, feel compelled, acting in the interest of the company, to reject the risk, notwithstanding the favorable recommendation of the examiner. The objectionable features in the case may have been only an incomplete family history and light weight compared with height.

The decision of the medical board may or may not be referred to the executive, or board of directors (not medical). They nearly always follow the recommendation of the medical board, but, of course, may do otherwise, if they so decide. To be binding, the policy must have the signature of the executive.

All appointments of medical examiners are made by the medical board or medical director. Some companies have a "medical referee," to whom all applications for appointment as examiner are sent. With some companies the medical referee acts as medical inspector, whose duty it is to visit the various agencies and acquire information as to the standing of the various medical examiners. He also occasionally is called upon to investigate the circumstances connected with death claims in the previous history of which there may be some unsatisfactory points to be explained.

No applicant who at the time of examination is suffering from disease in any form should be accepted at that time. Many, also, who are quite free from present disease must be considered bad or impaired risks. These, however, are usually insurable, but at rates and on plans varying with the nature of the impairment. With some this impairment is likely to diminish as they grow older, while with others the contrary is the case; hence we have those who may be classed as lives with "diminishing risks," and also lives with "increasing risks."

Gout, arteriosclerosis, and consequences—diseases more frequently found after middle life—are examples of the latter class. In the former a tendency to tuberculosis, especially of the lungs, may be included, inasmuch as the liability lessens as the individual grows older. Assurance companies take different measures to meet these various risks. Some, more especially the British, impose in nearly all cases an addition of a certain number of years to the age of the applicant, thus increasing the amount of premium required. Others, particularly American officers, offer the applicant an "endowment" policy, on the theory that the extra risk is overcome by shortening the term of the policy and exacting a correspondingly heavier premium. Either of these plans may be comparatively safe for cases of "increasing risks," but they can hardly be considered as based on sound actuarial principles when applied to the case of "diminishing risks."

It is the practice of some companies to place a "gradually reducing lien" or "contingent debt" on the policy issued on such a life. Both the amount of the lien and the duration of its existence vary according to the nature of the risk, and many authorities consider that this is a more correct method of dealing with such cases.

Duties of Medical Examiner.—The medical examiner must always remember that he is the official representative of the company, and that he acts purely in its interests. Whenever there is any doubt as to the advisability of accepting the risk as a first-class one, it is his duty to give the company the benefit of that doubt. Under no circumstances should he allow himself to be influenced, either by agent or applicant, in suppressing any information in regard to family or personal history. Illness of any kind for which the applicant may have consulted a physician, especially if within the last few years, should be fully reported on, both as to its nature, the length of the confinement to bed and to the house, and any other information of importance in connection with it. Before a policy will be issued the medical board must have full particulars of the past medical history of the applicant, to enable them to form an opinion of the value of the risk, quite independent of the medical examiner's views. It may not always be advisable for the medical examiner to put in writing on a printed form his opinion, especially as to habits, if they are objectionable. They will be sure to be read over by the agent, and probably related to applicant. This difficulty can be readily overcome by the medical examiner writing a confidential letter to the medical director giving more complete information as to any unfavorable point in either personal or family history.

In proceeding to examine the applicant the medical examiner should remember that he must do so with as much care as he would were it an ordinary office connection on the applicant's behalf, according to the printed form of the company. There are a number of questions he is expected to ask, both with regard to the family and also the personal history. The replies to these questions he must write down. Now, for this purpose it is advisable to have the applicant so placed in front of the light that, while getting the replies to the various questions, he may study his appearance, and thus form a general idea as to his age, general health, and prospects of longevity. A good rule is to commence these questions by asking the applicant if he has ever been refused by any company, and also if every company to whom he has applied has issued a policy on the plan applied for. The reason of this is that it is almost of daily occurrence in companies doing a large business to find that as soon as the agent who has canvassed the risk has the slightest hint that the applicant is not a first-class life, and probably because of conscientiously believing the examiner to have been unnecessarily strict, he will at once take the man to another company in the hope that its medical representative may not be so particular. Unfortunately, it often happens that through a hasty and incomplete examination the second doctor may overlook a slight heart murmur or some other feature recognized by the first examiner, and advise issuing a policy, with the consequence that his own services may, quite possibly, be dispensed with. This happens in this way: So soon as a risk is declined, notice of this refusal is sent to a central bureau, and from there a printed card is posted to all the companies who are members of the "exchange." The cards thus received are kept on file in cabinets. Before a policy can issue from the office every name that has been recommended for assurance is searched for in these cabinets, and if found in this black-list, information is obtained as to the reason why the previous

company did not issue its policy. In this way many a fraud on the part of the applicant (who has denied previous refusal) and many an error on the part of the physician have been discovered.

At the same time it must be remembered that the denial by the applicant of his refusal by another assurance company does not always mean fraud. He may be, and very often is, in ignorance of the reasons of the policy not having been issued.

In making this examination there are four distinct points which should carefully be inquired into by the medical examiner and reported upon:

1. Family history.
2. Past medical history.
3. Past and present habits.
4. Present state of health as indicated by medical examination.

In reporting upon all the above the medical examiner must not lose sight of the fact, already referred to, that he is examining in the interest of the company he represents. With that in view, he should be on his guard as to the possibility of the applicant concealing information connected with family or personal history which might influence the decision of the company as to issuing a policy. That concealment may be intentional or otherwise. Should a death claim arise within 3 or 4 years, notwithstanding the false statements made, the company is barred by the laws of many states from making this a point in the defense, unless it can be proved that this statement was fraudulently made and had a direct bearing on the cause of death. Nowadays most companies voluntarily adopt a limited period (generally 2 or 3 years) after which time the policy is absolutely indisputable, notwithstanding any misstatements.

Family History.—Taking up, now, the first of the headings above referred to—the family history—the replies to the questions as written down by the medical examiner are very frequently the cause of much inconvenience and delay in issuing a policy. In the case of death of either parent or other member of the family, the terms "general debility," "anemia," "la grippe," "burst a blood-vessel," "hemorrhage," or, in the case of sisters or mother, the terms "change of life" or "childbirth," are often used without any explanatory notes as to the duration of illness or presence or absence of cough. The experience of all medical directors shows that these terms are frequently made use of when the actual cause of death has been **tuberculosis** of the lungs. Many an applicant quite conscientiously gives "childbirth" as cause of death of mother or sister, believing it to have been the direct existing cause of the diseased condition, which may have terminated in death a few months after delivery. In view of this tendency on the part of the public in the absence of such definite information as will satisfy the medical director that tubercular disease may be completely eliminated, he will not be justified in treating the case as an unimpaired life, unless, indeed, there are other features of a personal character, which in his opinion may offset these unfavorable points.

The mortality from tuberculosis is so great that when indefinite statements are made regarding family history, suspicion is naturally directed that way. Hence the absolute necessity arises of the medical examiner furnishing such complete and detailed information as will enable the medical director to form an accurate opinion as to the facts of each case.

Other indefinite terms are occasionally made use of by inexperienced medical examiners, such as "dropsy" (a mere symptom of a diseased condition of some organ, such as heart, kidney, or liver), "heart failure," "dissipation," "congestive chill." All such cases require full inquiry and explanation.

When either parent has died of consumption, it is particularly desirable that inquiries should be made as to the cause of death (if any deaths) of other members of deceased's family, so as to be able to eliminate any chronic lung trouble, for, indeed, in an insurance point of view, the company should take the benefit of any doubt that may exist, and assume that every suspicious case is one of tuberculosis.

Seeing that consumption accounts for the largest number of death claims in the mortuary list of all assurance companies, it is one which, naturally, the medical department tries most to guard against. There is little doubt that some of these claims are avoidable. With our more modern views of the nature of the disease, and its manner of transmission, the question of heredity loses some importance. Although an important factor, the environment, occupation, and physique of the applicant are of even greater importance. As a rule, however, the progeny of strong and healthy parents possess more endurance, and are less susceptible to contagious diseases, other things being equal, than those of feeble parents. Therefore, when exposed to the contagion, the latter are less liable to resist the attack of the bacilli.

It is a debatable question in the case of either parent dying of consumption at an age when the children are very young, whether such a risk should be considered more or less hazardous on the part of the children subsequently seeking assurance. In favor of the latter view may be stated that they are exposed to the contagion at a time—early childhood—when the individual has great resisting powers to that disease. Later on, when developing into men and women, the danger of contracting the disease is greater should they be exposed to the contagion. On the other hand, it should not be lost sight of that if either parent died within a very short period of the birth of the child seeking assurance, there is a probability of that child inheriting, to some extent at least, the impaired vitality of the parent.

Living in the same house, especially sleeping in one, in which an individual has recently died from consumption, or is suffering from it, neutralizes to a certain extent the favorable importance of a first-class personal physique, and even of over average weight. This is especially the case in regard to man and wife, so that with young married men the fact of the wife suffering from the disease or from any chronic lung trouble which would give reason for suspecting consumption,

seriously impairs the life of the husband, so far as assurance is concerned.

Arteriosclerosis and its resultant affections of the system, such as some forms of **kidney-disease, apoplexy,** and the like, if the cause of 2 or more deaths in a family, should be considered as placing an applicant in the under average class, especially if associated with even a moderately free use of alcohol. Many of these causes are really the result of a "gouty" condition, and if death of either parent can be assigned to that cause, the risk is rendered more hazardous, as we have unfortunately many evidences of its hereditary nature.

When such a family history is present, it is the duty of the medical examiner to inquire minutely into the personal history of the applicant for any evidences of a similar condition, such as frequently occurring attacks of tonsillitis, bronchitis, and eczema. These remarks apply more to individuals over 45 years of age, and with almost equal emphasis in a family and personal history of rheumatism.

Past Medical History of the Applicant.—Naturally, this has an important bearing on the desirability of the company assuming the risk. Again, we think of the dreaded disease **consumption,** and cannot help observing in private and hospital practice that the frequent occurrence of catarrhal conditions in an individual who is the offspring of tubercular parents makes him a particularly hazardous risk, although at time of examination he may appear to be perfectly sound.

No less important is the history of the occurrence of **pleurisy** within recent years. The examiner should be most careful in making the examination. He may be able to locate where the pleuritic condition existed, but if the history of the case pointed to the probability of its being toward the apex of the lung and of recent date, the risk should be considered an impaired life. If a history of tuberculosis is present in the family, and the applicant is below the average weight, the risk should not be accepted at ordinary rates. A death in the family from pleurisy should be looked upon with suspicion as possibly being associated with tuberculosis.

The view too often entertained that a history of pleurisy in an applicant is of very little consequence is a grievous error. In recorded cases in which death has occurred from this disease and postmortem examinations have been made, nearly 50 percent have been tuberculous. Of those who have recovered from the attack almost one-fourth subsequently developed tuberculous disease of the lungs. In cases in which the disease has lasted any length of time fully 50 percent die of tuberculosis.

Hemoptysis, if within recent years, should certainly be considered sufficient grounds for refusing a risk. There are good reasons for believing that it may occur without tuberculous disease, but the cases of that kind are so very rare that for assurance views it is safe to look upon all such as tubercular. If an applicant has been in perfect health since the attack, and has increased in weight so that he is above the average weight for his height, and an interval of 8 or 10 years has elapsed since the hemoptysis, the risk may be considered fairly safe, but he cannot be a first-class life. He is safely assurable on some plan, such as an endowment, or with a small lien placed on the policy.

Cancer is a disease about which there appears to be but little unanimity in practice among companies with regard to the acceptance of those risks. There can be little doubt that the relative number of deaths from cancer is greater now than it was many years ago. This can, however, be readily accounted for by the fact that the mortality of the younger ages is very much less than formerly—that is to say, that more individuals survive to the ages at which cancer makes its appearance. The practice of some companies in disregarding a single death from cancer in the family history seems to be justified by mortality lists. Two or more deaths in the family from any cancerous affections are, however, sufficient to cause a life to be treated as impaired.

Diseases of the Genitourinary Tract.—An applicant suffering from an attack of gonorrhea should be put off until some time after the disease has been fully cured. It may result in a stricture which in late years (through secondary diseased conditions) may endanger life. Stricture, if obstinate and not readily and quickly yielding to treatment, may cause secondary diseased conditions, such as pyelitis or disease of the bladder or kidneys of a more chronic form. Such troubles may arise from an apparently insignificant stricture. Such an applicant should not be considered first class. Some years should be taken off his "expectation" and the premium increased accordingly, or a policy on a short term endowment only granted.

Syphilis.—That individuals may die of syphilis can be easily proved by referring to the pathologic museum of any hospital or school of medicine, and that many of them may die at periods remote from the primary inoculation, clinical history will attest. For these reasons a man who has had syphilis, although reported cured, cannot be considered a "selected" life. The practice of assurance companies varies with regard to such lives. Many companies will issue any form of policy provided a certain time, say 3 years, has elapsed since final disappearance of symptoms, more especially if they have had several months' treatment. Others again will issue only a limited policy, say 20-year endowment, without any extra premium. When an applicant has had syphilis and has undergone a regular course of medical treatment for say 3 years, and the individual has a healthy appearance and leads a regular life, and if at all uses alcohol only very moderately, the risk is considered by many companies as presenting no objections to being first class. Other companies again will demand an extra premium corresponding to that caused by the addition of 6 or 7 years to the age of the applicant. Still others again impose a lien running off in 15 to 20 years.

It must not be overlooked that many, even of the so-called cured, patients, may die 15 or 20 years after the infection from some such disease or locomotor ataxia or some affection of the brain, while others succumb at earlier periods from syphilitic affection of the lungs, kidneys, liver, etc.

Albuminuria is a condition regarding which there appears to be an utter absence of unanimity of action on the part of the medical boards of the various companies. All medical authorities are fully agreed that the presence of albuminuria in a young person is not incompatible with perfect health.

Many individuals in whom albuminuria is present, and who were declined for assurance—some as far back as 27 years ago—have during that time enjoyed the best of health. On the other hand, cases are so numerous in which the detection of albuminuria has been followed by so limited a term of existence, even in the young, that its presence at the time of examination should be sufficient to postpone the acceptance of the risk until such time as it can be reported that frequent examinations within some definite time have proved the absence of albumin.

Should an examiner meet with such cases, he should make a most careful examination of the **heart-sounds**, especially in the aortic region, so as to be able to conclude that very important indication of arterial changes, the accentuated second sound, and report in full all the facts.

Otorrhea is a condition which should be inquired into if present. It may be of little consequence, but as many of those in whom this condition is present die from the extension of the disease, as a result of septic infection or of inflammatory affection of the brain or its membranes, the life cannot be considered otherwise than as impaired. By the term otorrhea we understand a chronic suppurative inflammation of the middle ear. It is frequently a sequence of either measles or scarlet fever, but it may follow an acute inflammatory affection, as a result of cold in a person with scrofulous tendency. The mastoid cells may become involved and place the life of the individual in jeopardy. Even in cases in which the discharge has ceased for a time a slight existing cause may give rise to inflammatory processes which, by extension, may cause alarming cerebral symptoms.

In cases of this kind the examiner should elicit from the applicant the duration of the discharge, and, if it has now ceased, the time of its disappearance. He should also endeavor to find out whether or not it followed any of the eruptive diseases. All these facts should be fully explained in the medical report.

The actual presence of a discharge is not enough to cause rejection of the risk. Some companies may accept on a short term endowment, while others may place a small lien on the policy, running off in say 15 years; while others may meet the extra risk by charging a higher premium, resulting from adding an extra 7 years to the age.

Inflammation of the bowels, in the past history of an applicant, is a term about which examiners are very often not sufficiently accurate in their reports. When given as one of the ailments for which he has had medical care, the date of the occurrence and duration of illness should be fully reported. The medical examiner should get from the applicant a description of symptoms from which he suffered, and report accordingly. Without a detailed or satisfactory report the medical director will be in duty bound to accept the views of most physicians and surgeons, who look upon the great majority of such inflammatory cases as attacks of appendicitis, which, if recent, are so liable to recur. There can be no doubt that often when the applicant reports that he has had inflammation of the bowels it may have been only some catarrhal trouble, or an attack of enteritis, or a mild attack of dysentery. Should there be no satisfactory evidence, so far as the report goes, that the attack was not appendicitis, and if it occurred recently, say within from 3 to 5 years, the medical director will probably take the benefit of the doubt, and postpone the acceptance of the risk for a limited time after its occurrence (3 to 5 years generally), or advise issuing a policy only on some heavier payment plan, or its equivalent.

A perfect cure after removal of the appendix renders the risk unobjectionable on the ground of a previous appendicitis.

Habits.—The abuse of alcohol in its various forms is a source of great trouble to assurance companies. In the first place, a very large proportion of death claims are either directly or indirectly due to it. Most physicians agree that its very moderate use may cause no injurious effect on the health of the individual. All men know that its excessive use is decidedly injurious. It is an extremely difficult matter to decide as to the dividing line between the two conditions. It can be safely assumed that the man who uses over, say, 2 or 3 ounces of spirit or its equivalent a day, is producing injurious structural changes in his vascular system. But few individuals admit the full quantity taken daily. The facts tend to prove that the offspring of neurotic parents, when users of alcohol, are more prone to its excessive use. In estimating, on this ground, the value of a life seeking assurance, heredity should be considered. One who uses alcohol freely in any form, either of whose parents were addicted to its use, must be considered a very hazardous risk.

When any doubt exists, the company should unquestionably take the benefit of that doubt either by not assuming the risk or by issuing a policy on some short term plan, with heavy payments, such as a 10-year or 15-year endowment, or, again, by adding 7 to 10 years to the age with correspondingly increased premium.

Medical Examination of the Applicant.—By the time the medical examiner has completed his questions and noted down the replies thereto, he will have formed a fair idea of the nature of the risk his company is asked to assume. He will have observed the man's **general appearance**—whether anemic or plethoric—by the general appearance of face and ears, as well as the character of his breathing, whether or not there is a probable tendency to tubercular disease. At the same time he will have given the applicant a chance to overcome that nervousness so often met with in applicants for assurance, when knowing they have to undergo medical inspection. When possible, in fact in all cases, the **chest** should be uncovered so that an inspection, as well as a

LIGATURE.—A cord or thread of any material for tying arteries, etc.

Arterial hemorrhage is best arrested by simple ligation, and a ligature is occasionally required in venous bleeding. It is best to include as little of the surrounding tissues as possible in employing a ligature, except when arterial coats are diseased. In ovariotomy the pedicle is included in the ligature with the vessels *en masse*. Hemorrhoids and nævi may be treated by ligature. Silk linen thread, silkworm-gut, kangaroo tendon, hemp, catgut, ox aorta, fine wire, horsehair, and other materials have been used for ligature. Silk, silkworm-gut, and catgut are the materials most used. Dentists' floss has been recommended when large vessels are to be tied, since it does not easily slip. For sutures, silk or silkworm-gut is best. Silver and other wire sutures are not much employed. For cut ends of arteries catgut, properly prepared, is likely the best ligature material. Chromicized catgut is harder than ordinary catgut, and requires soaking in carbolic lotion for an hour before use. It then ceases to be slippery or brittle, and its knot will not yield. Animal ligatures disappear in course of time, while silk ligatures remain and may set up irritation. A single thread should always be used for ligation of arteries.

Preparation of Catgut.—Dry sterilization of catgut seemed to become the general procedure a few years ago, but extensive trial has shown that it cannot be relied upon in rendering the material absolutely safe for practical use. The many failures of catgut as an aseptic suture and ligature, as heretofore prepared, are responsible for the substitution of silk for catgut in the practice of many surgeons. Instances of even tetanus infection have been traced to the use of catgut. Silk can be readily sterilized by boiling, the simplest and quickest method of effecting absolute sterilization.

The ideal sterilization of catgut consists in rendering the material not only absolutely sterile, but also mildly antiseptic, without impairing its tensile strength. Every surgeon has been anxiously looking for a method by which catgut could be prepared so that it could be sterilized by boiling without impairing its strength. Experiments have shown that catgut and leather immersed for 48 hours in a 2 to 4 percent solution of formalin undergo an unknown chemic change, which alters their texture in such a way that its tensile strength is not impaired, but rather increased, by boiling. The commercial catgut is subjected to the action of the formalin without any previous preparatory treatment of the raw material. Hofmeister, who has done such excellent service in perfecting the formalin preparation of catgut, gives the following most recent method: (1) The catgut is wound on a glass plate with slightly projecting edges, so that the gut is free from the sides of the plate and exposed to the circulation of the boiling and flowing water. The ends of the gut are fastened through holes in the plate. (2) Immersion 12 to 48 hours in aqueous solution of formalin 2 to 4 percent. (3) Immersion in flowing water at least 12 hours to free the gut from the formalin. (4) Boiling in water from 10 to 30 minutes. Ten to 12 minutes are amply sufficient, as all microbes and spores are killed by exposure to boiling heat for that length of time. (5) Hardening and preservation in absolute alcohol containing 5 percent of glycerin and 0.1 percent of corrosive sublimate.

One of the essential conditions of success in this method of catgut sterilization is to wind the gut quite tightly around the glass plate or hollow glass cylinder during the process of sterilization.

The result of Senn's experience has led him to modify the procedure in several ways. Instead of glass plates, ordinary glass abdominal drainage-tubes have been employed, upon which the gut is wound quite tightly. These glass drains have been found an excellent substitute for the plates. An ordinary large test-tube would answer the same purpose. The remaining directions given by Hofmeister were followed to the letter. Numerous inoculations with fragments of catgut prepared by this method in sterile gelatin invariably gave negative results. The catgut is as strong as the raw material, hard, and the knot is less liable to slip than when the ordinary material is used.

In the preparation of catgut Senn has modified Hofmeister's method by substituting iodoform for the corrosive sublimate. After boiling the deformalinized catgut for 12 to 15 minutes, it is cut into pieces of desirable length, tied into small bundles containing from 6 to 12 threads, when it is immersed and kept ready for use in the following mixture: Absolute alcohol 950, glycerin 50, iodoform (finely pulverized) 100. The alcohol dissolves part of the iodoform. The bottle containing the catgut should be closed with a well-fitting glass cork and should be shaken well every few days to bring the dissolved iodoform in contact with the threads. The catgut can be kept in this mixture for any length of time without losing its strength. One of the valuable properties of iodoform applied to a recent wound is to diminish the amount of primary wound secretion. It does not destroy pus microbes, but inhibits their growth.

Silk may be prepared by boiling, after having been wound on glass spools, and kept in an ordinary test-tube, the mouth of which has been stoppered by sterile absorbent cotton. Before use it should be resterilized. It may be put in a carbolic solution, 1:20, to which two-thirds of its quantity of alcohol has been added. This is better than corrosive sublimate solution, since the needles may be threaded and placed in the liquid together with the ligature.

Kangaroo tendon has the advantage over catgut in being uncontaminated by germs when obtained from a healthy freshly-killed animal. It is very carefully prepared and dried and may be kept indefinitely in carbolic acid (1 to 20). The strands are especially valuable for large blood-vessels and varicoceles and deep-buried sutures of the abdomi-

nal wall, hernia and muscular union. They are absorbed in about 6 weeks.

Horsehair washed with ether and sterilized by heat is excellent for skin sutures when there is not much tension.

Silkworm-gut is commonly used by anglers. It may be purchased in bundles, and from them suitable pieces should be picked for surgical use. As a rule, pharmacists keep selected material for surgical use. It may be sterilized by heat or it may be soaked in a carbolic solution for 15 minutes before use. The first knot should be a double one, and the second knot tied very lightly or not at all, to obviate breakage. It is an excellent interrupted skin suture, but not adapted for vessels and deep tissues by reason of its remaining rigid and unabsorbed.

Silver wire is used for skin sutures when there is much tension, and combined with lead for bone suture. Its polished surface has the advantage of not attracting germs.

The method of tying a ligature is as follows: Usually a reef knot is used. See KNOT. The fingertips should be pressed down on the ligature surrounding the vessel, to obviate the danger of lifting up the artery from its bed. The ends should be cut short. Absolute cessation of pulsation of the artery below the ligature denotes sufficient ligation, but if the vessel is diseased, the knot should be made most deliberately. The preparation of ligatures is also discussed in the article on ABDOMINAL SECTION (*q. v.*). See also ARTERIES (Ligation).

LIGHTNING, INJURIES.—In nonfatal injuries sudden collapse, with unconsciousness, is followed by drowsiness, fever, much prostration, and occasionally by delirium and convulsions. Paralysis of one or more limbs, severe neuralgic pains, impairment of vision, and even blindness are results. A long list of sequels, due to progressive inflammatory changes and shock, has been recorded. Superficial injuries show spots of ecchymosis, burns greatly varying in extent and severity, and dusky patches due to fused buttons, chains, studs, etc. Arrest of the growth of the hair is another result of injury from lightning. The mortality of injuries from lightning is about 25 percent. When a person is killed suddenly, the body either falls at once to the ground or becomes rigid and remains fixed in a more or less erect attitude. Such a person may not present a visible mark of injury or the body may be mutilated and the bones of limbs or cranium widely comminuted and exposed. The clothes may be untouched or be reduced to shreds and torn away. Rigor mortis comes on rapidly in fatal cases. Instances of rupture of the heart and of the stomach have been recorded.

The treatment of the resultant shock consists in the application of warmth to the surface of the body; the administration of stimulants by mouth, rectum, or hypodermically, and, when necessary, the use of artificial respiration. Local lesions require their proper treatment, for which see BURNS, ELECTRICITY (Injuries). Burns caused by lightning heal very slowly. Paralyses ensuing often yield to the influence of galvanism when properly and regularly given.

LIGHT THERAPY.—See PHOTOTHERAPY.

LIME.—The popular name for calcium oxid, CaO (quicklime), and calcium hydroxid, $Ca(HO)_2$. Calcium oxid (quicklime) has a great affinity for water and for CO_2. On contact with the former, slaked lime is formed, with the evolution of heat. On living tissues it acts as a caustic. **L., Burnt, L., Caustic,** calcium oxid, quicklime. **L., Chlorid of, L., Chlorinated,** the chlorid of lime of commerce, is not a distinct chemic compound; its chief constituent. and the one on which its disinfectant properties depend, is calcium hypochlorite, which liberates chlorin. **L., Milk of,** a milky fluid consisting of calcium hydroxid suspended in water. **L., Quick-, L., Slaked,** common terms for lime. **L. Ointment,** an ointment consisting of slaked lime, 4; lard, 1; and olive oil, 3. **L.- water,** a solution of calcium hydroxid in water. It is astringent and alkaline and prevents the formation of dense coagula if added to milk. Dose, 4 to 8 drams. **L., Syrup of** (*syrup of calcium hydroxid*)—contains 6 1/2 percent of lime, and 40 of sugar, the latter aiding the solvent power. Dose, 10 to 60 minims. It is an antidote to poisoning by oxalic acid and phenol. **L., Liniment** (*Carron oil*)—contains equal volumes of lime-water and linseed oil, mixed by agitation. For local use.

Lime-water is a useful antacid. In diabetes, in uric acid diathesis, and in excessive nausea and vomiting, teaspoonful doses of milk and lime-water will be retained when nothing else will remain on the stomach. Lime-water is given in the dose of 1 dram to 2 ounces. Externally, lime-water is used in tinea capitis, and in burns when mixed with equal parts of linseed oil or olive oil, forming *carron oil*. In membranous croup and in diphtheria lime-water is useful as a spray or on a swab. Lime-water is made by pouring 2 quarts of boiled and filtered water upon a piece of unslaked lime about the size of a walnut. After stirring and allowing to settle in an earthen jar, the clear liquid is poured off for use. See CALCIUM.

LINIMENTS (Linimenta).—Very thin ointments for external application, intended to be applied with friction to the skin. They are solutions of various substances in oily liquids or in alcoholic liquids containing fatty oils. There are 8 official liniments.

Official Liniments.—

TITLE.	BASE.	CONSTITUENTS.
LINIMENTUM:		
Ammoniæ (ammonia), (*Volatile Liniment*),	Cottonseed oil.	Ammonia water, 350 c.c.; alcohol, 50 c.c.; cottonseed oil, 570 c.c.; oleic acid, 30 c.c.
Belladonnæ (belladonna),	Alcohol.....	Camphor, 50 gm.; fldext. belladonna, to make 1000 c.c.
Calcis (carron oil),	Linseed oil.....	Lime water, linseed oil, equal parts.
Camphoræ (camphor),	Cottonseed oil..	Camphor, 200 gm.; cottonseed oil, 800 gm.
Chloroformi (chloroform)	Alcohol.....	Chloroform, 300 c.c soap liniment, 700 c.c.

Title.	Base.	Constituents.
Linimentum: Saponis (soap),...	Alcohol.....	Soap (gran.), 60 gm.; camphor, 45 gm.; oil rosemary, 10 c.c.; alcohol, 725 c.c.; water to make 1000 c.c.
Saponis mollis (soft soap).	Alcohol	Soft soap, 650 gm.; oil lavender flowers, 20 c.c.; alcohol, to make 1000 c.c.
Terebinthinæ (turpentine).	Oil of turpentine.	Rosin cerate, 650 gm.; oil turpentine, 350 gm.

LINSEED (Flaxseed).—The seed of *Linum usitatissimum* (flax), a cultivated annual plant. It contains 15 percent of mucilage in the epithelium, also 30 to 40 percent of fixed oil in the embryo. Ground linseed should yield not less than 25 percent of the fixed oil.

Therapeutics.—Linseed is demulcent, emollient, expectorant, and diuretic. The oil is laxative in a dose of 1 ounce, and in smaller doses is oxidized in the system. The infusion contains the mucilaginous principle and a small portion of the oil, and is advantageously used in inflammations of the mucous membrane of the throat, the gastrointestinal tract, and the urinary passages. It is an excellent demulcent in coughs of various kinds, and will be found very serviceable in cystitis, irritable bladder, renal colic, strangury, etc. The oil may be administered internally as a laxative, and has considerable reputation as a remedy for hemorrhoids in doses of 2 ounces twice daily. For laxative purposes (especially in children) it is usually administered as an enema. Externally it is a favorite application to burns, when made into an emulsion with lime-water. The ground seed (linseed or flaxseed meal) is one of the best agents for making poultices, and is universally employed for that purpose, though it is objectionable from an aseptic point of view.

To make a **linseed poultice,** the following materials must be collected: (1) A sheet of tow, a folded flannel or cloth—in an emergency a sheet of brown paper or large cabbage-leaf—spread out on a table or board, and a little larger than the part to be poulticed; (2) a bowl and spoon; (3) the crushed linseed; (4) a kettle and boiling water. Warm the basin and spoon by pouring into the former some boiling water, and empty it out. Put in some meal and add a very little hot water. Stir into a paste with the heated spoon. Continue doing this until enough paste to cover the tow has been made. It should now be spread 1/4 inch thick evenly and flatly to within 1 inch of the edges of the tow or cloth, which edges are folded up to form a margin. Too much or too little water is harmful, making the poultice soft and sloppy or sticky. The poultice should be made at the bedside, and the linseed placed next to the skin, and removed after 2 hours. See Flaxseed; Poultice.

Preparations.—L., Ol., the fixed oil of linseed expressed cold; a glycerid of linoleic acid. Dose, 1/2 to 2 ounces. **Carron Oil,** linseed oil emulsified in lime-water, used for burns.

LINT.—A loosely woven or partly felted mass of broken linen-fibers, made by scraping and "picking" old linen cloth. It is used as a dressing for wounds and raw surfaces. Common lint is twilled on one side and "woolly" on the other. In the spreading of an ointment the twilled side is used.

LIPEMIA.—See Blood.

LIPOMA.—A fatty tumor. See Tumors.

LIPS, DISEASES. Herpes.—A crop of herpetic vesicles which burst in a few days, leaving a scab, is common upon the lips, especially in gastric and febrile disturbances. The vesicles may be moistened with alcohol, cologne water, camphor water, or smeared with alum, zinc ointment, boric ointment, etc.

Cracks and fissures of the lip following exposure to cold, etc., in dyspeptics, are very common, and if neglected, may form deep and painful fissures, prone to bleed and obstinate to heal. A simple ointment, and, if persistent, touching them with silver nitrate, will generally suffice to cure them. They must not be mistaken for the fissures about the corners of the mouth so common in congenital and acquired syphilis.

Papillomata or **warty growths** of the lips are of interest in that they are liable, as age advances, to become epitheliomatous. They may sometimes grow out in the form of horns. Extirpation with the knife is the proper treatment.

Superficial ulcers on the inner surface of the lip are common accompaniments of errors in digestion and of secondary syphilis. There are usually similar ulcers on the side of the tongue and cheeks. Silver nitrate or chromic acid lotions are the best local applications.

Nevus of the lip, when small, may be touched with nitric acid or sodium ethylate; and when pendulous and projecting from the free margin, ligated. When involving the whole substance of the lip, it may be treated by electrolysis, or, better, excised by means of a V-shaped incision.

Hypertrophy of the lip, generally the upper, is often met with in connection with cracks and fissures in strumous children, and is known as the *strumous lip.* A similar condition is sometimes met in congenital syphilis and in chronic nasal catarrh. The thickening, as a rule, disappears under constitutional treatment and as the patient grows older. The removal of a wedge-shaped piece, as advised by some, is seldom necessary.

Carbuncle of the lip is a most dangerous disease, as it is very likely to lead to infective phlebitis of the facial vein, which may spread thence through the ophthalmic vein to the cavernous and other cranial sinuses, and terminate in infective meningitis or in general blood-poisoning. Free incisions should be made, the sloughs scraped away, antiseptics applied, and the strength supported by fluid nourishment and stimulants.

Adenoma or **labial glandular tumor** (Paget) occasionally occurs in the lip as small, smooth, elastic growths projecting under the mucous membrane. It sometimes contains nodules of cartilage, and is then of harder consistency. It should be removed from the mucous surface to avoid scarring.

Cysts due to obstruction of the mucous follicles are frequent in the lip. They contain a glairy

fluid, and appear as small, tense, semitranslucent, globular, bluish-pink swellings on the mucous surface. A free incision through the mucous membrane, and removal of the cyst-wall with forceps, is perhaps the best treatment.

Mucous patches are sometimes observed on the mucous surfaces of the lips, most frequently at the angle of the mouth or in the groove between the gums and lips. They are usually superficial, not elevated, and present the appearance as if a silver nitrate stick had been drawn across the surface; the latter circumstance has given rise to the term "opaline patches." When situated at the angle of the mouth, they may become fissured, painful, and bleeding. Their surrounding area lacks the semblance of acute inflammation, being somewhat dull and congested; this fact proves important in differentiating them from the patches of aphthous stomatitis. The previous history, the adenopathy, the presence, perhaps, of a cutaneous lesion, and the resistance to ordinary local treatment would serve to render the diagnosis clear. See SYPHILIS.

Epithelioma nearly always occurs in men, and on the lower lip; and although it may affect non-smokers, it generally appears to be due to the irritation and heat of a short clay pipe. It begins as a crack, small ulcer, or indurated tubercle, and may either spread superficially along the free margin of the lip or extend deeply into its substance. Sooner or later it involves the whole lip and adjoining parts, becomes adherent to the jaw, and invades the bone. The lymphatic glands in the neck become involved, but dissemination through internal organs is rare. If removed early, it may not recur until after a long period of immunity or, perhaps, not at all. It seldom returns in the scar, but in the lymphatic glands, the patient dying of exhaustion induced by ulcerating and bleeding masses in the neck.

Diagnosis.—The affection is likely to be mistaken for hard chancre, and the latter has been cut away under the impression that it was an epithelioma. The following points should serve in diagnosis: (1) Epithelioma generally occurs in the old, and in men, and on the lower lip; chancre in the young, in women, and on the upper lip. (2) The epitheliomatous ulcer has hard, sinuous, and everted edges, and an indurated and warty base; the chancrous is raised, excoriated, smoother, and the induration is more circumscribed. (3) In the malignant affection the glands are not affected until late in the disease—perhaps 6 months; in the syphilitic, early—say 6 weeks. Moreover, in chancre secondary symptoms will be present or soon appear, and the disease readily yields to antisyphilitic remedies. See EPITHELIOMA.

Treatment.—Free and early excision is imperative. The growth may be either included in a V-shaped incision, the wound being afterward united by harelip pins, or, if superficial, freely shaved off. The glands in the neck, if enlarged and not too extensively diseased, should be extirpated at the same time. When the bone is involved, a portion of the jaw may be removed if the whole disease can be exterminated.

Harelip.—See HARELIP.

LIQUID AIR (Carbon Dioxid Snow).—See AIR, LIQUID.

LIQUOR.—In pharmacy any solution in water of nonvolatile substances, except infusions, decoctions, syrups. There are 25 official solutions: **Liquor Acidi Arsenosi.** Should contain arsenous acid, corresponding in amount to 1 percent of arsenic trioxid. Medical properties same as Fowler's solution. Average dose, 3 minims. **Liquor Ammonii Acetatis** (spirit of Mindererus). An aqueous solution which should contain not less than 7 percent of ammonium acetate, together with small amounts of acetic and carbonic acids. Diaphoretic in fevers. Average dose, 4 drams. **Liquor Antisepticus.** (Similar to listerine, etc.) Boric acid, 20 gm.; benzoic acid, 1 gm.; thymol, 1 gm.; eucalyptol, 0.25 c.c.; oil of peppermint, 0.50 c.c.; oil of gaultheria, 0.25 c.c.; oil of thyme, 0.10 c.c.; alcohol, 250 c.c.; purified talc, 20 gm.; water, to make 1000 c.c. Average dose, 1 dram. **Liquor Arseni et Hydrargyri Iodidi** (solution of arsenic and mercuric iodid) (Donovan's solution). Contains 1 percent of each of the active ingredients. Alterative. Average dose, 1 1/2 minims. **Liquor Calcis** (solution of calcium hydrate; lime water). A saturated solution. Antacid, tonic and astringent. Average dose, 4 drams. **Liquor Chlori Compositus.** Compound solution of chlorin. Chlorin water. (To replace Aqua Chlori, U. S. P., 1890.) An aqueous solution containing, when freshly prepared, about 0.4 percent of chlorin with some oxid of chlorin and potassium chlorid. Average dose, 1 dram. **Liquor Cresolis Compositus.** (Similar to lysol.) Cresol, 500 gm.; linseed oil, 350 gm.; potassium hydroxid, 8 gm.; water to 1000 gm. **Liquor Ferri Chloridi.** An aqueous solution of ferric chlorid which should contain not less than 29 percent of the anhydrous salt, corresponding to 10 percent of metallic iron. Average dose, 1 1/2 minims. Used in preparing tincture of ferric chlorid; also externally as a styptic to arrest hemorrhage. **Liquor Ferri et Ammonii Acetatis** (Basham's mixture). Contains in each thousand c.c. Tr. Ferri. Chlor. 40 c.c., Acid Acetic Dil. 60 c.c., Sol. Ammon. Acet. 500 c.c., Aromat. Elix. 120 c.c., glycerin 120 c.c., water to 100 c.c. Actively chalybeate, also astringent, and very largely used in Bright's disease. Average dose, 4 drams. **Liquor Ferri Subsulphatis** (solution of basic ferric sulphate, Monsel's solution). An aqueous solution of variable chemical composition, containing an amount of basic ferric sulphate corresponding to not less than 13.57 percent of metallic iron. Styptic to bleeding surfaces; used internally in hemorrhage of stomach and bowels. Average dose, 3 minims. **Liquor Ferri Tersulphatis.** An aqueous solution which should contain about 35 percent of normal ferric sulphate, corresponding to not less than 10 percent of metallic iron. Used for preparing other iron preparations, as in the preparation of the antidote for arsenic. **Liquor Formaldehydi** (formalin). An aqueous solution, containing not less than 37 percent by weight of absolute formaldehyd. **Liquor Hydrargyri Nitratis.** A liquid which should contain about 60

percent of mercuric nitrate, and about 11 percent of free HNO_3. Caustic application to chancre, etc. **Liquor Iodi Compositus** (Lugol's solution). Should contain not less than 5 percent iodin, 10 percent potassium iodid. Average dose, 3 minims. **Liquor Magnesii Citratis.** Made by dissolving 33 gm. citric acid in 120 c.c. of water and adding 15 gm. magnesium carbonate; dissolving; filtering into a bottle holding 360 c.c. (containing 120 c.c. syrup of citric acid), adding enough water to nearly fill the bottle, dropping in 2.5 gm. potassium bicarbonate; shaking until dissolved; corking, and securing the cork with twine. Average dose, 12 drams. **Liquor Plumbi Subacetatis.** (Sometimes called Goulard's extract.) An aqueous liquid, containing not less than 25 percent of lead subacetate. Used externally as a sedative in sprains, etc., when dilute, from 1/2 or 1 part to 16 parts distilled water. **Liquor Plumbi Subacetatis Dilutus** (lead water). Contains 4 percent of the stronger lead water. Astringent and sedative externally. **Liquor Potassii Arsenitis** (Fowler's solution). An aqueous solution which should contain potassium arsenite corresponding in amount to 1 percent of arsenic trioxid, formed by the combination of arsenous acid with potassium of the potassium bicarbonate (carbon dioxid being evolved). Compound spirit of lavender is added to give it taste, and prevent its being mistaken for water; 100 minims equal about 1 grain arsenic. Average dose, 3 minims. **Liquor Potassii Citratis** (Mistura Potassii Citratis). An aqueous liquid, containing in solution not less than 8 percent of anhydrous potassium citrate, together with small amounts of citric and carbonic acids. Made by dissolving separately potassium bicarbonate and citric acid, and afterward mixing the solution, under the names *neutral mixture, saline mixture,* or *effervescing draught;* long used as a refrigerant diaphoretic. Average dose, 4 drams. **Liquor Potassii Hydroxidi.** (Liquor Potassæ, U. S. P., 1880.) An aqueous solution containing about 5 percent of potassium hydroxid. Average dose, 15 minims. **Liquor Sodæ Chlorinatæ** (Labarraque's solution). An aqueous solution of several chlorin compounds of sodium, containing at least 2.4 percent by weight of available chlorin. Stimulant, antiseptic, and resolvent. Average dose, 15 minims. Also, use locally for fetor, etc. A powerful disinfectant. **Liquor Sodii Arsenatis.** Should contain sodium arsenate corresponding in amount to not less than 1 percent of exsiccated sodium arsenate. Average dose, 3 minims. **Liquor Sodii Hydroxidi.** (Liquor Sodæ, U. S. P, 1890.) An aqueous solution containing about 5 percent of sodium hydroxid. Average dose, 15 minims. **Liquor Sodii Phosphatis Compositus.** Sodium phosphate, 1000 gm.; sodium nitrate, 40 gm.; citric acid, 130 gm.; distilled water, to 1000 c.c. Average dose, 2 drams. **Liquor Zinci Chloridi.** An aqueous solution containing about 50 percent by weight of zinc chlorid. A substitute for Burnett's disinfecting fluid. Used locally to disinfect fetid discharges; also employed for preserving anatomical specimens.

LIQUOR AMNII.—See Amnii (Liquor).

LIQUORICE.—See Glycyrrhiza.

LITHEMIA.—Modified gout. A condition in which, owing to defective metabolism of the nitrogenous elements, the blood becomes charged with deleterious substances, principally, perhaps, of the uric acid group, although their exact chemic nature is not determined. See Uric Acid, Gout, Rheumatism.

LITHIA.—Li_2O. Oxid of lithium, an alkaline caustic. **L. Water,** mineral water containing lithium salts in solution. Among the best known in the United States are the Buffalo lithia water, water from Buffalo Lithia Springs, Mecklenburg County, Va.; Farmville lithia water, from Farmville, Va.; Londonderry lithia water, from Londonderry, N. H. The proportion of bicarbonate of lithium contained in the 3 waters mentioned is as follows: Londonderry, 8.620; Buffalo, 1.484 to 2.25; Farmville, 1.99.

LITHIUM.—Li = 7; quantivalence, 1. One of the rarer alkaline metals, a few of the salts only being used in medicine. Because of its low atomic weight, its high saturating power makes its salts more highly alkaline than those of sodium and potassium. The carbonate and citrate are used largely in rheumatism and gout. **L. Benzoas.** Dose, 5 to 20 grains. **L. Bromidum.** See Bromin. Dose, 5 to 20 grains. **L. Carbonas,** not deliquescent. Dose, 2 to 15 grains. **L. Citras,** deliquescent. Dose, 5 to 20 grains. **L. Citras Effervescens,** effervescent lithium citrate, prepared from citrate 5, with sodium bicarbonate 57, tartaric acid 30, citric acid 19 1/2. Dose, 1 to 3 drams in water, as an effervescent drink. **L. Salicylas.** See Salicylic Acid. Dose, 5 to 20 grains.

LITHOLAPAXY.—See Bladder (Stone).

LITHONTRIPTICS.—See Antilithics.

LITHOTOMY.—See Bladder (Stone).

LITMUS.—A blue pigment obtained from *Rocella tinctoria,* a lichen. It is employed in chemic determinations to detect the presence of acids and alkalies. **Blue litmus paper** is unsized paper steeped in a solution of litmus; it turns red on contact with acid solutions. **Red litmus paper** is unsized paper steeped in litmus tincture, colored red with acid; it turns blue on contact with alkaline solutions. See Acidity, Alkalinity, Urine (Examination).

LITTER.—The following qualities are essential for a litter or stretcher: 1. Firm and comfortable support for the patient, and capability of being readily cleansed. 2. Lightness. 3. Strength. 4. Simplicity of construction. 5. Capability of being folded up, if possible. 6. Such connection of component parts as to prevent risk of loss. 7. Provision for keeping patient a certain distance above ground when the litter is laid down. 8. Economy.

A two-handed seat or litter may be devised by 2 bearers facing each other, locking the fingers of the left hand of one with the fingers of the right hand of the other. The support is placed beneath the patient's thighs in front of the buttock for a seat, the disengaged hands resting upon and grasping each other's shoulders behind the patient, and thus forming a back support. The arms of the

patient may be passed around the neck of each bearer.

A three-handed seat may be made by 2 persons facing each other, the thick part of the forearm just below the elbow of one being grasped by his right hand and with the left hand the left forearm of the other being grasped. This left forearm now grasps the right forearm of the other bearer at about its middle. The right hand of the second bearer grasps the left shoulder of the other bearer to form a back support. The seat formed is a triangular one, and is formed by the 3 forearms.

A four-handed seat is made by 2 bearers grasping their own left forearms with their own right hands at or about their wrists. The left hand of each grasps the right forearm of the other.

Swords in their scabbards may be passed through the sleeves of a coat turned inside out and the coat skirts buttoned from below upward, for 2 or 3 buttons over the sleeves incasing the swords.

Improvised stretchers or litters may be made out of hurdles, shutters, or planks. In the 2 latter cases straps, ropes, or wooden traverses must be passed beneath, between 2 bearers at the head and 2 at the feet.

A rifle litter may be made with a blanket or rug, 2 rifles being laid on the ground at each side and the blanket folded over them.

LIVE BIRTH, TESTS.—See Viability.

LIVER, ABSCESS (Suppurative Hepatitis).—

Etiology.—Abscess of the liver is probably always of microbic origin. The infection may reach the liver by way of the hepatic artery, from ulcerative endocarditis, general septicemia, etc.; or the hepatic vein; or the common duct. Secondary to a suppurative cholangitis set up by biliary calculi or parasites, but generally it enters *viâ* the portal vein in the form of an infectious thrombus or embolus or the ameba coli. Thus septic emboli from suppurative appendicitis, gastric ulcer or dysentery may enter the liver. In most instances, however, abscess of the liver is due to the ameba coli and is preceded by amebic dysentery, though in some amebic abscesses there are no intestinal symptoms. Occasionally it results from infective traumatism. It may be secondary to an infected hydatid cyst. See Colon Bacillus Infection.

Pathology.—In two-thirds of the cases of abscess of the liver the middle portion of the right lobe is affected. The abscess varies in size and may be either single or multiple. Amebic abscess is usually single and large, while pyemic metastatic abscesses are small and multiple. Frequently both lobes are involved and the liver may be greatly increased in size. The pus may be reddish in color or creamy, and frequently it is sterile. The abscess may rupture into the bowel, abdominal cavity, or bronchi.

Symptoms and Clinical Course.—There are probably many cases of abscess of liver which are never diagnosed, owing to the latency of many of the symptoms in the early stages. The first subjective symptoms probably are: Pain in the right hypochondriac region, or region of the right scapula, of a deep-seated character; gradual decline of health with loss of flesh; intermittent, irregular high fever 105° F.; rapid and feeble pulse and frequent chills, followed by profuse perspiration. Hectic symptoms may be present. These are the classic symptoms of infection, yet they do not lead us to the correct diagnosis, and frequently the physical signs are distinctly misleading.

Physical Signs.—**Inspection** frequently detects bulging in the right hypochondrium, and slight jaundice.

Abscess of Liver.	Hepatic Intermittent Fever.	Cancer.	Malarial Fever.	Hydatid Cyst.
Subjective Symptoms.	*Subjective Symptoms.*	*Subjective Symptoms.*	*Subjective Symptoms.*	*Subjective Symptoms.*
1. History of traumatism, dysentery.	1. History of hepatic colic and transient jaundice.	1. Often inherited tendency.	1. History of malarial exposure.	1. History negative.

1. Jaundice slight.....	1. Jaundice intense....	1. Jaundice.....	1. No jaundice.....	1. Jaundice usually absent.
2. Bulging in right hypochondrium.	2. Negative.....	2. Negative.....	2. Negative.....	2. Bulging in epigastric or hypogastric region.
3. Liver enlarged and smooth; occasionally edema and fluctuation in right hypochondrium.	3. Liver slightly decreased in size.	3. Liver enlarged and nodular.	3. Liver may be slightly enlarged and smooth. Spleen enlarged.	3. Liver dulness increased in area.
4. Percussion confirms palpation.	4. Same.....	4. Increased area of dulness.	4. Percussion confirms palpation.	4. Percussion often detects a vibratory sensation.
5. Aspiration detects pus.	5. Negative.....	5. Negative.....	5. Negative; palsmodium in blood confirms diagnosis.	5. Aspiration detects clear fluid containing glucose.

Palpation detects enlargement and a deep-seated pain. Frequently there is an edematous condition over the affected part, and fluctuation may be present if the abscess is superficial. If the lower portion of the right lobe is affected, the enlargement extends downward. In the early stages the area is hard, but later, as the disease advances, it softens and may give rise to fluctuation.

Percussion detects an increased area of dulness in the direction of the portion involved. Osler states that the enlargement is most frequently upward, and that at the nipple-line the curve of liver dulness begins to rise and in the midaxillary line it may reach the fifth rib, while behind, near the spine, the area of dulness may be so high as to be on a level with the angle of the scapula.

Diagnosis depends upon the subjective and objective symptoms.

Prognosis is unfavorable.

Treatment.—If the pain is severe, opium, 1 grain, is advisable every 4 hours. Locally, a hot-water bag, mustard plaster, or hot turpentine stupes may afford some relief. The bowels should be kept open by means of salines.

Stimulants, such as whiskey, 4 drams, are allowable every 4 hours, if necessary. Quinin, 4 grains, with dilute nitrohydrochloric acid, 6 minims, may be of benefit.

Medicines, as a rule, are only palliative, and surgical measures give a better chance for recovery.

Surgical Treatment.—(1) If the skin over the swelling is red and pits on pressure, there can be little doubt either as to the existence of an abscess or to the presence of adhesions. In such circumstances an aspirating needle may be used as a preliminary, to act as a guide, but as soon as it has entered the cavity and the diagnosis is confirmed, the opening should be enlarged, so that the pus can escape as freely as possible, and a full-sized drainage-tube inserted. The following day, when the adhesions are firmer, the abscess cavity may be explored with the finger to make sure there are no other sacs in the immediate neighborhood, and, if necessary, washed out with iodin or some other antiseptic. (2) When there is no certainty as to the presence of adhesions the choice lies between aspiration, drainage with a trocar and cannula, and incision (Tyson).

Aspiration is chiefly of use for exploration; it rarely happens that an abscess cavity is completely emptied, and nearly always the swelling appears again within a few days. In a few instances, however, a cure has followed after 2 or 3 repetitions. Puncture with a trocar and cannula is also open to grave objections. If adhesions are present already, it is more satisfactory to make a free incision and allow of thorough exploration and drainage; if they are not, the peritoneal cavity is opened without any safeguard to prevent the pus entering it. Further, the constant movement of the liver in the abdominal cavity frequently renders the retention of a tight-fitting cannula or of a stiff drainage-tube a matter of very considerable difficulty.

Incision directly into the abscess sac can only be practised when the skin over it is reddened and it is certain that the walls are adherent. If this is not definite, either the operation must be carried out in separate stages, or an incision made into the abdomen over the swelling, the surface of the liver exposed, and the abscess opened with the usual precautions to prevent its contents entering the peritoneal cavity. The preliminary steps are the same in both, but while in one the incision is only carried down to the parietal peritoneum, and is then plugged, so that adhesions may form beneath, in the other the abdominal cavity is opened at once and the surface of the liver examined. In a few cases omentum has been interposed, or it has been found that the abscesses are multiple and that there is no hope of thorough evacuation; but if no difficulty of this kind is apparent, the wound is carefully packed around with sponges, and an aspirating needle thrust into the swelling. As soon as the pus is found, the opening is enlarged freely with the knife, and the contents of the abscess allowed to escape completely; the assistant, meanwhile, carefully supporting the liver in either side, so that it shall not fall away from the surface of the abdomen. When the sac is emptied, the cavity may be explored with the finger and the walls stitched to the skin margins of the wound all around. An aspirating needle may be thrust through the two layers of the pleura and diaphragm for the sake of exploring the posterior surface of the liver without risk; but if a permanent drain is required, a free incision should be made down to the parietal pleura, a portion of one of the ribs being resected if necessary, the two layers of the pleura accurately sutured together with catgut (there is no difficulty in this in the lower intercostal spaces), and then the trocar and cannula thrust through, so as to avoid the risk of air or pus entering into the pleural space.

LIVER, ACUTE YELLOW ATROPHY.—A fatal form of disease of the liver, characterized anatomically by a rapid destruction of the liver cells, diminution in size of the organ, and associated with deep jaundice and grave nervous symptoms.

Synonyms.—Malignant jaundice, acute parenchymatous hepatitis, icterus gravis.

Etiology.—(1) Female sex; (2) pregnancy; (3) infectious fevers; (4) alcoholism; (5) mental excitement. An acute toxemia may be the main exciting cause.

Pathology.—The liver is greatly reduced in size, often not more than one-third the usual volume during health. This rapid destruction may take place within the course of a few days, or from 1 to 2 weeks. The organ is soft, yellowish in color in the early stages, but later may be reddish (red atrophy). The capsule may be wrinkled. Microscopically, fatty degeneration of the liver cells occurs, taking place first in the periphery and later extending toward the center of the lobule. There is also fatty degeneration of the epithelial cells of the biliary ducts. The destroyed liver cells and epithelial cells subsequently undergo liquefaction necrosis and are rapidly absorbed, causing shrinkage of the organ. If the disease persists, there is a hyperplasia of the connective tissue, and the color becomes mottled.

Symptoms and Clinical Course.—The initial symptoms occupy a period of 2 or 3 days, and are marked by headache, loss of appetite, nausea and vomiting, gastric distress, jaundice, and, later, delirium or convulsions. Hemorrhages from the mucous membranes may occur, and hematemesis is common. The liver is rapidly reduced in size, while the spleen is considerably enlarged. The urine is deeply bile-stained, of high specific gravity (1030), slightly albuminous, containing fatty casts, leucin, and tyrosin.

Diagnosis.—See LIVER (Cirrhosis).

Prognosis.—The disease is always fatal.

Treatment is supportive and palliative.

LIVER, AMYLOID.—An enlargement of the liver due to infiltration of the tissues by an amyloid substance.

Synonyms.—Lardaceous liver; waxy liver; albuminoid liver.

Etiology.—(1) Prolonged suppuration as in tubercular bone-disease; (2) syphilis; (3) leukemia; (4) rickets.

Pathology.—The liver is enlarged and smooth; the cut surface is semitranslucent (waxy), and resembles in appearance boiled bacon. The amyloid deposit is found mainly in the central portion of the lobules. The initial process seems to be in the capillary blood-vessels, which are often coated with a hyaline material.

The amyloid substance is not deposited to so great an extent in the liver cells, but they may undergo fatty degeneration from want of a free blood supply.

Symptoms and Clinical Course.—The liver is smooth in contour and greatly enlarged, and may reach the umbilicus. There is no pain or jaundice. Ascites is absent except in the last stages. The spleen shares in the process and is greatly enlarged. Often the kidney becomes affected by the albuminoid infiltration, giving rise to albumin in the urine.

Diagnosis rests upon the history of the case; great enlargement of the liver and spleen; absence of jaundice, ascites, hectic symptoms, and the presence of albumin in the urine. From leukemia it must be differentiated by a blood examination.

Prognosis is unfavorable.

Treatment must be directed to the underlying cause.

LIVER, CARCINOMA. Etiology.—(1) Male sex after the fortieth year; (2) usually secondary from neighboring organs.

Pathology.—The organ is enlarged in size, the liver tissue being brownish or yellowish in color. Instead of the surface being smooth, it is generally irregular or nodular.

Varieties.—(1) Nodular form; (2) radiating form; (3) massive form.

In the **nodular form** there are small whitish areas or elevations which project from the external surface.

The **radiating form** produces multiple nodules that are pigmented. It is usually secondary.

In the **massive form** the disease is diffused throughout the whole organ, causing great enlargement. The color is usually grayish-white. The nodules may be hard or soft, the larger ones often showing a degree of fatty degeneration, and may give rise to extravasation of blood into the parenchyma.

Both the large and small nodules project slightly above the serous surface, and in the former variety a degree of umbilication may be seen.

Symptoms and Clinical Course.—There are severe pain over the region of the liver, persistent vomiting, cachexia with rapid loss of flesh and strength, and great anemia (red cells moderately reduced, 4,000,000; hemoglobin may be only 50 percent; moderate leukocytosis). Jaundice is nearly always present. Ascites is usually absent. There is moderate fever—101° to 103° F.

Physical Signs.—**Palpation** detects tenderness, and frequently nodular growths on the free border of the liver.

Percussion confirms palpation, and shows an increased area of dulness in all directions. It also shows the presence of cancer in neighboring organs (stomach, pancreas, etc.).

Diagnosis.—See LIVER (Abscess).

Prognosis.—The duration is from 3 to 15 months.

Treatment is symptomatic and palliative.

LIVER, CIRRHOSIS. Synonyms.—Chronic interstitial hepatitis, hob-nail liver, gin liver, granular liver.

A disease characterized by hyperplasia of the connective tissue, with a destruction to a greater or less extent of the parenchymatous cells, the liver being firmer in consistency.

Etiology.—(1) Male sex; (2) middle life; (3) alcoholism; (4) chronic malarial poisoning; (5) congenital syphilis; (6) passive hyperemia resulting from heart or lung disease; (7) gall stones; (8) rich diet; (9) cause unknown. The causes may act through the portal vein, the hepatic arteries, hepatic vein, or the biliary ducts. It seems probable, as Weigert has shown, that the cells irritated undergo degeneration and die, their place being taken by connective tissue overgrowth, the subsequent contraction of which causes still more destruction of the secreting cells.

Varieties.—(1) Atrophic; (2) hypertrophic.

Atrophic Cirrhosis. Synonyms.—Portal cirrhosis; Lænnec's cirrhosis.

Pathology.—The liver is much smaller and harder than normal and its surface is usually roughened with small granulations or nodules, though sometimes it is smooth, owing to a uniform distribution of the connective tissue. The elevations, when present, are due to the contraction of bands of connective tisue which have taken the place of parenchyma, and which surround normal areas of secreting cells. The entire surface is yellowish or mottled if the cells are fatty. Associated with the cirrhosis is frequently found fatty infiltration. The increase in size of the liver due to the latter condition may predominate over the reduction resulting from the cirrhosis. As the disease advances retrograde changes involve also the branches of the portal vein, and even the biliary ducts, causing obstruction in the portal circulation and ascites.

Hypertrophic Cirrhosis. Synonym.—Hanot's cirrhosis.

Pathology.—In this form the hyperplastic connective tissue has not the tendency to contract that it exhibits in the atrophic. Therefore, the liver is enlarged but smooth. Its color is generally yellowish-green. It is believed that the connective tissue overgrowth takes place especially within the lobules. The branches of the portal vein are not encroached upon, but there is obstruction of the biliary channels resulting in jaundice.

Biliary Cirrhosis.—A distinct form according to French clinicians, is believed by some observers to be identical with the hypertrophic variety. It is secondary to obstruction in the gall ducts. The retention of bile in the ducts leading to destruction of the parenchymatous cells, their place is taken by a proliferation of the interstitial connective tissue. There is a deposit of pigment. The organ becomes larger and harder.

Symptoms of Atrophic Cirrhosis.—In the early stages of cirrhosis of the liver symptoms may be absent. The onset is gradual, the initial symptoms being due to obstructed portal circulation which produces chronic gastrointestinal catarrh, with its run of symptoms—coated tongue, anorexia, nausea, flatulence, constipation. Deficiency in the amount of bile secreted is evidenced by the pale stools. As the compression of vessels increases there is a compensatory dilatation of the collateral vessels, as manifested by hemorrhoids, the overdistended superficial abdominal veins, which may be especially pronounced around the umbilicus, forming the **caput medusæ**. Similarly, there result gastric, intestinal, or esophageal hemorrhages; enlargement of spleen, ascites, and even edema of the lungs. Slight jaundice from obstruction of the bile ducts is present in about one-fourth of the cases, but its absence may be due to the paucity of the biliary secretions. There is progressive loss of flesh and strength. Uterine or nasal hemorrhages, or even hematuria may appear. Nervous signs, such as stupor, delirium, coma, sometimes supervene late in the disease.

Physical examination reveals a smaller area of hepatic dulness with increased splenic dulness. The urine is usually scanty, highly colored, of high specific gravity, with abundance of urates, reduction in amount of urea and only infrequently contains biliary pigment.

Symptoms of Hypertrophic Cirrhosis.—Jaundice is generally present, because of some obstruction in the biliary vessels. The liver is not only enlarged and smooth, but tender. There is usually little or no enlargement of the spleen, nor gastrointestinal congestion, nor ascites, nor hemorrhoids. The stools are sometimes pale, at others normal in color. The urine, although scanty and highly colored, frequently contains biliary pigment, while the quantity of urine is normal. There is a marked reduction in the number of red blood cells and increase in the number of leukocytes.

Complications.—Concomitant increase in the connective tissue of heart, lungs, blood-vessels, autointoxication from suppression of biliary secretion.

Diagnosis.—(1) **Of Atrophic Cirrhosis.**

In the early stages diagnosis is uncertain; but it is clear when reduction in size of the organ is found, associated with ascites. The emaciation and effusion of tuberculous peritonitis may be confusing, but, in the latter disease, the effusion is not so abundant and is of higher specific gravity, and there is abdominal tenderness and fever, and no reduction in the size of the liver. If doubt exists, the tuberculin test should be resorted to.

(2) **Of Hypertrophic Cirrhosis.**

Hypertrophic cirrhosis must be differentiated from chronic biliary obstruction, cancer of liver, amyloid liver, multilocular echinococcus cyst. In the secondary cirrhosis of chronic biliary obstruction the liver is not so enlarged, the course is more rapid and is attended with attacks of hepatic colic. In carcinoma the patient is older, with no alcoholic habit, or enlargement of the spleen, the liver is not so smooth, ascites is more general. In amyloid liver there is the characteristic etiology and no pain or jaundice. In hydatid disease the nodules on the surface become soft.

Prognosis.—The duration of hypertrophic cirrhosis is from 1 to 2 years. Atrophic cirrhosis has a longer coma. Fatal terminal symptoms, such as rapid pulse, fever, delirium, may appear rather suddenly. The disease, however, is not always fatal; if the process be not too far advanced and the cause, such as alcohol, removed, the patient may indeed recover tolerably good health. Usually, however, death ensues from exhaustion and toxemia.

Treatment.—The chief objects to be attained are the removal of the cause, the relief of the symptoms and restitution of the normal conditions in the liver. Alcohol must be interdicted. The gastrointestinal catarrh should receive careful attention. The diet should be nutritious, yet simple so as not to tax the more or less impaired digestion. Fats should be restricted and too much starchy food should not be allowed for fear of setting up additional fermentation. The free drinking of alkaline mineral waters, especially when hot, or of simple hot waters, before meals, particularly before breakfast, is valuable to remove the excessive mucus. The extensive fermentation may be alleviated by internal antiseptics, such as sodium phenolsulphonate or phenyl salicylate.

Depletion by salines or minerals is indicated. For instance 5 to 10 grains of blue mass at night followed in the morning by sodium phosphate or Hunyadi water one-half hour before breakfast, will relieve the congestion. Calomel in doses of 1/10 grain, frequently repeated, is excellent. Laxative mineral waters, such as Saratoga water, have a similar effect. Occasionally it is well to alternate with the salines cascara sagrada, or compound jalap powder. A diminution of the ascites effected by this treatment is further aided by diuretics. The potassium salt to be preferred is the acetate in doses of 20 grains t. i. d. citrated caffein may be given in doses of 2 to 5 grains. Theobromin has proved valuable in the hands of some observers.

Abdominal paracentesis, or tapping, must be employed when the effusion is sufficiently large to cause discomfort or additional symptoms of pressure. Frequently repeated treatment may be necessary, as the fluid may speedily reaccumulate.

Surgical Treatment of the Ascites.—Talma's operation—omentopexy—suture of the parietal peritoneum of the abdomen and omentum to the liver, to relieve the liver conditions by the establishment of a collateral circulation between the portal and systemic vessels has been found effective if not resorted to too late.

Attempts to check the progress of the degenerative changes and to effect repairs have been for the most part futile. Iodin in some form should be tried, especially if a specific origin is suspected. Potassium iodid is given for a long time in doses of 3 to 10 grains, well diluted, and on an empty stomach. Some observers prefer the syrup of hydriodic acid, 1 dram, well diluted, one-half hour before food. Other drugs, such as ammonium chlorid and nitrohydrochloric acid, have been used. Organotherapy is advocated by certain French clinicians.

LIVER, CONGESTION. Varieties.—(1) Active; (2) passive.

Etiology. Active Hyperemia.—(1) Overindulgence in food or drink; (2) warm climate; (3) infectious fevers. "Biliousness" is probably a form of active hyperemia.

Passive hyperemia usually results from valvular disease of the heart, disease of the lungs or pleura, or pressure on the vena cava.

Pathology.—The liver is enlarged in size from congestion of the blood-vessels. The organ is bluish-red or brownish-red in color. In certain areas the intralobular vein is filled with dark blood, while the adjacent capillaries are empty and opaque, giving rise to a mottled appearance—"nutmeg liver."

If of long standing, an overgrowth of the connective tissue occurs with a considerable amount of pigmentation and atrophy of the hepatic cells, giving rise to a condition called "cyanotic induration."

Symptoms and Clinical Course. Active Hyperemia.—There is anorexia, dull headache, mental hebetude, coated tongue, bitter, disagreeable taste in the mouth, feeling of nausea, often vomiting of material containing the biliary salts, fever, constipation or diarrhea in which the feces have a distinctly greenish color and cause great tenesmus. The urine is high-colored and scanty. Hemorrhoids are frequently produced.

Passive Hyperemia.—There is great enlargement of the organ, due to stagnation of the blood; and if the right heart is affected, there is often distinct pulsation in the liver.

Prognosis.—In active hyperemia the prognosis is good. In passive congestion, as there is disease in other organs, the prognosis is less favorable.

Treatment of Active Hyperemia.—Rest in bed and a liquid diet are demanded. Of many remedies recommended, calomel holds the first place. It is best given in small doses, 1/4 of a grain, every hour until 6 or 7 doses have been taken, and followed by a saline purge if the bowels do not move within 10 or 12 hours. If there is much pain in the right hypochondriac region, a series of small blisters, 1 by 2 inches, may be produced by means of cantharidal plaster, or the red iodid of mercury, 40 grains, with petrolatum, 1 ounce. In the more chronic forms the fats and foods containing sugar must be restricted. Frequent bathing and plenty of out-door exercise are invaluable.

Constipation may often be relieved by proper regimen, and the use of the fluidextract of cascara, 1/2 of a dram, at bedtime. Nitrohydrochloric acid, 6 minims, combined with pepsin, 5 grains, may afford relief.

The elixir of the phosphates of iron, quinin, and strychnin, 1 dram, is frequently beneficial.

Treatment of passive hyperemia must be directed mainly to the underlying cause. Depletion may be produced by rest in bed, a light diet, and a saline purge every day or two. A series of blisters may also afford some relief. See HEART-DISEASE, NEPHRITIS.

LIVER, EXAMINATION. Boundaries.—The liver is the largest gland in the body, weighing from 3 to 4 pounds. Its upper portion is convex and directed upward and forward; it is smooth and covered with peritoneum. The *upper* surface is in immediate relation with the under surface of the diaphragm. Its *under* surface is concave, directed downward and backward, and in relation with the stomach, duodenum, hepatic flexure of the colon, right kidney, and suprarenal capsule. The upper surface of the liver is divided into 2 unequal lobes—the right and the left.

The right lobe of the liver occupies the right hypochondrium, the upper border anteriorly extending from the base of the ensiform cartilage on the median line, in the fifth intercostal space on the right nipple-line, in the seventh intercostal space in the axillary line, and posteriorly below the base of the right lung, about the level of the tenth rib or dorsal spine. The lower border of the right lobe normally should not extend below the free margin of the ribs.

The left lobe of the liver occupies the epigastric region, extending 2 inches to the left of the median line, the lower margin usually being found immediately overlying the stomach and about 3 inches below the ensiform cartilage. The left lobe is in close relation with the heart, being separated from that organ through the medium of the diaphragm.

Inspection.—By this method of diagnosis we detect general jaundice and enlargement in the right hypochondrium. Bulging may be present in hydatid cyst and distended gall-bladder. Jaundice is present in catarrhal jaundice, biliary calculi, cancer, hypertrophic cirrhosis, acute yellow atrophy, and occasionally in acute hepatitis.

Palpation.—The patient should be in a dorsal position, with the shoulders elevated and the knees drawn up.

The liver is enlarged and smooth in amyloid disease, fatty liver, congestion of the liver, hypertrophic cirrhosis, and multiple abscesses. It is

enlarged but uneven in hydatid tumor, single abscess, and cancer.

Palpation detects pain which is present in acute congestion, catarrhal jaundice, biliary calculi, abscess, and cancer. Edema may be present in the right hypochondrium in hepatic abscess. Fluctuation may be detected in hydatid cyst and distended gall-bladder, and occasionally in abscess of liver.

The liver is diminished in size in atrophic cirrhosis and acute yellow atrophy.

Percussion.—The patient should be placed in a dorsal position. By percussion the size of the liver is obtained. The upper boundary of the organ is determined by first gently tapping over the right nipple to detect the lung resonance, then gradually going downward until the upper edge of the liver is found. In the axilla the same method is pursued. The upper boundary of the right lobe in the nipple-line will be found in the fifth intercostal space, in the axillary line in the seventh interspace, and posteriorly on a line with the tenth rib or tenth dorsal spine. The lower border of the liver extends to, but not beyond, the free margin of the ribs anteriorly. The left lobe of the liver may often be outlined by gentle percussion. The upper border is inseparable from the dulness of the heart. The lower border lies about 2 inches to the left of the median line, and extends downward midway between the ensiform cartilage and the umbilicus.

Examination in Children.—Douchez says: The exact determination of the borders of the liver in children is difficult, because of the involuntary contraction of the muscles, also on account of the resonance found over the thin lower edge and of the oblique position of the upper border.

The measure of dulness of the anterior face of the liver, in the living, is almost always less by 1 or 2 centimeters than the real measure on the cadaver, either before or after opening the abdomen; we should, therefore, estimate this dulness from its extreme limits, in order to reach as nearly as possible the truth.

The upper border of the liver corresponds in general to the interval between the fifth and sixth ribs.

In the healthy state, the vertical measurements increase almost regularly with each year's growth, excepting in certain individuals.

The liver was found somewhat large in cases of catarrhal jaundice and gastric disturbance; large in cardiac disease; very large with amyloid liver, syphilitic liver, fatty liver, and hydatid cysts.

The slightest disturbance of health may cause a variation of 2 to 4 centimeters, and a variation of 3 to 10 centimeters was found with certain grave lesions.

LIVER, HYDATID CYST. Etiology and Pathology.—Hydatid cysts are formed by the larvæ of the tænia echinococcus of the dog. This tape-worm is exceedingly small, provided with 4 sucking discs and a double row of hooklets (Osler). The eggs usually gain entrance through the mouth, and after the shell has become detached, the embryo is set free, and, becoming attached to the intestinal wall, may burrow its way to the external surface. It probably gains entrance to the liver through the medium of the portal vein. After a certain time the embryo develops into a cyst with two layers—the internal (breeding) or granular layer, and the external (dense) or laminated layer. Daughter cysts spring from the inner or granular layer; hence the process is a continuous one. The daughter cysts may be set free; hence there may be hundreds within the primary cyst. The investing membrane of the smaller growths is soft, thin, and gelatinous, containing a clear, nonalbuminous fluid of specific gravity 1005–1007, rich in chlorids and containing glucose.

Symptoms and Clinical Course.—In the early stages no symptoms are produced. Later, as the cysts multiply and the fluid accumulates, there is an irregular enlargement of the liver, producing a dragging sensation in the right hypochondrium, dyspnea, and palpitation of the heart. Fever and pain are only present if there is suppuration of the cyst.

Jaundice is generally absent, but may result if pressure is great enough to cause occlusion of the biliary ducts. Percussion over the area yields a vibratory or trembling movement. By aspiration the clear-colored fluid is obtained.

Complications.—Suppuration, metastasis to various organs, as lung, pleura, brain, spinal canal, and genitals.

Diagnosis.—See LIVER (Abscess).

Prognosis is unfavorable as to medicinal treatment. Surgical interference yields favorable results.

Treatment is purely surgica . See LIVER (Abscess).

LIVER, INJURIES.—See ABDOMEN (Wounds and Injuries), GUNSHOT WOUNDS.

LIVER, PERIHEPATITIS.—Inflammation of the peritoneal covering of the liver.

Etiology.—(1) Extension, by continuity, of hepatic inflammation; (2) extension of pleurisy, by contiguity; (3) secondary to ulcer of stomach, etc ; (4) as part of a general peritonitis.

Pathology.—In the acute type there is fibrinous or purulent exudation with formation of adhesions. Thus, between the liver and diaphragm a pocket filled with pus may be formed, *i. e.*, a subphrenic abscess.

In the chronic form the capsule of the liver is thickened, especially at the hilum, with stenosis of the blood-vessels and bile ducts, and shrinkage of the liver, while adhesions to neighboring organs may occur.

Symptoms.—None are characteristic; often it is unsuspected in life. Sometimes the symptoms resemble atrophic cirrhosis. Physical examination may disclose a friction-rub over the liver or epigastrium. If there is purulent exudation, symptoms, and signs of sepsis manifest themselves.

Diagnosis.—It is to be distinguished from an empyema by the early symptoms, which are abdominal rather than thoracic and accompanied by further downward displacement of the liver. Aspiration may be resorted to, and it is said that the spurting of the released fluid is synchronous in subphrenic abscess with inspiration, in empy-

ema with expiration. The nonpurulent form is rarely recognized until death.

Prognosis is grave in the suppurative form.

Treatment.—Before pus formation, bed, light diet, counterirritation by cupping or leeching, hot compresses, sinapisms are indicated. Surgery is necessary as soon as pus is manifest.

LIVER, SARCOMA.—Sarcoma of the liver is rare. In 1908, Knott was able to collect from the literature only fifty-nine cases in which it occurred as a primary lesion. It may occur at any time of life from infancy to old age. The tumor grows rapidly and constitutional symptoms soon develop. It is practically impossible to differentiate sarcoma from carcinoma when the disease affects a person in middle or advanced life. Unless the neoplasm is distinctly circumscribed no attempt should be made to remove it.

LIVER, SYPHILIS.—Syphilis of the liver is usually a tertiary lesion, although it may occur early in the secondary stage, as an acute diffuse low grade inflammation, causing considerable enlargement of the gland, and sometimes giving rise to jaundice. The prognosis of this form is usually good, active mercurial treatment bringing about complete resolution.

Tertiary syphilis may affect the liver either as an interstitial inflammation or in the form of single or multiple gummata. Interstitial hepatitis is similar to atrophic cirrhosis in many respects. The cellular infiltrate is changed into connective tissue which compresses the ducts and blood-vessels, with resulting atrophy of the hepatic cells.

Gummata are usually multiple and vary greatly in size.

For both tertiary forms of the disease large doses of potassium iodid together with mercurial inunctions or injections should be given. Gummata not relieved by such treatment have been excised or fixed to the abdominal wall, the interior scooped out and a strip of gauze inserted (Spencer and Gask).

LOBELIA.—The leaves and tops of *L. inflata*, an expectorant, diaphoretic, purgative, antispasmodic, and emetic; in larger doses a motor depressant and narcotic. It contains gum, resin, fixed oil, wax, lignin, salts of calcium, potassium, and iron, a liquid alkaloid, *lobelin*, also *lobelic acid*, and *lobelacrin*. Dose, 2 to 15 grains.

Lobelia has an acrid, nauseous taste, and heavy, unpleasant odor. It strongly resembles tobacco in its action. It is useful in paroxysmal spasmodic asthma, as well as in dry cough with constant tickling in the throat. As an enema in strangulated hernia, the infusion is safer than tobacco, and as efficient. In constipation from atony and deficient secretion, 10 minims of the tincture at bedtime will be found to act well.

Preparations.—**Fluidextractum L.** Dose, 1 to 15 minims. **Tinctura L.**, 10 percent. Dose, as expectorant 5 to 20 minims; as emetic 1/2 to 2 drams. **Infusum L.**, ℥j to a pint. Dose, 1 to 8 drams.

LOCHIA.—The bloody, serous discharge from the uterus after labor. For the first 4 or 5 days it is bright red in color (*lochia rubra*), and composed chiefly of blood. During the next few days it becomes lighter in color (*lochia serosa*), and is composed of some blood, pus, mucus, and serous discharge. Finally it becomes white or yellowish (*lochia alba*), and resembles an ordinary vaginal leukorrhea. The flow ceases entirely at the end of 3 to 6 weeks.

The amount of the flow varies considerably in different individuals and at different times. Ordinarily, 4 to 6 napkins are saturated in the 24 hours for the first 3 or 4 days; after that the number varies from 1 to 3 until the ninth or tenth day, when the discharge becomes so slight as not to require a protective.

The odor of the normal lochia is bloody or musty; should it become offensive, decomposition and, probably, sepsis have occurred.

LOCKJAW.—See TETANUS.

LOCOMOTOR ATAXIA (Tabes Dorsalis; Posterior Spinal Sclerosis).—Posterior spinal sclerosis is perhaps the preferable designation for the affection under consideration, because the most constant and the most conspicuous lesion is essentially that which this name describes. Although the disorder is the most common and the most important of the diseases of the spinal cord, it has been well recognized and differentiated only during the past sixty years.

Pathologic Anatomy.—The essential lesion is a more or less extensive degenerative process, of varying intensity, involving the paths for conducting sensory impressions, which is most pronounced and most conspicuous in the posterior nerve-roots and the posterior columns of the spinal cord. Macroscopically, the degenerated portions of the cord appear grayish or slightly pinkish and translucent, and somewhat depressed below the common level. The overlying pia mater may be turbid and slightly thickened. The differentiation between diseased and healthy structure is brought out more vividly by staining.

On microscopic examination the disease is found to begin on either side in the posterior nerve-roots, and to extend into the posteroexternal columns of Burdach, while at higher levels the posterointernal columns of Goll are also involved. A small area in the posterior columns, adjacent to the posterior commissure, invariably escapes, while an oval area, adjacent to the posterior median fissure, and a comma-shaped zone included between the columns of Burdach and those of Goll, remain long intact.

Histologic study shows the axis-cylinders to have disappeared from the degenerated areas partially or wholly, while the glia remains or has even undergone hyperplasia. The walls of the blood-vessels in the affected portions are thickened. The disease of the spinal cord is not confined to the white matter. In addition to the posterior roots the posterior vesicular columns of Clarke, the marginal zone of Lissauer, and the medullary bridge of Weigert also suffer sometimes. Further, the degenerative process may involve the ganglia of the posterior spinal nerves, whose medullated fibers and ganglion cells may be in part destroyed. Peripheral sensory nerves also have, in a number of instances, been found diseased. Sometimes, too, the cerebral nerves and the nuclei

situated in the medulla oblongata participate in the degenerative process. The morbid process usually begins, and is most common and most pronounced, in the dorsolumbar region of the cord, but a cervical and a cerebral type of the disease are also sometimes described.

Etiology.—Posterior spinal sclerosis is a disease of middle life, one-half of the cases occurring between 30 and 40 years, and almost all between 20 and 50 years. It is exceedingly uncommon in early life, and it rarely begins in late life. It is more common in men than in women, in the proportion of about 10 to 1; and in the larger cities than in the smaller towns. It is rare in negroes, if it occurs at all in the full black. Heredity, direct and indirect, exerts but little, if any, etiologic influence. The most potent, though scarcely the sole, cause is syphilis, albeit it must be borne in mind that even then the lesions themselves are not syphilitic. Among additional, though far less important, etiologic factors, are other infectious and toxic processes, exposure to wet and cold, traumatism, and excesses of various kinds. A long interval—from 5 to 20 years—often elapses between the incidence of the causative condition and the appearance of the first symptoms of the spinal disease, though cases have been reported in which the separation has been as short as 1 year and as long as 20 years respectively. Hereditary syphilis has been the antecedent condition in a small number of cases. The disease, further, is occasionally observed in the sequence of other affections of the spinal cord: *e. g.*, myelitis, gumma.

Duration and Course.—Posterior spinal sclerosis is essentially a chronic and progressive disease. It is often insidious in onset, and it may advance slowly. Not rarely there are remissions, sometimes with long stationary periods. Occasionally, the disease pursues a relatively acute course. Once established, however, recovery is out of the question. The duration is, as a rule, protracted, and may cover many years. The disease is not fatal of itself, death resulting from complications or intercurrent disease. Its course may be divided into three periods: (1) neuralgic; (2) ataxic; (3) paraplegic.

The prognosis is relatively favorable as to life, but distinctly unfavorable with regard to recovery, although arrest of the disease may take place at any stage.

Symptomatology.—The symptoms of posterior spinal sclerosis concern especially and almost exclusively the sensory functions of the nervous system, and they may represent any degree of disturbance, from mere diminution to absolute loss. Among the earliest are shooting pains in the thighs, the so-called **lightning** or **lancinating pains.** These usually occur in paroxysms of varying duration (from hours to days), at longer or shorter intervals (from days to months). The pains may be boring, tearing, cutting, or burning, and they are sometimes present in the upper extremities, and rarely in other portions of the body. Possibly allied to these, although commonly they occur at a later period of the disease, are the painful paroxysmal seizures known as crises; laryngeal, pharyngeal, cardiac, gastric, intestinal, rectal, anal, hepatic, renal, vesical, vaginal, etc.

Laryngeal crises are characterized by a sense of constriction of the throat, with great distress and choking; pharyngeal crises by dysphagia and regurgitation of food; cardiac crises by intense precordial pain and other symptoms of angina pectoris; intestinal crises by tormina and tenesmus and burning pain; gastric crises by intense epigastric pain, with vomiting, flatulence, eructation, hiccup, and consequent wasting; hepatic crises by symptoms of biliary colic; and renal and vesical crises by those of calculus or colic.

Sensibility is often deranged in other directions. Most commonly its acuity is diminished—hypesthesia; sometimes it is lost—anesthesia; occasionally it is heightened—hyperesthesia. Often sensory conductivity is retarded or delayed. Abnormal sensations are frequently present—paresthesias—as of numbness or tingling, formication, of crawling or creeping, of cold or of burning, of running water, etc. A not uncommon symptom is a feeling of constriction or a sensation as of a band, rope, or cord about the waist, the so-called girdle-sensation. Some patients cannot distinguish the density of the surface on which they walk. In addition to alterations of common sensibility, changes in other varieties of sensory perception may be present, as of the sense of weight or of pressure, of position, of pain, of temperature, of localization.

Another early symptom is want of muscular coordination—**ataxia.** This is most common and usually most pronounced in the lower extremities, and is responsible for the unsteadiness in walking and standing. When it affects the upper extremities, it renders difficult, if at all possible, the performance of fine, delicate movements with the hands. In standing the patient holds his feet far apart, or keeps his eyes fixed upon the ground. If the feet are brought in juxtaposition, or if the guidance of the eyes is removed, or both, the patient will sway, and he might fall if not supported. The gait is staggering, not unlike that of a drunken man, and walking in the dark or backward is difficult or impossible; the feet are raised high from the ground, thrown somewhat outward, and permitted to fall awkwardly. Fatigue is induced with undue readiness. Sometimes associated movements take place, a voluntary muscular act in one part of the body being accompanied by a like involuntary act in the corresponding members of the opposite side, or even by a movement in some unrelated and perhaps remote part.

While muscular coordination suffers in varying degree, muscular power and muscular nutrition, and the response of the muscles to electric stimulation, remain practically unaltered, except when, late in the disease, they are affected in consequence of disuse.

With the ataxia there is usually associated inequality or enfeeblement or **absence of the knee-jerks,** while the cutaneous reflexes are altered in accordance with the changes in cutaneous sensibility. When the cervical portion of the cord is affected, the deep reflexes inthe upper extremities

suffer, while the knee-jerks may be preserved. **The reaction of the pupils** to light stimulation is generally impaired early—reflex iridoplegia—although their contractility in accommodation and in convergence is, as a rule, preserved throughout (Argyll Robertson phenomenon). Reflex dilatability from stimulation of the skin of the neck may also be diminished or lost. The pupils are usually small, and may be unequal, though sometimes they are large.

Paralysis of one or more ocular muscles is a common symptom, from which not rarely recovery takes place; and at times there is more or less **ophthalmoplegia,** internal as well as external. In this way there will result strabismus, diplopia, ptosis, paralysis of accommodation, etc.

Optic atrophy, of varying degree and unilateral or bilateral, occurs in many cases and is responsible for the blindness present. Impairment or loss of hearing or of smell or of taste is occasionally observed. Symptoms of involvement of the medullary nerves or their nuclei are not rarely noted. Retention of urine may result from insensibility of the mucous membrane of the bladder, and incontinence from the same cause, or from overflow, or in consequence of weakness of the sphincter vesicæ. Cystitis may develop and lead in turn to ureteritis and pyelitis. The sphincter ani is generally competent, and constipation is the rule. Sexual desire and sexual potence are often diminished and sometimes entirely lost, perhaps in the train of satyriasis. Some cases are marked by drowsiness and lassitude.

Various vasomotor, secretory, and trophic disturbances have been observed in individual cases: *e. g.*, hyperemia, hyperhidrosis or anidrosis, epiphora, sialorrhea, polyuria, glycosuria, diarrhea, ecchymoses, purpura, urticaria, herpes, ichthyosis, loss of nails, painless loss of teeth, bed-sores, perforating ulcer of the foot, gangrene of the toes, spontaneous laceration of the fibers of tendons, and spontaneous fracture of bones. Sometimes morbid alterations take place in one or more joints—arthropathies—the synovial sac filling with fluid and the articular cartilage and adjacent bone undergoing atrophic or hyperplastic changes. The foot may become thickened and deformed from alterations in joints, tendons, and muscles. Atheroma or arteriosclerosis not rarely attends posterior spinal sclerosis, and it may engender obstruction at the aortic orifice and incompetency of the aortic valves, with systolic and diastolic murmurs at the base of the heart on the right side. Rarely there are symptoms of degeneration of cerebral or spinal motor nerves, resulting in facial or lingual hemiatrophy, paralysis of the diaphragm, and weakness and wasting of other muscles. In some cases, also, symptoms of progressive paralysis of the insane are superadded. Finally, apoplectiform and epileptiform seizures and hemiplegia have been observed.

Diagnosis.—The recognition of posterior spinal sclerosis is to be based on the lightning pains, the unsteadiness of gait and station, the want of coordination in the upper extremities, the diminution or loss of knee-jerks, the narrowing of the pupils and their immobility on exposure to light, the ocular palsies, the optic atrophy, the sensory disturbances, the loss of sexual desire and sexual vigor without psychic manifestations, muscular weakness and wasting, and changes in electric reactions.

The spinal disease is to be differentiated from **multiple neuritis** by its insidious rather than acute onset, by the presence of visceral symptoms (incontinence of urine, impotence, crises), of lightning pains, of girdle-sensation, of optic atrophy rather than neuritis, often by the absence of nerve tenderness, and of muscular weakness and wasting.

Posterior spinal sclerosis may bear a close resemblance to **syphilis of the spinal cord,** but with the latter the clinical picture is likely to be atypical, while the knee-jerks may be present and even exaggerated, headache and papillitis are more commonly present, and other symptoms of syphilis may be more or less obvious.

Cerebellar tumor may present many of the symptoms of posterior spinal sclerosis, but lightning pains are likely to be absent, the knee-jerks are variable (sometimes absent, sometimes present), vesical symptoms are wanting, severe and persistent headache is a usual symptom, and papillitis, rather than optic atrophy, occurs.

Treatment.—While the lesions of posterior spinal sclerosis are little amenable to treatment, much can sometimes be done by judicious management to mitigate the severity of the symptoms, and possibly to prevent the advance of the disease. Of primary importance is the maintenance of the general health, the avoidance of intercurrent disorders, and the prevention of complications. If there is a history of syphilis or evidence of that disease, with the possibility of inadequate specific treatment, mercury (by inunction, by hypodermic injection, by internal administration) or iodids (sodium, potassium, strontium, lithium, hydriodic acid) or both may be administered within the limits of tolerance. Either or both of these remedies may also be tried carefully in the absence of syphilis. Intraspinal therapy in tabes is the most popular method at the present time of employing salvarsan or neosalvarsan. These drugs should not be injected directly because of dangerous toxicity. To overcome this Swift and Ellis devised a technic in which these drugs are injected intravenously, blood serum subsequently withdrawn and injected into the spinal canal. The technic is described by Kolmer as follows: "From 0.6 to 0.9 gm. of salvarsan or neosalvarsan is injected intravenously. One hour later 40 c.c. of blood are withdrawn directly into centrifuge tubes and allowed to coagulate, after which it may be centrifugalized. The following day 12 c.c. of serum are pipeted off and diluted with 18 c.c. of sterile normal salt solution. This 40 percent serum is then heated at 56° C. for 1/2 hour. After lumbar puncture the cerebrospinal fluid is withdrawn until the pressure is reduced to 30 mm. cerebrospinal fluid pressure. The barrel of a Luer syringe (which has a capacity of about 30 mils) is attached to the needle by means of a rubber tube about 40 cm. long. The tubing is allowed to fill with cerebrospinal fluid, so that no air will be injected. The serum is then poured into the syringe,

and permitted to flow slowly by means of gravity into the subarachnoid space. At times it is necessary to insert the plunger of the syringe to inject the last 5 mils of fluid. It is important that the larger part of the serum should be injected by gravity, and if the rubber tubing is not more than 40 cm. long, the pressure cannot be higher than 400 mm. Usually the serum flows in easily even under a low pressure. By the gravity method the danger of suddenly increasing the intraspinous pressure to the danger-point, such as might occur with rapid injection with a syringe, is avoided." Ogilive's modification of the Swift-Ellis method is as follows: Fresh blood serum is taken from the patient on the day of the injection, from 0.25 to 0.75 mg. of salvarsan, arsenobenzol or diarsenol is added, and it is placed in a water-bath at 37° C. (98.6° F.) for 45 minutes and then 56° C. (132.8° F.) for 30 minutes. The usual quantity of blood serum so treated is 10 c.c.; it is injected into the spinal canal by replacing an equal quantity of cerebrospinal fluid. All patients are required to go to the hospital for from 12 to 24 hours and remain quietly in bed. The lumbar puncture is done in the usual manner by inserting the needle in the median line between the spinous processes of the third and fourth lumbar vertebræ. The discomfort is generally no greater than that experienced in taking blood from a vein; hence no local anesthetic is needed. Rest in bed is essential, but restriction of diet is not necessary. At least 50 percent of the patients do not experience any discomfort, and are able to resume their work the following day. Head pains, such as follow lumbar puncture, in which fluid is not replaced, do not occur. The use of intraspinal injections of autoserum (salvarsanized) has affected an improvement in a large number of cases and many observers claim for it a distinct value. The estimate of its ultimate effect can be determined only by much longer observation than has been possible since the inauguration of the treatment. *Coordinated movements*, to re-educate the coordinating power of ataxic subjects by definite exercises, produce great improvement in locomotion. Among other drugs that have been used are salts of iron, of zinc, of arsenic, of silver, and of gold, strychnin, belladonna, ergot, quinin, and phosphorus. Lancinating pains and crises may require the administration of antipyrin, acetanilid, phenacetin, sodium salicylate, codein, or even of morphin. Suspension of the body from the head, in order to exert traction upon the spine, has been practised at different times for many years, and in some cases with encouraging results. Overextension of the spine by raising the feet of the recumbent patient over his head, with flexion of the trunk, has also been employed with the same object. Rather a more promising mode of procedure than any of those yet mentioned consists in courses of gymnastics calculated to improve and restore the failing coordination. The patient is systematically instructed and trained in the most varied movements, from the simplest to the most complex, in this way retaining the faculties of all the nerve-fibers whose functions have not been lost by destruction of their axis-cylinders. All forms of exercise should, however, be kept within the limits of fatigue. Massage and baths are capable of maintaining the general nutrition, to which, further, a proper diet and a suitable mode of life should be directed. Cystitis is to be avoided, so far as possible, and extension of inflammation to the pelvis of the kidney prevented; and the formation of bed-sores is to be guarded against. Arthropathies may require surgical or orthopedic treatment.

LOGWOOD.—See Hematoxylon.

LORDOSIS.—See Spine (Curvature).

LOTION.—A solution or mixture of medicinal agents intended for external application. It usually consists of some soluble astringent salt dissolved in water, with perhaps some glycerin or alcohol. A *fomentation* is a similar preparation used hot. A *collyrium* is an eye-wash, and generally contains a soluble astringent salt, dissolved in rose-water or distilled water, in the proportion of 1 to 4 grains to the ounce. The only official preparation suitable for a lotion is **lead-water.**

Black lotion or wash is prepared by adding calomel, 30 grains, to lime-water, 10 ounces, producing the black oxid. It is used as an application to syphilitic sores. **Goulard's lotion** contains liquor plumbi subacetatis. See Liquor. **Yellow lotion** or wash is prepared by adding mercuric chlorid, 18 grains, to lime-water, 10 ounces, producing the yellow oxid. It is a favorite application for syphilitic sores.

LOZENGES.—See Troches.

LUCID INTERVALS.—These may occur in the course of a mental disease, and are defined by Bucknill and Tuke as not consisting in a mere cessation of the violent symptoms of the disorder; but as intervals in which the mind, having thrown off disease, has recovered its general habit. The party must be capable of forming a sound judgment of what he is doing, and his state of mind such that any indifferent person would think him capable to manage his own affairs.

LUDWIG'S ANGINA.—An acute cellulitis, usually of streptococcic origin, which begins in the region of the submaxillary gland, spreads along the connective tissue planes of the neck and involves the floor of the mouth and walls of the pharynx. It generally occurs during an infectious disease but may be due to traumatism or carious teeth. The neck becomes swollen and indurated and the mouth and throat very much inflamed. As a rule the onset is sudden, but the characteristic violent local and general symptoms may be preceded for a few days by localized swelling and tenderness of the submaxillary gland. Edema of the glottis may cause sudden death or fatal septic pneumonia; pleurisy or pericarditis may occur if the morbid process extends to the mediastinum.

Treatment consists of free multiple incisions, the removal of necrotic tissue, cauterization with carbolic acid and iodin, drainage-tubes and hot moist dressings. Stimulants should be given freely and antistreptococcic serum injected whenever it can be obtained.

LUETIN REACTION.—The luetin test is performed by injecting 0.05 c.c. of luetin intracutaneously in two places on the left arm and at the same time 0.05 c.c. of a control suspension, consisting of the medium without any growth of spirochetes, at two points on the right arm. Local inflammation on the left arm, appearing in two to ten days and sometimes resulting in the formation of a pustule, is regarded as a positive test. The test is often negative in the earlier stages of syphilis.

The various diagnostic tests for syphilis are now extensively employed. Microscopic search for the spirochete is of value in the untreated primary and secondary stages. The complement-fixation test becomes positive a few weeks after the appearance of the primary lesion and is generally regarded as indicating an active syphilitic process. The luetin test may be positive in latent or inactive syphilis when the Wassermann is negative. Further experience with the luetin test is necessary in order to determine its real significance (MacNeal).

LUMBAGO.—A form of muscular rheumatism affecting the muscles of the loins and their tendinous attachments. It is one of the most common and painful forms of rheumatism. It is most frequently found among workmen. Its onset is sudden, and in very severe cases it completely incapacitates the sufferer, and he may be unable even to turn in bed or arise from a sitting posture. As a rule, it is a transient affection, lasting from a few hours to a few days. It may be constant in character or occur only when the muscles are drawn into certain positions. Instead of being painful, it may take the character of a simple ache, which is relieved by pressure.

Treatment.—Rest of the affected muscles is of the first importance. Porous plasters are believed to be efficacious by the public. A hypodermic injection of morphin into the affected muscles will relieve the severe and agonizing pain. Acupuncture, in acute cases, is a most effective treatment. Sterilized needles, 3 or 4 inches in length, may be thrust into the lumbar muscles at the seat of pain, and after 5 to 10 minutes withdrawn. The relief is often immediate. The constant current is sometimes beneficial. The thermocautery may be employed in light strokes over the affected muscles. Blisters may be tried in obstinate cases. Hot fomentations are soothing, and, at the outset, a Turkish bath may cut short the attack. Salicylates are the standard remedy in all forms of myalgia. See Salicylic Acid. In chronic cases potassium iodid may be used, and guaiacum and sulphur have been strongly recommended. Proper clothing and diet are needed. Large doses of nux vomica are sometimes beneficial. See Rheumatism.

LUMBAR PUNCTURE.—Spinal (subarachnoid) puncture is used for anesthesia, and it has become a measure of marked value both for diagnosis and treatment. Tapping of the spinal theca may be practised readily and with impunity, provided perfect asepsis be observed, in any interlaminal space between the second lumbar and the first sacral vertebræ. It has been found valuable in diminishing intracranial pressure, as, for instance, in tuberculous meningitis. Great benefit has been derived from it in uremic convulsions. Lumbar puncture should be performed in cases of doubtful infantile paralysis. It is the only means available at present of differentiating between epidemic meningitis and that form of anterior poliomyelitis which resembles it so closely. In tetanus magnesium sulphate and tetanus serum are administered by injection following lumbar puncture; similarly antimeningococcus serum is given in epidemic cerebrospinal meningitis. See Intraspinal Anesthesia, Meningitis.

LUMBRICOIDS.—Large round-worms (*Ascaris lumbricoides*) infesting man and animals. See Worms (Round).

LUNACY.—A popular name for insanity, so called from the traditional belief that it was influenced by the moon. For the divisions and legal aspect of insanity see Insane (Laws Relative), Insanity. See also Delirium, Mania, Melancholia, etc.

LUNGS, CIRRHOSIS (Chronic Interstitial Pneumonia).—A chronic inflammatory disease of the lungs, characterized by an overgrowth of the connective tissue.

Etiology.—(1) Sequel of croupous pneumonia; (2) fibroid phthisis; (3) fibrinous pleurisy; (4) bronchopneumonia; (5) inhalation of dust—pneumoconiosis; if due to stone-dust—chalicosis; to coal-dust—anthracosis; metallic dust—siderosis.

Pathology.—The disease is generally unilateral, the chest on the affected side being retracted and the heart displaced. The lung is greatly atrophied, only leaving the interstitial tissue, and is frequently so shrunken that its contour is totally changed. If due to tuberculosis, cavities may be found. Microscopically, an overgrowth of connective tissue is seen. The unaffected lung is in a condition of emphysema.

Symptoms and Clinical Course.—There is a severe cough, accompanied by slight or profuse expectoration, mucopurulent in character. On account of the diminished size of the lung dyspnea is a common symptom. Fever may be absent, and the health remain good for many years. If due to tuberculosis, pulmonary hemorrhages are common.

Physical Signs. Inspection.—There is retraction of the chest on the affected side. The apex-beat is displaced.

Palpation.—Vocal fremitus may be diminished or increased, depending upon involvement of the pleura.

Percussion shows impaired resonance on the affected side, and hyperresonance on the opposite side.

Auscultation.—There is heard cavernous or amphoric breathing at the apex, but feebler at the base of the lung, with large and small mucous râles.

Diagnosis.—The affection has to be distinguished only from Tuberculosis (*q. v.*).

Prognosis.—It is fatal in from 10 to 15 years.

Treatment is palliative. A change of occupation and out-of-door gymnastics may be demanded. See Tuberculosis.

LUNGS, CONGESTION.—An increase in, or abnormal fulness of, the capillaries of the air-cells:

active, when the result of an accelerated circulation; *passive,* when caused by an impeded outflow from the capillaries. For etiology, diagnosis, and treatment, see HEMOPTYSIS.

LUNGS, CONSUMPTION.—See TUBERCULOSIS (Pulmonary).

LUNGS, EDEMA.—An exudation of serum into the pulmonary interstitial tissue and the alveoli of the lungs, characterized by dyspnea, cough, and a frothy, blood-streaked expectoration.

Etiology.—Pulmonary edema is the result of stasis, occurring when the outflow of venous blood in the lung meets an obstacle that cannot be overcome by the right ventricle, as in cardiac diseases in which the left ventricle fails. It also follows Bright's disease and alcoholic excesses, causing cardiac depression and lung inflammations.

Pathologic Anatomy.—The lung tissue is swollen, and does not collapse when the chest is open. The elasticity of the tissue has disappeared, and it pits upon pressure. If following congestion of the lungs, the color is red; if a symptom of general dropsy, its color is pale. On cutting into the edematous spots an enormous quantity of albuminous fluid, sometimes clear, at other times of a red color, mixed more or less with blood, flows over the cut surface.

Symptoms.—The preeminent symptom is dyspnea, the breathing being hurried, labored, and rattling, all the accessory muscles of respiration being called into action. The sense of oppression and anxiety is extreme. There is also a constant, harassing, short cough, and the expectoration of a blood-streaked, frothy mucus. The action of the heart may be tumultuous or feeble. The face is at first flushed, but as the left ventricle fails, or if the effusion into the air-cells is sufficient to prevent the entrance of air, symptoms of cyanosis rapidly supervene, the pulse becoming feeble, the surface cold, the breathing shallow and hurried, the cough suppressed, stupor replacing the restlessness, soon deepening into coma.

Percussion.—If there is no other lung-disease, the percussion-note is but slightly, if at all, impaired.

Auscultation.—The vesicular murmur is lost by the diffused subcrepitant and bubbling râles.

Diagnosis.—Acute pneumonia in the earlier stages is the only condition likely to be confounded with edema of the lungs, but as the two diseases progress, the picture of pulmonary edema is so characteristic that it cannot be mistaken.

Prognosis is grave, and particularly if the disease occurs in pneumonia, heart-disease, or Bright's disease. In the majority of instances it is a terminal symptom, coming on in all forms of acute and chronic diseases.

Treatment.—As a rule, remedies are useless. The indication is to stimulate the left heart, and this is best done with hypodermic injections of strychnin sulphate, 1/24 grain, repeated every half hour; citrated caffein, 3 to 5 grains; spartein sulphate, 1 to 2 grains every hour or two, or digitalin, 1/60 to 1/30 grain, repeated every hour or two. Two or more of these drugs may be advantageously combined. Atropin sulphate, 1/60 to 1/100 grain, and ergot in some form are valuable remedies. Occasionally relief follows a free venesection or the application of wet cups. Alcoholic stimulants are often invaluable. These means may be aided by counterirritation to the chest, hot mustard foot-baths, active saline purgatives, and diuretics.

LUNGS, EXAMINATION.—See CHEST (Examination).

LUNGS, HEMORRHAGIC INFARCTION (Pulmonary Apoplexy).—An effusion of blood into the air-cells and interstitial tissue of the lungs.

Etiology.—It is usually the result of an embolus which comes from the heart or from a thrombus in the pulmonary artery. The smaller vessel becomes dilated after the embolus lodges, and from the effect of the blood-pressure the vessel ruptures, giving rise to the condition.

Pathology.—The infarction is usually in the periphery of the lung and of a conic shape—the base toward the pleura, the apex toward the root of the lung. The red patches of infarction are clearly seen on the pleura. The infarction, when cut, collapses readily.

Symptoms.—These are of an indefinite nature. Naturally, there is dyspnea, and if there is a valvular disease of the heart with expectoration of dark blood, a blowing breathing at the lower lobes, and dulness on percussion, we may suspect pulmonary apoplexy

Treatment should be directed to the cause. The prime indications are to bring down the blood-pressure with such drugs as aconite, in doses of 3 to 6 drops of the tincture every 3 or 4 hours, and to reduce the frequency of the pulse-beat by avoiding excitement, and the applications of ice-cloths over the chest for periods of 10 minutes. A hypodermic of 1/4 a grain of morphin is often the best thing to prevent excitement and danger of further hemorrhage.

LUNGS, INFLAMMATION.—See PNEUMONIA, TUBERCULOSIS, PLEURISY.

LUNGS, INJURIES.—Injuries of the lungs may occur from mere contusion or compression of the thorax; they are very common as a result of fractures of the ribs; and occasionally they occur as a result of external wounds, penetrating from the outside. The wound may be superficial or deep; it may be punctured, incised, or lacerated, with or without the entrance of foreign bodies, and it may be so trivial that it is never diagnosed, or it may cause instant death. The simpler forms of wound heal at once by first intention, without any inflammation, and with very great rapidity. Severe contusion, owing to the extravasation into the air vesicles, is attended with a greater amount of consolidation and with rusty, blood-stained sputum for several days, but the dulness rarely extends, and there is little or no fever. If, however, the extravasation is very great, or there is an external wound, so that the blood decomposes, intense septic pneumonia, and even gangrene, may follow; but there is always such an amount of pleural effusion, and the lung, as a rule, in these cases is so collapsed and compressed against the back of the thorax, that the physical signs are very obscure.

Symptoms.—The two characteristic signs of wound of the lung are hemorrhage and the escape of air. The former may take place into the bronchi, so that the sputum consists either of pure blood or of a frothy, bright-red mixture, which in a day or two becomes rusty and black; or it may collect in the cavity of the pleura (hemothorax), and gradually soak into the surrounding tissues, so that the skin on the loins becomes dark and ecchymosed; or it may escape externally, mixed with air, or almost pure. So with the air. In very rare instances, when the vesicles alone are torn without the pleura being injured, it may escape into the cellular tissue of the lung and make its way along the outside of the bronchi into the mediastinum, and so gain the root of the neck; or it may collect in the pleural cavity, entering at each expiration, until it distends the thorax to its utmost and compresses the lung against the back; or, what is far more common, without entering the pleura at all, it finds its way across into the cellular tissue, and gives rise to surgical emphysema; or, finally, if there is a large open wound, it is sucked in and out of the chest at each respiration, mixed more or less with blood.

Beside these, other symptoms are usually present. The shock of such an injury is severe and sometimes fatal, even when the amount of bleeding is not great; anxiety and distress are always marked; sometimes the dyspnea is slight, but usually it is severe, and if the lung becomes rapidly collapsed, it may be extreme; there is a constant sense of irritation and tickling in the throat, with an intense desire to cough, but the deep, fixed pain in the chest prevents it, and if the hemorrhage is severe, the patient may sink rapidly into a state of collapse.

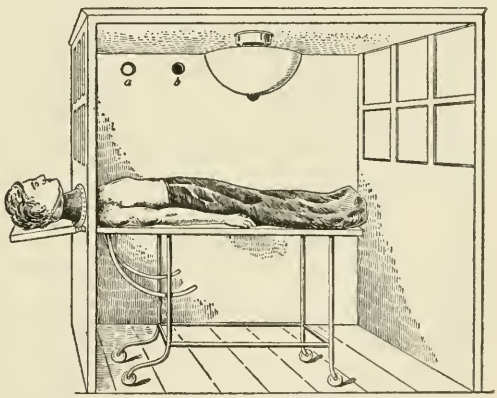
Treatment is directed to control of the hemorrhage by compression and the use of hemostatics, fixation of the chest, and general supportive measures. See HEMOPTYSIS.

Pneumatocele, hernia, or prolapse of the lung is an occasional but rare complication of injuries of the thorax. It may be either immediate or secondary. In the former case there is generally a wound of some extent in the parietes, and the lung is forced out through it by a violent effort at expiration when the glottis is closed. It may be injured itself or it may not, but as soon as it is squeezed out through the rent, it expands so that it cannot return, and rapidly becomes congested. In extreme cases it may be strangulated. If seen shortly after the accident, an attempt may be made to return the protrusion, and, if necessary, the wound may be slightly enlarged for the purpose; but if some time has elapsed, and the tissue is very much congested, it is better left where it is to slough off and granulate over; or its separation may be assisted by ligature or actual cautery. A very few instances are recorded in which, owing to extensive injury of the thorax, an immediate prolapse of the lung has occurred without an external wound.

The consecutive variety may not make its appearance until some considerable time after the receipt of the injury, and if there has been a wound, it must have healed first. It forms a soft, circumscribed tumor, projecting through the wall of the thorax under the skin, swelling out on expiration and shrinking on inspiration. On coughing there is a distinct impulse; if it is pressed upon, it collapses readily, with a feeling of soft crepitation, and the margins of the opening can be plainly felt. It is resonant on percussion, and the respiratory murmur is loud and coarse in comparison. In some cases it is the result of extensive rupture of the intercostal muscles; in others, where its formation is very gradual, it is probably due to chronic inflammation weakening the walls of the thorax at one spot, and allowing the lung slowly to force its way through. The only treatment required is a belt or truss, according to the size and situation of the protrusion, to restrain it and protect it from injury.

For further discussion of injuries of the lung, see CHEST (Injuries), PLEURA, PLEURISY, PNEUMONIA.

LUNGS, SURGERY.—The dangers of intrathoracic surgery have been lessened by the ingenious methods devised for preventing collapse of the lung when the pleura is widely opened. Both positive and negative pressure are employed. The former prevents collapse of the lung by distending it from within, the latter by making suction upon its exposed surface. When positive pressure methods were first introduced, and for sometime thereafter, they were assailed as being dangerous, but evidence based upon continued animal experiments and also upon the results of their application to the human subject, show that



SAUERBRUCH'S PNEUMATIC CABINET.

a. Opening of pipe connecting with suction pump; *b*, valve to let in air, and regulate the negative air pressure. —(Bryant and Buck's *American System of Surgery*.)

the objections were theoretical rather than practical. Kuttner, Dreyer, Robinson and others have demonstrated that the air exchange in the trachea, the venous pressure, the aortic and pulmonary pressure, and the expansion of the thorax are the same under positive pressure as they are under negative pressure.

With regard to the apparatus employed, that for positive pressure is simpler than that for negative. Robinson and Leland state that the requirements of any positive pressure apparatus

are a supply of compressed air; an anesthetizing segment; a device for introducing air and ether into the respiratory tract; a means of varying the resistance of the exhaled air. It would seem that all of these requirements are not perfectly met by any single apparatus thus far devised, but they are present in sufficient degree to make the ingenious instruments of great practical value.

Sauerbruch's apparatus for negative pressure is an air tight cabinet in which the surgeon operates. The patient's head projects outside the cabinet and a tight fitting rubber collar is placed around his neck. Negative pressure is obtained by means of an electric suction air-pump. As the bronchioles are subjected to ordinary atmospheric pressure at the time that the thorax is exposed to negative pressure, collapse of the lung does not occur. It is interesting to note that an increased number of successful intrathoracic operations are being done in the clinics where this apparatus is in use. And see Intratracheal Insufflation of Ether.

Incision of the lung (pneumotomy) has been practised in cases of gangrenous cavities, abscesses caused by the extension of suppuration from other parts into the lung, abscesses connected with foreign bodies, bronchiectatic cavities, provided they are single (multiple ones can hardly receive much relief this way), and tubercular cavities, if there is only one, and the cough is very harassing. In one or two cases a similar operation has been practised for hydatid disease, and a few instances are recorded in which tumors have been removed from the lung. The localization of the disease and the treatment of the pleura are the chief difficulties. No incision may be made until the existence and accessibility of the cavity have been proved by puncture, and even then the greatest care is required, for the lung, unless it is consolidated by inflammation, is so yielding that a thick-walled sac can easily be pushed to one side. As a rule, cavities should not be approached from behind, for the large vessels run for the most part along the posterior surface of the bronchi. The size of a cavity cannot be estimated from the amount of fluid that is coughed up; according to Godlee, upward of a pint may come within 24 hours from a space that would not hold so much as 44 c.c. If a cavity is found, the lung tissue should be incised, and explored as far as possible with the finger, part of a rib being removed if necessary, and a large drainage-tube inserted. The shape is always very irregular, and it must be a long time before the sloughs have separated, and cicatrization can procure its obliteration.

The treatment of the pleura presents unusual difficulties. There can be no doubt that it is not advisable to incise a putrid cavity in the lung unless the pleural surfaces are adherent. If there is localized gangrene, and if it has already lasted for some time, the danger is not so great; adhesions are usually present under these conditions, and the lung is so consolidated by inflammation that it is in but slight danger of collapsing; but in acute cases and in bronchiectasis it is impossible to be certain. An attempt made be made to find out by ascertaining the mobility of the lung; if a needle is driven through an intercostal space into the pulmonary tissue, it will show to a certain extent by its movement whether the lung is fixed or not, but it is very easy to place too much reliance upon this. In some instances it may be possible to suture the two surfaces together and wait for a week, or to procure adhesions by means of the cautery applied to the intercostal muscles, but often it is impossible to wait so long, and even then the adhesions are so soft and delicate that the greatest care must be taken not to break them down (Moullin).

Excision of lung tissue (pneumonectomy) has been suggested to remove diseased portions. To remove the apex, the third or fourth rib is excised without opening the pleura until it is removed. The lung is then grasped and drawn into the pleural opening, which it plugs, and relieves the distress occasioned by allowing the air to enter. The portion of lung to be removed is ligated *en masse* and then cut away, the stump being seared with the cautery. The wound in the pleura is closed and sealed with collodion. The ligature must be firmly applied and asepsis must be rigid (Pyle). The results of the operation are not yet definitely determined.

LUPINOSIS (Lathyrism, Chick-pea Disease).—An affection due to prolonged use of meal made from the chick-pea (or vetches) which is mixed with barley and wheat. It is observed in India, France, Italy and Algiers. The symptoms are gastro-intestinal derangement, pain accompanied by weakness and tremor followed by spastic paralysis of the legs with exaggerated reflexes. Treatment consists in removing the cause and relieving the symptoms.

LUPULIN.—The yellow, resinous powder of hops, composed mainly of dried glands from the strobiles of the plant; it is the *lupulinum* of the U. S. P. Its oleoresin is official. Dose, 5 to 15 grains. In nervous irritability lupulin may be used as a calmative and hypnotic. In irritable bladder, in alcoholism, and as an anaphrodisiac in chordee, gonorrhea, spermatorrhea, and other affections of the genitourinary organs, it is serviceable. See Hops.

In dysmenorrhea:

℞. Lupulin, ʒ j
Confection of rose, q. s.
Make into 20 pills. One pill 3 times a day.

LUPUS ERYTHEMATOSUS.—A cutaneous new growth characterized by well-defined reddish patches covered with yellowish or grayish adherent scales.

Symptoms.—The disease begins as one or more rounded or oval, pinhead-sized to pea-sized erythematous spots, which increase in size, either by peripheral extension or by coalescence of neighboring lesions. When fully developed, the disease appears as one or more sharply marginated, reddish or violaceous patches, varying in size from a small coin to the palm of the hand. The surface is covered by grayish or yellowish scales, firmly adherent to and dipping down into the patulous

and distended openings of the sebaceous glands. The border of the patch is somewhat elevated, while the central portion is slightly depressed. Whitish atrophic scarring is usually present, and is characteristic of the disease. There is more or less infiltration and thickening. The subjective symptoms consist of moderate itching and burning.

The region most frequently affected is the face, particularly the cheeks and nose. The lips and, more rarely, the buccal mucous membrane may also be attacked.

The disease pursues a slow course, lasting months, and at times years. Occasionally involution of the patches occurs, with or without the persistence of scars.

Etiology.—The cause is obscure. Erythematous lupus is essentially a disease of adult life. It is more common in women than in men. Disorders of the sebaceous glands act as predisposing causes.

Diagnosis.—Lupus erythematosus may be distinguished from lupus vulgaris as follows:

Lupus Erythematosus.	Lupus Vulgaris.
1. Develops in adult life.	1. Develops in childhood or youth.
2. Disease is superficial.	2. Disease is deep-seated.
3. The lesions well-defined, scaly patches.	3. The lesions discrete papules and tubercles.
4. Sebaceous ducts patulous or distended.	4. Sebaceous system not involved.
5. Ulceration never occurs.	5. Ulceration with scarring nearly always present.

Prognosis.—Favorable as to ultimate cure, but guarded as to duration of disease.

Treatment.—But little reliance is to be placed upon internal treatment, although such drugs as iodin, arsenic, cod-liver oil, etc., are occasionally of value.

The local treatment consists of the use of sedative or stimulating applications, caustics, or surgical manipulation, according to the nature of the case.

Inasmuch as a certain number of cases recover spontaneously, with little or no scarring, the milder remedies should always be given a fair trial before proceeding to the use of caustics and the like.

Most cases do well under stimulating applications. An admirable method is vigorously to rub into the part, every day or every other day, sapo viridis or the tincture of green soap. This may be followed by a soothing ointment. Plasters are frequently of great value. Those most employed are the ordinary mercurial plaster and a 10 to 20 percent salicylic acid plaster.

When these remedies fail, and when the affection is severe and of long standing, one may cautiously resort to the use of such caustics as pure carbolic or trichloracetic acid, liquor potassæ, nitrate of silver, etc. Scarification and superficial curetting are often followed by good results. Sulphur, either in ointment (1 to 2 drams of precipitated sulphur to 1 ounce) or lotion, is a most efficient remedy.

A combination of sulphur and tar makes a useful formula:

℞. Precipitated sulphur, ʒ j
Oil of cade, ʒ j
Zinc oxid ointment, ℥ j.

Apply twice a day.

Crocker speaks well of the use of collodion, either alone or with salicylic acid (10 to 30 grains to 1 ounce) incorporated in it.

Liquid air or, preferably, carbon dioxid snow has been used with excellent results.

LUPUS VULGARIS.—A tuberculous cellular new growth, characterized by reddish or brownish patches consisting of papules, nodules, and flat infiltrations, usually terminating in ulceration and scarring.

Symptoms.—The disease commonly begins as numerous pinpoint-sized to pinhead-sized, grouped or disseminated, reddish, yellowish, or brownish flat papules. They are softer than the surrounding skin, in which they appear to be embedded. Hutchinson has likened their appearance to "apple jelly."

These papules develop later into pea-sized or larger tubercles or nodules, which ultimately become aggregated in variously sized and shaped patches covered with imperfectly formed epidermis. After a variable duration the nodules coalesce, chiefly by individual extension, forming dull red, raised, soft patches.

The lupus nodules or patches may remain stationary for some time, but sooner or later undergo retrogressive change. The lesions may disappear by absorption, leaving a somewhat scarred, scaly, and atrophic skin (*lupus exfoliativus*), or, as is the more usual course, by ulceration, with resulting crusts and cicatrices (*lupus exedens, lupus exulcerans*). At times exuberant granulations spring up upon the borders of the ulcer (*lupus hypertrophicus*), or there may develop even papillomatous outgrowths (*lupus papillomatosus*).

The most frequent seat of lupus is upon the face, particularly the nose, cheeks, and ears. The trunk and extremities may also be involved. Besides the skin, lupus occasionally attacks the mucous membrane and cartilage of the nose, mouth, pharynx, larynx, or ears.

Subjective symptoms are, as a rule, wanting, although there may be slight pain.

The course of the disease is eminently chronic, the affection persisting for years, and frequently a lifetime.

Etiology.—The vast majority of cases begin before the age of 20, and many before the age of 10. The disease, however, is never congenital.

Lupus vulgaris is due to the invasion of the skin by the tubercle bacillus.

Pathology.—A section of lupus tissue shows, under the microscope, sharply circumscribed nests of cell-infiltration in the deeper layers of the corium. Epithelioid cells are present in varying numbers, and giant cells in abundance. Tubercle bacilli are few, and only discoverable by examination of many sections. When ulceration occurs, the

centers of the nodules undergo coagulation necrosis and fatty degeneration.

Diagnosis.—The diseases most likely to be confounded with lupus vulgaris are the tubercular syphiloderm, lupus erythematosus, and epithelioma.

Lupus Vulgaris.	Tubercular Syphiloderm.
1. Develops usually before the age of puberty.	1. Develops after the age of puberty.
2. Course slow.	2. Course rapid.
3. History, perhaps, of scrofulous hereditary tendency.	3. History of infection.
4. Concomitant signs of tuberculous diathesis.	4. Concomitant signs of syphilis.
5. Nodules soft.	5. Nodules hard.
6. Ulcers are comparatively superficial, with irregular, undermined edges; discharge slight; crusts scant and reddish-brown.	6. Ulcers are deep, with sharp-cut edges; discharge copious; crusts bulky and greenish.
7. Scars yellowish, shrunken, and hard.	7. Scars whitish, soft, and smooth.
8. Refractory to all but destructive measures.	8. Rapid healing under the iodids and mercury.
Lupus Vulgaris.	**Epithelioma.**
1. Develops usually before puberty.	1. Develops in middle and advanced life.
2. Course extremely slow.	2. Course more rapid.
3. Little or no pain.	3. Usually painful.
4. Ulcers multiple and superficial.	4. Ulcers single and deep.
5. Edges and base soft.	5. Edges and base hard; characteristic pearly border.

Prognosis.—The disease runs a decidedly chronic course. The prognosis depends upon the age of the patient and the form, extent, and duration of the disease. Occurring in small, circumscribed patches, the prognosis is favorable.

Treatment.—General hygienic measures, such as nutritious diet, fresh air, exercise, etc., should receive attention. In many cases the administration of such remedies as cod-liver oil, iodid of iron, etc., is indicated, although no direct curative influence is to be expected from their use. Thyroid extract and tuberculin have been used in some cases with encouraging results. Their curative value, however, is at the present time still conjectural.

Local treatment has for its object the extirpation of the lupus tissue with as little resultant scarring as possible. Before resorting to chemic caustics or surgical interference, it is well in some cases to employ milder measures. In hyperemic cases the condition is sometimes improved by the continued application of calamin lotion. Mercurial plaster occasionally exerts a beneficent influence on the disease. A salicylic acid (20 percent), creosote (40 percent), or resorcin plaster has been used with good results. Most cases, however, require more heroic treatment. The *solid stick of silver nitrate* is useful in the treatment of small discrete lesions. It is bored into the tissue until the nodule is destroyed. Every few days new lesions are attacked. *Pyrogallic acid* is a slow but practically painless caustic. It may be used in ointment or as a paint.

Brocq advises the following:

℞. Pyrogallic acid, Salicylic acid, each, gr. 1
Collodion, ʒ j.

Paint on the part every day until a slough is produced.

Arsenic trioxid is a rapid caustic, exerting a selective action upon diseased tissue. It is, however, very painful, and can only be used over small areas, on account of the danger of absorption.

℞. Arsenic trioxid, gr. xx
Powdered acacia, ʒ j
Water, q. s.

Spread on lint and apply for 24 hours. Then poultice until slough comes away.

Zinc chlorid is an efficient caustic, not so painful as arsenic. It does not, however, select diseased tissue.

℞. Zinc chlorid, ℥ xvj
Powdered opium, ℥ jss
Hydrochloric acid, ʒ vj
Boiling water, ʒ xx.

(Middlesex Hospital formula.)

To 1 ounce of the solution add 2 drams of wheaten flour. Spread the paste upon lint and apply for 24 hours.

Curetting is an extremely valuable procedure. It is often supplemented by the use of a caustic or the application of the Paquelin cautery.

Scarification is a most useful measure, particularly in diffuse superficial patches. Numerous parallel incisions, crossed at right angles by others, are made through the skin by means of a sharp scalpel or scarifier. This is often advantageously followed by the application of an iodoform ointment or a bichlorid lotion.

The *galvanocautery* and the *Paquelin cautery* find a distinct field of usefulness in the treatment of certain forms of this disease.

Direct *exposure to sunlight* for 4 to 5 hours a day for months is reported to be effective. Remarkably good results have been attained by the use of the X-rays.

LYCETOL.—A tartrate of dimethyl diethylenediamin (dimethyl piperazin). It is said to be a reliable diuretic and uric acid solvent, free from untoward effects on the stomach, even though its use be long-continued. Dose, 15 to 30 grains daily in carbonated water or in lemonade.

LYCOPODIUM.—A very mobile, pale yellow, fine powder, consisting of the spores of the club-moss (*Lycopodium clavatum*) and of other species

of Lycopodium. Lycopodium is odorless, tasteless, floats on water, which does not wet it, and burns quickly when thrown on a flame. It should be free from pine-pollen, starch, sand, and other impurities, which are detected by means of the microscope the lycopodium spores being about 1/800 of an inch in diameter, four-sided, and reticulated, with short projections on the edges. They contain about 47 percent of a bland, fixed oil.

The plant was formerly considered to be diuretic and antispasmodic, and was used in rheumatism, epilepsy, and pulmonary and renal disorders. The powder is now employed quite extensively in pharmacy to facilitate the rolling of a pill-mass and to prevent adhesion of pills to each other. It makes an excellent absorbent and protective powder when dusted over an excoriated surface, as seen between the thighs of infants.

LYMPHADENOMA (Hodgkin's Disease; Lymphatic Anemia, Lymphadenosis Pseudoleukemia; Malignant Lymphoma.)—A form of anemia characterized by a hyperplasia of the lymphatic glands, usually a hypertrophic condition of the spleen, and without leukocytosis.

Etiology.—It generally occurs in people under 25 years of age, the majority of cases collected by Gowers being males. The exciting cause is not known. It has been attributed to constant irritation of the skin, to decayed teeth, to nasal catarrh—these conditions exciting a local glandular swelling which becomes general.

Pathology.—A hyperplasia of the lymph-glands is always present. A hypertrophic condition of the spleen is found in the majority of cases. The cervical lymph-glands are usually the first to enlarge, and soon involve the whole chain of glands. The axillary and inguinal glands are next affected. The marrow of the long bones is said to be converted into the soft lymphoid material. The liver is often enlarged, and is the seat of lymphoid tumors.

Symptoms and Course.—In the early stages the blood is either normal or there is a slight degree of anemia. Later there is a leukocytosis, the adult cells (polymorphonuclear leukocytes) alone being greatly increased. Myelocytes are occasionally found. With the advance of the destruction of red cells there is a corresponding diminution in the percentage of hemoglobin. The enlargement of the superficial glands of the neck usually marks the onset. They may be small and movable at first, but later involve the superstructures, and become hard and painful. They rarely suppurate. The liver and spleen are usually found enlarged. With the increase in the size of the lymph-glands there is a corresponding impoverishment of the blood. Dyspnea may be common. If there is enlargement of the abdominal lymphatics, pressure-symptoms arise, and there will be edema of the lower extremities. In the beginning there is slight fever, with a variation in the daily temperature, that in the evening being higher.

Diagnosis.—Syphilis may give rise to enlargement of the lymphatics, but the history will clear up the doubtful nature and an examination of the blood will confirm it.

Tuberculous glands usually occur in younger persons, and generally suppurate. In Hodgkin's disease suppuration is rare. In scrofulous (tuberculous) glands ordinarily only one chain of glands is involved, and usually these are the submaxillary, while in Hodgkin's disease the anterior and posterior cervical glands are generally first affected. The tuberculin test should be employed.

In tuberculous adenitis the liver and spleen are not enlarged to so great a degree as in pseudoleukemia. Lastly, as the disease advances, in pseudoleukemia there is a corresponding degree of anemia, as shown by the blood examination.

Leukocythemia is differentiated by its characteristic leukocytosis.

Carcinoma of lymphatic glands is generally secondary to cancer in another region. Lymphosarcoma tends to invade neighboring tissues. Diagnosis in malignant disease is confirmed by microscopic examination of a section of the tumor.

Prognosis.—Recovery is rare. Death usually occurs before the end of the third year of the disease.

Treatment.—If the glands are superficial, they should be excised, to prevent the disease spreading. Neighboring glands should also be removed. Late in the course an operation does no good. Of medicines, arsenic seems the most effective. Any of the prescriptions recommended under ANEMIA (*q. v.*) may be given. The injection of arsenic into the involved tissue is said to be especially valuable. Bone-marrow, sodium cacodylate or atoxyl may be used. With the use of medicine it will also be beneficial to surround the patient with the best possible hygienic conditions or recommend a change of climate. Phosphorus, in doses of 1/100 of a grain after meals, may also be given. Iodid of potassium in 10-grain doses, cod liver oil, iron, strychnin, inunctions of iodin (1 percent) are recommended. Improvement is reported as resulting from X-ray treatment. Local applications have never proved of much benefit.

LYMPHATICS, DISEASES. Lymphangitis, or inflammation of the lymphatic vessels, is generally associated with more or less inflammation of the lymphatic glands.

Etiology.—The most common cause is the absorption of septic or of infective products from a wound, which, however, is often very trivial, such as a simple scratch, abrasion, sting, or puncture; more rarely, the inflammation may follow upon mere irritation of the skin, as a chafe of the heel, excessive friction, or sunburn.

Pathology.—The walls of the lymphatics become infiltrated with cells, swollen, and softened, while the endothelium is shed and the lymph contained in the vessels often undergoes coagulation. The inflammation spreads to the surrounding tissues, but seldom higher in the course of the lymphatics than the first set of glands, which also become swollen and infiltrated and arrest the further absorption of the septic products. It may terminate in resolution, or in suppuration in and around the glands or, more rarely, around the lymphatics

themselves. Sometimes the septic products appear to escape the glands, and general blood-poisoning ensues.

Symptoms.—In severe cases lymphangitis generally begins with a chill or rigor, followed by high temperature and fever, and perhaps vomiting and diarrhea. Red lines, when the superficial lymphatics are affected, are seen running from the wound to the nearest lymphatic glands, with here and there erysipelatous patches of redness. There are generally pain and tenderness, especially in the region of the swollen glands, and swelling and edema, sometimes of the whole limb. It may be differentiated from phlebitis by the redness being superficial and in the course of the lymphatics, not in the course of the veins, by the absence of the cord-like and knotty feel of plugged veins, and by the presence of glandular enlargement; from erysipelas by the redness having no defined margin, and generally running in lines.

The treatment consists in attending to any wound or abrasion, allaying other sources of irritation that may be present, and placing the inflamed part at rest in an elevated position. Hot fomentations of poultices, or glycerin and belladonna, may be applied, and abscesses should be opened as soon as they form. If any swelling is left, pressure, or ammoniac and mercury plaster, may be used to disperse it.

Lymphatic varix, or lymphangiectasis, is very rare. It is attended by a condition of elephantiasis of the parts where the lymphatics are blocked. When the superficial vessels are affected, "the varix first appears in the form of small elevations, giving the skin an appearance which has been compared to the rind of an orange. It subsequently takes the form of little vesicles, covered with a thin layer of dermis" (Erichsen). At times the dilated lymphatics form distinct tumors (*lymphangiomata*).

Treatment.—Slight elastic pressure and protection from injury or irritation.

Lymphatic fistula, or lymphorrhea, though exceedingly rare, is a condition sometimes met, and more especially in the groin, scrotum, or labium. It is said to be due to a wound of a lymphatic or to the giving way of a varicose lymphatic, but the cause is not clearly understood.

Lymphadenitis, or inflammation of the lymphatic glands, may be acute, subacute, or chronic.

Acute or subacute inflammation of lymphatic glands is nearly always secondary to inflammation of the parts from which the afferent lymphatics proceed. Indeed, in most inflammations there is some tenderness of the neighboring glands. The lymphatic vessels themselves often escape, although the glands may become extensively involved, and even suppurate. The inflammation, however, rarely proceeds further in the course of the lymphatics than the first series of lymphatic glands, although it often spreads to the surrounding tissues (*perilymphadenitis*). The changes in the inflamed gland are like those of other inflammations. The whole gland is enlarged, the vessels dilated, and the lymph sinuses crowded with cells. Microorganisms similar to those found in the inflammatory lesions, giving rise to the lymphadenitis, have been discovered in the glands.

The symptoms are tenderness, heat, pain, and swelling, followed by redness of the skin and edema. The gland, at first movable, becomes fixed, and if the process runs on to suppuration, the usual signs of an abscess ensue. Familiar examples of lymphadenitis are seen in the **bubo** of gonorrhea, in the tender glands of erysipelas, and in the suppurating bubo of soft chancre. In from 2 to 3 weeks after the appearance of the chancroid, in the proportion of about 1 case in 4, a single lymphatic gland in the groin becomes swollen, painful, and tender; the overlying skin becomes red, edematous, hot, swollen, and inflamed; a soft spot appears upon the swelling, and after a little while there is decided fluctuation and an abscess is formed in the gland.

The treatment consists in subduing the inflammation of the part from which the lymphatics proceed, painting the glands with glycerin and belladonna, applying a hot poultice, and, if suppuration has occurred, in making a free incision. Some surgeons dissect out the glands if suppuration threatens. As soon as a bubo beings to swell and becomes tender, it is advised to charge a syringe with the 1 : 500 solution of corrosive sublimate or with a 3 percent solution of carbolic acid and to inject a few drops into the gland, repeating this in different portions of the diseased structure until 15 or 20 drops of the solution have been introduced. If this does not arrest the formation of pus, it will be necessary to wait, and when the pus is formed lay the abscess freely open.

Chronic lymphadenitis is very common in strumous children, especially in the neck. The affection of the glands can frequently be traced to some exciting cause, as the irritation of pediculi on the head, eczematous affections about the mouth, enlarged tonsils, or carious teeth. It also occurs as a result of chronic affection, especially of tuberculosis and syphilis. The glands slowly enlarge and become infiltrated with small round cells; while in the tubercular case nonvascular areas containing giant cells, lymphoid corpuscles, and tubercle bacilli are found. The enlargement may subside, or the inflammatory products may caseate, and suppuration occur in or in and around the gland; at times the caseous mass may dry up and become cretaceous, or atrophy or fibroid thickening may ensue. In rare instances, it is said, the tubercle may become disseminated, leading to general tuberculosis.

Symptoms.—The glands, when those of the neck (the most common situation) are affected, enlarge on one or both sides of the neck, but without pain. They are at first distinct and movable, but later often coalesce and become adherent to the surrounding parts. After a time they may soften and break down: the skin then becomes adherent and red, gives way, and a curdy pus is exuded. After the abscess has been opened, a portion of the broken-down gland may be seen in the floor of the ulcer, the edges of which are bluish-pink and undermined. The ulcers are very indolent,

and, when finally healed, leave characteristic raised, puckered, pinkish-white scars. Concomitant signs of struma or tubercle are frequently present.

Treatment.—Any source of irritation, such as pediculi, carious teeth, etc., should be sought and removed; and if the patient is syphilitic or tuberculous, specific treatment is indicated. If suppuration threatens, the glands should be removed. If an abscess has already formed, it should be opened early to prevent scarring. This may be done by a small incision, after which the capsule of the gland may be cleared out by a Volkmann's spoon. Should an indolent ulcer or sinus remain, as often happens if the abscess is allowed to burst spontaneously, it should also be scraped with a Volkmann's spoon and its edges destroyed by silver nitrate or potassium hydroxid or, better, excised. With good drainage established, Bier's suction glasses may be efficient. In some cases injection of iodoform emulsion or iodoform packing may be advantageous. If streptococci or staphylococci are found in the pus, autogenous vaccines may be of decided value.

Treatment of Tuberculous Glands.—The X-rays have been used with success. Bier's constriction hyperemia may be markedly beneficial. (The elastic bandage may be used at first, then if an abscess forms, after incising and evacuating, suction should be applied.) Tuberculin injections, the results of which seem very encouraging, should be tried. (See Tuberculosis.) If no improvement results in three months the bovine strain should be used. In adults and those with a family history of the disease the human bacillus is generally the cause, but in children the bovine type is usually found, due to milk infection. According to Ritchie, to the bovine type is generally due glandular, skin, and eye tuberculosis; to the human, bone and lung varieties. Another valuable remedy is guaiacol in the form of inunctions.

LYMPHATISM.—See Status Lymphaticus.

LYSIDIN (Methylglyoxalidin).—Lysidin is prepared by the interaction of sodium acetate and ethylendiamin hydrochlorid. It is a bright-red crystalline mass, very hygroscopic, and characterized by a peculiar mouse-like odor. It is sold in a 50 percent solution. Lysidin is recommended as a solvent for uric acid deposits, being given in doses of 1/2 and 2 1/2 drams of the 50 percent alkaline solution dissolved in an excess of carbonated water. It is claimed that lysidin possesses five times the power of piperazin.

LYSOL.—An antiseptic and disinfectant saponified product of coal-tar, chiefly composed of cresols, occurring as a clear brown, oily liquid, readily miscible with water, and forming clear solutions with glycerin, alcohol, chloroform, and various other fluids. It is generally employed in a 1 percent solution, and only as a local application. It is said to be superior to carbolic acid, creolin, and other analogous coal-tar products as a germicide, but it has no advantage over other antiseptics of established reputation, and is only efficient in solutions of sufficient strength to be irritating or caustic. It is useful to arrest epidemics or in prophylaxis, and is particularly serviceable in disinfection of privies, premises, ships, and stables, being readily soluble, active, and cheap. A solution of 1 : 1000 is said to destroy streptococci in 15 minutes.

LYSSA.—See Hydrophobia.

M

MACROGLOSSIA.—Hypertrophic development of the tongue, a condition seen in cretins, in whom it is probably due to lymphangioma. See TONGUE.

MADELUNG'S DEFORMITY.—This is a progressive forward (rarely backward) subluxation of the radiocarpal joint, due to relaxation of the ligaments or to disturbance in the growth of the radial epiphysis. Eighty per cent. of the cases occur in girls during adolescence. The lower end of the ulna is prominent, the radius often curved, and the hand usually adducted but occasionally abducted. Extension and sometimes flexion of the wrist are impaired. The treatment in the early stages is a retentive apparatus, *e. g.*, a leather cuff. At a later period tenotomy, reduction through an incision, or cuneiform osteotomy of the radius may be indicated (Stewart).

MADURA FOOT.—See MYCETOMA.

MAGNESIUM.—Mg; atomic weight 24.3; quantivalence II; specific gravity 1.75. One of the metals of the alkaline earths, widely distributed in inorganic nature and forming also a constituent of animal and vegetable tissues. The physiologic effects of its salts are antacid and laxative.

Therapeutics.—Magnesia and magnesium carbonate are used as antacids and laxatives, in acidity, sick headache, flatulent colic, etc., and as antidotes in poisoning by acids, arsenic, phosphorus, and mercuric and cupric salts. The citrate is an agreeable laxative, cooling and acceptable to the stomach. The sulphate (Epsom salt) is one of the most efficient of the saline cathartics, and has a wide field of application. In acute inflammatory conditions, renal and cardiac dropsy, ascites from obstruction of the portal circulation, increased blood-pressure within the cranium, intestinal obstruction without acute inflammation, the constipation of lead-poisoning, and habitual constipation from deficiency of the intestinal secretions, this agent will be found to be exceedingly serviceable. Acute dysentery is well treated by magnesium sulphate combined with diluted sulphuric acid, and followed by opium and starch enemata. Bleeding from hemorrhoids and uterine hemorrhage are often relieved by the same combination when other agents fail. In acne vulgaris and other obstinate eruptions due to derangement of the stomach and intestinal canal good results are often obtained by a purgative dose of the sulphate daily before breakfast or by doses of 5 grains in water 3 or 4 times a day. The same salt, finely triturated, makes an excellent dusting-powder for cases of acne rosacea. A saturated solution of magnesium sulphate, continuously applied, has beneficial influence on local inflammation, especially erysipelas and orchitis.

In heartburn:

℞.	Calcined magnesia,	ʒ ss
	Peppermint-water,	℥ jss
	Tincture of orange,	ʒ j.

Give at a draft.

In dyspepsia with acidity:

℞.	Magnesium carbonate,	gr. xx
	Compound infusion of gentian,	ʒ xj
	Compound tincture of cardamom,	ʒ j.

Give at a draft, twice daily.

In obstinate constipation:

℞.	Magnesium sulphate,	℥ ij
	Glycerin,	℥ j
	Water,	℥ iv.

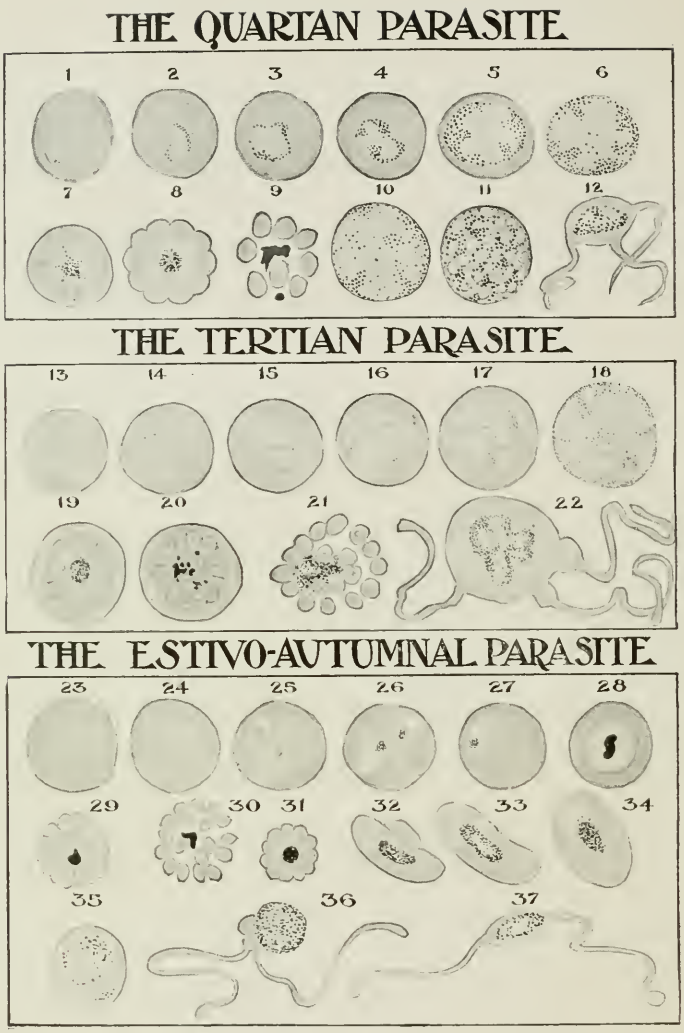
Use as a rectal injection.

Incompatible with *magnesium oxid* are: Acids, copaiba (forms a solid mass), water (in small quantity hydrates it). With *magnesium salts* are: Alkalies, arsenates, carbonates, lead acetate, lime-water, oxalates, phosphates, silver nitrate, sulphites, tartrates.

Preparations.—**M. Carbonas**—light, friable masses, or powder, odorless and tasteless, insoluble in alcohol, almost insoluble in water. Dose, 10 to 60 grains. **M. Oxidum,** *magnesium oxid, magnesia*—is made by heating the light carbonate in a crucible to expel nearly all the carbonic acid. A white, light and very fine powder, almost insoluble in water, insoluble in alcohol, and gelatinizes with 15 of water after standing 1/2 hour, having become hydrated. It is a constituent of pulvis rhei compositus, and ferri hydroxidum cum magnesii oxido. Dose, 10 to 45 grains. **M. Oxidum Ponderosum,** *heavy magnesium oxid, heavy magnesia*—is a white, dense and very fine powder, corresponding in other properties and reactions to magnesia, except that it does not gelatinize with water. It is made by calcining the heavier carbonate, and is much slower in action than the light magnesia. Dose, 10 to 45 grains. **M. Sulphas** (*Epsom salt*)—colorless prisms or acicular needles, slowly efflorescent, odorless, of cooling, saline taste, and neutral reaction, very soluble in water, insoluble in alcohol. Is a constituent of infusum sennæ compositum. Dose, 1 to 8 drams in plenty of water. **M. Sulphas Effervescens**—is prepared from the sulphate 50, sodium bicarbonate 40.3, tartaric acid 21.1, citric acid 13.6. A coarsely granular, white, deliquescent salt, of acid taste and reaction, soluble in water, insoluble in alcohol. Dose, 1 to 8 drams. **Liquor M. Citratis**—prepared from the carbonate 15, citric acid 33, syrup of citric acid 60, potassium bicarbonate 2 1/2, water to 360. Dose, 6 to 20 ounces, for catharsis.

MAGNET.—Strictly speaking, a magnet is a body having the power to attract the unlike pole of another magnet, or to repel the like pole, and

PLATE I.



DESCRIPTION.

Quartan 1, 2, 3, 4, 5, and 6, show the development from the hyaline form to the mature intracellular (6) and large extracellular (10) forms; 11 shows vacuolization of an extracellular form; 7, 8, 9, show segmentation stages; 12, the flagellate form.

NOTE.—In the tertian and estivo-autumnal organisms the same phases are shown.

NOTE.—

A. Relative depth of color in the erythrocyte host, deepest in the quartan, lightest in the tertian.

B. Comparatively coarse, scant, and dark granules of the quartan as compared with the tertian.

C. Tendency to shrinkage in the erythrocyte host of quartan *vs.* large pale host of tertian.

D. Peripheral arrangement of pigment in development stage of tertian and quartan followed by central grouping initiating segmentation.

E. Greater regularity in quartan as compared with tertian forms.

F. Relative number of segments.

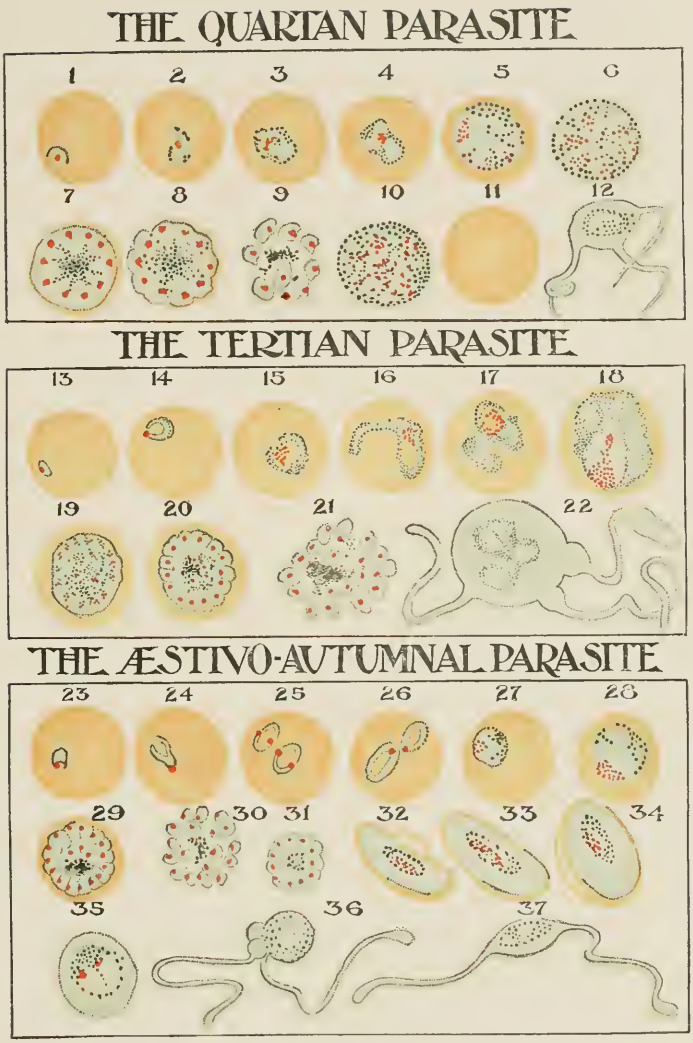
G. Greater density and clearer outline of quartan forms.

H. Star-like arrangement of pigment in early segmentation stage of quartan.

I. Relatively small flagellate forms of quartan and estivo-autumnal.

J. The peculiar ovals and crescents of the developed estivo-autumnal form, its scantily pigmented spherical form (35) and the ring bodies of the early stage.

—*Greene's Medical Diagnosis.*)



DESCRIPTION.

Malarial organism of types shown in plate but treated with Wright's stain.

Quartan Parasite.

1. Non-pigmented form.
2, 3, 4. Young organisms showing chromatin bodies (red) and pigment granules.
5, 6. Full-grown parasites, the former intracellular, the latter extracellular.
7, 8. Presegmentation forms.
9. Segmentation.
11. Normal blood cell.
12. Flagellate body.

Tertian Parasite. The forms are self-explanatory in connection with the preceding description.

Estivo-autumnal form. Various ring forms are shown together with the characteristic crescents, Nos. 32, 33, 34.

(In both this and the preceding plate the drawings are almost entirely based upon personal observation, though certain forms have been adapted from Thayer's valuable monograph.)—(*Greene's Medical Diagnosis.*)

also to attract easily magnetizable bodies. Lodestone, an oxid of iron, is a natural magnet. The electromagnet is a piece of soft iron temporarily magnetized by induction or by insertion into a helix. The electromagnet is used for locating and extracting foreign bodies, especially from the eye. See Eyeball (Injuries).

MALACOSTEON.—See Bone (Diseases).

MALARIAL FEVERS (Malaria). Synonyms.—Chills and fever; ague; fever and ague; swamp fever; intermittent fever; remittent fever; paludism; miasmatic fever.

Definition.—A specific infectious disease depending upon the presence in the blood of a protozoan parasite, the hematozoon or plasmodium malariæ of Laveran, which develops within, and at the expense of, the red blood-corpuscles of the infected individual, resulting, according to the species and number of the parasites present, in more or less periodic febrile paroxysms or in continued fever.

Distribution of the Disease; Climatic and Telluric Conditions under Which Malaria Prevails; Manner of Infection.—Malarial fever is especially prevalent in moist tropical districts, but occurs in almost all parts of the world, being absent only from the coldest regions. The most pernicious forms are seen in tropical Africa, India, South America, the East and West Indies; here the disease prevails throughout the year. In temperate countries malaria is most prevalent during the later summer and early fall. Moisture favors the development of the disease, which is particularly frequent in lowlands bordering upon rivers, lakes, and marshes; it is rare in mountainous districts. Drainage and cultivation prevent the disease, while extensive turning up of soil often gives rise to an outbreak. In malarious regions unaccountable cycles of variation in severity and frequency of the disease often occur. Mosquitos prevail in all regions and under all conditions favorable to malaria. The dark-skinned races are much less susceptible to the disease than are the whites.

The Manner of Infection.—The only mode of infection is through the bites of mosquitos belonging to the genus anopheles. The experiments and observations of Manson, Ross, Grassi, Bignami, and Bastianelli have shown that certain varieties of mosquitos are normal intermediate hosts of the hemameba malariæ, which undergoes a sexual cycle of existence, lasting about 10 days, in the walls of that insect's intestine. At the end of the period large numbers of sporozoids become stored in the cells of the salivary gland, from which they are introduced into the human body with the bites. In its human host the parasite reproduces itself asexually by sporulation. It breaks up into sporocytes each of which penetrates a red blood cell in which it grows and upon which it feeds. When mature it breaks into spores. Some of the sporocytes, however, are sexual cells, gametocytes, and do not break up into spores. If they gain entrance into the mosquito they reproduce themselves sexually. See Mosquitos.

The period of incubation lasts apparently from several days to several weeks.

The Infectious Agents.—The hemamebæ malariæ were discovered in 1880 by Laveran. They have since been shown to belong to the class of sporozoa, order of Hemosporidia. Three distinct species of the parasite have been differentiated: (1) The tertian parasite; (2) the quartan parasite; (3) the estivoautumnal parasite.

The first two parasites are associated with more or less regularly intermittent fevers; the last variety with fevers which may be regularly intermittent, but are more often irregular or continued.

1. **The Quartan Parasite.**—This organism exists in the blood in great groups, all the members of which are approximately at the same stage of development and pass through their cycle nearly in unison. The cycle lasts almost exactly 72 hours, at the end of which time the parasites which have reached maturity undergo sporulation, the fresh spores attacking new corpuscles. Sporulation of a group of parasites, if it has reached a sufficient size, is always associated with a paroxysm in the infected individual. The immediate cause of the malarial paroxysm is thought to be the liberation of some toxic substance, probably by the parasites at the time of sporulation.

Not infrequently 2 or 3 groups of parasites are present. When this is the case, they almost always reach maturity on different days, resulting in paroxysms on 2 successive days, with a day of intermission between, or in daily paroxysms. Very rarely the presence of multiple groups causes irregular or continued fever. In a triple quartan infection the disease assumes a daily or quotidian type.

In its youngest form the quartan parasite is represented by a minute, colorless disc, about 1 mm. in diameter, lying within the red corpuscle. This shows more or less active ameboid movements. As it increases in size the activity of the ameboid movements diminishes, and fine, dark pigment granules begin to develop. These show a lazy motion in the younger forms, but are almost motionless in the adult bodies. The pigment granules lie about the periphery of the parasite, the outlines of which are usually quite distinct. The red corpuscle tends to retract about the growing organism, and sometimes assumes a somewhat deeper, slightly brassy color. At the end of about 3 days the parasites reach a size about two-thirds that of the normal red corpuscle, while the rim of the retracted corpuscle becomes almost imperceptible. At this stage the pigment begins to collect toward a single point, usually at the center of the parasite, flowing in radial lines. The organism then breaks up into from 6 to 12 radially arranged leaflets, surrounding the central pigment like a roset. Finally, the surrounding shell of red blood-corpuscles ruptures and the separate segments spring apart, appearing as small, round, colorless bodies. These represent complete young parasites, and immediately attack new red blood-corpuscles, to pursue again their cycle of existence.

Not all adult bodies undergo segmentation. Some become vacuolated and fragmented, a process indicative probably of degeneration. From other full-grown bodies there are developed, at

times, actively motile filaments (flagella), which will be spoken of later.

2. **The Tertian Parasite.**—The tertian parasite, like the quartan, exists in the blood in great groups. Its life cycle, however, lasts but 48 hours, so that sporulation occurs every other day. Infections with 2 groups of organisms segmenting on successive days are common, the disease assuming a quotidian or daily type. Infections with multiple groups, causing irregular or continued fever, occur, but are rather uncommon.

The tertian parasite shows certain morphologic differences from the quartan organism. In the early stages the parasites are more actively ameboid; the pigment granules are smaller, more motile, and show less tendency to accumulate about the periphery of the body. The parasite is paler and less refractile, and at maturity reaches a larger size. The surrounding corpuscle expands with the growth of the parasite and becomes progressively decolorized. At segmentation the pigment does not flow in toward the center in such characteristic radial lines as in the quartan organism, when the number of segments is materially larger, ranging usually from 12 to 20 or even 30.

3. **The Estivoautumnal Parasite.**—This variety is responsible for the more serious, more chronic, malignant or pernicious forms of malaria. The estivoautumnal parasite differs from the tertian in that the regular arrangement in groups is less frequent. When this is the case at the beginning of an attack, multiple groups, as a rule, rapidly appear, resulting often in the development of irregular or continued fever. The parasite of estivoautumnal fever is smaller than the tertian or quartan organisms, and, as a rule, only the earlier stages are to be found in the peripheral circulation. The later stages and segmenting forms are to be found only in internal organs, especially the bone-marrow, spleen, or, in some pernicious cases, in the brain or intestine. The earliest stages are represented by very minute, colorless bodies, which often are sharply refractive, and frequently assume a ring-like appearance. Commonly, these ring-like forms show rapid transitions into disc-like or actively ameboid bodies. The amount of pigment contained is relatively slight, the earliest granules being so minute as to be almost imperceptible. At full development the parasites may be no more than half the size of a red corpuscle. Segmentation occurs in the same manner as in the tertian parasite.

A certain number of full-grown forms do not, however, segment, but accumulate larger, coarser, pigment granules, and develop gradually into an ovoid or crescentic shape, about which the rim of the red corpuscle may, with difficulty, be distinguished. Usually only a bit of red corpuscle is visible, hanging from the concave side of the crescent. At times these bodies may be seen to change into round forms with a central clump or ring of pigment.

The Flagellate Forms (Gametocytes).—In all three forms of parasites delicate motile filaments may develop from certain full-grown forms. In the estivoautumnal organism these come only from the round bodies derived from crescents. Their appearance is preceded by extremely active dancing movements of the pigment granules, after which suddenly from 1 to 4 of such filaments, 2 or 3 times the length of the diameter of a red cell, break out from the periphery. These are at first attached to the mother body, but often break loose and swim about with active serpentine motion. In several instances these bodies have been observed to penetrate other full-grown parasites. The significance of flagellate bodies has long been a question of dispute. The remarkable observations of McCallum, however, make it extremely probable that they are sexual elements, the penetration representing a process of fecundation. It is apparently only these fecundated bodies which are capable of undergoing further development within the stomach-wall of the mosquito.

Symptoms.—The symptoms of malarial fever differ according to the species of parasite with which the individual is infected.

Quartan Fever.—In infections with a single group of the quartan parasite the symptoms consist of regularly intermittent paroxysms occurring every fourth day at nearly the same hour. The paroxysm consists of 3 stages: (1) Chill; (2) fever; (3) sweating. The entire duration of the fever, which begins often before or during the chill, amounts to as much as 10 to 12 hours in severe cases. The chill varies greatly in intensity, and may be entirely absent, though chilly sensations are present in over 95 percent of the cases. This is followed by a sensation of extreme heat, which may last from but a short time to several hours. Both stages are often associated with severe headache, pains in the back and extremities, nausea, vomiting, and sometimes diarrhea. The febrile stage is usually succeeded by profuse sweating, the temperature rapidly falling, generally to a subnormal point, the patient experiencing great relief from all his symptoms. Between paroxysms the temperature is usually subnormal.

Infections with 2 or 3 groups of parasites following on different days, resulting in paroxysms occurring on 2 successive days, with a day of intermission between, or in daily paroxysms are common. Occasionally irregular or continued fever, as a result of infection with multiple groups of parasites, may be present.

Tertian Fever.—The paroxysms here occur every other day. Infections with 2 groups of tertian parasites are very common, resulting in daily paroxysms. Multiple infections with irregular fever are rare.

Tertian and quartan fever are the commonest types in temperate climates, and in the more severely malarious regions prevail during the healthy season.

Estivoautumnal Fever.—Estivoautumnal fever is the prevailing type in the severely malarial districts of the tropics, and occurs in temperate regions only at the height of the malarial season. The manifestations differ from those of tertian and quartan fever, (1) in that the paroxysms are, as a rule, much more irregular; (2) they are much

longer in duration; (3) the chills are more frequently absent; (4) the fever is often irregularly intermittent, remittent, or continuous in character, owing probably to the presence of multiple groups of parasites.

When the fever is regularly intermittent, the paroxysms occur usually about 48 hours apart; the intervals, however, may be as short as 24 hours, and in other instances longer even than 48. As a general rule, the longer the interval, the longer is the paroxysms, which may, in some instances, last more than 36 hours. When the fever is irregular and continuous and chills are absent, the clinical picture may closely resemble that of typhoid fever.

The spleen is enlarged in all forms of malaria, and in the majority of instances it is palpable. Herpes on the lips is common. Urticarial eruptions are occasionally seen.

Pernicious Fevers.—With severe estivoautumnal infections the malarial paroxysms may assume an extremely malignant, and often rapidly fatal, form. These intense infections are often referred to as "pernicious." There are several well-recognized types of pernicious fever.

The *comatose* type is the commonest. With the onset of the paroxysm the patient becomes profoundly unconscious. Local paralyses or irritative symptoms may be present.

In other instances the pernicious paroxysm may assume an *algid*, *choleriform*, *hemorrhagic*, *sudorific*, *bilious*, *gastralgic*, or *pneumonic* type. The picture in choleriform malaria may be similar to that in Asiatic cholera.

Malarial Hemoglobinuria.—The malarial paroxysm may be accompanied by hemoglobinuria. These instances are unusual, excepting in certain very malarious tropical districts. This extremely grave condition of paroxysmal hemoglobinuria is also known as **black-water fever.** The symptom usually arises in individuals who have had repeated attacks of malaria; rarely or never does it occur with the first manifestations of the disease.

Sometimes, if the first attack is not fatal, several successive paroxysms may be accompanied by hemoglobinuria. More commonly, however, the recovery from a hemoglobinuric paroxysm is followed by at least a temporary disappearance of the symptoms of malaria. This is probably due to the fact that with the extensive blood destruction the parasitiferous corpuscles are almost all destroyed, and the parasites, being set free, are killed. Often the hemoglobinuric attack is postmalarial. In all instances the onset occurs with an intense chill, rapidly followed by the passage of deep red and then almost black urine. If death does not occur during the immediate paroxysm, it may follow shortly afterward from complete suppression of the urine, or, after several weeks, from a severe acute nephritis.

Malarial Paroxysms with Long Intervals.—Cases of malaria may occur in which the paroxysms occur at long intervals—5 or 6 days to several weeks. These symptoms, which may occur with all 3 types of infection, are due to the fact that so many parasites are destroyed at the time of sporulation that practically a new incubation period must be passed through before the number is sufficient to cause symptoms again.

Sequels and Complications.—Relapses are frequent in ill-treated malaria. They may occur after long periods—months, and even years. There is no essential difference between the symptoms of the relapse and the initial attack.

Anemia.—Owing to the destruction of red blood-corpuscles, resulting from the growth of the parasite, anemia is a common sequel. In some instances it may assume a pernicious type.

Chronic Malarial Cachexia.—In patients with ill-treated or frequently recurring infections, a condition of grave cachexia sometimes develops. There are marked anemia, enlargement of the spleen and of the liver, and a tendency toward dropsical effusions.

Nephritis.—Acute nephritis may accompany or follow an attack of malarial fever, as of any other severe acute infection. The course is usually mild, though sometimes grave chronic changes may follow.

Amyloid degeneration has been noted after long-continued and frequently recurring malaria.

There is some evidence that **cirrhosis of the liver** may follow malaria. Its frequency, however, is probably much exaggerated.

Peripheral neuritis may occasionally occur.

Complications.—Mixed Infections.—Pneumonia, typhoid fever, tuberculosis, or any acute infectious disease may complicate malaria. An individual with malarial cachexia is probably more susceptible to most acute infections than a healthy subject. There is nothing especially characteristic about the course of these cases.

Pneumonia, as a complication of malaria, pursues its usual course.

In individuals with combined **typhoid** and malarial infections the malaria usually remains quiescent during the course of the typhoid fever, reappearing again with or after defervescence. Sometimes, however, active symptoms of the two diseases may be present at the same time. These instances are, however, unusual. *There is nothing to show that the course of typhoid fever in malarious districts differs in any essential way from that in other parts of the world.*

Pathologic Anatomy.—In individuals dead from acute malaria there is more or less marked pigmentation of all the organs. The **spleen** is always greatly enlarged and soft. The other changes depend upon the especial localization of the parasites, which varies in different cases. When the **brain** is especially affected, the capillaries are crowded with parasites, actual thromboses sometimes occurring. There may be numerous punctate hemorrhages. Finer degenerative changes in the neurons themselves have been described by Monti. In other instances the organisms seek especially the mucous membrane of the **stomach** and **intestines**, resulting in great injection of the mucosa with hemorrhage and superficial ulceration. The liver is enlarged, shows great numbers of parasites and macrophages in its capillaries, and often areas of focal necrosis not dissimilar to those seen in other

acute intoxications. Similar areas are to be found in the **spleen** and the **bone-marrow**, where great accumulations of parasites and pigment are also to be found.

In chronic cases the spleen is enormously enlarged and shows extensive fibrous changes. Similar changes are sometimes to be found in the liver and bone-marrow.

Diagnosis.—In most instances the diagnosis of malaria is simple, and based upon the nature of the paroxysms—chill, fever, sweating—and their characteristic periodicity.

Chills and fever, however, do not of necessity mean malaria and a positive diagnosis is only to be made by an examination of the blood and the discovery of the parasites. Examination of the blood is, perhaps, best made with the fresh specimen though the examination of dried and stained blood films, prepared according to the ordinary methods, is also satisfactory.

The disappearance of the symptoms under treatment with quinin is strong confirmatory evidence that the process is malarial.

In instances of continued or remittent fever the process may so far simulate typhoid that the distinction is impossible without an examination of the blood or the therapeutic test.

Prognosis.—In temperate climates the prognosis is almost always good. This is always true with tertian and quartan fever. In estivoautumnal fever there is always a certain danger that pernicious symptoms may appear.

Pernicious Malaria.—The prognosis, when pernicious manifestations appear, is always very grave. In the comatose cases death may occur a week or more after the beginning of treatment, when the blood is entirely free from parasites, a result, apparently, of the grave anatomic and chemic changes produced by the acute infection.

Hemoglobinuria.—The prognosis in hemoglobinuria, occurring with or after malaria, is always grave.

Prophylaxis.—Since extermination of the mosquitos belonging to the genus anopheles means the wiping out of the disease, attempts should be made to destroy the larvæ by disinfection (with kerosene) and drainage of the breeding places, and by removal of stagnant water. See DISINFECTION.

Mosquitos should be excluded from houses by wire netting. Careful screening of the malarial patient is important, in order to prevent infection of mosquitos. Exposure after nightfall should be avoided since the mosquito is chiefly nocturnal in its biting habits. Quinin has been proved to be of decided value as a prophylactic and 5 to 10 grains should be taken daily by new arrivals in malarial districts and also at intervals by the residents. Arsenic and iron are advocated by some observers as prophylactics; their value, however, probably lies in their increasing the quality and quantity of red blood-corpuscles.

Treatment.—In every case of acute malaria the patient should, if possible, be compelled to give up his occupation for at least 2 days. He should have physical and mental rest. If there is constipation, a purgative should be given. Medicinally, the treatment is simple and absolutely satisfactory, consisting in the administration of quinin. At present quinin or some salt of the alkaloid is used in malaria instead of preparations of cinchona, and the various methods of using this drug are described by Stitt as follows:

By Mouth.—This is the usual method and is the one to be preferred in all cases where other methods of administration are not necessitated. It is usual to give the quinin in capsules or cachets, the pills and tablets being often so hard that they do not dissolve in the alimentary tract. The method usually in vogue in military services is to give quinin sulphate in acid solution. This method is trying to the stomach.

By Subcutaneous Injections.—This method is liable to be followed by necrosis and abscess formation or fibrous indurations. Quinin and urea hydrochlorid is preferable either for subcutaneous or intramuscular injection. The present view is that subcutaneous injections deserve condemnation.

Intramuscular Injections.—Many prefer this method to the subcutaneous. It is best to inject the solution into the gluteal muscles above the ischial tuberosities. Of course in the use of quinin salts through the medium of the hypodermic needle everything must be aseptic and the skin of the patient painted with iodin.

Intravenous Injections.—Bass and many others think that when quinin cannot be administered by mouth it should be given intravenously. Not only is there the objection of inflammatory reactions or necrosis when the drug is given subcutaneously or intramuscularly but the absorption of the drug is so slow that the patient may die before we obtain the desired effect. Ross condemns the subcutaneous method and recognizes the advantages of the intravenous method over the intramuscular one when rapidity of action is desirable. In giving quinin intravenously Bass thinks that 10 grains at one time is sufficient and that a 20-grain dose is not without danger. When used in cerebral malaria he repeats the 10 grains intravenously in 8 hours if the drug cannot then be given by mouth. Bass thinks that theoretically amyl nitrite might relax the cerebral capillaries which are obstructed by parasite-infected red cells and thus enable the quinin in the circulation to reach such cells. The best known method of administering quinin intravenously is that of Bacelli. In this method 1 gram (15 grains) of a soluble salt of quinin is given in 10 c.c. of water. MacGilchrist has shown experimentally that such a strength of quinin (1 : 10) will coagulate blood serum. In Stitt's opinion this is a dangerous method and should not be used. There is no doubt as to the necessity for using the intravenous channel in cerebral or algid types of perniciousness when intramuscular injections do not give results. The generally accepted method is to use a salvarsan technic with a dilute solution of quinin, giving 1 gram (15 grains) of some soluble salt of quinin in 250 mils salt solution. MacGilchrist considers the very soluble acid salts as hemolytic and prefers to give quinin base—3 pints of a solution of the alkaloid, containing about 12 grains. Some authorities recommend the administration

per rectum of a soluble salt of quinin in about 3 times the usual dose by mouth or hypodermically. It is considered applicable in cases where there is marked vomiting. It certainly is the least satisfactory way of giving quinin.

Dosage and Length of Treatment.—In Panama the standard treatment is to give from 3 to 5 grains of calomel followed by 2 ounces of 50 percent magnesium sulphate. So soon as the diagnosis is made give 15 grains of quinin 3 times daily (45 grains in 24 hours) and continue such treatment for a week or until the temperature has been normal for 5 or 6 days. Then give 10 grains 3 times daily for 10 or 12 days. Tonics of iron, arsenic and strychnin are valuable in treating the anemia, but it is not advisable to add small doses of quinin to such tonic mixtures. In Nocht's method we give the quinin in small doses repeated several times in the day, as 3 or 4 grains given 5 or 6 times daily. Such treatment is thought advisable when there is a tendency to hemoglobinuria or when giving quinin to pregnant women. There is frequently hesitancy in giving quinin to pregnant women but unless the malaria is controlled the patient will be apt to abort. Potassium bromid is thought to control the ecbolic influences of quinin. In a benign malarial infection Manson prefers to wait until the hot stage has been passed and the patient is beginning to perspire, his idea being that the headache and other symptoms are aggravated and that very little advantage is gained by treatment during the early part of the paroxysm. He gives 10 grains at the onset of the sweating stage and afterward 5 grains, 3 or 4 times daily, for the following week. He then gives a daily tonic containing arsenic and iron, with a quinin treatment every seventh day for about 2 months. For regularity he advises the quinin treatment on Sunday giving a dose of salts in the morning followed by three 5-grain doses during the day. Manson notes the danger of large doses of quinin as producing not only serious disturbances of sight and hearing but pronounced cardiac depression as well. There are many who speak highly of Warburg's tincture in treatment. It is both laxative and sudorific. The dose is 1/2 ounce (15 mils) which contains about 5 grains of quinin sulphate and 4 grains of extract of aloes. As a rule, it is better to give the quinin and the laxative as such. More recently the tendency has been to give large doses of quinin, not only for its greater curative value but, as well, for the prevention of relapses. Craig, however, states that in his experience with estivoautumnal infections he has yet to see a single case, in which treatment was promptly instituted, that did not recover with a daily treatment of 30 grains.

Drugs Other than Quinin.—Salvarsan and neosalvarsan have been extensively used and with some success in benign infections but without material effect in malignant tertian ones. Some have thought that salvarsan aided the specific action of quinin. It has been claimed that radium and X-ray treatment, when directed to the spleen, assist the action of quinin. Methylene blue, next to quinin, has been considered as the most valuable drug. It is given in 2-grain doses every 4 hours. Surveyor has recommended picric acid in the treatment of malaria in doses of 2 grains 2 or 3 times daily. Recently hectin, a remedy somewhat similar to the cacodylates, has been strongly recommended by the French. It is given intramuscularly in 2-grain doses. It is said to be valuable when there is a leukopenia as it has a tonic action. It has been recommended to combine this treatment with quinin. It is said to be a good substitute for quinin in "blackwater fever."

Treatment of Hemoglobinuria.—The treatment of hemoglobinuria depends upon its relation to the malarial paroxysm. If acute malaria exists, as revealed by the presence of actual parasites, quinin should be administered intravenously or hypodermically. On the disappearance of the parasites it is advisable to reduce the quantity of quinin, continuing treatment as in any other case. If the parasite is absent, the case should be treated symptomatically—with rest and careful diet and tonics. Recrudescence of malarial paroxysms after an attack of hemoglobinuria should be treated in the ordinary manner. See BLACKWATER FEVER.

The treatment of the various sequels of malarial fever presents no special points.

Arsenic has a well-established reputation in the treatment of the grave **postmalarial anemias** and **cachexias.**

℞.	Arsenic,	gr. $\frac{2}{3}$
	Quinin,	gr. xl
	Reduced iron,	ʒij
	Extract of gentian,	q. s.

Make 30 pills or capsules. One pill or capsule after each meal.

The new arsenical compounds, especially sodium cacodylate, are recommended.

In some of these instances the removal of the patient to a healthy region where there may be no danger of a reinfection may be imperative.

MAL DE MER.—See SEA-SICKNESS.

MALE FERN.—See ASPIDIUM.

MALIGNANT EDEMA.—See GANGRENE.

MALIGNANT PUSTULE.—See ANTHRAX.

MALINGERING.—The feigning of disease. The simulation of various morbid conditions is common. There are many cases of professional malingering, principally encountered by street car, railroad and accident insurance companies. The surgeon of the army, or navy, or prison must especially be on his guard against malingering. In the voluntary and short service attempts are not so usual. Headaches, rheumatism, colic, diarrhea, and other more or less subjective affections are complained of. In continental armies, mutilation and resort to imitation of chronic diseases are comparatively common. To avoid conscription, an infinite variety of artifices is resorted to. Functional affections so closely simulate organic disease that suspicion is often disarmed. Hysteria or neurasthenia explains the greater number of cases, a deranged nervous system being responsible. In these cases the simulation may be

voluntary. In other cases the patient may voluntarily exaggerate symptoms or add new ones to those already present. In a third group of cases fraud is attempted, through some strong motive, by deliberate simulation of an injury or disease. Paraplegia, incontinence of urine, joint affections, in short, almost any disease which does not admit of palpable objective demonstration, may be feigned. A sudden shock, the pressure of poverty, or the absolute necessity for immediate exertion will often effectually and permanently arouse a bedridden hypochondriac of years, and restore him to usefulness and his friends.

When face to face with the deliberate malingerer, natural cunning must be overcome by the superior sharpness of science. Incontinence of urine, dysentery, hemoptysis, jaundice, and insanity are among the most favorite rôles of such persons. The yellow conjunctivæ of jaundice can hardly be feigned; incontinence of urine is often found attended by an expulsive effort; blood from the lungs is not always mixed with pulmonary mucus, and blindness, deafness, or paralysis are not always proof against some shock or mental impression. A blood test will determine whether an anemia is genuine or not. The X-ray will expose a feigned fracture. Skin lesions deliberately produced can be detected by the application of a fixed plaster-of-Paris dressing. Simulated cancer is readily disproved by microscopic examination. The stethoscope and absence of bacilli and fever will expose feigned tuberculosis. Epilepsy that is simulated may be detected by a hypodermic of apomorphin or a pinch of snuff. Feigned blindness and deafness may be discovered by special tests. See Blindness, Ear (Examination). Electricity may clear up apparently anomalous nervous symptoms; the stethoscope and sphygmograph record the actual condition of the heart. Administration of chloroform or ether will expose feigned contractures, wry neck, paralysis, as well as unconsciousness. Simulated unconsciousness, or anesthesia, may be detected by the electric current. Subjective sensations are hard to detect, and it is often well to give a patient the benefit of the doubt.

MALLEIN.—See Glanders.

MALLET FINGER.—See Baseball Finger.

MALPRACTICE.—A term applied to the treatment of a disease that is contrary to that taught by experience, or a failure on the part of a medical practitioner to use such skill, care, and judgment in the treatment of a patient as the law requires; and thereby the patient suffers damage. If due to negligence only, it is *civil malpractice.* But if done deliberately, or wrongfully, or if gross carelessness or neglect have been shown, or if some illegal operation (such as criminal abortion) be performed, it is *criminal malpractice.* See Abortion.

MALT.—The seed of common barley, germinated until the maximum amount of diastase, the ferment that converts starch into grape-sugar, is developed. It is nutritive and valuable also, for the diastase, which aids in the digestion of farinaceous foods. It is employed in wasting diseases, preferably mixed with milk. Many popular "foods" consist mainly of granulated extract of malt. **M. Ext.,** the soluble principles of malt, mainly diastase and glucose, in a concentrated form, unfermented. Dose, 1 to 8 drams. **M. Liquors,** fermented and clarified solutions of malt that have been subjected to vinous fermentation, hops being added to prevent acetous fermentation subsequently. *Beer* is made by a comparatively slow fermentation, and contains about 2.5 percent of alcohol. *Ale* and *porter* are fermented more rapidly, and contain about 4.7 percent of alcohol. The malt used in making porter is browned, giving the liquor a darker color. Malt liquors contain about 5 percent of albuminous matter, 2 of phosphates, and 1 of carbon dioxid.

MALTA FEVER. Synonyms.—Mediterranean Fever, Neapolitan Fever, Rock Fever, Undulant Fever. An endemic fever observed along tropic or subtropic sea coasts or river banks, of irregular course, with undulatory pyrexial relapses, profuse sweats, rheumatic pains, arthritis, and enlarged spleen. It occurs chiefly in the countries bordering on the Mediterranean Sea. A number of cases have been observed, however, in Porto Rico, Cuba, the Philippine Islands, etc. The disease attacks most frequently the young.

Etiology.—The cause of this infectious disease, the micrococcus melitensis, discovered by Bruce, is found in the spleen. It generally occurs singly, occasionally in pairs, or in chains, is aerobic and nonmotile, although according to some observers it has one or several flagella, and grows fairly well upon the ordinary media such as agar. Pale colonies are observed in about three days.

In most cases infection can be traced to goat's milk, but not always. Even mere contact with the infected goats or with their blood may transmit the disease. Laboratory infection seems to occur more readily with Malta fever than with glanders of plague. A case is reported in which the probable source of the contagion was the patient's habit of laying his cigarette from time to time on his work table.

Symptoms.—After an incubation period of about a week the disease develops gradually, the onset being marked by headache, anorexia, insomnia, and lassitude. The disease is of long and indefinite duration. The undulations of pyrexial intensity are the most constant and characteristic feature of the disease. Constipation, profuse perspiration, and frequent symptoms of neuralgic and of arthritic nature accompany its course. There is enlargement of the mesenteric glands. The spleen, too, is enlarged and softened after death, and many of the other organs are congested, but Peyer's patches are not enlarged or ulcerated, and ulceration is not present in other parts of the small intestine. There are no red spots.

Diagnosis.—The disease may be overlooked because of its infrequency. It may be differentiated from typhoid fever by the negative Widal test, by the study of the temperature chart, from malarial fever by the absence of the plasmodium of malaria in the blood and by the therapeutic

test. A most valuable means of diagnosis is the agglutination test—the serum of the patient's blood reacts upon fresh cultures of the micrococcus melitensis. The blood is allowed to stand for 24 hours, the serum pipeted off, and it is diluted to a given degree, say 1:11, with distilled water, or even 1:22, with normal saline solution, and added to some of the pure culture of the micrococcus. In distilled water the micrococcus retains its motility and does not clump for an indefinite time. With serum from a typhoid patient no reaction occurs. A control test should be made with normal blood serum from a healthy person.

Treatment.—The general measures indicated for typhoid fever are advised. An initial dose of calomel or castor oil should be given. Food should be liquid during the febrile period, and either the cold bath or pack used every time the temperature reaches 103° F. Symptomatic treatment is otherwise indicated. No drugs have any special influence on the fever. Serum therapy does not seem very promising. One case, however, is reported to have been cured by the administration of Malta fever antitoxin. During convalescence iron and plenty of nourishing food are indicated. A change of climate may promote convalescence.

MAMMARY ABSCESS.—See BREAST (Diseases).

MANGANESE.—Mn = 54, quantivalence II, IV. A silver-white metal having the general properties of iron. It is used in medicine and pharmacy in the form of oxid, sulphate, permanganate, and hypophosphite.

Therapeutics.—The salts of manganese in small doses improve the appetite and the digestion and stimulate the action of the heart. Potassium permanganate is a powerful oxidizing agent, and hence is actively antiseptic, disinfectant, and deodorant; but its germicidal power is limited. It is considered by some authorities to be an efficient emmenagog. Used internally, it is probably not absorbed in its own state.

The salts of manganese are used in amenorrhea, gastrodynia, and pyrosis, and in many skin-diseases and in jaundice. Manganese is becoming more of an acknowledged remedy in derangements of the menstrual function, as irregular or scanty menstruation, amenorrhea, menorrhagia, and even metrorrhagia. The best preparation is the dioxid, in freshly made pills of 2 grains each, of which 1 to 5 pills may be taken twice or thrice daily.

Potassium permanganate has generally been the preparation given when the effects of manganese were desired; but it is a difficult matter to get patients to take it for any length of time. It is employed as an antiseptic and oxidizing agent in such affections as diphtheria, scarlatina, septicemia, erysipelas, etc., in which it may be given internally and used locally at the same time. It is given with apparent benefit in dyspepsia, flatulence, lithemia, and obesity, and has often seemed to be of service in acute rheumatism. In amenorrhea it is reported to be very efficient, and has lately been used with success as a remedy for the bites of venomous serpents and for other animal poisons. For internal use the drug should be given in pill, as the taste of a solution is very disagreeable. Locally, it is frequently employed (1 dram to the pint) to correct fetor in cancer, ulcer, caries, abscesses, ozena, and it will destroy the odor of a foul breath or that of the fetid perspiration of the feet. It is used both as a test and as a corrigent for organic impurities in drinking-water. The stain left on fabrics may be removed by sulphurous acid, but, as sulphuric acid is formed in the reaction, the fabric should be immediately washed or rinsed in water. Potassium permanganate has lately come into use as an antidote against morphin or opium in the stomach. It exerts no oxidizing effect, in the presence of albumin, on atropin, hyoscyamin, hyoscin, caffein, cocain, aconitin, veratrin, pilocarpin, muscarin, or phosphorus (Murrell).

Preparations.—**M. Dioxidum Præcipitatum,** is chiefly manganese dioxid, MnO_2, with small amounts of other oxids of manganese, a heavy, fine black powder, odorless and tasteless, insoluble in water or alcohol, giving off oxygen gas at a red heat, and if heated with hydrochloric acid it causes the evolution of chlorin gas. Dose, 2 to 10 grains. **M. Sulphas,** colorless prisms, of slightly bitter and astringent taste and faintly acid reaction, very soluble in water, insoluble in alcohol. Dose, 2 to 6 grains. **Potassii Permanganas,** deep, purple-violet prisms, of sweet and astringent taste, neutral reaction, soluble in 16 parts of water with a scanty, brown residue, decomposed by alcohol and heating to 464° F. It should be kept in well stoppered bottles, and should not be triturated or combined in solution with organic or readily oxidizable substances. Dose, 1/2 to 2 grains in pill. For the **Hypophosphite,** see PHOSPHORUS.

MANIA.—A form of insanity marked by great exaggeration of nervous action. It may occur suddenly or follow an attack of melancholia. The patient presents an infinite variety of moods, is the subject of hallucinations and illusions, often shows a tendency to destroy what he comes in contact with, and is untidy; there is a marked change in character and decided insomnia. There is rapid and progressive emaciation. The brain is found to be in a hyperemic condition. The disease is probably due to a loss of the inhibitory action of the highest controlling centers of the brain. Mania is most common in young adult life. Heredity is a strong predisposing cause, while mental strain, bereavements, shocks, and alcoholism may act as exciting causes.

Varieties.—**Acute delirious mania,** typhomania, is a psychosis of sudden onset, attended with increased bodily temperature, and marked by delirium with sensuous hallucinations, marked incoherence, restlessness, refusal of food, loss of memory, and rapid bodily wasting, terminating frequently in death.

The term **menstrual mania** is often used for attacks of mania occurring at the menstrual epoch. Homicidal, suicidal, and various hysteric impulses are common.

Mania-a-potu is an attack of acute delirium during a debauch, or in those who have drunk

heavily and eaten little for a comparatively short time. See ALCOHOLISM.

Asthenic mania is mania in which there is a general anemia associated with neurasthenic symptoms. See HYSTERIA, NEURASTHENIA.

Dancing mania is a hysteric mental state in which, through sympathy and imitation, dancing of a most grotesque and extravagant character occurs. Usually epidemic.

Delusion mania is the result of fixed delusions, either causing or associated with the maniacal outbreak. See DELUSION.

Erotic mania, erotomania, presents systematized delusions of an erotic character, not necessarily accompanied by animal sexual desire.

Nymphomania is a morbid, irresistible impulse to satisfy the sexual appetite, peculiar to the female sex.

Epileptic mania follows an epileptic paroxysm, and is often of a most violent kind, the maniacal acts being of the most treacherous and malicious character. See EPILEPSY.

Hallucination mania presents visual, olfactory, and other sense hallucinations. See HALLUCINATION.

Homicidal mania is any variety of mental disease in which there is a desire or an attempt on the part of the patient to commit murder. The condition may be the result of delusions that the persons attacked either are persecuting or going to kill the patient, or of the excessive excitement that vents itself in destructiveness, combativeness, or desire to kill; or there may be a morbid desire, impulse, or craving to do murder, or the homicidal act may be unconsciously done during an acute delirium or a paretic or epileptic maniacal impulse.

Morphinomania is the insane craving for the stimulating action of morphin—a moral insanity. See OPIUM.

Puerperal mania is the maniacal outbreak occasionally seen in puerperal women. This is now thought to be of septic origin, although the mental strain through which the female has been passing is a predisposing factor.

Recurrent mania, or chronic mania, with lucid intervals of longer or shorter duration. Generally of alcoholic origin.

Transitory mania, or ephemeral mania, is a rare form of maniacal excitement, of sudden onset, violent and decided in character, accompanied by great insomnia, incoherence, and more or less complete unconsciousness of familiar surroundings. The attack as suddenly terminates, the duration being from a few hours to a few days.

Senile mania is the mental exaltation occurring in persons with senile arterial changes or senile cerebral atrophy. It is soon followed by dementia.

Prognosis.—In about 50 percent of the cases of acute mania not due to organic disease, the patients recover after periods varying from 1 month to several years. A fair proportion make a partial recovery and are able to return to their work, but always showing some alteration in character or affection or some eccentricity or a slight mental weakness. About 20 percent terminate in dementia or mental death, and this is always the fear in each case. Two percent die, either the result of exhaustion or from the organic condition causing or associated with the attack. The question of recovery, partial or complete, is always difficult to determine, depending upon the cause, temperament, disposition, education, nationality, and the normal mentality of the individual. Recovery is usually gradual; rarely sudden restoration occurs.

Treatment.—Persistent administration of drugs appears to have a deteriorating influence on the nerve-centers and their routine use is condemned. It is not advisable to restrain disorderly actions by mechanic means. The best measure to adopt in acute mania is to get the patient to be in the fresh air and work off as much excitement as possible by muscular exercise. Walking a patient about all day will often prove the best hypnotic, and sleep obtained in this way is more valuable than that procured through drugs. In acute cases forced feeding is sometimes necessary, and it is important that abundant nutriment be introduced into the system. Stimulants are often useful, and should be given with food. A dry tongue is an indication for pushing the administration of food and stimulants. Acute mania is with difficulty treated at home, and it is generally necessary to remove the patient from his home surroundings and sympathetic friends. Moral treatment is far more efficacious than drugs in acute mania. In acute delirious mania the great effort should be to produce sleep by various methods. Opium must not be given, as it may produce a slight narcotism for a short time only, and, if the dose is increased, narcotic poisoning and death ensue. Hyoscin finds its greatest and most useful application in maniacal violence and noisiness. Coniin, 1/2 to 3 minims, or 1/10 of a grain hypodermically, conjointly with morphin, is used in acute mania. Duboisin, 1/100 of a grain hypodermically; or 1/100 of a grain by the mouth, gradually increased to 1/30 of a grain of hyoscyamus, when there is no congestion; chloral and bromids, large doses of gelsemium, as 15 to 30 minims, stramonium, belladonna, daturin, veratrum viride, and camphor, cannabis indica, paraldehyd, and digitalis are variously useful. Tincture of iron chlorid, in 5- to 10-minim doses, is of benefit as a restorative in chronic mania. Croton oil, 1/4 to 1/3 of a minim, every hour, is used as a revulsive in mania from acute congestion of the brain. Cimicifuga is often efficient in puerperal mania or that of a pregnant condition. It may be necessary, to temporarily control violent cases, to employ chloroform by inhalation. The cold douche applied to the head while the patient's body is in a warm bath is of service in maniacal delirium. In congestive cases, ice may be applied to the head. Galvanism is also applied to the head and cervical sympathetic region in chronic mania. See DELIRIUM.

MANNA.—The concrete, saccharine exudation of *Fraxinus Ornus*, the flowering ash, and other trees. It contains from 40 to 90 percent of *mannit*, or manna-sugar, which does not undergo vinous fermentation, and is chemically allied to the alcohols and to glycerin. It also contains glucose, mucilage, some acrid resin, and a small

quantity of the glucosid, *fraxin*. There are no official preparations, but manna itself may be given in doses of 1 to 8 drams. Manna is a mild laxative, with some tendency to produce flatulence and colic. It is usually combined with other purgatives, as senna, rhubarb, and magnesia, to disguise the taste and increase the effect. It is a constituent of the official infusum sennæ compositum. Manna may be administered dissolved in milk.

MARASMUS (Infantile Atrophy; Simple Wasting).—The form of wasting termed marasmus is a nutritional disorder, and occurs independently of any constitutional disease, as tuberculosis or syphilis, in which diseases, of course, an extreme condition of wasting is seen.

Etiology.—Marasmus occurs in bottle-fed babies. It is rare in country children, and in those in the city who have good care and hygienic surroundings, but is common in dispensary practice, among the poor and neglected. The principal causes, therefore, are improper feeding, and lack of sunlight, fresh air, and healthful surroundings. Excepting the atrophied condition of the muscular system, there are no characteristic pathologic lesions. All the organs after death may be found in an apparently normal condition.

Symptoms.—The symptoms are those of starvation—the child steadily loses weight and strength. The eyes are large and sunken, the fontanels usually open, the skin becomes wrinkled and hangs from the bones in folds, and the child presents an old appearance. The appetite, which early may have been good, diminishes, and after a time becomes nearly lost. In other cases it is irregular, being ravenous at times. The bowels may be normal, but are more often constipated or irregular, and contain a large proportion of curds. Vomiting at times is a prominent symptom. The child is usually listless or apathetic. The temperature is generally subnormal (96° to 97° F. per rectum). Unless arrested by treatment, the course is steadily downward, death occurring from the extreme degree of malnutrition or exhaustion, or from an intercurrent disease.

The prognosis in a child under 6 months old is very unfavorable, and even while they are improved by treatment, relapses are likely to occur. Older children more frequently recover.

Treatment.—Hygienic treatment is important, and consists in daily bathing, massage with oil, warm clothing, and, if the temperature is subnormal external heat by hot-water bottles, etc.

In order to expand its lungs the child should be made to cry once or twice a day by mild flagellation or alternate hot and cold baths.

The principal treatment is the institution of proper feeding. When practicable, wet-nursing will be the best means of giving nourishment, but in cases in which this method cannot be used, a properly modified milk diet must be given. No set rules can be laid down for all cases, as the digestive powers will be found to vary, but generally a mixture, such as that given below, will be found to agree with a weak child 4 or 5 months old:

℞. Cream, Whey, Water,	each,	℥ j
Sodium bicarbonate,		gr. x
Milk-sugar,		1 teaspoonful.

This may be partially peptonized by adding extract of pancreatin, or peptogenic milk powder, and allowing to stand in a temperature of about 110° F. for 8 or 10 minutes. It should be given from a bottle every 2 hours, and as the child's digestive powers increase, the amount should be increased, and later milk substituted for the whey.

No medicines internally are of any use in marasmus, but any indications should be properly met, and it is well to begin the treatment by giving, for 2 or 3 days, mercury in small doses to clear out the intestinal tract.

℞. Mercury and chalk,		gr. ij
Sodium bicarbonate, Sugar of milk,	each,	gr. xij.

Mix and make 12 powders, and give 1 every 2 hours until 4 are taken, repeating daily for 3 days, and giving every morning following about 1/2 a teaspoonful of magnesia dissolved in milk or water.

The child should be weighed regularly, as this is the only reliable means of judging as to its progress. See INFANT FEEDING, MILK (Modified).

MARJOLIN'S ULCER.—An epithelioma developing from the edge of a chronic ulcer or an old scar. It is very painful and secretes a foul discharge. Late in its course the anatomically related lymph nodes become affected. Diagnosis may be made by excising a piece of tissue from the margin of the ulcer and examining it with the microscope.

Treatment consists in free extirpation of the diseased area together with removal of the associated lymph nodes; and, in advanced cases in which the diseased area is upon an extremity, amputation is demanded.

MARRUBIUM (Hoarhound).—The leaves and tops of *M. vulgare*. They contain a bitter principle, *marrubiin*, and a volatile oil. In small doses hoarhound is a mild stomachic tonic; in larger doses a laxative, diuretic, and diaphoretic. It exerts a soothing effect in catarrh of the nasal passages, and is, therefore, an ingredient of various cough mixtures. Dose, 20 to 60 grains.

MARSH-FEVER.—See MALARIAL FEVER, MALTA FEVER.

MARSH-MALLOW.—See ALTHÆA.

MASSAGE.—A method of effecting changes in the local and general nutrition, action, and other functions of the body by rubbing, kneading, and other manipulations of the superficial parts of the body by the hand or an instrument. A male operator is called *a masseur*, a female operator a *masseuse*. Persons skilled in massage should have a general knowledge of the superficial anatomy of the body and the position of the chief organs. Massage means treating the soft parts, muscles, organs, etc., only, while by Swedish movements is meant the movements of the joints, as flexion,

extension, adduction, abduction, pronation, supination, traction, etc.

Metzger, of Wiesbaden, divides massage into 4 principal manipulations:

1. **Effleurage (Stroking).**—(1) With palm of one hand, used on small surfaces. (2) With palms of both hands, used on large surfaces (is most generally used). (3) With thumb or thumbs, on tendons or between muscles or small surfaces. (4) With tips of fingers, on tendons or between muscles or small surfaces. Light stroking has a soothing influence on the system; heavy stroking has stimulating influence on the superficial structures, increasing the arterial, venous, and lymphatic circulation.

2. **Frictions (Firm Circular, Semicircular, or To-and-fro Motions.)**—(1) With one hand, used on small surfaces. (2) With both hands, used on large surfaces. (3) With thumb or thumbs, used on small surfaces, as the face, below the eyes, hand, around joints. (4) With tips of fingers, used on small surfaces, as the face below the eyes, hand, around joints. This manipulation reaches deeper than the former, to the subcutaneous connective tissue and fat overlying the muscles, its aim being to transform pathologically changed parts into a condition that will permit them to be incorporated into the healthy tissues by absorption by the veins and lymphatics.

3. **Pétrissage (Kneading or Pinching).**—(1) With two thumbs, used to get the effect upon a certain small localized area. (2) With thumb and fingers. (3) With two hands, used on large surfaces. (By pinching is meant the squeezing of the muscles between the fingers and the fleshy part of the palm.) The aim of this manipulation is to reach the separate muscles or groups of muscles; to reach as deep as possible; to cause circulatory, nutritive, and alterative changes in the soft tissues within reach—muscles, tendons, organs, etc.

4. **Tapotement (Tapping or Percussing.)**—(1) Clapping, used with palms of both hands. (2) Hacking, used with ulnar border of hands. (3) Pinctating or titillation, used with tips of fingers with a shoving motion. (4) Beating, used with clenched hand, with the ulnar edge, or with the knuckles. These manipulations are mainly used on muscular parts, as the back, back of legs, gluteal region, and well-developed subjects in general.

It is well known that the circulation at the surfact is not so active as that of the interior of the body; therefore in massage effleurage is applied first in order to warm the surface—to stimulate the blood and lymph changes, to remove the old epithelial scales, that the pores and sebaceous glands may be freed from matter which causes obstruction. The frictions which are next applied reach a little deeper. Pétrissage goes below the skin and fat overlying the muscles, and reaches the muscular structures the deep-lying organs. Tapotement imparts its stimulus to the deepest structures.

General massage is useful when the nutritive functions are to be extensively stimulated, when tissue changes in the different organs are to be promoted and the excretion of waste products increased.

Local massage accelerates the circulation in the blood-vessels and lymphatics and greatly increases the nutrition in the parts, promotes excretion, makes muscles firmer, and increases muscular power. It is of especial value in infantile paralysis, in cases in which splints or supports have been worn for a long time, in hysteric affections of the joints and limbs, and in long-standing paralysis.

Massage is applied to the abdomen in cases of atonic dyspepsia with flatulent distention. In constipation a course of kneading and rubbing throughout the length of the colon may lead to regularity of action, and is of especial value in cases of fecal accumulations. See CONSTIPATION.

MASSES (Massæ).—Pill masses are official under this name. There are two official masses:

Massa Ferri Carbonatis.—100 gm. ferrous sulphate; 46 gm. monohydrated sodium carbonate; 38 gm. clarified honey; 25 gm. sugar; syrup and distilled water, each q. s. Dose, 4 grains.

Massa Hydrargyri.—33 gm. mercury; 10 gm. glycyrrhiza; 15 gm. althæa; 9 gm. glycerin; honey of rose, 33 gm. Dose, 4 grains. See PILLS.

MASSOLIN.—A pure culture of the bacillus bulgaricus of Massol. The culture has the tendency to prevent the growth of pathogenic and pyogenic organisms. It is recommended in suppurative conditions.

MASTIC (Mastiche).—A concrete, resinous exudation from *Pistacia Lentiscus*. Alcohol dissolves about 90 percent, including the resin, *mastichic acid*, the remainder consisting of another resin, *mastichin*, which is soluble in ether and resembles copal. There are no official preparations, but mastic is an ingredient of the official Pil. Aloës et Mastiches. Dose, 20 to 45 grains.

Mastic was formerly used for supposed properties analogous to those of other oleoresins, but its application is now confined to dentistry, being employed as a temporary filling for carious teeth. A solution in ether is applied on cotton with moderate pressure, and remains as a firm plug after evaporation of the solvent.

MASTITIS.—See BREAST (Diseases).

MASTOID DISEASE, AND OPERATION.—See EAR (Disease of Middle).

MASTURBATION.—Production of the venereal orgasm by the hand. The evils arising from this habit have been generally exaggerated. With children, if there is any cause, such as an adherent prepuce, phimosis, or a very long foreskin, circumcision will generally effect a permanent cure. The operation makes a distinct break in the habit, and, combined with close supervision and good moral treatment, complete emancipation may be obtained. In girls cleanliness of the genital organs, with close supervision, may remove the trouble. With older girls only moral treatment will be of use. The practice is often a symptom of mental deficiency or the first indication of psychologic disturbance, and has too often been regarded as the cause instead of the result of insanity. Moral treatment failing, mechanic methods, such as tying the hands after undressing at bedtime, arranging so that the

patient does not sleep alone, or fastening a hard body, like an empty cotton-reel, over the spine, so that resting upon the back will be prevented, may be tried. Blistering the penis or labia is a severe measure, and, used alone, is not likely to be followed by any permanent benefit. Free purgation or regular emptying of the rectum, and the removal of thread-worms or anal irritation are not to be overlooked. Bad companions, filthy conversation, and impure literature are to be avoided. Open-air exercise, pushed to fatigue; plain, unstimulating food; and change of amusements and surroundings, will improve the physical tone. Drugs are not to be depended upon when there is a continual struggle between an unhealthy sexual appetite and a weakened will. Potassium bromid or sodium bromid, with potassium iodid, and cold baths, are occasionally used with benefit. Blistering of the occiput and upper cervical spine may be occasionally useful in allaying excitability of the sexual centers. It is a question whether warnings against the evils of the practice, of which nothing is known, will prevent or promote indulgence in it. Such warnings must be most judiciously administered to innocent and sensitive youths.

MATCHES, Poisoning by.—See PHOSPHORUS (Poisoning).

MATICO.—The leaves of *Piper angustifolium*, containing a crystallizable acid, *artanthic acid*, also resin, tannin, and a volatile oil. Its odor is aromatic, and its taste astringent, spicy and somewhat bitter. Dose, 1 1/2 to 1/2 drams.

Matico is an aromatic tonic and stimulant, also aphrodisiac, vulnerary and hemostatic. It acts like cubeb on the urinary passages, and is an excellent alterative stimulant to mucous membranes. It has been used with considerable success in mucous catarrhs, as gonorrhea, leukorrhea, and chronic cystitis, also in epistaxis, hemorrhoids, menorrhagia, hemoptysis, hematemesis and other hemorrhages. The under surface of the leaf is so formed as to promote coagulation of blood if applied to a bleeding surface, and is a good local hemostatic for trivial cuts or wounds.

Fluidextractum Matico.—Dose, 1/2 to 1 1/2 drams.

MATRICARIA.—The dried flower-heads of *Matricaria chamomilla*, German Chamomile. They contain 1/4 percent of a blue volatile oil, the color of which is due to *azulen*, also a bitter extractive, tannin, etc. There are no official preparations, but the flowers may be eaten or a decoction used almost *ad libitum* (average dose, 4 drams).

Matricaria is a mild tonic, in large doses emetic, anthelmintic and antispasmodic. It is much used in Germany, and in this country is a popular domestic remedy among German people, who use it in infusions as a diaphoretic. It is the *chamomilla* of the homeopaths.

MAXILLARY SINUS.—See NOSE (Accessory Sinuses)

MAY-APPLE.—See PODOPHYLLUM.

MEAL, TEST-.—See STOMACH-CONTENTS (Examination).

MEASLES (Morbilli; Rubeola).—An acute, infectious, highly contagious disease, characterized by a well-marked prodromal stage, with coryza and fever, followed by a characteristic eruption on the face and body. While probably due to a **microorganism**, the proof of this is wanting, as the specific germ has not yet been determined.

Measles occurs in wide-spread epidemics, being most common in the spring of the year. It is **contagious** from the time of the beginning of catarrhal symptoms, being most contagious during this period and while the rash is coming out. With the fading of the eruption and subsidence of the catarrh the communicability diminishes.

The duration of the infective period is about 3 weeks, or as long as the patient is desquamating or the cough remains. Children of all ages over 6 months are very susceptible to measles, and they usually contract it the first time they are fairly exposed to the contagion. Exceptions to this rule occur, some persons not having the disease, though exposed, until later life; others, notwithstanding exposure, never contract it.

One attack usually, though not always, confers immunity. Direct contact with a patient is usually necessary, the infection seldom being carried by a third person, or in fomites, the poison not having the power to cling long to clothing or apartments, as does that of scarlet fever.

The period of incubation is 7 to 14 days, and if 16 days, at the longest, elapses after exposure without the disease developing, the person may be considered safe from the attack.

The pathologic lesions of measles consist of a superficial inflammation of the skin and a catarrhal inflammation of the mucous membranes, including, in some cases, besides the conjunctiva and upper and lower respiratory tracts, which are so constantly affected, those of the middle ear, intestinal tract, and vulva as well. Sometimes in severe cases a pseudomembranous exudate is present in the throat.

Symptoms.—The prodromal or catarrhal stage is characterized by the symptoms of a "cold," with lacrimation and photophobia, coryza, and a hard bronchial or, sometimes, a croupy cough. The child is irritable and peevish. A somnolent condition is often present at this time, and in some cases a headache or earache is complained of. Rarely a convulsion marks the onset. The tonsils and fauces are usually congested, but not so severely as in scarlet fever. The cervical lymph-glands are in many cases enlarged early. The temperature during this stage is elevated, varying from 100° to 104° F., which increases until the rash is fully developed.

The symptoms mentioned, when occurring in a child, strongly suggest the probability of an attack of measles; and when on the second or third day there are seen on the hard palate papules of a dark purplish color, a diagnosis may safely be made without waiting for the eruption to appear upon the skin.

Koplik's spots—which are characteristic, minute bluish-white spots on a reddish punctate area—may be observed on the mucous membrane of the cheeks and lips, in the preeruptive stage of mea-

sles. They usually disappear when the skin eruption is at its height. The specks observed in thrush have a more yellowish center.

The eruptive stage usually begins on the fourth day, the rash appearing on the neck, forehead, trunk, and extremities, in the order mentioned, taking about 4 days to spread over these parts. The eruption consists of small papules on a slightly reddened base, and is never vesicular or pustular in character. The surface is covered in patches, which sometimes assume a crescentic shape, between which is seen the normal skin. The face, as a rule, is more generally covered than the other parts, and it has a swollen appearance, especially about the nose and eyes.

The rash remains for from 1 to 6 days—4 days on the average—and begins to fade on the parts first affected, while it may still be appearing elsewhere. By the fifth or sixth day of the disease the fever, cough, and other symptoms subside rapidly (their continuance after the rash is fully out would indicate some complication), and by the eighth or tenth day after the beginning of the prodromal symptoms the eruption, except for a mottled discoloration of the skin, which may remain for a few days or a week, has entirely disappeared, and in favorable cases convalescence is rapid. Desquamation of a fine, branny nature is usually seen following the fading of the rash.

The severity of measles markedly varies, some epidemics being quite uniformly of a mild, and others of a severe, type. Different individuals are also more or less severely affected, depending greatly upon the season of the year, the condition of the patient, and the surroundings and care. The severe cases occur more frequently among infants than among older children. In some instances there is no fever and the exanthem is trivial or even absent.

Complications and Sequels.—Bronchopneumonia is the most common complication. Catarrhal or sometimes membranous laryngitis, chronically enlarged lymphatic glands which are apt to become tuberculous, catarrhal or purulent otitis media, conjunctivitis, endocarditis, vulvovaginitis, and, especially in the summer months, intestinal disorders, as enterocolitis, are quite frequent. Keratitis and severe conjunctivitis occur among poor children and may persist for a long time. In many cases the health of the child remains impaired for a long time, and the danger of tuberculosis following measles in a delicate child should be remembered.

Diagnosis.—The fact that the patient has been exposed to the infection, or that there are other cases in the neighborhood, is always a valuable point in reaching a diagnosis in any of the contagious diseases. The marked coryza and dread of light, the erythema of the mouth and fauces, the presence of Koplik's sign, the quite uniform period of incubation, and the characteristics of the rash must all be considered. In certain mild or irregular cases a conclusion can be arrived at only after carefully weighing the symptoms as a whole.

The following table gives the principal points of difference in the eruptive diseases. See EXANTHEMS.

The prognosis in healthy children, under favorable surroundings, is good; but in tuberculous and wasted children, especially when there are serious complications and sequels, it may be of a grave or fatal character. Occurring before the fifth year, measles is a much more dangerous disease than after that age.

Treatment.—Infants and weak children should be carefully protected from exposure to measles. The patient should be isolated in order to prevent the spread of the disease. He should be placed in a large, darkened, well-ventilated room, the bed being protected from drafts by a screen, and when the laryngeal symptoms are severe, the air in the room should be kept moistened with steam. The patient should be kept in bed until the temperature has been normal for a week, and kept in the house for at least a week longer. Water or acidulated drinks, as weak lemonade, should be freely

	MEASLES.	VARIOLA.	VARICELLA.	SCARLATINA.	RUBELLA.
Incubation.....	10 days.....	12 days.....	17 days.....	4 days.....	12 days or longer.
Prodromes.....	3 days. Coryza, cough, etc. Koplik's spots.	3 days. Rigor, high fever, headache, lumbar pains.	A few hours or often none. Very slight.	24 to 48 hours. Angina, vomiting, rapid pulse, high fever.	A few hours. Slight catarrh, etc., usually enlarged cervical glands.
Character of eruption.	Bluish papules; swelling of face; discrete or confluent circular outlines.	Macules, papules, vesicles, and pustules; discrete or confluent.	Vesicles, discrete...	Erythema; scarlet color, confluent or punctate.	Papules; discrete or confluent in patches; rosy color.
Parts first affected.	Forehead, face, or neck.	Forehead.....	Face, scalp, or shoulders.	Neck, face, and chest.	Face.
Desquamation....	Furfuraceous.....	Large crusts.....	Small crusts.....	Lamellar.....	Slight, furfuraceous.
Duration.....	7 to 10 days.....	3 weeks.....	1 week.....	7 to 10 days.....	1 week.
Complications and sequels.	Eye and lungs; tuberculosis.	Larynx and lungs..	.....	Kidney, ear, and heart.	

given, as the thirst is usually great. The diet during the febrile stage should be liquid, milk being the best. There are no remedies which will cut short the attack. The treatment is symptomatic and directed toward making the patient as comfortable as possible and protecting against complications. When the case is first seen, an enema or a mild laxative, such as castor oil, to act upon the bowels, is beneficial, being careful, owing to the irritability of the intestinal tract, not to produce too marked an effect in this direction.

For the bronchial cough and the fever, the following mixture is very useful:

℞. Potassium citrate, ℥ iv
Lemon-juice, ℥ j
Camphorated tincture of opium, Syrup of ipecac, each, ℥ ij
Syrup of tolu, q. s. ad ℥ iij.

Give 1/2 to 1 teaspoonful every 2 or 3 hours.

When there are nervous symptoms, manifested by headache, restlessness, etc., phenacetin or acetanilid, 1/2 grain for each year of the child's age, given every 3 or 4 hours, will give relief.

The eyes should be bathed 2 or 3 times a day with a solution of boric acid (10 grains to the ounce) or with the following:

℞. Mercuric chlorid, gr. 1/100
Zinc phenolsulphonate, gr. iij
Boric acid, Sodium chlorid, each, gr. xv
Aqueous extract of hamamelis, ℥ v
Camphor-water, Distilled water, each, ℥ jss.

Vaselin rubbed on the edges of the lids in the evening will prevent the eyelids from becoming glued together during the night.

For the coryza:

℞. Menthol, gr. x
Liquid albolene, ℥ j.

Apply 2 or 3 times a day in the nares with an atomizer or with a piece of cotton wrapped on a probe.

From the beginning of the attack until desquamation has ceased, a warm bath (95° to 100° F.), followed by inunctions of cacao-butter, should be given daily; and when the temperature is high, sponging the body with cool or tepid water and alcohol, as in other febrile affections, may be safely practised.

The period of convalescence should be carefully watched, and the child allowed plenty of fresh air, but should be guarded against exposure to cold or damp weather.

Creosote and cod-liver oil should be given when there is a tendency to tuberculosis or when a cough remains.

MEASLES, GERMAN.—See Rubella.

MEASURES.—See Weights and Measures.

MEAT.—See Beef.

MEATUS, URINARY.—See Urethra.

MEDIASTINUM, DISEASES.—The mediastinum is the space in the thorax between the pleural sacs, divided into 2 parts: the anterior, situated before, and the posterior, behind, the heart. In the anterior mediastinum are the remains of the thymus gland and the origins of some of the hyoid and laryngeal muscles. It is narrowed at the center, and in the lower part there is some areolar tissue, together with the left triangularis sterni muscle. The posterior mediastinum is larger than the anterior, and contains the aorta, the vena azygos, the thoracic duct, the esophagus and its nerves, the trachea, the splanchnic nerves, and some lymphatic glands. A middle mediastinum is sometimes described, containing the heart and the origin of its great blood-vessels, with the bifurcation of the trachea.

Emphysema of the mediastinum is the presence of air in the cellular tissue thereof, and sometimes exists apart from emphysema of the neck. It has been found in fatal cases of diphtheria in which tracheotomy has been performed.

Inflammation of the mediastinum gives rise to 2 prominent symptoms: dyspnea and severe pain referred to the poststernal region. Physical examination does not render much aid in diagnosis. In most cases of abscess in the anterior mediastinum some history of a cause is obtainable. If not, it is very difficult to distinguish between it and an aneurysm.

Surgical treatment, to open the abscess and establish drainage, is imperative. The inflammatory action is liable to spread, and to involve the lungs or the pericardium.

New Growths.—Almost every form of morbid growth has been encountered in the mediastinum—cancer, sarcoma, osteosarcoma, enchondroma, lymphadenoma, fibrous tumors, steatoma, lardaceous and tubercular masses, and syphilitic gummata. The growth of some is more rapid than that of others, and constitutional symptoms are more pronounced in some than in others. The duration of malignant intrathoracic growths is rarely more than a year. The more prominent symptoms are the cardiac, and the development is inward rather than outward, and only rarely do the chest-walls become eroded. Derangements of the circulation give rise to phenomena of diagnostic importance. It is not from pressure alone, but also from involvement of the vessels themselves, that the symptoms arise. Hemoptysis, sanguineous effusion into the pleura, and infarcts are frequent. Febrile disturbances are not marked, if at all present, at any time. Disturbances of innervation vary in severity and in character. Neuralgic pains are very common. Cough is either reflex or from bronchial irritation. Respiratory phenomena range from paroxysms of dyspnea to orthopnea.

Treatment.—Palliation of the most urgent symptoms is demanded. Bodily rest, freedom from moral disturbances, maintenance of general nutrition, change of air and hygienic conditions, are essential. Certain symptoms call for special treatment, such as counterirritation, sinapisms, and small blisters for pain. Opium, chloral, potassium bromid, and minute doses of antimony may alleviate the distress. Chlorodyne, Hoffmann's

anodyne, and chloroform inhalations are often useful. Paracentesis may be resorted to, and iodin, chalybeates, and other constitutional methods may be employed.

MEDICINES, ADMINISTRATION.—Medicines may be introduced into the circulation by various routes, including the mouth, the stomach, the rectum, the respiratory tract, the veins and arteries, the subcutaneous cellular tissue, and the integument.

The mouth is the usual receptacle for medicines intended for the stomach, but may itself be employed for the introduction of minute quantities of powerful agents. A drop of the tincture of aconite placed on the tongue is quickly absorbed and soon manifests that fact by its symptoms. Many of the small tablets used for hypodermic administration, if placed under the tongue, are readily conveyed into the system, and, used in this way, form a very convenient means of medication with alkaloids and other active principles.

The stomach is the most convenient organ for the absorption of medicines and the one most frequently employed. After having been swallowed, the remedies find their way into the current of the circulation through the walls of the gastro-intestinal blood-vessels and the lacteals. When the stomach is empty and its mucous membrane healthy, crystalloid substances in solution pass rapidly through the walls of its vessels. *Colloid substances* (fats, albumin, gum, gelatin, etc.) require to be digested and emulsified before they can be absorbed. *Iodin* and *iodids* should be given on an empty stomach, so that they may diffuse rapidly into the blood; if administered during digestion, the acid gastric juice and the starch of the food will alter their chemic constitution and weaken their action. *Acids* should be given, as a rule, on an empty stomach, especially when they are intended to check the secretion of the acid of the gastric juice. *Alkalies*, of which sodium bicarbonate may be taken as the type, are given after meals to neutralize excessive acidity, and before meals to stimulate the acid gastric secretions. *Silver oxid* and *silver nitrate* should be administered after the digestive process is ended; if given during digestion, chemic reactions destroy or impair their special attributes and defeat the object for which they were prescribed. *Metallic salts* (especially corrosive sublimate), also *tannin* and pure *alcohol*, impair the digestive power of the active principle of the gastric juice, and should only appear in the stomach during its period of inactivity. *Malt extracts*, *cod-liver oil*, *phosphates*, etc., should be given with or directly after food, so that they may enter the blood with the products of digestion. *Bismuth* should be given before meals, as it is usually employed for its local sedative action on the gastric mucous membrane. *Potassium permanganate* should be given after meals, for in an empty stomach it would irritate the mucous membrane and might possibly produce ulceration thereof. *Arsenic*, and other irritant and dangerous drugs (the salts of copper, zinc, and iron), should be given directly after food, except when local conditions require their administration in very small doses on an empty stomach. *Morphin* by hypodermic injection should only be given when the patient is lying down, unless previously habituated to its use. *Pilocarpin*, administered to produce sweating, should be given when the patient is in bed in a warm room. *Ammonium acetate* acts as a diaphoretic when the recipient is warm in bed, but as a diuretic when the patient is in a cold atmosphere. *Sulphonal* should be given 2 or 3 hours before its hypnotic action is desired, as it is very slow of solubility and absorption (Potter).

Under some circumstances it becomes necessary to introduce medicines directly into the stomach, as in case of the patient's inability to swallow, through narcotic poisoning or other causes. The stomach-pump or the stomach-tube may then be employed to convey both food and medicine to that organ. In obstruction of the esophagus, as from stricture or malignant disease, it may become necessary to make an opening through the abdominal wall and the wall of the stomach itself. Nasal feeding, by the use of a soft catheter with a hard-rubber funnel inserted into its end, is a very efficient method of conveying liquids into the stomach. The eye end of the catheter is oiled and passed gently along the floor of the nose and down the pharynx, the fluid being then poured into the funnel. In many cases, especially insane ones, the patient will so constrict the muscles of the throat as to force the catheter into the mouth; but if it is withdrawn until nearly out of the pharynx, the presence of the fluid as it drops down will excite swallowing, and the patient may be fed as well as if the tube were in the esophagus. This method is particularly serviceable in cases of acute tonsillitis or other painful affections of the mouth and palate also after excision of the tongue, when swallowing is to be avoided as much as possible. See GAVAGE.

The rectum will absorb many substances applied in the form of enemata or suppositories. Those most suited to this route are the salts of the alkaloids in solution, especially those of morphin, atropin, and strychnin, the latter being absorbed more rapidly by the rectum than by the stomach. Acid solutions, if not too frequently repeated, are well administered by this channel. Nutritive enemata must be small, not exceeding 3 or 4 fluid-ounces, or they will not be retained. They become necessary in many cases, especially in cases of gastric ulcer, in order to afford rest to the stomach. It is often found advantageous to have the food predigested before being administered by the rectum, for which purpose pancreatin is used. See SUPPOSITORY, ENEMA.

The respiratory tract admits of the rapid absorption of medicinal substances through its extensive blood-supply. The inhalation of vapors or atomized fluids, the insufflation of powders into the nares, fauces, larynx, etc., and the use of a medicated nasal douche, are methods whereby this channel may be utilized. See INHALANT, HYPODERMIC MEDICATION, INTRAVENOUS INJECTION, INUNCTION, etc.

MEDULLARY ANESTHESIA.—See INTRASPINAL ANESTHESIA.

MEGRIM.—See Migraine.

MEL (Honey).—The substance deposited in the honeycomb by the common honey-bee, *Apis mellifica*, and a few other hymenopterous insects. It consists of a solution of cane-sugar and grape-sugar, with coloring and odorous matters. It is emollient, nutritive, and often laxative, its properties depending mainly on the character of the flowers from which it is taken. It is an excellent vehicle for expectorant gargles, etc. In pharmacy **mellita**, or **honeys**, are thick liquid preparations closely allied to syrups, but having honey as a base. There are three official honeys: **Mel**, **Mel Depuratum**, clarified honey, prepared by heating, skimming, and straining the natural product. **M. Rosæ**, honey of rose; fluidextract of rose 120, clarified honey to 1000. It is used locally as a gargle.

MELANCHOLIA.—A form of insanity characterized by depression of spirits and gloominess, without any adequate cause, the central idea being one of personal unworthiness. As the case develops, delusions, associated with illusions and hallucinations, appear, and the patient may at times show suicidal tendencies. The general nutrition suffers, and in females menstruation is usually suppressed. The usual age at which melancholia appears is during middle life. It follows any depressing cause, acting in conjunction with a strong hereditary tendency. It usually terminates in recovery, but some cases develop into dementia or mania, while others die from exhaustion or commit suicide.

Treatment.—It is generally useless to argue with a patient about the folly of his delusions or hallucinations. Removal of the condition of the brain upon which the morbid feeling depends is important. The first indication is to improve the general health and restore the exhausted nerve force by fresh air, good food, and tonics. Foreign travel is often highly efficacious, but a quiet rest at a health resort is as beneficial in most cases. Removal to an asylum is often productive of great benefit, the orderly, settled life and discipline being efficacious. Refusal to eat is often difficult to treat. It may be necessary to resort to forcible feeding 2 or 3 times daily with milk, meat-extracts, liquid custards, etc. Attention to the gastro-intestinal canal is of the greatest value, as the dyspepsia and constipation of melancholic patients are the greatest barriers to their recovery. Frequent bathing, with friction to the surface, aids in the eliminative action of the skin. Such tonics as quinin sulphate, arsenic, iron, and strychnin sulphate are all of value in building up the patient. As the strength improves, open-air exercise must be added to the other means used. Insomnia must be combated by evening bathing and feeding, and the use of trional, sulphonal, or hyoscin at bedtime. When stupor is present, the effect of the continuous electric current is often markedly beneficial.

MELANEMIA.—See Blood.

MELANODERMA or **MELASMA.**—See Chloasma, Suprarenal Disease.

MELENA OF THE NEW-BORN.—A greater or less amount of blood in the stools of children is not rare, and its presence may be due to blood having been swallowed with the milk, or from lesions in the nose, mouth, or throat. It may come from the large intestine, as in dysentery, when it is red and fluid, or from an ulcer of the stomach or small intestine, when it is black and tarry in appearance. True melena of the new-born, however, is a rare disease. It is more common in hospital cases than in private practice, occurs the first 2 weeks of life, usually the second or third day, is apparently self-limited, when recovery takes place, the course being 5 to 9 days, and after death no lesion may be found in the gastrointestinal tract to account for the hemorrhage. For these reasons it is thought to be of an infectious nature, but further than this the etiology is not known.

Symptoms.—When the hemorrhage is considerable, the child will become suddenly pale and present the symptoms of collapse. The bowel movements will consist of thick, dark blood, and may follow one another in rapid succession, the later ones consisting of bright blood. When the amount of blood lost is slight, it may be discovered only when the napkin is changed, and the little patient will retain a normal appearance. A rise in temperature (101° to 103° F). during the attack has been noticed in all cases. The hemorrhage may recur for several days, and the child is worn out by the excessive loss of blood and becomes emaciated and dies, or, when recovery takes place, convalescence is likely to be long and troublesome. The mortality rate is given as 50 to 80 percent.

Treatment.—Food should be given cold. The infant must be kept absolutely at rest, and if the body and extremities are cold, hot-water bottles should be placed about it. Morphin in minute doses, 1/1000 to 1/500 of a grain hypodermically, or 1 drop of paregoric by the mouth, may be necessary to quiet the child. One-drop doses of spirits of turpentine suspended in mucilage, given every hour, seem to have a controlling influence on the hemorrhages.

In other cases 1-drop doses of chlorid of iron have given good results. Ergotin, in 1/2 grain doses by the mouth or hypodermically, should be tried.

MEMORY, LOSS.—See Amnesia.

MÉNIÈRE'S DISEASE.—The symptom complex known as Ménière's disease is probably the result of a morbid process in the labyrinth or auditory nerve endings. It is characterized by excessive vertigo, loud tinnitus aurium, nausea, vomiting, and other phenomena. The symptoms appear at first in distinct paroxysms, ushered in by a shrill ringing in one ear, followed by pronounced dizziness. Consciousness is impaired; the skin is pale and cool, and the face is bathed in cold perspiration. The first paroxysms are of brief duration, but they may persist for years until overcome, or deafness is complete on that side.

This affection is not to be confounded with epilepsy or apoplexy. The sudden onset of the paroxysm, and the complaint of vertigo, together with ear symptoms, lead to a certain diagnosis.

Treatment.—The following remedies have been

used: Quinin, 5 to 10 grains; bromids, 30 grains; salicin or salicylates, 30 grains; digitalis, 10 minims of the tincture every 4 or 8 hours, along with counterirritation behind the mastoid, and by the continuous current. Pilocarpin, 1/8 grain or less, and ammonium bromid with ammonium chlorid, 15 grains of each, have given relief. Sometimes air charged with chloroform vapor, injected into the eustachian tube, dispels the discomfort.

MENINGITIS.—Inflammation of the membranes of the brain. The several varieties are considered below; and see CEREBROSPINAL MENINGITIS.

Pachymeningitis

Inflammation of the dura; when the external layer is primarily involved, it is termed external pachymeningitis; when the internal layer is primarily involved, it is termed internal pachymeningitis.

Etiology.—External pachymeningitis is a surgical malady, induced by fractures, penetrating wounds, and other injuries of the skull. Internal pachymeningitis is due to blows upon the head without injury to the skull. A predisposition may be created by chronic alcoholism, scurvy, nephritis, and syphilis. Chronic internal otitis and suppurative inflammation of the orbit, and inflammation in the venous sinuses, the result of a thrombus undergoing suppurative changes, may be causes.

The symptoms are very obscure, and are principally those of cerebral pressure. Persistent headache, vertigo, photophobia, anorexia, insomnia, gradual impairment of intellect and locomotion, followed by delirium and convulsions and coma, or by apoplectic attacks and paralysis, are suggestive signs in the aged, or those in whom some one of the causes of pachymeningitis is present. Circumscribed painful edema behind the ear and less fulness of the jugular of the corresponding side are indicative of thrombosis in the transverse sinus.

Diagnosis is always problematic, as the symptoms are masked.

Prognosis is most unfavorable for either form, although the course of the malady is usually slow. Surgical treatment in traumatic cases offers some hope.

Treatment.—External pachymeningitis should be treated surgically. Trephining is indicated in some cases. It is claimed that benefit has followed a thorough course of potassium iodid. In the great majority of cases, however, all that can be done is to treat the distressing symptoms. See BRAIN (Inflammation).

Simple Acute Meningitis

Under simple acute meningitis are classed those cases of inflammation of the pia not due to a specific organism, such as the tubercle bacillus. The affection is most common in children.

Etiology.—Meningitis may follow traumatism of the skull and sunstroke. It also occurs secondary to the infectious diseases, such as pneumonia, scarlet fever, variola, influenza, acute nephritis, or rheumatism, and may result from purulent otitis media, caries of the small bones of the skull, or erysipelas of the head. Some cases are idiopathic, the cause not being apparent.

Pathology.—The cerebrospinal fluid is increased in quantity, and there is an inflammatory condition of the pia, also of the dura and the gray matter of the brain. When the disease continues for a considerable length of time the membranes become thickened, and the pia becomes adherent to the cortical substances. The inflammation may be nonpurulent, but in severe cases pus is found in the pia, the subarachnoid spaces, and over the convolutions of the brain. When recovery takes place the exudate is absorbed, but the membranes may remain thickened and adherent.

Symptoms.—The disease usually comes on gradually, and is indicated by a feeling of malaise, headache, nausea, and vomiting, which symptoms may continue for several days. The vomiting occurs independently of taking food, and, although it is so persistent, it may be associated with a clean tongue. The bowels are, as a rule, constipated. The patient becomes listless, apathetic, and drowsy, and may have a convulsion. Later, there are restlessness, delirium, and, finally, coma; the back of the neck is stiff, and there may be opisthotonos, repeated convulsions, or paralysis. The eyes are set, and optic neuritis may give rise to blindness. There is loss of control of the bladder and rectum. The temperature varies from 101° to 104° F., but there may be hyperpyrexia (106° or 107° F.). The pulse, which at first is very rapid, becomes irregular and slow. In unfavorable cases the symptoms all increase in severity; the coma is deepened, and the respiration becomes of the Cheyne-Stokes character, ending in death. On the other hand, when recovery is to take place, the symptoms remain stationary for a time after the comatose stage is reached, then gradually abate, and consciousness and improvement slowly follow.

The course of the attack is from 4 to 12 weeks.

The prognosis is always grave, and when recovery occurs, there are frequently left traces of the disease, such as blindness, paralysis, speech-defects, or a defective intellect.

Diagnosis.—It is important not to confound true meningitis with the **pseudomeningitis,** which is a purely nervous or toxic condition, occurring with digestive disturbances or with the infectious diseases, as influenza, pneumonia, or the exanthems, and which in children so frequently give rise to grave cerebral symptoms.

Tubercular meningitis is differentiated by the fact that in this affection there are usually prodromes, intermissions in the temperature, an irregular course, perhaps a longer duration, and a greater tendency to coma. The family history and diathesis of the child will give valuable information. An error is easily made, however, in these cases, and the prognosis must therefore be guarded.

In **cerebrospinal meningitis** the onset is more sudden, the course shorter, there may be an eruption on the skin, and it usually occurs in more or less wide-spread epidemics. See CEREBROSPINAL MENINGITIS.

When the diagnosis is at all doubtful, lumbar puncture should be resorted to.

Treatment.—The patient should be kept in a darkened, absolutely quiet room, attended by a careful and intelligent nurse, and given at first a purgative dose (1 to 5 grains, repeated if necessary) of calomel, continuing with smaller doses (1/10 to 1/2 grain) every 3 or 4 hours. Since urotropin seems to have an antiseptic action on the cerebrospinal fluid, its administration is advoctaed in beginning meningitis or when meningeal infection is feared as a complication. To protect against the action of the mercurial, the mouth should be frequently washed with a solution (5 to 10 grains to the ounce) of chlorate of potassium. The hair should be cut short, and an ice-bag kept applied to the head. For the restlessness and wakefulness, a warm bath or sponging with warm water will often have a quieting effect but if not, chloral and the bromids, sulphonal, or trional must be used. Large doses of the bromids (10 to 15 grains every 2 hours for a child 2 years old) may be necessary before the desired result will be secured.

The following formula will be found a convenient combination:

℞. Chloral hydrate, ℥ ss
Sodium bromid, Sodium iodid, each, ℥ ij
Water, ℥ iv.

One teaspoonful in water every 3 hours to a child 3 or 4 years old.

If the treatment outlined above does not lessen the severity of the symptoms, alternate lukewarm and cold douching of the neck and upper part of the spine should be practised 3 times a day, and inunctions of mercury thoroughly applied twice a day. For the relief of severe pain, it may be necessary to give morphin (1/24 to 1/4 of a grain) hypodermically. When the pulse is rapid, irregular, or weak, alcohol in some form and digitalis are called for. Retention of urine may occur, when it will be necessary to use the catheter; and when there is refusal or inability to take food, the patient must be fed by gavage or by the rectum. For the paralysis which may remain after the attack, massage, warm baths, and friction should be employed, but electricity only after all symptoms of central irritation have subsided. Iodid of potassium should be given for a long period when the symptoms persist, as it aids the absorption of inflammatory products. Lumbar punctures have proved beneficial.

Tuberculous Meningitis

Synonyms.—Tuberculous leptomeningitis; basilar meningitis; acute hydrocephalus, water on the brain.

An inflammation of the soft intracranial membranes, more particularly the basal pia mater, attended with or due to the deposit of gray miliary tubercles; characterized by gradual decline of the bodily and mental powers.

Etiology.—It is usually a secondary affection, a sequel to tuberculous disease of some other organ. It occurs most frequently in children between 2 and 6 years of age, although numerous cases are reported between the ages of 20 and 30. The so-called scrofulous children possess a special susceptibility to tubercular meningitis.

Pathologic Anatomy.—The deposition of tubercle usually occurs at the base of the brain. Depositions of grayish-white granules, of a translucent, somewhat gelatinous appearance—miliary tubercle—are distributed along the vessels of the pia mater, resulting in inflammation and the exudation of lymph, with the consequent thickening and opacity of the membranes. The cerebral tissue is not usually involved, although on section the lines indicative of blood-vessels are very much increased in number. The ventricles are distended by a clear or milky, or even bloody, serum. Tubercular deposits occur in the lungs, intestines, and, at times, in other organs. The presence of the tubercles alone may give rise to no symptoms until the exudative products of the resultant inflammation develop.

Symptoms.—The advent is either gradual and insidious, or with convulsions, in which case the after-progress is rapid.

Prodromes.—The child grows irritable, with loss of appetite, loss of flesh, swollen abdomen, constipation alternating with diarrhea, irregular attacks of feverishness, grinding the teeth during sleep, or insomnia. The child exhibits symptoms of headache. The duration of this stage is from 1 week to a month or two.

Stage of Excitation.—The onset is somewhat sudden, with obstinate vomiting, severe headache, convulsions, fever, 102° to 103° F. in the evening, falling to 99° F. in the morning, pulse soft and compressible, with irregular rhythm. On drawing the finger-nail lightly over the surface, a red line results. The symptoms grow progressively worse with exaltation of the special and general senses, the least pinch or even touch causing exquisite pain; there are spasmodic movements of the muscles with contraction and rigidity, and at times even opisthotonos. The duration of this stage is about 2 weeks.

Stage of Depression.—The symptoms of this stage are the result of the pressure of the exudation. The pulse is slow and compressible, with irregular rhythm; the temperature is depressed; there is a tendency to somnolence alternating with quiet delirium, mental stupor, and continual movement of the fingers, as in picking up objects. From time to time convulsions appear with strabismus, oscillation of the eyeballs, followed by intervals of wakefulness, when the headache is excruciating, causing the peculiar, shrill shriek—"the hydrocephalic cry," associated with contraction of the muscles of the face, as if suffering were experienced. Finally collapse occurs, with the Cheyne-Stokes respiration, the coma deepening, followed by death, convulsions often ending the scene. The duration of this stage is from 1 day to 2 weeks.

Diagnosis.—Simple acute meningitis and tubercular meningitis have closely analogous symptoms during the stage of excitation, but the history and clinical course of the two maladies determine the diagnosis.

Prognosis is unfavorable. The usual duration is

3 or 4 weeks after fully developed prodromes. If ushered in by convulsions, the duration is shorter.

Treatment is unsatisfactory. There are no means of retarding the disease. The symptoms should be treated as they develop. Blisters, leeches, active purgation, pustulating ointments, potassium iodid, and mercury are all useless. Lumbar puncture has been praised highly by some.

If the hereditary tendency is marked, nutritious food, cod-liver oil, iron iodid, and quinin may be used in prophylaxis and treatment. See TUBERCULOSIS.

MENINGOCELE.—A meningocele is a congenital hernia protruding through an opening of the skull. When, in addition to the meninges, the brain-substance protrudes, it is termed **encephalocele,** and when this mass also contains liquid, **hydrencephalocele.**

The most frequent site of these tumors is at the occiput, when the protrusion occurs from an opening through or at the edge of the occipital bone; the next most common location is the nasofrontal region; they are rarely seen on other portions of the skull.

Symptoms.—The tumor varies in size from a mere nodule to a size as large or larger than the rest of the child's head, and whatever the exact character of its contents, it can be more or less reduced by compression, but such compression usually produces cerebral symptoms, such as stupor or fretfulness, vomiting, and strabismus. The skin covering the tumor may be tense and covered with a scant growth of hair, or red and vascular.

Diagnosis.—An encephalocele pulsates, and, when the child cries, becomes tense; it is usually opaque, and indistinct fluctuation may be felt. A true meningocele is always small, and, as a rule, pedunculated; its contents admit of complete reduction, and it is translucent.

Prognosis.—The occipital tumors are usually more serious than the frontal ones. In the majority of cases death occurs during the first few weeks of life, the result of meningitis, convulsions, or rupture, and when death does not take place, most of the patients exhibit signs of mental impairment or other evidences of organic brain-disease.

Treatment.—The growth should be carefully protected from injury, operation being justifiable only in case of impending rupture. Repeated tappings and injection of Morton's fluid (iodin, 10 grains; iodid of potassium, 30 grains; glycerin, 1 ounce) have succeeded in cases of meningocele in reducing the tumor, but unless it is pedunculated and very small, the probability of a good result is very remote. See SPINA BIFIDA.

MENINGOCOCCUS SERUM.—See CEREBRO-SPINAL MENINGITIS.

MENINGOMYELOCELE.—See SPINA BIFIDA.

MENOPAUSE.—The period at which menstrual activity ceases. This usually occurs between the fortieth and fiftieth years.

The final cessation of menstruation may occur in one of several ways: it may cease abruptly, there may be a gradual diminution in the amount of blood lost at each successive period until it finally ceases entirely, or there may be a gradually lengthening interval between the periods. Besides the cessation of menstruation there are other phenomena, such as disturbances of digestion, flushes of heat, and nervous derangements. These disturbances may be entirely absent or they may last for a period varying from a few months to 2 years. Associate symptoms of beginning presbyopia must not be overlooked. Return of bleeding after it has once ceased, or profuse bleeding at the time of the menopause, should always arouse suspicion in the mind of the physician. It is frequently caused by malignant disease of the uterus, fibroid tumors or fungous endometritis.

The treatment of the menopause consists in attention to the general health and regulation of the bowels and diet. Plenty of fresh air and a proper amount of exercise will be found beneficial. For the nervous symptoms, change of surroundings and nerve sedatives are indicated. Saline purgatives are especially beneficial. The influence of beginning presbyopia in causing headaches should be considered, and reading glasses ordered. The other reflex phenomena are best treated with potassium bromid, which drug also diminishes the amount of blood determined to the sexual organs. Occasional bleeding or cupping gives relief. Diet should be plain and unstimulating, beer and spirits prohibited, and light wines allowed. Tepid baths are useful. Late hours are to be avoided. Abstracting blood from the uterus generally does harm, but leeches to the anus are sometimes beneficial.

MENORRHAGIA AND METRORRHAGIA.—By the first term is meant profuse or excessive bleeding at the menstrual periods. By the second is meant bleeding between the menstrual periods.

Menorrhagia is a relative term, since the duration of the menstrual period and the amount of blood lost at each period vary so widely in different women. To judge of this condition, therefore, in any particular case the present menstrual condition must be compared with the previous menstrual history.

The causes, pathology, and treatment of the foregoing conditions are practically the same.

The most important **causes** are endometritis, subinvolution and displacements of the uterus, lacerations of the cervix, fibroid tumors, and tubal and ovarian disease. Endometritis is present in the great majority of instances, either alone or associated with one of the above conditions. After the age of 30, cancer of the cervix or of the body of the uterus should always be suspected.

The treatment will depend upon the cause. Cancer and fibroid tumors usually require hysterectomy. Lacerations of the cervix should be repaired, and displacements should be corrected by pessary or operation. Salpingo-oöphorectomy will be necessary in the majority of cases due to chronic disease of the tubes and ovaries.

Thorough curettage will relieve, temporarily at least, a large proportion of cases. Rest in bed, copious vaginal douches of hot water, glycerin tampons, and moderate purgation are all beneficial.

Hydrastis, viburnum, and ergot are the drugs which have given the best results in the above cases. Thyroid extract has been used with success. The following formula will be found useful:

℞. Fluidextract of ergot, ℥ ij
Fluidextract of hydrastis, } each, ℥ j.
Fluidextract of viburnum, }

One teaspoonful in water 3 times a day.

MENSTRUATION.—A periodic discharge of a sanguineous fluid from the uterus and Fallopian tubes, occurring during the period of a woman's sexual activity, from puberty to the menopause. It is suspended during pregnancy and early lactation. The flow is alkaline and composed of blood, shreds of mucous membrane, and vaginal and uterine secretion; it is darker than ordinary blood, and should not clot; its odor is characteristic and disagreeable; the usual quantity is from 4 to 6 ounces.

For discussion of the **anomalies of menstruation**, see AMENORRHEA, DYSMENORRHEA, MENOPAUSE, MENORRHAGIA AND METRORRHAGIA, PREGNANCY, etc.

MENTAL DISEASES.—See INSANITY.

MENTHA PIPERITA (Peppermint).—The dried leaves and flowering tops of *M. piperita*, or common peppermint, having properties due to a volatile oil, in which form it is commonly used. It is an aromatic stimulant, carminative, and antispasmodic, and is valuable internally to relieve flatulent colic, and externally to relieve superficial neuralgia.

M. Pip., Aqua, contains 2 parts of the oil in 1000 of distilled water. Dose, 2 to 6 drams. **M. Pip., Ol.**, the volatile oil. Dose, 1 to 5 minims. **M. Pip., Spt.**, essence of peppermint, contains 10 percent of the oil and 1 percent of the herb in alcohol. Dose, 10 to 45 minims.

MENTHA VIRIDIS (Spearmint).—The dried leaves and flowering tops of *M. spicata*, the "mint" of the kitchen garden. Its constituents and properties are identical with those of peppermint, but its odor and taste differ therefrom. Spearmint corresponds in action to peppermint, but is less powerful. It is employed to correct flatulence and to relieve colic, and makes an agreeable flavoring for mixtures.

Oleum M. V. is the volatile oil distilled from the plant. Dose, 2 to 5 minims. **Aqua M. V.** has 2 parts of the oil in 1000 of distilled water. Dose, 2 to 6 drams. **Spiritus M. V.**, *essence of spearmint*, is an alcoholic solution containing 10 percent of the oil and 1 percent of the bruised herb. Dose, 10 to 45 minims.

MENTHOL.—$C_{10}H_{19}OH$. A secondary alcohol, obtained from oil of peppermint, from which it separates in crystalline form on cooling. Slightly soluble in water, freely so in alcohol, ether or chloroform. Dose, 1/2 to 3 grains, in a pill or spirituous solution several times a day.

Therapeutics.—Menthol is highly praised as an external application in various neuralgias, sciatica, pleurodynia, and toothache. For neuralgia it is used in saturated alcoholic solution painted over the affected nerve. For toothache a crystal introduced into the carious cavity is promptly anodyne. In spray containing 5 to 20 percent it is highly efficient in epidemic influenza and in tuberculous laryngitis. It is a good application in parasitic skin diseases, and has marked value as an antipruritic. Its vapor by inhalation is efficient against cough, and it has considerable power as an anti-emetic, having stopped nausea and vomiting after the usual remedies had failed. For this purpose ten drops of a 20 percent solution in olive oil are given on sugar.

The drug has been used in the vomiting of pregnancy, in hourly doses of a teaspoonful of the following:

℞. Menthol, gr. xv
Whisky, ℥ vj
Syrup, ℥ j.

It is also used as a carminative and in gastralgia, in the dose of 1 to 2 grains 3 times daily in pill or solution.

MERCUROL.—A compound of mercury with yeast nuclein. It contains about 10 percent of mercury. It is used extensively as an injection in 1 percent solution, in gonorrhea and cystitis. Dose, 1/2 to 3 grains, three times a day.

MERCURY (Hydrargyrum; Quicksilver).—Hg = 200; quantivalence II, IV. The only liquid metallic element, hence the common name, *quicksilver*. In medicine the metal, its nitrate, oxids, chlorids, and iodids are the salts most commonly, the sulphid less frequently, used.

Therapeutics.—In small doses, continued not too long a time, it is a tonic, purgative, and alterative. In larger doses, or too long continued, it is likely to produce a condition called hydrargyrism, salivation, or ptyalism. In "biliousness" mercurial purgatives have long been a favorite remedy, blue mass and mercurous chlorid or calomel being usually employed. In syphilis mercuric chlorid and mercuric iodid are generally considered specific. Mercury in the form of calomel is useful in glandular inflammations, and locally in corneal inflammations. Formerly calomel was much used in typhoid fever and malarial fevers. The soluble salts of mercury are highly poisonous.

The metal itself is inert, but by combination with the acids and fluids of the body becomes active, and is easily absorbed in any form. In the blood its effects, in small doses, are tonic, but in quantity it indirectly produces impoverishment thereof. From the blood it enters the tissues, where it remains for an indefinite period, exerting a peculiar influence, termed alterative, on all processes characterized by growth of young cells. It stimulates most of the glands of the body to the production of pathologic secretions, especially the salivary glands and the pancreas. It tends to accumulate in the liver, stimulating the flow of bile. Its excretion is hastened and completed by the use of potassium iodid. In small doses administered for a short time the mercurial preparations are blood-tonics.

A purgative and cholagog pill:

℞. Extract of colocynth, ℥ ss
Powdered scammony, gr. xx
Calomel, gr. xij.

Make into 12 pills; take 1 at night, as necessary.

In chorioretinitis:

℞. Mercuric chlorid, gr. iij
Extract of belladonna, gr. vj.
Make 60 pills; give 1 pill after each meal.

In eczema (calomel ointment):

℞. Calomel, Magnesium carbonate, } each, gr. xl
Cold cream, ℥ j.
Use in eczema.

In dropsy of chronic heart- and liver-disease:

℞. Mass of mercury, Powdered squill, Powdered digitalis, } each, gr. xx.
Mix and make into 20 pills; give 1 pill thrice daily.

In late syphilis:

℞. Mercuric chlorid, gr. j to jss
Potassium iodid, ℥ jss to iv
Compound syrup of sarsaparilla, ℥ j
Water, enough to make ℥ ij.
Give 1 teaspoonful 3 times daily.

In syphilis:

℞. Mercury biniodid, gr. j
Potassium iodid, ℥ ij
Peppermint water, q. s. ℥ iij.
Give 1 teaspoonful after each meal.

In late syphilis, for hypodermic use:

℞. Mercuric chlorid, gr. vj
Sodium chlorid, gr. xxxvj
Distilled water, ℥ iijss.
Inject 5 to 8 drops daily, hypodermically.

In constipation:

℞. Mercuric chlorid, Strychnin sulphate, } each, gr. ss
Quinin sulphate, gr. xij
Extract of belladonna, gr. ij.
Mix and make into 12 pills; take 1 night and morning.

Yellow wash:

℞. Bichlorid of mercury, gr. xv
Lime-water, O ij.
Mix and make into a lotion; apply to syphilitic sores.

Poisoning.—The first symptoms of **salivation** are fetid breath, swollen and spongy gums, having a bluish line along their margins, stomatitis, sore and loosened teeth, inflamed and tender salivary glands pouring out a peculiar, thin saliva of foul odor in large quantity, and a metallic taste in the mouth. Emaciation, pallor, edema, ulcerated skin, erythematous, vesicular, or pustular eruptions, headache, insomnia, neuralgia, tremor through paresis of the muscles of the head and extremities, epilepsy, coma, and convulsions may ensue. An influenzal condition is not uncommon.

Salivation is most readily produced by blue mass, next by calomel, and less easily by gray powder. Children are not easily salivated. Inhalation of mercurial vapors is likely to affect the nervous system most; its internal administration and that by inunction are more likely to produce salivation. Treatment consists in the withdrawal of the mercury, antiseptic mouth-washes, particularly the potassium chlorate, and, later, the use of the iodids as eliminatives.

Poisoning by the bichlorid requires the prompt oral administration of large amounts of albumin, the whites of eggs being most easily obtained. The stomach should be washed out, external heat applied about the body, and stimulants to the respiration and circulation given. It has been suggested that the intravenous injection of calcium sulfid, grain for grain of bichlorid of mercury taken, is the safest and most rapid. An advantage of the intravenous method lies in the assurance that the patient receives the required amount of the antidote and that it is more direct. Calcium sulfid may also be administered by mouth (when the intravenous method is not a practical one) in 2- to 5-grain doses every hour until all symptoms of mercurialism have disappeared, since it is nontoxic. For intravenous administration the solution must be freshly prepared or it loses its sulfur and becomes ineffective. It should not be used stronger than 1 grain to the ounce of water; boiled, then filtered through cotton. If death does not ensue at once, the organic changes in the gastrointestinal tract, such as strictures, sloughs, and destruction of the peptic glands and ulceration, generally cause a protracted convalescence, or may eventually result in a fatal issue.

Preparations.—H. Ammoniatum, ammoniated mercury, "white precipitate," mercuric ammonium chlorid, NH_2HgCl, is used externally. **H. Ammoniati, Ung.,** "white precipitate ointment"—ammoniated mercury 10, white petrolatum 50, hydrous wool fat 40. **H. Chloridum Corrosivum,** $HgCl_2$ (**H. Perchloridum,** B. P.), corrosive chlorid of mercury, mercuric chlorid, "bichlorid of mercury," "corrosive sublimate." Soluble in water and alcohol; antisyphilitic. Dose, 1/80 to 1/10 grain. Very poisonous. **H. Chloridum Mite,** Hg_2Cl_2 (**H. Subchloridum,** B. P.), mild chlorid or subchlorid of mercury, mercurous chlorid, "calomel"—laxative, tonic, and antipyretic. Insoluble in water and alcohol. Dose, 1/20 to 5 grains. **H. cum Creta,** mercury with chalk, "chalk-mixture," "gray powder," contains mercury 38, clarified honey 10, prepared chalk 57, water sufficient quantity. Dose, 1/2 to 10 grains. **H., Emplastrum,** mercurial plaster—mercury 30, oleate of mercury 1, hydrous wool fat 10, lead plaster 59. **H., Arsenii et Iod., Liq.,** Donovan's solution. See ARSENIC. **H. Flav., Lotio,** unof., "yellow wash" for syphilitic sores—corrosive sublimate 18 grains, lime-water 10 ounces. **H. Iodid. Flavum,** HgI, yellow iodid of mercury, mercurous iodid, protiodid. Dose 1/10 to 1/3 grain. **H. Iodid. Rubrum,** HgI_2, red iodid or biniodid of mercury, mercuric iodid. Soluble in a solution of potassium iodid. Poisonous. Dose, 1/50 to 1/10 grain. **H., Massa,** "blue mass," "blue pill," has mercury 33, licorice 10, althæa 15, glycerin 9, honey of rose 33. It is used mainly as a purgative. Dose, 1/2 to 10 grains. **H.**

Nigra, Lotio, unof., "black wash" for syphilitic sores—calomel 30 grains, lime-water 10 ounces. **H. Nitrat., Liq.,** solution (60 percent) of mercuric nitrate. It is used as an escharotic. **H. Nitrat., Ung.,** citrine ointment—mercury 7, nitric acid 17, lard oil 76. **H., Oleat.,** contains yellow oxid 25, distilled water 25, oleic acid to 100. **H. Oxid. Flav.,** yellow oxid of mercury. Insoluble in water; soluble in nitric and hydrochloric acids. It is used in the preparation of ointments, etc. **H. Oxid. Flav., Ung.,** contains 10 percent of the oxid. **H. Oxid. Rub.,** red oxid of mercury. Dose, 1/50 to 1/10 of a grain. **H. Oxid. Rub., Ung.,** contains 10 percent of the oxid. **H. Oxycyanid.** It is said to be less irritating than mercuric chlorid. It has greater antiseptic power than the latter, it is said; and it does not corrode steel instruments. Dose, hypodermically, is the same as the chlorid; it is used locally in 1:5000 solution. **H. Subsulph. Flav.,** yellow subsulphate of mercury, basic mercuric sulphate, "turpeth mineral." Soluble in nitrohydrochloric acid. Dose, for emesis, 2 to 5 grains. **H., Unguent.,** mercurial ointment—mercury 50, lard 25, suet 23, oleate of mercury 2. These are triturated until the globules of mercury disappear under a magnifying glass. It is used to produce the physiologic effects of mercury by inunction. **H. Ung., Dil.,** *Blue ointment* has of the preceding 67, and petrolatum 33, well mixed. **Gray Oil,** *Oleum cinereum,* a semifluid, fatty, mercurial liquid introduced into medicine by Lang, of Vienna, in 1886. It is used in the treatment of syphilis by injections. It is prepared as follows: A given quantity of lanolin—1 or 2 drams—is rubbed up with sufficient chloroform to emulsify it. This mixture is to be thoroughly triturated, during which operation the chloroform will evaporate. While the mixture is still in a fluid state metallic mercury to the amount of double the quantity of the lanolin is to be added, the trituration being meanwhile continued. As a result, a pomade of mercury is left, which represents 2 parts of mercury and 1 part of lanolin. This is called strong gray lanolin ointment. From this salve-basis a 50 percent oleum cinereum, or *gray oil,* may be obtained by mixing 3 parts with 1 part of olive oil. A mild gray lanolin ointment may be made in the same manner as the strong, by taking equal parts of lanolin and mercury and thoroughly mixing them. From this salve-basis a 30 percent gray oil may be made by mixing 6 parts with 4 parts of fresh almond oil or olive oil.

MERYCISM.—See Rumination.

MESENTERIC CYSTS.—The chief tumors of the mesentery are cysts of congenital origin, a sequestration from the intestinal canal (vitelline duct), the pronephros (Müllerian duct) or mesonephros (Wolffian duct) showing an epithelial lining or not, and a wall of muscular or fibrous tissue or both. An hydatid or dermoid cyst and a teratoma or included fetus may also occur, and sometimes an ovarian cyst may become detached from its pedicle and grafted on to the mesentery. Formerly these cysts were held to be chyle cysts from obstruction of the lacteals, or degeneration in the lymphatic glands. Now such chyle cysts, if they occur, are considered quite the exception. The typical cyst should contain fluid with epithelial débris. Blood or chyle may gain entrance secondarily by estravasation. The special *signs* are a movable tumor covered by resonant intestine. At times there are symptoms of abdominal obstruction.

Treatment.—The cyst should be carefully shelled out after pushing aside the mesenteric vessels; only when absolutely necessary should the cyst-wall be sutured to the abdominal wound and drained. If the mesenteric vessels are involved the portion of intestine supplied has also to be excised to avoid gangrene (Spencer and Gask).

MESENTERIC GLANDS.—See Tabes Mesenterica.

MESMERISM.—See Hypnotism.

MESOTAN.—Ericin. The methyl-oxymethyl-ester of salicylic acid. A yellow fluid, containing 71 percent of salicylic acid, is readily absorbed by the skin, and, mixed with an equal quantity of olive oil, is used with friction as an external remedy in rheumatism.

METATARSALGIA (Morton's Disease).—It is characterized by severe neuralgic pain beginning at the side of the distal end of the third or fourth metatarsal bone and extending up into the foot and leg. It is the result of tight shoes. Treatment consists in wearing a flat-foot brace if necessary and properly fitting shoes, or, in extreme cases in resection of the head of the bone or excision of the superficial branch of the external plantar nerve.

METEORISM.—See Tympanites.

METHYL.—In chemistry a radical molecule of the composition of CH_3. It is the base of a large number of compounds, including alcohol, methyl spirit, and several ptomains.

Methyl acetanilid. See Exalgin.

Methyl chlorid is a colorless gas with an odor resembling ether or chloroform, and used to produce local anesthesia. It is applied to the skin in a spray or by means of a cotton tampon. The spray should not continue longer than from 2 to 4 minutes. Its advantages over an ether spray are its noninflammability and its more rapid effect. Methyl chlorid is employed in minor surgical cases, such as opening boils and removing small growths, in pruritus, in neuralgias, and to allay spinal irritation.

Methyl salicylate is the active principle of wintergreen, of which the oil contains about 90 percent. It has the same properties as the oil of gaultheria, and may be used for the same purposes. It is also used to disguise the taste of unpalatable drugs, and as a substitute for the salicylates in rheumatism. It is valuable as an external application in arthralgias. A liniment is prepared as follows:

℞. Ether, Alcohol, Methyl salicylate, each, ʒ j
Soap liniment, enough for O j.
Use as a liniment.

Methyl-violet, or **pyoktanin,** is an anilin dye appearing in the form of a blue, odorless powder, soluble in 75 parts of water. It is a moderately efficient antiseptic, and is not coagulated by albu-

min, and stains the tissues blue. In solutions of 1:2000 or 1:1000 it has been used in ulcerative keratitis, purulent ophthalmia, and in iritis. The same strength solutions have been used in empyema to flush out the pleural sac, and it has been employed in diphtheria and forms of infectious laryngitis. In circumscribed sarcoma and carcinoma deep injections of methyl-violet have been used.

METHYLENE.—CH_2. A bivalent hydrocarbon radicle occurring in many compounds.

Methylene-blue, methylthionin hydrochlorid, is a coal-tar dye prepared from dimethyl anilin; it is much used in the arts and as a stain in bacteriology. Its 10 percent solution is recommended as a local application in diphtheria, tonsillitis, scarlatinal sore throat, and other inflammatory conditions, and internally administered it has proved serviceable as an antiperiodic and analgesic. Dose, 1 to 6 grains in capsule; 2 grains of powdered nutmeg should be given with each dose, to prevent strangury.

Methylene bichlorid, CH_2Cl_2, is a general anesthetic. It is asserted by Genther and Eichholz to be more susceptible of management than chloroform in protracted operations. Much of the methylene bichlorid contains 50 to 75 percent of chloroform. Unof.

METRIC SYSTEM.—A decimal system of weights and measures employed in France, Germany, and other countries, and used generally in the sciences. The standard is the *meter*, the 1/10,000,000 part of a quadrant of a meridian circle of the earth. The standard of capacity is the *liter*, a cubic volume 1/10 of a meter in each dimension. The standard of weight is the *gram*, the weight of 1/1000 of a liter (1 cubic centimeter) of distilled water at its maximum density. The unit of superficial measure is the *are*, a square whose side is 10 meters, or a decameter. As the unit of microscopic measurement, the thousandth part of a millimeter has been adopted. It is called micron or microm, micromillimeter; represented by the sign μ. The multiples are expressed by the prefixes *deca*, *hecto*, and *kilo;* the subdivisions by the prefixes *deci*, *centi*, and *milli*.

1000	meters	= 1 kilometer.
100	meters	= 1 hectometer.
10	meters	= 1 decameter.
.1	meter	= 1 decimeter.
.01	meter	= 1 centimeter.
.001	meter	= 1 millimeter.
1000	liters	= 1 kiloliter.
100	liters	= 1 hectoliter.
10	liters	= 1 decaliter.
.1	liter	= 1 deciliter.
.01	liter	= 1 centiliter.
.001	liter	= 1 milliliter.
1000	grams	= 1 kilogram.
100	grams	= 1 hectogram.
10	grams	= 1 decagram.
.1	gram	= 1 decigram.
.01	gram	= 1 centigram.
.001	gram	= 1 milligram.

In common practice, however, the following divisions only are used, the others being expressed in figures.

10 millimeters	= 1 centimeter.
100 centimeters	= 1 meter.
1000 meters	= 1 kilometer.
1000 cubic centimeters	= 1 liter.
1000 milligrams	= 1 gram.
1000 grams	= 1 kilogram.

The following are the equivalent values:

1 meter	= 39.37 inches.
1 liter	= 1 quart ¼ gill, U. S. measure.
1 gram.	= 15.43 grains.
1 minim	= 0.161 cubic centimeter.

See also WEIGHTS AND MEASURES.

The following **metric conversion table** has been compiled by Mr. C. W. Hunt, of New York:

Millimeters multiplied by .03937 equals inches.
Millimeters divided by 25.4 equals inches.
Centimeters multiplied by .3937 equals inches.
Centimeters divided by 2.54 equals inches.
Meters equals 39.37 inches. (Acts of Congress.)
Meters multiplied by 3.281 equals feet.
Meters multiplied by 1.094 equals yards.
Kilometers multiplied by .621 equals miles.
Kilometers divided by 1.0093 equals miles.
Kilometers multiplied by 3280.7 equals feet.
Square millimeters multiplied by 0.155 equals square inches.
Square millimeters divided by 645.1 equals square inches.
Square centimeters multiplied by .155 equals square inches.
Square centimeters divided by 6.451 equals square inches.
Square meters multiplied by 10.764 equals square feet.
Square kilometers multiplied by 247.1 equals acres.
Hectares multiplied by 2.471 equals acres.
Cubic centimeters divided by 16.383 equals cubic inches.
Cubic centimeters divided by 3.69 equals fluidrams (U. S. P.).
Cubic centimeters divided by 29.57 equals fluidounces (U. S. P.).
Cubic meters multiplied by 35.315 equals cubic feet.
Cubic meters multiplied by 1.308 equals cubic yards.
Cubic meters multiplied by 264.2 equals gallons (231 cubic inches).
Liters multiplied by 62.022 equals cubic inches. (Act of Congress.)
Liters multiplied by 33.84 equals fluidounces (U. S. P.).
Liters multiplied by .2642 equals gallons (231 cubic inches).
Liters divided by 28.316 equals cubic feet.
Hectoliters multiplied by 3.531 equals cubic feet.
Hectoliters multiplied by 2.84 equals bushels (2150.42 cubic inches).
Hectoliters multiplied by .131 equals cubic yards.
Hectoliters divided by 20.42 equals gallons (231 cubic inches).
Grams multiplied by 15.432 equals grains. (Act of Congress.)
Grams multiplied by 981 equals dynes.
Grams (water) divided by 29.57 equals fluidounces.
Grams divided by 28.35 equals ounces avoirdupois.
Grams per cubic centimeter divided by 27.7 equals pounds per cubic inch.
Joule multiplied by .7373 equals foot-pounds.
Kilograms multiplied by 2.2046 equals pounds.
Kilograms multiplied by 35.3 equals ounces avoirdupois.
Kilograms divided by 1102.3 equals tons (2000 pounds).
Kilograms per square centimeter multiplied by 14.223 equals pounds per square inch.
Kilogrammeters multiplied by 7.233 equals foot-pounds.
Kilograms per meter multiplied by .672 equals pounds per square foot.
Kilograms per cubic meter multiplied by 0.26 equals pounds per cubic foot.
Kilograms per cheval vapeur multiplied by 2.235 equals pounds per horse-power.
Kilowatts multiplied by 1.34 equals horse-power.
Watts divided by 746 equals horse-power.
Watts divided by .7373 equals foot-pounds per second.
Calory multiplied by 3.968 equals B. T. U.
Cheval vapeur multiplied by .9863 equals horse-power.
Centigrade multiplied by 1.8+ 32, equals degrees Fahrenheit.
Francs multiplied by .193 equals dollars.

METRITIS.—See UTERUS (Inflammation).

METRORRHAGIA.—See MENORRHAGIA.

MEZEREUM (Mezereon).—The bark of *Daphne Mezereum*, containing an inert, fixed oil, an inactive glucosid, *daphnin*, and an acrid *resin*, which is the anhydrid of a resinous acid named *mezereinic acid*. Mezereum is an ingredient of the compound fluidextract of sarsaparilla. Dose, 1 to 10 grains. **Fluidextractum mezerei**, is too acrid for internal use. Mezereum is a sialogogue, and an intensely acrid, irritant poison, producing violent vomiting, purging, nephritis and gastroenteritis. In small doses it is laxative and diuretic, and has had considerable reputation as an alterative. Externally the recent bark is a powerful local irritant, speedily producing vesication. Mezereum is rarely used internally by itself, but is employed in mixtures with sarsaparilla, etc., as an alterative in syphilis, rheumatism and some skin diseases of chronic type, but with doubtful efficacy. It has been used with good effect in toothache and as a masticatory in paralysis of the tongue. Its principal use is as a local irritant to keep up the discharge from issues or blisters, and to stimulate indolent ulcers.

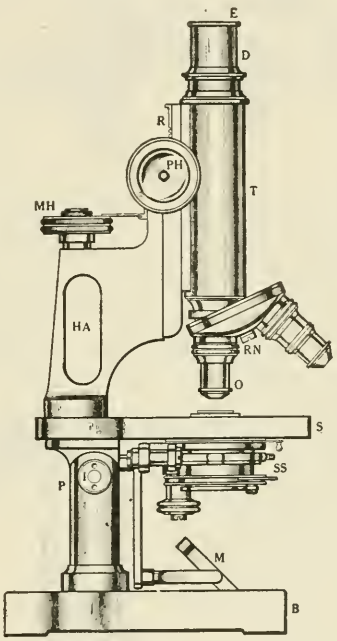
MICROCEPHALUS.—A condition in which a child is born with the skull completely ossified, or one in which ossification has taken place soon after birth.

The operation for the relief of microcephalus is known as **linear craniotomy**; it is performed by making a longitudinal incision through the skin to one side of the sagittal suture, from the occipital bone to the hair line in front, and a transverse incision from the hair line downward. The flap is to be reflected back and a small opening made in the skull by means of a trephine; then, with Rongeur forceps, a groove is cut as far forward as the angle of the wound in front; from this point a lateral groove is made. The parts are then irrigated, all hemorrhage controlled, and the flaps brought together by means of interrupted silkworm-gut sutures. In from 6 to 12 months a similar operation should be performed on the other side of the sagittal suture.

MICROPHOTOGRAPHY.—The production of photographs of microscopic size, usually of large objects. These photographs must then be examined with a magnifier or microscope. In French and German this term is also employed for PHOTOMICROGRAPHY (*q. v.*).

MICROSCOPE.—An optical apparatus for giving an enlarged and distinct image of a minute and near object. There are usually 2 or more lenses or lens-systems, of which one, the objective, placed near the object, gives an enlarged and inverted real image. The other, the ocular, acting like a simple microscope, gives an enlarged virtual image of the real image.

The microscope is the most important laboratory instrument, and should be, so far as means will permit, the best that skill can produce. American microscopes are now as well made as those of foreign firms. The medium form of stand is of preference. The large stand is too heavy and too high. The necessary objectives are a low, a high, and a 1/12 oil-immersion. Two eye-pieces, a low and a high, will be found sufficient for ordinary purposes. The oil-immersion lens should always be cleaned after using by wiping off the oil with an old linen or silk handkerchief or with fine tissue-paper. If the lens is sticky, moisten the cloth with water or, where the oil has dried, with benzol or xylol. The same process may be used for the dry lenses, but it must be done quickly, so as not to soften the balsam in which the lenses are embedded. Ordinarily, a dry cloth is sufficient. The concave mirror is to be used only when some near object, such as wall objects, is reflected into the field of vision or when artificial light is employed. A Welsbach burner, or, better, the incandescent electric light with ground-glass globe, furnishes the best illumination. A piece of blue glass inserted over the mirror or just below the object to be examined will correct the slightly yellowish tint of these lights.



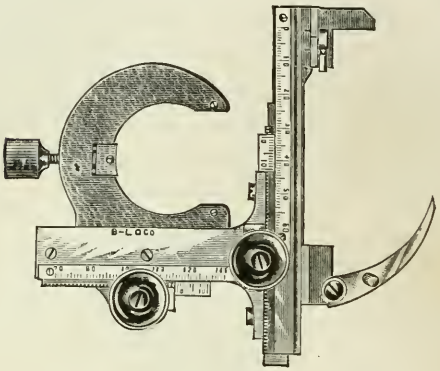
MICROSCOPE.

E. Eyepiece; *D*. Draw tube; *T*. Body tube; *RN*. Revolving nosepiece; *O*. Objective; *PH*. Pinion head; *MH*. Micrometer head; *HA*. Handle arm; *S*. Stage; *SS*. Substage; *M*. Mirror; *B*. Base; *R*. Rack; *P*. Pillar; *I*. Inclination joint.

It must be recognized that the microscope is but an aid to one of our senses. It merely extends our power of observation. The formation of a diagnosis—the first aim of practical medicine—is the result of judgment founded upon observation, and the microscope permits wider application of the sense of sight.

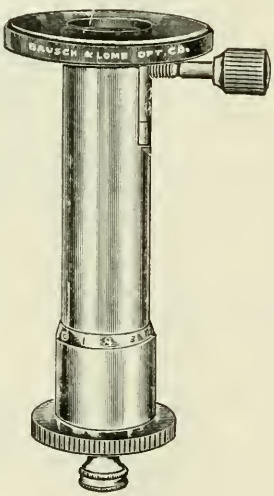
With a **mechanical stage** the microscopist can examine systematically and conveniently an entire slide area. By means of the graduated scale readings, he also can locate a particular point on the field and return to it at any time by simply attaching his stage in the same position and setting his adjustments to accord with his original readings.

The clinical uses of the microscope extend to the investigation of the various discharges and secretions of the body, such as the urine, gastric contents, vomitus, feces, sputum, blood, milk, morbid discharges, cyst contents, cerebrospinal fluid, new growths, parasites, and to examinations of food-stuffs, drugs, and in medicolegal inquiries. Besides the microscope, the use of additional apparatus is required for the examination of tissues, microorganisms, and their secretions and products. As most secretions and discharges of the body are of a fluid nature, they do not require the addition of any medium; but if necessary, a 0.75 percent solution of sodium chlorid, or a 3 percent solution of glycerin in distilled water, having a few crystals or carbolic acid added to prevent the growth of fungi, will suffice. The preparation of specimens for microscopic examination is described under Pathologic Technic (*q. v.*).



Mechanical Stage.

MICROSTOMA.—Any lessening of the size of the mouth, even to complete imperforation of the lips. It is either congenital or traumatic, arising from burns or syphilitic ulcers, etc. It is very rarely seen, except as the result of an accident. If there is complete imperforation, or if the mouth is so small that the child is unable to hold the nipple by the lips, a plastic operation must be immediately performed.



Hand Microtome.

MICROTOME.—An instrument for making thin sections for microscopical examinations. The microtomes of Schanze, Rutherford, Hamilton, Williams, Lewis, Jung, Leiter, Ryder, Minot, Bardeen, Ranvier, and Cathcart are the most used. **A freezing microtome** is one in which the tissue is frozen, in order to secure the hardness required for properly cutting sections. It operates by the rapid evaporation of ether or rhigolene through the medium of a special apparatus, after which the specimen is cut by means of the blade of a carpenter's plane. CO_2 liquid gas, also used, offers the most rapid and convenient method for freezing specimens for sectioning.

Celloidin Microtome.—Of this variety there are 2 types—one in which the section is raised by a screw, the other in which the object is raised by being moved up an inclined plane. (The first variety is preferred by Mallory and Wright.) By means of a sharp blade having the shape of a razor, placed at an angle, the specimen is easily cut after being hardened in celloidin.

Paraffin Microtome.—Frequently paraffin sections may be cut in a celloidin microtome, but one made specially for this work is preferable. That devised by Minot is advised.

MICTURITION.—See Urethra, Urinary Stream, Urine (Retention, Suppression).

MIGRAINE.—A unilateral paroxysmal pain in the head, periodic, accompanied by nausea, often vomiting, intolerance of light and sound, and incapability of mental exertion, the brain being temporarily prostrated and disturbed.

Synonyms.—Megrim; hemicrania; sick headache; bilious headache; blind headache.

Causes.—In the majority of patients the nervous predisposition to migraine is inherited, but whether inherited or acquired, it commonly develops before the age of 30.

Among the many exciting causes are eye-strain, disturbances of digestion, irritation of the ovaries or uterus, worry, exacting mental labor, sexual excesses, and insufficient sleep. The causes of many attacks, however, are wrapped in mystery.

Symptoms.—Attacks of migraine occur in irregular paroxysms, the intervals between being free from pain or nervous disturbance. For a day or two preceding the paroxysm it will be ascertained, on close questioning, that there were a feeling of fatigue without apparent cause, heaviness over the eyes, with some flatulency and indigestion. The attack proper is ushered in by chilliness, nausea, often vomiting, yawning, and general muscular soreness, with intolerance of light, and noises in the ears and incapability for mental exertion, and pain of a sharp, shooting character, of great intensity and persistency, localized most frequently in the frontal, temporal, or occipital regions of the left side; at the same time there is tenderness over the whole side of the head. Rarely, the pain is felt on the right side, and still more rarely on both sides at the same time. The nausea and other digestive symptoms may follow the onset of the pain instead of preceding it. There is more or less disturbance of the circulation, temperature, and secretions of the affected parts. At times there is a marked contraction of the vessels, when the face is pale, the eyes shrunken, and the pupils dilated; again, the vessels may be dilated, when the face is flushed, the conjunctivæ injected, and the pupils contracted. Motion, sound, and light aggravate the acute suffering.

The attack may continue with more or less intensity from a few hours to 2 or 3 days, the average duration being 24 hours.

Diagnosis.—The symptoms are so characteristic that an error seems impossible. It may, however, be confounded with anemic headache, hyperemic headache, dyspeptic or bilious headache, and neuralgic or rheumatic headache. The pains of organic brain disease must be excluded.

Prognosis is favorable. The affection is free from danger to life. In a fair number of cases the susceptibility to attacks declines as the person advances in years, it being rarely seen after 50 years.

Treatment must be directed to the cause. Any eye-strain, digestive trouble, or uterine disease must be corrected. To abort an attack of migraine or dispel a paroxysm after its onset, any one or two of 4 remedies are almost infallible. One is a hypodermic injection of morphin sulphate, 1/4 grain, with atropin sulphate, 1/120 grain, or antipyrin, 20 grains, repeated in an hour or two; or phenacetin, 10 grains, repeated in an hour or two. In many attacks fluidextract of cannabis indica, 2 or 3 drops every half hour or hour for a number of doses, is curative. The local use of menthol pencils eases the pain.

The following may be given:

℞. Acetanilid, gr. xx.
Codein sulphate, } each, gr. v.
Monobromated camphor, }
Make 10 pills. Take 1 pill every 2 hours until relieved.

In the intervals between the paroxysms measures to improve the general system should be used, and to overcome as far as possible any of the etiologic factors in its production. For this purpose extract of cannabis indica, 1/4 grain 3 times daily for several months, is highly recommended. See Headache.

MILIARIA (Prickly Heat).—See Sweat Glands; Urticaria.

MILIARY FEVER (Sweating Sickness).—A rare infectious fever, occurring in epidemics in limited districts in Europe, characterized by miliaria, fever, and profuse sweating. Treatment is expectant and symptomatic.

MILITARY SURGERY.—Military surgery differs little from ordinary emergency surgery. The surgeon in daily practice has learned long ago that every accidental wound must practically be regarded and treated as an infected wound. In this respect the military surgeon of to-day has the advantage over his colleague in civil practice in knowing that the small-caliber bullet inflicts wounds which *per se* are more often aseptic than septic. Senn's experience in Cuba showed that the small jacketed bullet seldom carries with it into the tissues clothing or any other infectious substances. Most of the wounds of the soft tissues, uncomplicated by visceral lesions, which in themselves would become a source of infection, healed by primary intention in a remarkably short time. If infection followed, it usually did so in the superficial portion of the wound in connection with the skin, and, what is more than suggestive, the wound of exit was more frequently affected than the wound of entrance. This can be readily explained from the larger size of the wound and more extensive laceration and tearing of the tissues. In many of the cases ideal healing of the wound did not occur, owing to a sudsequent limited superficial suppuration. The beep tissues were seldom implicated.

The many failures in protecting the more serious wounds against infection are attributable to 3 principal causes: (1) Inadequate supply of first dressing; (2) faulty application of first dressing; (3) unnecessary change of dressing. In all cases in which the first examination does not reveal the existence of complications which require subsequent operative treatment the diagnosis tag should convey this important instruction: "*Dressing not to be touched unless symptoms demand it.*" Such instruction is significant, and must be followed to the letter by all surgeons in subsequent charge of the patient.

For years Senn used as an antiseptic powder a combination of boric acid and salicylic acid, 4 : 1, with the most satisfactory results. He was also partial to sterile absorbent cotton for this particular purpose, as it constitutes a more perfect filter than loose gauze. A teaspoonful of this powder dusted on the wound forms, with the blood that escapes and the overlying cotton, a firm crust, which seals the wound hermetically. Should the primary dressing become saturated with blood, the same powder should be dusted over the wet dressing, and an additional compress of cotton is added to the dressing. After the first dressing has been applied it should not be removed except for good and convincing reasons. Much can be done in the after-treatment in the way of adjusting the bandage and immobilizing the injured part, but the first dressing must remain unless local or general symptoms set in which would warrant its removal. Malaria and yellow fever, in the tropics, are responsible for many unnecessary changes of dressing. The appearance of fever in a wounded man naturally leads to the suspicion that there is something wrong in the wound. Many dressings were changed on this ground; nothing abnormal was found in the wounds, and a day or two later the nature of the fever was recognized, and the patients were either given quinin or were sent to the yellow-fever hospital, in accordance with the diagnosis made. Every change of dressing, more especially in military practice, is attended by risk of infection, and must be scrupulously avoided, unless local or general symptoms indicate the existence of complications which demand surgical intervention. See Gunshot Wounds, Roentgen Rays.

MILIUM (Grutum).—A skin-disease characterized by the formation of small, roundish, whitish, sebaceous, noninflammatory elevations situated just beneath the epidermis. They are found mainly on the face, eyelids and forehead of elderly persons, and may exist in immense numbers. They may undergo calcification, giving rise to *cutaneous calculi.*

Colloid milium is a rare skin disease, characterized by the presence, especially on the bridge of the nose, forehead, and cheeks, of minute, shining, flat, or slightly raised lesions of a pale lemon or bright lemon color. It is a form of colloid degeneration of the skin affecting persons of middle or advanced age.

MILK.—The secretion of the mammary glands of mammalia, consisting of water, casein, albumin, fat, milk-sugar, and salts. Cream consists mainly of the fats that rise to the surface of the milk. Skim-milk is the residue left after the removal of the cream. Buttermilk is cream from which the fatty matter has been removed. It should contain not less than 10 percent of cream. The reaction of milk, when first secreted, is alkaline, but it becomes acid on standing, as a result of fermentative processes.

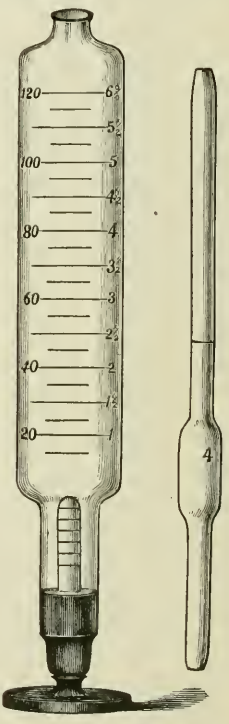
The following table (from Bartley) shows the chief differences between human and cow's milk:

Properties.	Human Milk.	Cow's Milk.
Physical appearance.	Bluish, translucent, odorless, sweetish.	Opaque, white or yellowish-white, distinct odor, feebly sweet taste.
Specific gravity.	1026 to 1036.....	1029 to 1035.
Reaction....	Amphoteric or slightly alkaline.	Amphoteric or slightly acid; becomes quickly acid on exposure to air.
Behavior on boiling.	Does not coagulate, and forms a very slight pellicle, scarcely observable.	Does not coagulate, but forms a distinct pellicle of casein and lime-salts.
Spontaneous coagulation.	Coagulates only after one to two days, at room temperature.	Coagulates after six to twelve hours at room temperature; due to lactic acid.
Coagulation with rennet.	Coagulates incompletely in small, isolated flocculi, never forming visible curds.	Coagulates at body temperature, separating into curdy masses and opalescent whey.
Fat.....	Butter yellowish, similar to cow-butter; sp. gr. at 15° C. = 0.966; melts at 34° C.	Butter yellow-white; sp. gr. at 15° C. = 0.949 to 0.996; melts at 35.8° C.
Composition of fat.	Olein, palmitin, stearin, butyrin, caprin, caproin, myristin.	Olein, palmitin, stearin, caproin, caprylin, caprin, laurin, myristin, arachin, butyrin, lecithin, cholesterin.
Relation of acids.	Volatile acids relatively small; oleic acid, one-half non-volatile acids.	Volatile acids relatively large, oleic acid small, palmitic and stearic large.
Casein.....	Precipitated with difficulty by salts and acids; easily soluble in acids; leaves no pseudonuclein with peptic digestion.	Precipitated easily by salts and acids; precipitate not easily soluble in excess of acids; leaves residue of pseudonuclein.
Composition of proteids.	Lactalbumin, lactoglobulin, and casein; ratio of casein to albumin, 1 to 2 (?).	Lactalbumin and globulin small; casein to albumin, 1 to 7, or even 1 to 10.
Mineral matters.	Relatively small amount: contains one-sixth as much CaO and one-fourth as much P_2O_4 as cow's milk.	Contains relatively large amount.
Bacteria.....	Generally sterile; rarely staphylococcus albus and aureus.	Contains numerous bacteria, and occasionally typhoid, diphtheria, tubercular organisms, etc.
Citric acid...	About 0.05 per cent...	About 0.1 to 0.15 per cent.
Enzymes....	Amylase, lipase, and fibrin ferment.	Amylase, oxidase, and proteolytic ferment.

Determination of Specific Gravity and Percentage of Fat.—The specific gravity of milk may be easily determined by a **lactometer** or **"lactodensimeter"** (such as Quevenne's). The temperature of the milk should always be 60° F.

Estimation of Percentage of Fat.—For this the **lactoscope** of Feser is used. The process, as given by Simon, is as follows:

Quevenne's Lactodensimeter.—(*Simon's Clinical Diagnosis.*)



Feser's Lactoscope.—(*Simon's Clinical Diagnosis.*)

Milk is drawn into the pipet up to the mark "M" when it is emptied into the cylinder "C." The former is then at once rinsed with water and the washings added to the milk. While shaking, water is further added, until the black lines upon the milk-colored glass plug "A" can just be discerned. The figure upon the right of the scale which is reached by the mixture will then directly indicate the percentage amount of fat, while the number upon the left indicates the amount of water that has been added. See COLOSTRUM.

MILK, ARTIFICIAL. See MILK (Modified).

MILK, DRUGS EXCRETED IN.—When taken during lactation, the following drugs are excreted in the milk: the oils of anise, cumin, dill, wormwood and garlic, turpentine, copaiba, the active principles of rhubarb, senna, scammony and castor oil, opium, iodin, indigo, antimony, arsenic, bismuth, iron, lead, mercury and zinc. Acids given to the mother cause griping in the child. Natural salts, as a rule, and the purgative agents above-named, act as purgatives to the child, and potassium salts as diuretics. Turpentine, copaiba and potassium iodid given to the mother, can be detected in the urine of the child. Opium given to the mother may narcotize the child, and mercurials in the same manner may salivate it. Atropin, hyoscyamin, the salicylates and potassium sulphid have been found in the milk after their ingestion by the woman.

MILK, FILTERED.—It has been observed that milk carefully filtered through a thick layer of absorbent cotton is freed from dirt and, to a great extent at least, from germs, and the quality of the milk is in no way altered. In this process we have, therefore, a simple method of sterilizing milk for infants' food without the application of heat, which, no doubt, in many cases changes the nutritive quality, and is in certain instances a cause of scorbutus and other disorders of nutrition.

Milk may be satisfactorily filtered by placing in a clean glass funnel a piece of absorbent cotton about an inch thick, and allowing the milk to percolate through it into the nursing-bottle.

MILK, MODIFIED.—The modification of cow's milk consists in changing the proportions of the different ingredients until they resemble as closely as possible those of mother's milk. The following table gives the average percentage of the different ingredients in cow's milk and mother's milk:

	Cow's Milk.	Mother's Milk.
Fats	4 percent	4 percent
Sugar	4.30 percent	7 percent
Proteids	4.00 percent	1.50 percent
Salts	0.70 percent	0.20 percent
Water	87.00 percent	87.30 percent
Specific gravity	1029	1031
Reaction	Acid (not sterile).	Alkaline (sterile).

By referring to the foregoing table it will be noticed that in altering cow's milk to the standard of human milk the greatest differences to be overcome are in the proportions of the proteid elements, the salts, and the sugar; in cow's milk the two first being too abundant and the last deficient. In laboratories specially fitted up for the purpose milk may be modified exactly to any desired proportions, but in the household or nursery this is not possible, and we are obliged, therefore, to follow certain general and simple rules by which we may practically be able to adjust the milk to the child's digestive powers and furnish its system with the proper elements of nutrition.

To accomplish this end, keeping in mind woman's milk as the standard, it is necessary:

1. To reduce the proteids. This is done by adding water—as much or a little more water than we have milk.

2. To increase the sugar, which at first was deficient, and by dilution has been made still more so. It is necessary to add about 10 grains of sugar to each ounce, or a heaping teaspoonful to each 8-ounce feeding. Milk-sugar is usually recommended, but as it is more liable than cane-sugar, especially in hot weather, to cause fermentation, the latter is better for ordinary use. Whichever is used, it should be dissolved in a little hot water before being added to the milk.

3. To add cream, which at first was sufficient, but has been much reduced by the water which has been added. It is necessary, to bring the fats up to the standard, to add about 1 1/2 to 2 teaspoonfuls to each ounce, or 1 1/2 to 2 ounces of cream to each 8-ounce feeding.

4. It is necessary to add an alkali—about 10 grains of bicarbonate of sodium to an 8-ounce bottle. The salts, by dilution, have been reduced to about the standard.

5. The milk must be freed from germs, which may be practically accomplished by filtering or, if preferred, by pasteurizing.

Milk modified as above would be expressed in the following recipe for a child 6 or 7 months old:

℞.	Cream,	℥ jss
	Milk,	℥ iij
	Boiled water,	℥ iijss
	Sodium bicarbonate,	gr. x
	Sugar,	℥ j.

Mix, filter or pasteurize, heat to 98° F., and feed every 3 hours.

See MODIFIED MILK IN INFANT FEEDING.

MILK, MOTHER'S.—For table giving the average percentage of the different elements of human milk, see MILK, and MILK (Modified).

The color is bluish-white; taste, sweet. Microscopically may be seen great quantities of fat globules and, perhaps, a few epithelial cells. Slight coagulation is produced by adding acetic acid or digestants, such as liquid rennet; but when in a normal condition, it never coagulates in large, hard masses, as does cow's milk.

The first 2 days after parturition the amount secreted is very small, but after 3 to 5 days there should be an abundant supply. Milk is formed to some extent in the gland all the time, but most plentifully while it is being stimulated by the child suckling.

Colostrum is the secretion of the first 2 or 3 days

and it differs quite markedly from the later milk. It is a deep yellow color; is not so sweet as the later milk; has a specific gravity of 1040 to 1046; coagulates into a solid mass by heat; is very rich in proteids and salts, and has a laxative effect. Microscopically there are seen, besides the fat globules, large numbers of granular bodies, known as colostrum corpuscles, which gradually disappear from the milk by the end of a week or 10 days. See COLOSTRUM.

Tests.—When a child fed at the breast does not thrive, the milk should be tested. The specimen used should be the whole quantity, preferably, from a breast, as the quality varies according to the time it is taken, the first milk being poorer in fats and richer in proteids, and the last milk, or the strippings, being rich in fat and low in proteids.

An easy clinical method of testing the milk is the following:

Too high specific gravity shows excess of proteids. Too low specific gravity, excess of fats. The sugar and salts are practically constant.

To ascertain the percentage of fats, take a cylinder holding 10 c.c., graduated to 100 parts; fill to the 100 mark with the milk, and allow the cream to rise for 24 hours. The cream bears the relation of 5 : 3 of the fat, so if the reading on the cylinder shows 7 of cream, the fats would equal three-fifths of 7, or 4.2 percent.

Normal human milk will frequently vary considerably in the percentage of its elements and be at the same time abundantly nutritious to the child which is fed upon it. If the percentages are far from the average, however, and the child shows symptoms of inadequate nursing, much may often be done toward correcting the faulty condition by regulating the mother's mode of life, as regards her exercise and diet. As a general rule, it should be remembered that lean and rare meats and other albuminous foods will increase the fats, and exercise will reduce the proteids. Below are given some of the conditions which affect the secretion of the milk.

1. **Too frequent** or **prolonged nursing** causes the milk to be poor and weak.

2. **Age.**—A woman very young or over 40 is likely to have milk weak in cream and rich in proteids.

3. **Acute illness,** except fevers of a severe type, do not alter the quality. Such fevers, however, will reduce the cream and increase the proteid constituent.

4. **Menstruation** does not materially affect the quality.

5. **Pregnancy.**—The milk of a pregnant woman is usually small in quantity and poor in quality.

6. **Drugs.**—See MILK (Drugs secreted in).

7. **Nervous impressions,** when marked, have a decided effect upon the milk. Fatigue, exhaustion, great excitement, sudden fright, grief, or passion may affect it so as to cause an acute indigestion only, or, in other cases, grave toxic symptoms, as high temperature, great prostration, or even convulsions.

8. **Diet.**—Nitrogenous foods increase the fats and proteids. Vegetable diet diminishes both the fats and proteids. A very low diet diminishes the fats and may either increase or diminish the proteids. An excessively rich diet increases both the fats and proteids. Liquids increase the quantity. Alcoholic drinks or malt extracts, porter, etc., increase the quantity; also the fats and usually the proteids.

9. **Massage of the breasts** is one of the most efficient means of stimulating the milk-supply. It should be done with great care and gentleness, and with every precaution against infection. The entire breast should be rendered aseptic, as should also the hands of the operator, and massage should be done 2 or 3 times a day. Some mild antiseptic ointment may be used with the massage.

See BREAST; MILK.

MILK, PASTEURIZED.—By pasteurizing milk we mean heating it to a temperature of 140° to 160° F. for a period of 20 minutes. This process has been shown to be sufficient to destroy the germs (but not their spores) most commonly to be found in milk, as the bacilli of typhoid fever, cholera, diphtheria, tuberculosis, and the pus germs. Milk thus treated will keep 2 or 3 days in a room at the ordinary temperature, and on ice for several days. Milk heated to 167° F. has no objectionable taste, and it is thought that its digestibility and nutritional qualities are not changed.

MILK, PEPTONIZED.—The following is a simple rule for peptonizing milk: In a clean glass jar containing 4 ounces of cold distilled or boiled water dissolve 15 grains of sodium bicarbonate and 5 grains of pancreatin (extractum pancreatis), to which add 12 ounces of good milk. Set the jar in a vessel of water at a temperature of 105° to 115° F. for from 5 to 20 minutes to partially peptonize, and for 2 hours to completely digest or peptonize.

MILK, PREPARED.—See MILK (Modified).

MILK, STERILIZED.—Sterilized milk is that in which the germs have been destroyed by heat. This can be accomplished absolutely only by heating it to 212° F. or higher on 2 or 3 successive days, as in preparing a culture medium. The ordinary method of sterilizing is to place the milk in jars, which are then exposed to the action of steam for an hour and a half. Heating to so high a degree causes the quality of the milk to be changed, and it is therefore rendered unfit for infant's food, except as a makeshift in very hot weather when ice cannot be procured, or when it is necessary for it to be kept for a considerable time, as in traveling when fresh milk cannot be obtained.

MILK LEG.—See PHLEGMASIA ALBA DOLENS.

MILK SICKNESS (Trembles, Slows, Puking Fever).—An acute infectious disease prevailing in newly settled lands in the western and southwestern States, and acquired from cattle suffering from the "trembles," and transmitted to man through milk, cheese, butter, flesh of affected cattle.

Etiology.—The specific cause unknown.

Symptoms.—Restlessness and malaise are usually the prodromal symptoms. After 2 or 3 days the patient suffers severe epigastric pain, with nausea, vomiting, and constipation; there may be fever of moderate or high degree, and muscular tremors are noticeable.

Prognosis.—The disease is either short and fatal, or recovery may occur after a prolonged convalescence.

Treatment.—This is symptomatic, and consists mainly of food and tonics. Care should be taken to avoid the use of infected food and milk.

MINERAL WATERS.—Natural water differs from distilled water in containing saline and other constituents in varying proportions; from common water, in which they are so small in quantity as not to alter the taste, color, etc., up to the sea-water, having 3 1/3 percent, and that of the Dead Sea, with 26 1/2 percent. Spring waters impregnated with foreign substances so as to have a decided taste and a marked action on the human system are called mineral waters, and may be subdivided into various groups, according to their prevailing constituents, as carbonated, alkaline, saline, sulphureted, silicious, etc. Full analyses of all the principal mineral waters of Europe and America are given in the fifteenth edition of the United States Dispensatory, but a few of the most prominent will be mentioned here.

Alkaline Mineral Waters.—Ems, Germany; Salzbrunn, Germany; Gleickenberg, Austria; Vichy, France; Vals, France; Bladon Spring, Ala.; Congress Spring, Cal.; Seltzer Spring, Cal.; St. Louis Spring, Mich.; Buffalo Lithia Spring, Va.; Hot Spring, Va.; Warm Spring, Va.; Berkeley Spring, Va.; Bethesda Spring, Wis.; Gettysburg Spring, Pa.

These waters are generally cold, those of Vichy and Ems being warm. They contain a considerable amount of sodium carbonate, also sodium chlorid and sulphate, and various other chlorids, carbonates, and sulphates, with carbonic acid gas in varying quantity. Vichy and Vals waters depend for their efficacy almost wholly on the quantity of sodium carbonate contained in them, which is for Vichy from 26 to 50 grains and for Vals about 60 grains to the pint.

Saline Mineral Waters.—Freidrichshall, Germany; Hunyadi János, Germany; Baden-Baden, Germany; Cheltenham, England; Kissingen, Bavaria; Reichenhall, Bavaria; Wiesbaden, Germany; Carlsbad, Bohemia; Püllna, Bohemia; Seidlitz, Bohemia; Marienbad, Bohemia; St. Catherine's, Ontario, Canada; Adelheidsquelle, Bavaria; Kreutznach, Prussia; Saratoga Springs, N. Y., Ballston, N. Y.; Hot Springs, Ark.

These waters are of more complex composition, the various waters of Saratoga containing more than thirty constituent salts. Those usually present are the sulphates and carbonates of sodium, calcium, magnesium, etc. (*magnesian waters*); chlorids of sodium, potassium and lithium(*chlorinated waters*); ferrous salts (*chalybeate waters*), with iodin, bromin, manganese salts, and phosphates in some few. Carbonic acid gas is present in all. Most of them are purgative, some are considered alterative, and many are warm (100° to 160° F.). The most powerful of the saline group is the Hunyadi János, containing about 150 grains each of magnesium and sodium sulphates to the pint; it is effectively purgative. Püllna water is nearly as strong, with 124 grains of sodium sulphate and 93 grains of magnesium sulphate to the pint. Friedrichshall is less powerful, but a better aperient water in 6- to 10-ounce doses. Marienbad contains no magnesium sulphate, but has 36 grains of sodium sulphate, 9 of sodium carbonate, 11 of sodium chlorid, and a small quantity of ferrous carbonate to the pint; in transportation it loses its carbonic acid and deposits the iron; in ordinary doses it is not aperient. Carlsbad water contains 20 grains of sodium sulphate and 9 each of sodium carbonate and chlorid to the pint. "Carlsbad salt" is simply sodium sulphate with a trace of the carbonate. These waters are either imported or are made in the United States.

Sulphurous Mineral Waters.—Aix-la-Chapelle, Prussia; Barèges, South France; Eux-Bonnes, South France; Llandrindrod, Wales; Harrowgate, England; Blue Lick Springs, Ky.; Sharon Springs, N. Y.; Yellow Sulphur Springs, Va.; White Sulphur Springs, W. Va.

These waters contain sulphureted hydrogen gas, also carbonic acid gas and carbonates, chlorids and sulphates of sodium, potassium, magnesium, and calcium; sometimes carbonate and oxid of iron, iodid and bromid of sodium.

Carbonated Mineral Waters.—These waters are cold, contain generally carbonates of calcium, magnesium and sodium (in some, iron), which are held in solution by the excess of carbonic acid, also chlorids of sodium and potassium, sulphates, phosphates, etc.

Silicious Mineral Waters.—Hot Springs, Iceland; and the geysers of Yellowstone Park. The constituents of these waters are chiefly alkaline silicates.

Therapeutics.—An undue value is placed by the laity and interested proprietors upon the medicinal value of mineral waters. The benefit in most instances from them is due to change of climate and scene, freedom from business and home cares and worry, regularity of life and diet, drinking water in quantity, and, in many instances, the substitution of water for alcoholic beverages. Those springs which are furthest removed from the patient's residence, are, as a rule, of the most value to him, as similar invalids whose homes are in the vicinity of the springs are often not benefited by its water.

The principal affections in which mineral waters are esteemed are the following: Cirrhosis of the liver, dyspepsia, gout, rheumatism, uricacidemia, lithiasis, hepatic diabetes, constipation, strumous disorders, obesity, plethora of the pelvic organs, hypochondriasis, skin-diseases, especially those dependent on gastric derangement, phthisis, constitutional syphilis, metallic poisoning, etc. Aperient and purgative waters are useful when a prejudice exists against purgative medicine. See WATER, GOUT, RHEUMATISM, CONSTIPATION, etc.

MIOSIS.—Contraction or decrease in the size of the pupil. See PUPIL.

MIOTICS (Myotics).—Agents which cause the contraction of the pupil. They act by stimulating the motor oculi nerves supplying the circular muscular fibers of the iris, and produce this effect when locally applied or internally administered, except morphin, which acts centrally, and does not affect the pupil when applied locally. Physostigmin (eserin) is the chief miotic for local use, and the

only one employed in ophthalmic practice. Others are muscarin, pilocarpin, and nicotin. *Physostigmin* also contracts the ciliary muscle, leaving the eye accommodated for the near point only, and lessens intraocular tension, antagonizing exactly the eye-actions of atropin. *Morphin* given internally produces miosis by stimulation of the oculomotor centers probably, the dilatation which occurs as death approaches being due to final paralysis of the same (Wood). The *general anesthetics* dilate the pupil in the first and last stages of their action, but contract it in the middle stage, that of complete anesthesia. When in this stage dilatation occurs, it is a dangerous sign of failing respiratory power, unless it is accompanied by symptoms of returning consciousness, as reflex movements and vomiting.

MIRYACHIT.—A peculiar disease observed in some Oriental tribes, the chief characteristic of which consists in mimicry by the patient of everything said or done by another. The same disease is called *lata* by the Javanese. It is also allied to the disease of the "jumpers" of Canada.

MISCARRIAGE.—The expulsion of the fetus between the fourth and the sixth months of pregnancy. See ABORTION.

MISSED ABORTION.—Death of the ovum during the first few months of gestation, followed by symptoms of abortion, which gradually subside without expelling the uterine contents. The ovum may remain inside the uterus for an indefinite period. More frequently decomposition, resulting in some form of sepsis, will occur. The treatment should be complete removal of the blighted ovum. See ABORTION.

MISSED LABOR.—Retention of a dead fetus in the uterus for a variable period of time after the normal expiration of pregnancy. There are usually a few slight pains at term, which gradually subside. Missed labor is most frequently the result of an extrauterine pregnancy that has advanced to term, or of pregnancy in one horn of an imperfectly developed uterus. It may be due to cicatricial contraction of the cervix. See LABOR.

MITRAL DISEASE.—See HEART-DISEASE (Organic).

MIXED TREATMENT.—See SYPHILIS.

MIXTURES (Misturæ).—Aqueous liquid preparations intended for internal use, which contain suspended insoluble substances. The term "mixture" is used somewhat indiscriminately. There are four official mixtures, as follows:

TITLE.	CONSTITUENTS.	PROPERTIES AND DOSE.
MISTURA: Cretæ (*chalk mixture*).	Compound chalk powder, 20 gm.; cinnamon water, 40 c.c.; water, sufficient to make 100 c.c.	Antacid, 4 drams.
Ferri composita (*Griffith's mixture*).	Ferrous sulphate, 6 gm.; Myrrh, 18 gm.; sugar, 18 gm.; potassium carbonate, 8 gm.; spirit of lavender, 60 c.c.; rose water, sufficient to make 1000 c.c.	Tonic, 4 drams.
Glycyrrhizæ composita (*Brown mixture*).	Extract of liquorice, 30 c.c.; syrup, 50 c.c.; acacia, 30 gm.; camphorated tincture of opium, 120 c.c.; wine of antimony, 60 c.c.; spirit of nitrous ether, 30 c.c.; water, sufficient to make 1000 c.c.	Expectorant, 3 drams (child, 1 dram).
Rhei et Sodæ	Sodium bicarbonate, 35 gm.; fluidextract of rhubarb, 15 c.c.; fluidextract of ipecac, 3 c.c.; glycerin, 350 c.c.; spirit of peppermint, 35 c.c.; water, sufficient to make 1000 c.c.	Carminative. Dose, 1 dram.

MODIFIED MILK IN INFANT FEEDING.—*No substitute can compare with mother's milk* for infant feeding; and next to mother's milk modified cow's milk is the best. Where cow's milk is not obtainable, the adaptation has been made from the animal which, in that region, can produce the most abundant supply of milk. Thus in certain places goat's milk or the milk of the ass may be used. Cow's milk in this country has always offered the best substitute in infant feeding. It contains the same ingredients as human milk, but in materially different proportions. The first attempts at feeding with cow's milk were made by simple dilutions with water. This procedure met with success in many instances, and continues to do so when a perfectly healthy, normal baby is the subject. But it was soon found that a certain percentage of infants thus fed developed indigestion. At first attention was focussed on the tough hard curds that these cases either vomited or passed in their movements. This was attributed to the higher amount of proteid that appears in cow's milk as compared with human milk. When simple dilutions failed, the fact that cow's milk differs slightly in its reaction from that of human milk—being amphoteric instead of alkaline—was considered to be the cause of such failures. Therefore lime water was added to all milk given to infants in order to overcome this slight acidity, or bicarbonate of sodium was added to produce a more marked alkalinity. Later on, pancreatizing, or peptonizing as it was then called, was used in special cases to facilitate digestion. Breaking up of the curds was also attempted by the use of cereal diluents which produced a fine division of the proteid matter in the milk mixtures.

The first attempt to direct a more scientific spirit rather than empiric toward the question of infant feeding was in the comparative study of the different ingredients in human milk and cow's milk. The prevalent idea was that an exact reproduction of the percentage composition of human milk would solve all the difficult problems in the use of cow's milk. This premise though a failure, has, as a scientific advance, proved a right

step. The successes of percentage feeding have not been due to the often attempted and as often defeated plan of reproducing or imitating nature, but to the plan of adaptation.

Present Understanding of Percentage Substitute Feeding.—To-day advocates of scientific accuracy in infant feeding make no attempt at blindly following nature, but teach the use of the means nature has given us more scientifically and accurately. Thinking of the elements of milk in percents is the simplest as well as the surest way of dealing with such a complex food. It is *not*, however, a method of feeding in itself, but of adapting the proper parts to the demands of the individual infant. Any successful method of feeding devotes its time to acquiring a complete understanding of the demands and needs of the individual infant. This is the most important premise in infant feeding. There are no rules in infant feeding which a text-book or lecturer can give as absolute or infallible.

Let it be understood, then, that the percentage system is not a method of feeding, but a scientific procedure of computing the ingredients which we are to use in our milk for feedings.

The first step in the intelligent understanding of infant feeding is to know as accurately as possible the feeding history of the infant to be cared for. What food it has been having is hardly sufficient—a knowledge here of the exact amounts of each ingredient, how each of these has been assimilated and how excreted; the amounts at each feeding, and the intervals between feedings; the source of the milk, whether dirty or clean, whether cooked or raw; the weight of the child, its average loss or gain in weight; all these are vitally necessary questions. The age of the child is of less importance and it is often of advantage to form our judgments of the needs and powers of assimilatoin of the infant before we know its age. No rules can be based upon age alone. What the child should have as food depends on far more essential features than age. The physiologic development, the powers of assimilation, the individual response to outside energy, *i. e.*, food, the powers of resistance, the equilibrium of the child in its relation to the outside world—these are the important features of the case. Every child is a law unto himself and only broad principles for treatment can be laid down.

Cow's milk has the following average composition according to König:

Water,	87.7
Casein,	3.0
Whey proteid,	0.4
Fat,	3.7
Sugar,	4.5
Ash,	0.7

Breast milk is composed of water, proteid, fats, sugar and salts. The proteids, fats and sugar, vary widely even within normal limits during different periods of lactation and under various conditions. This is well shown by a comparison of different authorities:

Authorities.	Proteid, percent.	Sugar, percent.	Fat, percent.
Pfeiffer	1.049–3.04	4.20– 7.60	0.70–9.00
Johanesson and Wang	0.900–1.30	5.90– 7.80	2.70–4.60
V. and J. Adriance	0.230–2.60	5.35– 7.95	1.31–7.61
Schlossman	0.560–3.40	5.20–10.90	1.60–9.46

Under even these wide variations a breast-fed infant normally does perfectly well.

The same variations occur from simple cow's milk, especially in the fats and proteids, according to Von Styke: Proteid, 2.19 to 8.56 percent; fat 2.25 to 9.00 percent. This can be almost wholly overcome by using the mixed milk for a herd when the variation ought never to be more than fat 3 to 5 percent; proteid 3 to 4 percent.

But even minimizing these variations is often not enough. The different elements vary in the different breeds of cows. Jersey and Guernsey cows' milk is always higher in its fat percentage; and, what is more important, the form in which the fat is emulsified is different. In Jersey milk the fat globules are large and the emulsion coarse. The digestion and assimilation of fat so coarsely emulsified is very much more difficult than is the finer emulsification found in Holstein, Durham or Ayrshire breeds of cows. Therefore either a pure or a mixed herd from these breeds is best chosen for producing milk for infant feeding. The conditions under which the milk is produced plays an important part. Unless milk is produced under the most approved sanitary and hygienic conditions, such as are demanded by certified milk (10,000 bacteria to the c.c.), disastrous results may follow in the form of acute bacterial intestinal infections, to which is due a large part of the infant mortality, especially in our large cities. Hence first of all in infant feeding we must know the kind of milk we are to use, both as to its average composition and under what conditions it is produced.

The individual ability for assimilation and digestion of the various constituents of milk differs with each infant. No rules can be laid down, but the following general principles (gained from scientific study) are of value.

Amount of Feedings.—The amount given must depend on the size of the infant. At any age an infant's physiologic capacity exceeds what is called its anatomic gastric capacity. Mosenthal's data give perhaps the best figures as to the amounts that can be given at a single feeding:

At the end of the first month 115 c.c., a scant 4 ounces.
At the end of the second month 125 c.c., a trifle more than 4 ounces.
At the end of the third month 145 c.c., a trifle less than 5 ounces.
At the end of the fifth month 170 c.c., a trifle less than 6 ounces.

Intervals of Feeding.—This would rationally depend on the rapidity with which an infant empties its stomach. A breast-fed infant empties its stomach in from one and a half to two hours, because of the physiologic fact that human milk is prepared for its passage into the duodenum

sooner than cow's milk, this latter requiring from three to three and a half hours. This is due to the complex processes that takes place in the stomach during digestion. It has been shown that the weaker the food the more rapidly is the stomach emptied. In its physiologic activity, the stomach begins the secretion of rennin and hydrochloric acid a few minutes after milk first enters so that the coagulation of the casein is finished in a few minutes after milk enters the stomach; the liquid part of the food, water, sugar, and salts are rapidly passed on into the duodenum. The esophageal orifice remains open as long as the contents of the stomach are alkaline and closes when they become acid. Whereas the pyloric orifice responds to exactly the opposite reaction, opening when the fluid portions coming in contact with it are acid, and closing when they are alkaline. The effect is the opposite in the reaction on the duodenal side of the pyloric orifice, which permits of an opening only when the duodenal contents are alkaline. The pyloric orifice reacts by closure to any but finely divided particles, making it difficult for the stomach to empty itself when digesting the more resistant curds formed from cow's milk. It takes longer for an acid reaction to appear because casein predominates to such an extent in cow's milk that the appearance of hydrochloric acid is delayed for two or three hours after the coagulation of cow's milk. After taking human milk, the hydrochloric acid appears between forty minutes and one hour and a half.

The capacity in the healthy infant for digesting and assimilating casein, whether human or cow's appears to be about equal. The difference in the two proteids comes from the great variation in proportion in which the whey proteids and the casein exist in the two milks. The proportion in human milk is almost 1 to 1, while in cow's milk it is 1 to 6. And this difference is the more important when we appreciate the biologic work on the colloidal properties of milk done by Alexander and Bull on the difference of the two proteids. Colloids are of two classes. One is readily coagulated when it comes in contact with electrolytes, such as hydrochloric acid, and after being acted on or coagulated is not reconvertible. These are called irreversible or unstable colloids. Casein belongs to this class.

The other class can be redissolved after dessication and is not affected by electrolytes. They further have the property of protecting the irreversible colloids from the action of electrolytes. The importance of whey mixtures in certain cases where the electrolytic action is too strong or where there is need of protecting the casein from too rapid coagulation is easily comprehended. And this biologic fact explains more clearly why we have such a fine flocculent coagulum formed in human milk as compared with the tougher coagulum or curd found in cow's milk from the action of hydrochloric acid. At present it is even being questioned whether "Casein Curds" are ever due to the casein in cow's milk. It has been argued that because there is no relation between the nitrogen content of the food and the nitrogen content of the stools "casein curds" do not point to proteid indigestion. However, Talbot has proved by indisputable biologic methods that cow's casein does appear in the so-called "casein curd." And there can be little question clinically that casein indigestion does exist and can be produced experimentally in certain cases by the addition of fat-free milk. In some cases the addition of even an ounce of fat-free milk will be sufficient to produce tough curds in the movement, whereas the addition of whey would have no like effect. So it may be safely said that although the proteid element in milk will cause us the least amount of trouble in substitute feeding, yet it can and does cause definite trouble if not properly managed, and may do considerable damage if the symptoms are not recognized and the casein element diminished low enough to check the formation of curds. Whey may even be the portion of the proteid at fault as shown by Meyer's experiment of substituting cow's whey to a mixture of mother's casein and fat, which caused an intestinal upset that did not occur when mother's whey was used in combination with cow's casein and fat.

The digestion of fats in infants is a still more complex problem. Schwartz has shown that the fat globules of cow's milk are rolled together in large clusters and clumps and that the fat globules are surrounded by a zone of clear substance called periglobular substance, which in cow's milk is easily broken through, allowing the globules to flow together into larger clusters. In human milk, the globules are much finer and more evenly distributed about the field and the periglobular substance is not as easily broken through. Upon heating, the periglobular substance in cow's milk seems to become more elastic and the fusion of the fat droplets much less easily accomplished. This may account for the greater digestibility of heated cow's milk over raw cow's milk in some cases. These mechanical differences certainly play important rôles, but there are some chemical and physiologic differences which are of great importance. There is more oleic acid found in human milk which has a lower melting point than fatty acids found in cow's milk (100 to 102° F. in human; 104 to 106° F. in cow's). In human milk there are lesser amounts of volatile acids, and the iodin combining power is higher in human milk—30 to 50 percent—while it is only 20 to 30 percent in cow's milk. Fat is also the last element to leave the stomach and in several instances more fat has been recovered from the stomach contents than had been taken in the previous 24 hours. With an excess of fat in the food, which at present we can only regulate quantitatively, we are not in a position to do anything but reduce the total amount. Future investigations will undoubtedly explain many things and point out how we can better adapt the fat of cow's milk to the infant's digestive capacity. One thing we have learned is that, normally, any percentage above four is fraught with danger, and in the infant below normal a much smaller percentage is alone safe even though there is no sign of fat intolerance or insufficiency shown in the stools.

MODIFIED MILK IN INFANT FEEDING

Uffenheimer claims that all the necessary ferments exist from the first in infants, so that it is possible that starches can be broken down and the double sugars split into simple sugars, in which condition alone can they be absorbed from the very first. Milk sugar has the slowest ratio of absorption. The amyolytic action of saliva is very weak before the sixth month, but after that time it increases rapidly until at the tenth month the action is double the strength of that at birth. From then until the fourth year there is very little gain in strength. Sugars and starch cause little trouble in the normal infant, but they may become very important and disturbing elements if the fat assimilation is much disturbed. According to Finkelstein, sugars and starch together with the salts may become the most important factors in alimentary decomposition and intoxication. "Sugar," says Finkelstein, "is the element that produces the temperature in these cases of decomposition."

The importance of salts in metabolism has been increasing steadily as our appreciation of their intimate relation and significance in vital processes has become more exact. Human milk supplies less salts than cow's milk, but the amount of salts that is capable of absorption in human milk exceeds that in cow's milk by about 20 percent. And the amount retained varies even more, being about 40 to 50 percent for human milk and only 15 percent for cow's milk. When there is fat intolerance the salts appear in the stools as soaps, and the loss of these salts cannot be made up by the addition of salts to the feeding. The salts principally affected are calcium and magnesium. These salts are also changed into insoluble forms by heating, and this important fact may explain the objection to heated milk when there is need of salts in the infant's metabolism. The rate and amount of absorption also changes during any illness, especially intestinal, though the extent of these changes has not been worked out, but their close relation to the weight curve when given in sufficient or insufficient amounts is fairly indicative of their importance. The next few years will probably see many changes in the knowledge of their exact and relative importance. It is necessary for us to consider these more scientific findings of late years as dominant factors in any attempt at feeding infants. We must understand the physiologic processes in an infant, and appreciate as fully as our present knowledge will allow us to do what these physiologic powers will permit in the digestion of the different food stuffs which we give in cow's milk. Besides appreciating these physiologic facts of digestion we must also understand the needs of each individual child. An infant needs nourishment for more purposes than an adult. The necessity for growth is far greater in infancy than at any other time. This body substance can alone be supplied by the proteid or nitrogen element in cow's milk. The younger the child the higher is the percentage of nitrogen that can be utilized. This varies greatly in health and disease. It is undoubtedly less during sickness, but may even exceed the normal during convalescence. Proteid also goes toward the repair as well as the building up of the body, and under certain conditions it may lend itself to furnishing body heat and energy, though when used for this it is far from being an economical process, as over 25 percent is not available for body heat and is given off as free heat. This function of supplying heat and energy is better supplied by the carbohydrate portion of the diet which has the same value per gram as the proteid, but is far more easily and completely vitalized and protects the wasteful combustion of proteid more than any other element. Heat and energy are supplied to a far less degree by the fats, which, however, go toward the increase in weight and stored-up energy. Just how this is accomplished is not perfectly clear nor is it known in what proportions the fats are carried through the blood and lymph.

In determining the needs of an infant, therefore, its weight is an important factor and, except during the time of sickness when the weight is less, fairly represents the physiologic stage of development. It must also be remembered that during convalescence from acute infections other than alimentary disorders the needs and power of assimilation may far exceed that indicated by the weight. At such a time the age plus the approximate normal needs is a better guide in determining the immediate needs of the infant. It has been generally accepted that during the first two or three months 110 calories per kilo are needed, that from the third to the sixth month 100 calories suffice, and from the sixth to the twelfth month from 90 to 80 calories are needed. The demand for body growth on the proteids in the early months has been noted. This is calculated to amount to about 7 percent of the caloric need during the first year, or it may be even more since the utilization of cow's proteid is probably not as great as human.

In estimating the energy quotient of the different elements found in milk, Rubner's figures are accepted.

1 calorie is the amount of heat necessary to raise 1 liter of water to 1 degree Centigrade, and, according to Rubner,

1 gram of fat yields 9.3 calories,

1 gram of carbohydrates yields 4.1 calories,

1 gram of proteid yields 4.1 calories,

Or, if we wish to use ounces and quarts,

1 ounce of fat yields 288 calories,

1 ounce of carbohydrates yields 123 calories,

1 ounce of proteid yields 123 calories,

Or

1 percent of proteid in 1 ounce of mixture will yield 1.23 calories,

1 percent of carbohydrates in 1 ounce of mixture will yield 1.23 calories,

1 percent of fat in 1 ounce of mixture will yield 2.88 calories.

So that taking milk at 3.50 percent proteid, 4.75 percent carbohydrates, and 4 percent fat, we have about 20 calories to the ounce, or about 670 calories to the quart. Fat free milk or skimmed milk will yield about 400 calories per quart, while gravity cream (16 percent) will yield 860 calories per pint.

MODIFIED MILK IN INFANT FEEDING

It will be apparent to any student of the subject that a complete understanding of an infant's needs cannot be met simply by supplying a sufficient number of calories irrespective of the quantity of each ingredient used. The physiologic capacity of the infant must be gauged, its power of assimilation studied and the particular individual element appreciated. In judging the powers of assimilation the stools are an important factor from two different standpoints; first of all, macroscopic, chemical and microscopic study must be carried out if we wish to know whether digestion is normal. The stools of a normal infant are one or two yellow, soft, homogeneous ones. If there is an excess of proteid, the stools are a brownish yellow color, with a cheesy odor, and have an alkaline reaction. Tough casein curds the size of kidney beans may appear which are insoluble in ether and are hardened by formalin. When there is an excess of starch in the food, the movements are a darker brown color, have an aromatic acid odor, and an acid reaction. This excess of starch tends to increase the bacterial fermentation and may produce the excessive scalding so often seen in intestinal fermentation with loose movements. Starch granules may also be found by chemical examination. The fat stools are pale gray, soft, slimy, or green with small soft curds which give the characteristic chemical reactions and pictures of neutral fat globules or fatty acid crystals or fatty soaps.

On the other hand, the importance of the intestinal flora and the influence of the different elements of food on their activity are only now becoming evident. In this the sugars undoubtedly play a big part and their balance with the proteid constituent is an important element in whether fermentative or putrefactive processes will predominate or whether the normal equilibrium will be maintained.

In order to accomplish these results with any assurance of success we must think of the different elements that enter into feeding in the most exact terms, which are percents. Otherwise our specialized knowledge will not carry us as far on the road to success as we are entitled to go. The processes in calculating these percents may be as simple or as complex as we wish to make them. The simpler we make them the more serviceable they will be, but the accuracy, and ability to get whatever percents of the various elements we need to meet the demands of each case must not be sacrificed to our ease in giving directions.

If we take cow's milk to be on the average fat 4.00 percent, sugar 4.75 percent and proteid 3.50 percent; and gravity cream to be fat 16 percent, sugar 4.50 percent, proteid 3.20 percent; fat-free or skimmed milk to be fat 0.0 percent, sugar 4.50 percent, proteid 3.20 percent, they will give us fairly constant and accurate averages in making up mixtures from the mixed milk of a good herd. If we wish to compute any desired formula the process is a very simple one and the necessary figures to remember are brought down to a minimum. Thus if we wish to feed a child ten months old, weighing 22 pounds, a mixture composed of 4 percent fat, 7 percent sugar and 1.50 percent proteid, 8 ounces at a feeding and 5 feedings in 24 hours, we would have the following example:

4/16 of 40 (ounces in total mixture) = 10 ounces of 15 percent cream would give 4 percent fat.

10 of 16 percent cream would also yield 10/40 of 3.20, the proteid in 16 percent cream or .80 percent of proteid.

10 ounces of 16 percent cream would also yield 10/40 of 4.50 sugar in 16 percent cream or 1.12 percent sugar. So that 10 ounces cream would furnish 4 percent fat, 1.12 percent sugar and 0.80 percent proteid, and this subtracted from the original amount wanted would give what was still needed or 0.0 percent.

$$\frac{4 = \text{percent of fat wanted}}{16 = \text{percent of cream used}} \text{ of } 40 = \text{ounces in total mixture.}$$

= 10 ounces of 15 percent cream, which gives 4 percent fat.

10 ounces of 16 percent cream would also yield 10/40 of 3.20 (percent of proteid) in 16 (percent cream) or .80 percent proteid.

10 ounces of 16 percent cream would also yield 10/40 of 4.50 (percent of sugar in 16 percent cream) or 1.12 percent sugar, so that 10 ounces of cream would furnish 4 percent fat; 1.12 percent sugar; 0.80 percent proteid, and this subtracted from the original amount wanted would give what was still needed or fat 0.0 percent; 5.90 percent sugar; 0.70 percent proteid. .70 percent proteid is derived from the fat-free milk or skimmed milk which has a working percentage of

Fat 0.0 percent; sugar 4.50 percent; proteid 3.20 percent.

We need then

$$\frac{.70 \text{ (percent of proteid needed)}}{3.20 \text{ (percent of proteid in fat free milk}} \text{ of } 40$$

= 8.75 ounces of fat-free milk.

8.75 ounces of fat-free milk contains not only .70 percent of proteid, but also

$$\frac{8.75 \text{ (ounces of fat-free milk)}}{40 \text{ (total quantity fat-free milk).}} \text{ of } 4.50 \text{ (percent of sugar in}$$

= .97 percent sugar.

In 8.75 ounces of fat-free milk so far we have

Fat	Sugar	Proteid	
4 %	1.12	.80 %	from .10 oz. of 16 % cream
0	.97	.70	" 8.75 " " fat-free milk
4 %	2.09	1.50 %	18.75

5 percent of sugar is still needed, which can be obtained in the following way:

5 percent of 40 (total ounces in mixture) = .05 x 40 = 2 ounces of sugar of milk, or 4 tablespoons of sugar.

21.25 ounces of water is needed to bring up the total amount to the required 40 ounces.

The caloric value of this food would be figured as follows:

Mixture =4–7–1.50 40 ounces = (1200 c.c.)
4 percent fat =.04 x9.3x1200 =446.4 calories.
7 percent sugar =.07 x4.1x1200 =344.4 calories.
1.5 percent sugar =.015x4.1x1800 = 73.8 calories.
Total, 864.6 calories.

The caloric need of an infant weighing 22 pounds in its tenth month would be about 85 calories per kilo or 850 calories. This mixture then would just about satisfy the caloric needs of this infant.

When whey mixtures are needed the same plan of computing the necessary amounts are carried out as follows:

Mixture wanted: Fat, Sugar, Proteid
3 6 90 whey
50 casein

40 oz. in total mixture.

Using 16 percent cream we have

3/16 of 40 = 7.5 ounces cream = 3 percent fat.

7.5 ounces of 16 percent cream furnishes $\frac{7.5}{40}$ of 3.20 (percent of proteid in 16 percent cream) = .60 proteid, and as 5/6 of this is casein we have the total amount of casein needed and .10 percent of whey is furnished.

We still need .80 (percent of whey proteid) of 40 which equals 32 ounces of whey.

7.5 ounces of cream + 32 ounces of whey = 39.5 ounces amount furnished by cream and whey.

$\frac{39.5}{40}$ of 4.50 (percent of sugar in whey and cream) =4.50 percent sugar furnished, which leaves 1.5 percent of sugar still needed to complete the amount needed, which equals .015x40 = $\frac{6}{10}$ of an ounce of sugar or about 1 1/4 tablespoons of sugar of milk.

Therefore we have Cream, 7.5 ounces.
Fat-free milk, 0.0 ounces.
Whey, 32.0 ounces.
Sugar, 1.25 tablespoonfuls.
Boiled water, 0.5 ounces.

The calories furnished by such a mixture would be:

From the cream, .03x9.3x1200(c.c.) =335 calories
From the proteid .074x4.1x1200(c.c.) =364 calories
and sugar, A total of 699 calories

The question of alkalinity has been a much discussed one but, as stated before, has been very much overestimated. The addition of lime water, besides acting as a mild alkali, stimulates the secretion of hydrochloric acid, so that when lime water is added the total amount of hydrochloric acid is increased and there is very little protective power from the lime water unless given in large proportions. The amount added should always be calculated, with reference to the amount of cream and milk in the mixture and not with reference to the total amount of the mixture. The calculated maximum percent to produce a mild neutralization of the hydrochloric acid secreted by the stomach is 20 percent of the milk and cream, which delays the coagulation of the casein, giving a longer time for the protective action of the albuminoid portions of the proteid to affect some colloidal action on the casein, and so further delaying the coagulation and helping finally to a more rapid evacuation from the stomach because of the smaller size of the coagulum formed. A percentage of 50 to the amount of milk and cream suspends totally the action of the gastric digestion by hydrochloric acid and hastens the emptying of the stomach contents into the duodenum. Sodium bicarbonate acts even more strongly in neutralizing the hydrochloric acid, but exerts no stimulation on the hydrochloric acid secretion of the stomach. It requires 0.68 percent of the milk and cream used to facilitate this neutralization, and 1.70 percent to suspend all action of the hydrochloric acid on the proteid in the food, and so hasten the contents into the duodenum.

Sodium citrate appears to be the ideal protector of casein. For, as has been pointed out before, it has a definite protective action on the casein, being itself a stable colloidal substance with the power of protecting unstable colloids of the casein class, and sodium citrate also combines with hydrochloric acid to form sodium chlorid and so lessens the available hydrochloric acid. Two grams to the ounce of milk and cream used is needed to accomplish this, and double this amount in cases with hyperchlorhydria. For this same purpose a small percentage of gelatin, 1 to 2 percent of the amount of milk and cream in the mixture, can be used as also can decoctions of any of the cereal grains. These weak decoctions from barley, oats, rice, and other cereals contain the colloidal portions of the proteid in these grains without much of the starch. After the 6 months when, as has been seen, starch digestion begins to become useful, the cereal flours can be made use of and they will furnish a slight amount of nourishment, especially if used in the strength of 3 percent for the diluent in our mixtures, so serving a double purpose. They may act also mechanically in the aid of constipation when there is very little choice among the different cereals. The conversion of starch is first into dextrin and then into maltose. The assimilation of the different sugars varies greatly. Lactose (milk sugar) is the least convertible, whereas maltose is the most easily convertible into dextrose, the body sugar, forming two molecules of dextrose, while lactose is capable of forming but one of dextrose and one of galactose. It is not surprising then that the effect on weight is greater from the use of the more easily convertible and assimilable sugars, as cane and malt or even of starch. When prepared with this in view—which means careful dextrinization easily accomplished in an hour by the addition of

takadiastase—its food value is increased in proportion to the amount of malt converted into dextrose. See Infant Feeding, Milk, etc.

MOLDS.— See Parasites (Vegetable).

MOLE.—1. A proliferative degeneration of the chorionic villi, producing a mass of berry-like vesicles attached to the placenta. It is called vesicular mole, and hydatidiform or myxomatous degeneration of the placenta. See Chorion. 2. Also applied to a small, pigmented spot of the skin. See Nevus.

MOLLITIES OSSIUM.—See Bone Diseases.

MOLLUSCUM CONTAGIOSUM.—An epithelial disease characterized by pinhead-sized to pea-sized or larger, smooth, semiglobular, waxy-white or pinkish elevations. The disease is uncommon.

Etiology.—The disease occurs chiefly in the children of the poorer classes. It is probably contagious.

Pathology.—The disease consists of an enormous hyperplasia of the cells of the rete mucosum, the process, in all probability, beginning in the hair follicles. The center of the molluscum tumor is made up of a number of lobules filled with ovoid or rounded, fatty looking, degenerated epithelial cells, designated as "molluscum bodies."

Symptoms.—The lesions are discrete, usually split-pea-sized, of the color of the skin or pinkish, with often a distinct waxy appearance. The summits are somewhat flattened, and contain a central, darkish opening, from which a cheesy secretion may be expressed. They are usually situated upon the face, particularly about the eyelids, cheeks, and chin. They increase slowly in size, eventually terminating in suppuration and disintegration. As a rule, no scarring is left. The lesions are few, a half dozen or more being the usual number present.

Diagnosis.—The characteristic features of the disease are: The size of the lesions; their waxy appearance; the presence of a central orifice giving exit to a whitish secretion; and the history and course of the affection.

Prognosis.—The condition sometimes disappears spontaneously. It is readily amenable to treatment.

Treatment.—The tumors may be destroyed by incision, expression of their contents, and cauterization of the cavity with the stick of nitrate of silver. Again, they may be curetted away or snipped off with a pair of curved scissors. Pedunculated growths may be ligated. When the lesions are small, the following ointment may be used:

℞. Ammoniated mercury, ʒ j
Ointment of zinc oxid, ℥ j.

MONK'S-HOOD.—See Aconite.

MONOMANIA.—A form of mania or madness in which a single delusion or form of delusion is especially dwelt upon. See Mania, Paranoia.

MONOPLEGIA.—Paralysis of a single limb or of a single set of muscles. See Paralysis.

MONOTAL.—Guaiacol methylglycholate. It is said to have the action of guaiacol without being irritant or toxic. It is recommended as an analgesic for local application to painful areas of the skin, which readily absorbs it.

MONSEL'S SALT, and SOLUTION.—See Iron.

MONSTROSITY.—A teratism; a fetus or being with an abnormal development or superfluity or deficiency of parts or some vice of conformation. These may be compound or double, single or simple, according as the monster is composed of the malformations of one or more elementary organisms. A table of monstrosities is appended.

TABLE OF MONSTROSITIES.*

According to Geoffroy Saint-Hilaire, Altered by Hirst and Piersol.

HEMITERATA

I. **ANOMALIES OF VOLUME. HEMITERATA.**
- A. Of Stature.
  1. *General diminution*, as in a dwarf—delayed growth.
  2. *General increase*, as in a giant—precocious development.
- B. Of Volume (strictly speaking).
  1. *Local diminution*, affecting—
     (*a*) *Regions*, as a limb.
     (*b*) *Systems*, as undeveloped muscles.
     (*c*) *Organs*, as small breasts, stenosis of canals, etc.
  2. *Local increase*, affecting—
     (*a*) *Regions*, as the head.
     (*b*) *Systems*, as the adipose tissue.
     (*c*) *Organs*, as large breasts in women, lactiferous breasts in men.

II. **ANOMALIES OF FORM.** *Single order*, including—deformed heads; anomalies of shape of the stomach; deformed pelves, etc.

III. **ANOMALIES OF COLOR.**
- A. *Deficiency*, complete, partial, or imperfect albinism.
- B. *Excess*, complete, partial, or imperfect melanism.
- C. *Alteration*, as in unusual color of the iris.

IV. **ANOMALIES OF STRUCTURE.**
- A. *Deficiency in consistency*, as cartilaginous conditions of bones.
- B. *Excess in consistency*, as anomalous ossification.

V. **ANOMALIES OF DISPOSITION.**
- A. By Displacement.
  1. *Of the splanchnic organs*, as anomalous direction of heart or stomach, hernias, exstrophy of the bladder, etc.
  2. *Of the nonsplanchnic organs*, as club-foot, curvature of the spine, misplaced teeth, misplaced blood-vessels, etc
- B. By Change of Connection.
  1. *Anomalous articulations.*
  2. *Anomalous implantations*, as teeth out of line.
  3. *Anomalous attachments*, as of muscles and ligaments.
  4. *Anomalous branches*, as of arteries and nerves.
  5. *Anomalous openings*, as of veins into the left auricle, of the ductus choledochus in an unusual situation, of the vagina into the rectum, of the rectum into the male urethra, of the rectum at the umbilicus, cloaca.

* Reproduced from "Human Monstrosities," by Barton Cooke Hirst, M. D., and George A. Piersol. M. D., Philadelphia: Lea Brothers and Co., 1892.

C. In Continuity.

1. *Anomalous imperforations*, as of rectum, vulva, vagina, mouth, esophagus.
2. *Anomalous union of organs*, as of kidneys, testicles, digits, teeth, ribs; adhesion of the tongue to the palate.

D. By closure, as in complete transverse septum in the vagina.

E. By Disjunction.

1. *Anomalous perforations*, as persistence of foramen ovale, ductus arteriosus, urachus.
2. *Anomalous divisions*, as splits, fissures in various organs, harelip, hypospadias, fissured tongue, cleft palate, fissured cheek.

VI. ANOMALIES OF NUMBER AND EXISTENCE.

1. *By numerical defect*, as absence of muscles, vertebræ, ribs, digits, teeth, a lung, a kidney, the uterus, the bladder, etc.
2. *By numerical excess*, as supernumerary digits, ribs, teeth, breasts, a double uterus.

HETEROTAXIS

I. Splanchnic Inversion.
II. General Inversion.

HERMAPHRODITES*

I. True Hermaphrodites.

(*a*) *Bilateral hermaphrodites.*
(*b*) *Unilateral hermaphrodites.*
(*c*) *Lateral hermaphrodites.*

II. Pseudohermaphrodites, with double sexual formation of the external genitals, but with unisexual development of the reproductive glands (ovaries and testicles).

(*a*) *Male pseudohermaphrodites* (with testicles).
1. *Internal pseudohermaphrodites.* Development of uterus masculinus.
2. *External pseudohermaphrodites.* External genitals approach the female type; the monstrosity presents a feminine appearance and build.
3. *Complete pseudohermaphrodites* (internal and external). Uterus masculinus with tubes; separate efferent canals for bladder and uterus.

(*b*) *Female pseudohermaphrodites* (with ovaries). Persistence of male sexual parts.
1. *Internal hermaphrodites.* Formation of vas deferens and tubes.
2. *External hermaphrodites.* Approach of the external genitals to the male type.
3. *Complete hermaphrodites* (internal and external) Masculine formation of the external genitals and of a part of the sexual tract.

MONSTERS

CLASS I.—SINGLE MONSTERS.

Order I.—Autositic Monsters.

- Genus I,
  - Species 1. *Ectromelus.*
    - Phocomelus
    - Hemimelus
    - Micromelus
    - Ectromelus
  - Species 2.
    - Symelus
    - Uromelus
    - Sirenomelus
- Genus II, Single species, *Celosoma.*
  - Aspalasoma
  - Agenosoma
  - Cyllosoma
  - Schistosoma
  - Pleurosoma
  - Celosoma
- Genus III,
  - Species 1. *Exencephalus.*
    - Notencephalus
    - Proencephalus
    - Podencephalus
    - Hyperencephalus
    - Iniencephalus
    - Exencephalus
  - Species 2. *Pseudencephalus.*
    - Nosencephalus
    - Thlipsencephalus
    - Pseudencephalus
  - Species 3. *Anencephalus.*
    - Derencephalus
    - Anencephalus
- Genus IV,
  - Species 1. *Cyclocephalus.*
    - Ethmocephalus
    - Cebocephalus
    - Rhinocephalus
    - Cyclocephalus
    - Stomocephalus
  - Species 2. *Octocephalus.*
    - Sphenocephalus
    - Octocephalus
    - Endocephalus
    - Opococephalus
    - Triocephalus

Order II.—Omphalositic Monsters.

- Genus I,
  - Species 1. *Paracephalus.*
    - Paracephalus
    - Omacephalus
    - Hemiacephalus
  - Species 2. *Acephalus.*
    - Acephalus
    - Peracephalus
    - Mylacephalus
  - Species 3. *Asomata.*

Genus II, Single species, *Anideus.*

CLASS II.—COMPOSITE MONSTERS.

Order I.—Double Autositic Monsters.*

A. *Terata katadidyma.*
Genus I, Diprosopus
Genus II, Dicephalus
Genus III, Ischiopagus
Genus IV, Pygopagus

B. *Terata anadidyma.*
Genus I, Dipygus
Genus II, Syncephalus
Genus III, Craniopagus

C. *Terata anakatadidyma.*
Genus I, Prosopothoracopagus
Genus II, Omphalopagus
Genus III, Rhachipagus

Order II.—Double Parasitic Monsters.

- Genus I,
  - Species 1. *Heterotypus.*
    - Heteropagus
    - Heterodelphus
    - Heterodymus
    - Hetertoypus
    - Heteromorphus
  - Species 2. *Hcteralius.* Epicomus
- Genus II,
  - Species 1. *Polygnathus.*
    - Epignathus
    - Hypognathus
    - Paragnathus
    - Augnathus
  - Species 2. *Polymelus.*
    - Pygomelus
    - Gastromelus
    - Notomelus
    - Cephalomelus
    - Melomelus
- Genus III, *Endocyma.....*
  - Dermocyma
  - Endocyma

Order III.—Triple Monsters.

* Kiebs' classification of hermaphrodites, as given by Ahlfeld, is substituted for that of Geoffroy Saint-Hilaire.

* The third order of Geoffroy Saint-Hilaire, single parasitic monsters, under which name he describes dermoid cysts, is omitted. Forster's classification is substituted, with slight modification, for that of Geoffroy Saint-Hilaire.

MORBILLI.—See MEASLES.

MORPHEA.—Circumscribed scleroderma; Addison's keloid; the most common form of scleroderma, usually occurring in young female adults. Its usual seats are about the breasts and the face and neck, and often it follows the course of the nerve distribution. It occurs in the form of patches—rounded, ovoid, or irregular in outline; small or large, soft or firm, smooth or shining, pale yellowish or brownish in color. The lesions are, as a rule, asymmetric. The course of the disease is chronic; it may also manifest itself in the form of atrophic, pit-like depressions in the skin, and as lines, streaks, and telangiectases.

MORPHIN.—$C_{17}H_{19}NO_3$. The name of the principal alkaloid of opium, to which the properties of that drug are chiefly due. It is an anodyne, hypnotic, and narcotic. One-fourth of a grain corresponds in activity with 1 grain of opium of average strength. See OPIUM.

Preparations.—**M. Acetas,** soluble in water. Dose, 1/8 to 1/2 grain. **M. Hydrochlorid** occurs in silky crystals, soluble in water. Dose, 1/8 to 1/2 grain. **M., Pulv., Comp.,** Tully's powder, contains morphin sulphate 1 1/2, camphor, 32, licorice 33, and calcium carbonate, 33 1/2 parts. Dose, 5 to 15 grains. **M. Sulphas,** acicular crystals, soluble in hot water. Dose, 1/8 to 1/2 grain.

MORRHUÆ OLEUM.—See COD-LIVER OIL.

MORTALITY.—See DEATH-RATE; LIFE (Expectation).

MORTON'S DISEASE.—See METATARSALGIA.

MORVAN'S DISEASE (Analgic Panaritium).—A disease characterized by disorders of sensations of pain, temperature and touch, and painless felons. Probably this disease is identical with syringomyelia in most instances. In some cases it is leprosy.

MOSCHUS.—See MUSK.

MOSQUITOS.—There are three varieties which are of medical interest, Culex, Stegomyia, and Anopheles. The following table (by Jackson) will be found helpful:

	Culex.	Stegomyia.	Anopheles.
Diseases conveyed.	Mostly nonpathogenic for man but may convey filarial diseases.	Stegomyia fasciata conveys yellow fever in man.	Conveys malarial disease. Conveys filarial disease in man.
Breeds..	In and about houses, gardens, back yards, old flower pots, or tins, vessels, tubs, cisterns, barrels, gutters, drains. "Home bred."	Resembles Culex.	Puddle breeding—shallow, small pools, in rock or soil, also at margins of lakes and rivers, quiet bays, ponds, in rice fields and water covering submerged grass. Less "home bred."
Bites....	By day or night—at twilight. Females only.	Often bites by day. Females only.	Nocturnal chiefly. Females only.
Wings...	Rarely spotted...	Never spotted..	Usually spotted. There are a few exceptions.
Larval motility.	Larvæ float with heads downward. When disturbed wriggle to bottom of vessel.	Resemble Culex.	Float at surface of water like sticks and have a backward, skating motion.
Resting posture.	"Hunch-backed." Axis of head and proboscis forms an obtuse angle with body.	Resembles Culex.	Axis of head, proboscis and body in same line. Appears as if standing on its head. Some exceptions to this rule.
Eggs....	Deposited in ellipse-shaped masses, convex below, concave above (boat shaped). Eggs arranged in rows, perpendicular and adherent, have one pointed end. Color dirty white. 200 to 400 in a batch.	Eggs are more oval and are not deposited in rafts or masses. Float singly upon their sides, or sink, hatching submerged.	Deposited in masses of 40 to 100 eggs, not adherent, each egg floating on its side, and regularly elliptic in outline, at middle of each side appears a clasping wrinkled membrane. Dark in color.
Singing tone	High pitched.....	Resembles Culex.	Low pitched.
Bodies..	Dull gray in color.	Body and legs covered with black scales and white markings in spots or lines. S. Fasciata has transverse striations on ventral aspect of body.	Dark gray or brown.

Destruction.—The most rational method of procedure is to aim at the extermination of these insects by destroying all larvæ through drainage, ditching and leveling of their breeding places and especially by covering these places with kerosene. The adult insects may be killed by disinfection (especially with sulphurous acid) of rooms and clothing, etc., in which they lurk. See DISINFECTION.

To Keep Mosquitos Away.—Howard recommends the following to keep mosquitos from one while asleep:

℞. Oil of citronella,
Spirit of camphor, } each, ℥i
Oil of cedar, ℥ss.

Mix and apply a few drops on pillow and on a towel near the head of the bed.

Mosquitos do not like the smell of: Spirit of camphor, oil of peppermint, oil of pennyroyal, oil of lavender, oil of hedeoma, oil of erigeron, cade oil.

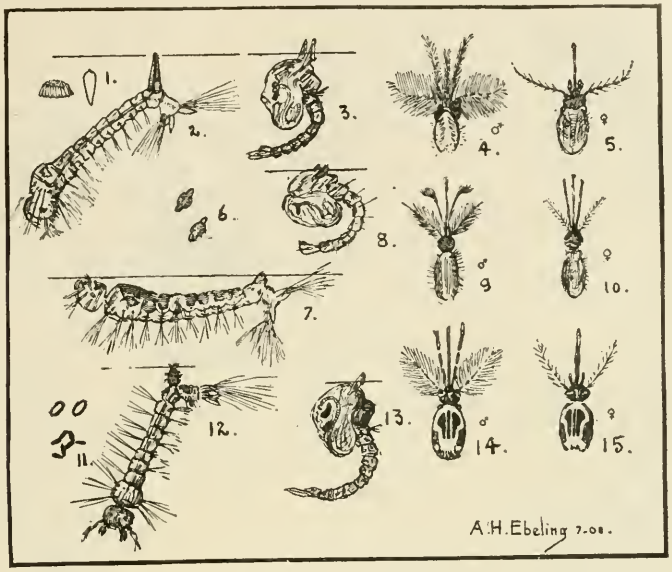
Another preparation is:

℞. Oil of lavender, Alcohol, Castor oil. } equal parts.

Mix and apply on face and hands and sprinkle a few drops on a towel hung at the head of the bed.

For Mosquito Bites.—Apply plain soap to the bitten places; other remedies used are: alcohol, ammonia, bichlorid of mercury, calcium chlorid, glycerin, indigo, ichthyol, potassium hydroxid (10 percent solution), potassium permanganate, phenol, naphthalin, salicylic acid.

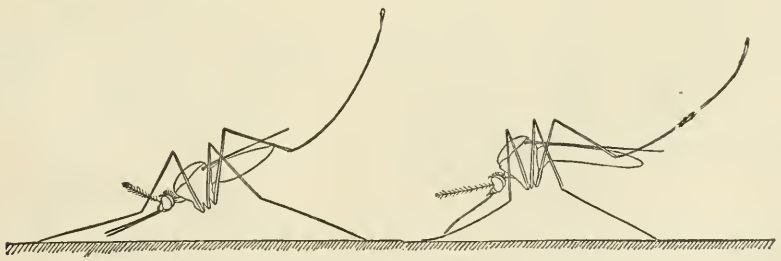
See Filariasis, Malarial Fevers, Yellow Fever.



Metamorphosis of Mosquitos

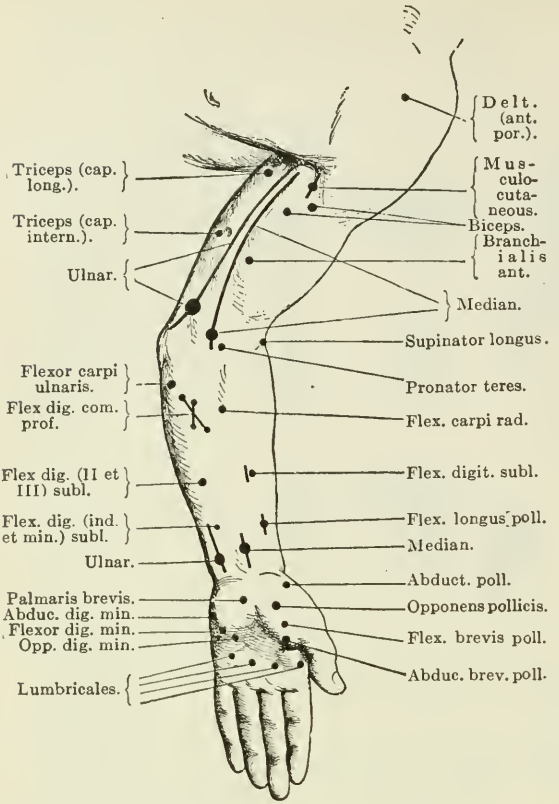
1, 2, 3, 4 and 5. Eggs, larva, pupa and heads of male and female Culex; 6, 7, 8, 9 and 10, eggs, larva, pupa and heads of male and female Anopheles, 11, 12, 13, 14, and 15, eggs larva, pupa and heads of male and female Stegomyia.—(*Stitt.*)

MOTOR POINTS.—The points on the surface of the body where the various branches of the motor nerves supplying the muscles may be affected by electricity. See Electricity, Degeneration (Reaction), Muscles, etc. The accompanying illustrations show the principal motor points:

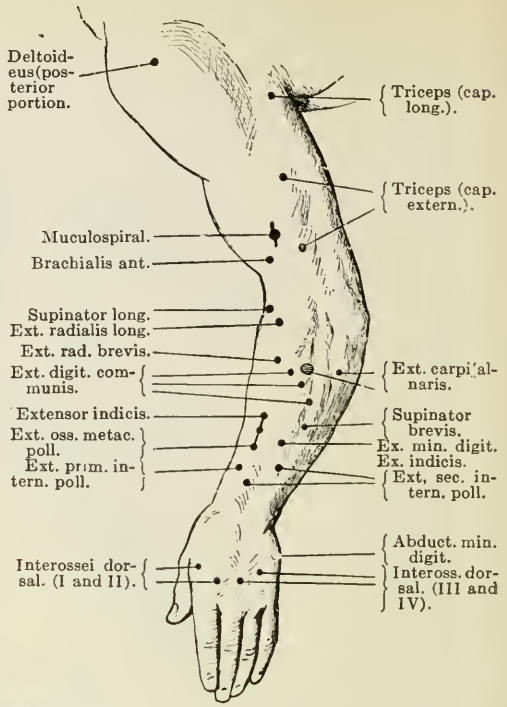


Anopheles. Culex.

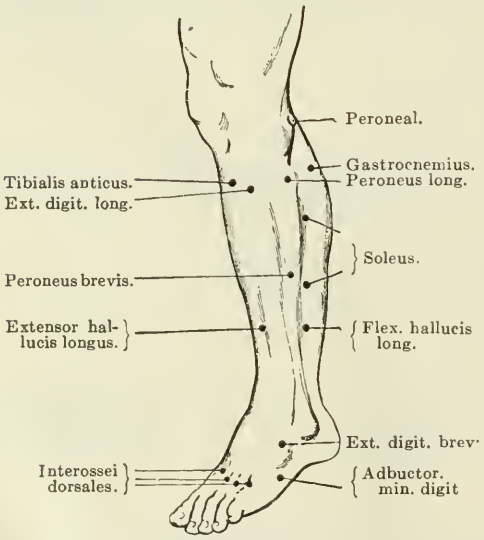
Resting Positions of Anopheles and Culex Insects.—(*Stitt.*)



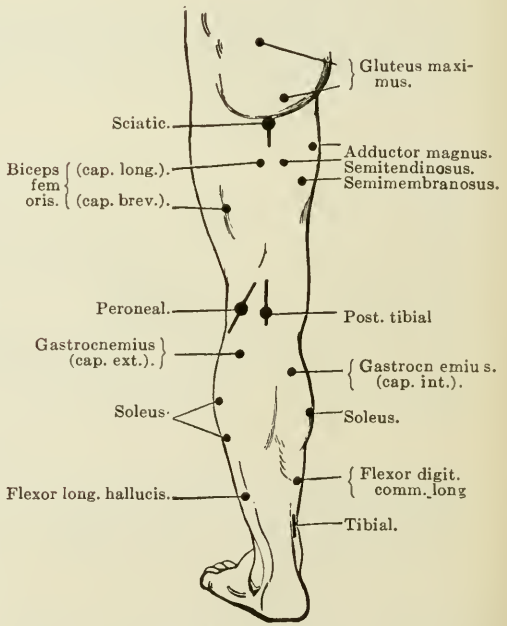
Motor Points of Palmar Aspect of Left Arm.



Motor Points of Dorsal Aspect of Left Arm.



Motor Points of Outer Aspect of Left Leg.

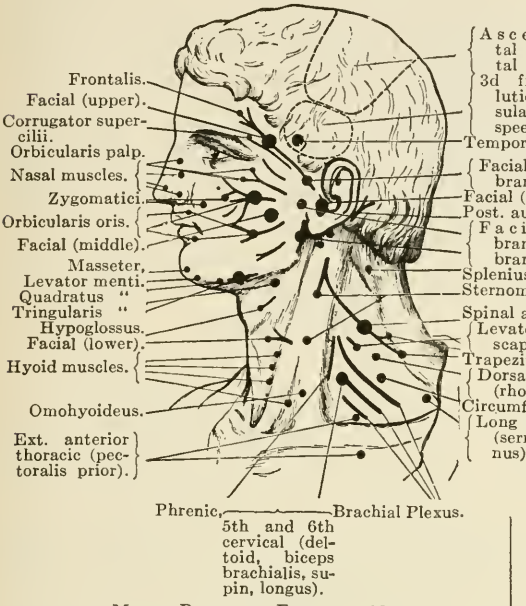


Motor Points of Posterior Aspect of Left Thigh and Leg.

MOUNTAIN SICKNESS.—A condition resulting from excessive exertion at high altitudes characterized by rapid pulse, dyspnea, epistaxis, slight rise of temperature and intense fatigue on exertion.

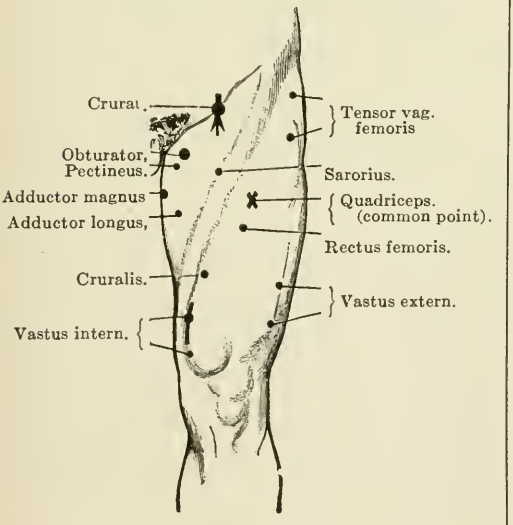
MOUNTING.—See Pathologic Technic.

MOUTH, Diseases.—See Stomatitis.



Motor Points of Face and Neck.

MUCOUS PATCHES.—These are papules deprived of epithelium, a frequent lesion of acquired secondary and of inherited syphilis. They are associated with papular eruptions in early secondary syphilis. They are situated usually on mucous membranes, or on thin and moist skin, are gray in color, are circular or oval, moist, and excrete an offensive and virulent discharge, which is highly contagious. They appear as areas of congestion, swelling, and abrasion of the epidermis upon the lips, palate, gum, tongue, cheeks, vagina, vulva, scrotum, anus, and under the prepuce, and are often accompanied by some fissuring and ulceration of the adjacent parts.



Motor Points of Anterior Aspect of Left Thigh.

The treatment requires scrupulous attention to cleanliness of the affected region, applications of solid silver nitrate or copper sulphate, and frequent dusting with calomel powder. They may be touched with blue stone every day, at the same time employing an astringent mouth-wash. If the areas proliferate, they should be excised or burned. Growing papules may be cauterized with chromic acid (1:5), or nitric or carbolic acids may be used as caustics. A solution of zinc chlorid, 10 grains to the ounce, makes a good astringent dressing for after-treatment. General treatment must be carried out at the same time. See Syphilis.

A mouth-wash:

℞. Boroglycerid, ℥ ss
Water, ℥ viij.

Use as a mouth-wash several times daily.

MULTIPLE IMPREGNATION.—See Pregnancy (Multiple).

MULTIPLE NEURITIS.—See Neuritis (Multiple).

MULTIPLE SEROSITIS.—An extensive inflammation of serous membrane with primary seat in the pericardium, peritoneum or pleura, characterized by ascites and sometimes edema of the extremities. It is probably due to an organism of low virulence. The pathology and symptoms vary with the seat of invasion. If perihepatitis is primary, Glisson's capsule has the appearance of icing.

Associated with the ascites may be found pleurisy and pericarditis. The affection develops slowly and insidiously. The patient gradually loses strength and death ultimately ensues from exhaustion. Treatment is symptomatic.

MUMPS (Epidemic Parotitis).—An acute contagious disease, manifested locally by swelling and inflammation of the parotid and, rarely, of the other salivary glands.

Etiology.—While probably of microbic origin, the specific organism has not been established.

Mumps is highly contagious, and is usually communicated by the breath or exhalations, but may be carried by a third person or by fomites. Those between the ages of 10 and 14 are the most susceptible. Sporadic cases are sometimes observed. It is most likely to be communicated during the beginning of the attack, but possibly while the febrile symptoms remain. One attack usually gives immunity, but if only one of the parotids has been affected during the first attack, the other may be involved subsequently.

Pathology.—Parotitis begins as a catarrhal in-

flammation of the ducts, involving later the periglandular connective tissue. The inflammation is seldom of such a nature as to cause suppuration.

Symptoms.—The period of incubation is 10 to 20 days; about 14 days, usually. The invasion is marked by languor and fever (101° to 103° F.), with perhaps headache and vomiting. The patient complains of pain at the angle of the jaw, which is greatly increased on swallowing an acid, such as vinegar. With these symptoms is noticed a swelling of the parotid gland on one side, the one on the opposite side usually soon becoming also involved. Occasionally but one of the glands is affected, and in other cases both may show the swelling at the same time. The swelling increases gradually until the third to sixth day, and produces marked disfigurement, filling the depression beneath the ear and extending to the cheek and neck. The most prominent point is just below the lobe of the ear, causing it to be pressed outward. The salivary glands are usually also involved, and the mouth, as a rule, is dry, although in some cases there is marked salivation. When the swelling has reached its height, the pressure on the adjacent tissues causes a disagreeable feeling of tension; chewing, swallowing, and even speaking are painful and difficult. Ringing in the ears and earache are quite common. As a rule, the patient is not seriously ill, but in some cases the fever is high, and there may be nervous symptoms, such as headache or delirium.

The duration of the attack is about a week, after which the swelling subsides, and by the tenth or twelfth day entirely disappears.

Complications and Sequels.—Mumps usually runs a mild course, without any serious symptoms, but occasionally complications arise which add greatly to the severity of the disease. The most common complications are orchitis in the male, and, much less frequently, mastitis, ovaritis, or vulvovaginitis in the female. These inflammations usually occur in those who have reached puberty, seldom being seen in children, and usually do not appear until the swelling in the glands of the neck has subsided. These complications lengthen the course of the attack and increase the constitutional symptoms, but in most cases recovery without serious trouble occurs.

Among the less common complications and sequels are otitis media and deafness, meningitis, arthritis, and albuminuria.

Prognosis.—In the great proportion of cases mumps is a mild disease, recovery taking place in a few days.

Diagnosis.—Parotitis is most likely to be confounded with acute swelling of the cervical lymph-glands. In a parotid swelling the lobe of the ear is near the center of the enlargement, while that of a lymph-node is below the ear and behind the jaw, never extending upon the face. The throat symptoms in acute tonsillitis, diphtheria, or scarlet fever would prevent the swollen neck in these diseases from being mistaken for mumps.

Treatment.—Cases of mumps occurring in schools or institutions and in private practice, when there are susceptible persons in the family, should be quarantined for 3 weeks. The patient should be confined to one room, and when the symptoms are at all severe, should be in bed during the disease, as the danger of complications is much increased when the patient is allowed to run about. The diet should be restricted to milk and light broths. The bowels should be acted upon by small doses of calomel (1/12 to 1/6 grain every 2 hours), after which the following mixture may be given:

℞. Antimony and potassium tartrate, gr. j
Magnesium sulphate, ʒ iv
Spirit of nitrous ether, ʒ iij
Syrup, ʒ j
Water, q. s. ʒ iv.

A teaspoonful every 3 or 4 hours.

For the pain, restlessness, or nervous symptoms, 1 to 3 grains of phenacetin should be given every 3 or 4 hours. The nose and mouth should be sprayed and washed 3 or 4 times a day with a weak Dobell's solution or with any alkaline mouth-wash. Ichthyol ointment (10 percent) or belladonna ointment should be applied to the gland if it is painful, and it should be supported by a bandage and absorbent cotton. For the anemia which quite often follows an attack of mumps, there should be given iron, codliver oil, etc. For the treatment of orchitis, see TESTICLE.

MURMURS, CARDIAC.—Any one of those adventitious sounds produced by the abnormal passage of blood through the cavities and orifices of the heart or by perverted cardiac action. The names given to these murmurs correspond with the period of the cardiac cycle in which they occur. A murmur that occurs in the period of auricular systole is termed presystolic or auricular systolic; one that occurs in the period of ventricular systole, systolic; one that occurs during the diastole of the ventricles, diastolic; and should the murmur immediately follow the first or second sound, postsystolic or postdiastolic respectively. In relation to their seat of generation cardiac murmurs are designated mitral, aortic, tricuspid, and pulmonary. All murmurs should be timed by the carotid pulse, not by their relation to the apex-beat. Murmurs are most frequently caused by some change in one of the cardiac valves or orifices, allowing of a reflux of the blood or obstructing its onward progress. See HEART-DISEASE (Organic).

TABLE OF ORGANIC ENDOCARDIAL MURMURS.

Name, in Order of Frequency.	Time.	Site of Maximum Intensity.	Line of Conduction.	Direct or Indirect.	Basic or Apical.	Lesion.	Quality.
Mitral regurgitant.	Systolic.	Center of mitral area, above and to left of apex.	At sixth rib opposite apex, a line drawn from the anterior fold of axilla to lower angle of left scapula.	Indirect mitral.	Apical.	Mitral insufficiency or incompetence.	Variable; usually soft, blowing, bellows: may be distinctly musical.
Aortic obstructive.	Systolic.	Midsternum or to right of it, opposite third rib or second interspace.	Toward top of sternum, and along aorta and its large branches.	Direct aortic.	Basic...	Aortic obstruction or constriction.	Usually loud and harsh. Harshness is one of its distinguishing characteristics.
Aortic regurgitant.	Diastolic.	Midsternum opposite upper border of cartilage of third rib.	Down sternum to ensiform cartilage.	Indirect. aortic.	Basic...	Aortic insufficiency or incompetence.	Soft, blowing, sometimes rough, frequently musical. It has the greatest area of diffusion of all the cardiac murmurs.
Mitral obstructive.	Presystolic.	Over mitral area around the apex.	Usually not transmitted.	Direct mitral.	Apical..	Mitral obstruction or constriction.	Generally low-pitched, rough, churning, grinding, or blubbering. Subject to great variation of pitch and quality.
Tricuspid regurgitant.	Systolic...	Midsternum just above the ensiform cartilage.	Toward the epigastrium.	Indirect tricuspid.	Apical..	Tricuspid insufficiency or incompetence.	Low-pitched, superficial, blowing, soft, faint.
Tricuspid obstructive.	Presystolic.	Midsternum opposite the cartilage of fourth rib.	Not transmitted...	Direct-tricuspid.	Apical..	Tricuspid obstruction or constriction.	Undetermined.
Pulmonary obstructive.	Systolic...	Second interspace to the left of sternum or at the level of third rib.	Upward a short distance and to left of sternum, stopping abruptly.	Direct pulmonary.	Basic...	Pulmonary obstruction or constriction.	Often harsh and audible over the whole precordia; may be very faint; at times bellows.
Pulmonary regurgitant.	Diastolic...	Second left interspace.	Down left edge of sternum to ensiform cartilage.	Indirect pulmonary.	Basic...	Pulmonary insufficiency or incompetence.	Soft and blowing.

MUSCÆ VOLITANTES.—Strings of nucleated rings or dots which float before the eye, and in some conditions, such as high myopia, are so numerous that they cannot be ignored, and cause considerable disturbance of vision. The origin of muscæ is not exactly understood. Examination of the muscæ is of interest, and they can be best studied by lying on the back and looking at a bright cloud in the sky. By what is called **ocular ballottement**—turning the eye downward and arresting the movement very sharply and suddenly—one may get a rebound of muscæ from the bottom of the chamber up to the line of visual perception. While probably of no pathologic import, many patients drift from one oculist to another in the hope of relief. In such a case any existing ametropia or muscular imbalance should be corrected, and strict hygiene of the eyes advised. Very often these patients are sufferers from excessive uric acid formation, and are much relieved by a continued course of salines, such as phosphate of sodium or other antiuric-acid remedies. The diet should be carefully regulated and outdoor exercise insisted upon.

MUSCLES, TABLE OF PRINCIPAL

NAME.	ORIGIN.	INSERTION.	INNERVATION.	FUNCTION.
Abductor hallucis....	Outer head of os calcis, plantar fascia, intermuscular septum; inner head, internal annular ligament, and tendon of tibialis posticus.	Inner portion of lower surface of base of great toe and inner side of internal sesamoid bone.	Internal plantar division of posterior tibial nerve.	Flexes and abducts first phalanx of great toe.
Abductor longus pollicis.	See *Extensor ossis metacarpi pollicis.*			
Abductor minimi digiti manus.	Pisiform bone.....	First phalanx of the little finger.	Ulnar.....	Abducts little finger.
Abductor minimi digiti pedis.	Outer tuberosity of the os calcis and plantar fascia.	First phalanx of the little toe.	External plantar.....	Abducts little toe.
Abductor ossis metatarsi quinti.	Outer tubercle of calcaneum.	Tuberosity of base of 5th metatarsal bone.	External plantar.....	.Abducts little toe.
Abductor pollicis manus.	Trapezium, scaphoid, annular ligament, palmar fascia.	First phalanx of thumb.	Median.....	Abducts and flexes first phalanx of thumb.
Abductor pollicis pedis.	Inner tuberosity of the os calcis.	First phalanx of great toe.	Internal plantar.....	Abducts great toe.
Accelerator urinæ....	Central tendon of perineum and median raphe.	Bulb, spongy and cavernous parts of penis.	Perineal.....	Ejects urine.
Adductor brevis.....	Ramus of pubes.....	Upper part of the linea aspera of femur.	Obturator.....	Adducts, rotates externally, and flexes thigh.
Adductor hallucis....	Tarsal ends of the three middle metatarsal bones.	Base of the first phalanx of great toe.	External plantar.....	Adducts great toe.
Adductor longus.....	Front of pubes.....	Middle of linea aspera of femur.	Obturator.....	Adducts, rotates outward, and flexes thigh.
Adductor magnus....	Rami of pubes and ischium.	All of the linea aspera of femur.	Obturator and great sciatic.	Adducts thigh and rotates it outward.
Adductor minimus...	A name given to the upper portion of the adductor magnus.			
Adductor pollicis.....	Third metacarpal.....	First phalanx of thumb..	Ulnar.....	Draws thumb to median line.
Anconeus.....	Back of external condyle of humerus.	Olecranon process and shaft of ulna.	Musculospiral.....	Extends forearm.
Attollens aurem.....	Occipitofrontalis aponeurosis.	Pinna.....	Temporal branch of facial.	Elevates pinna.
Attrahens aurem.....	Lateral cranial aponeurosis.	Helix.....	Facial.....	Advances pinna.
Azygos uvulæ.....	Posterior nasal spine of palate bone.	Uvula.....	Facial through sphenopalatine ganglion.	Raises uvula.
Biceps.....	1. Long—Glenoid cavity. 2. Short—Coracoid process.	Tuberosity of radius....	Musculocutaneous.....	Flexes and supinates forearm.
Biceps femoris.....	1. Ischial tuberosity. 2. Linea aspera.	Head of fibula and outer tuberosity of head of fibula.	Great sciatic and external popliteal.	Flexes and rotates leg outward.
Biventer cervicis.....	Transverse processes, 2–4 upper dorsal vertebræ.	Superior curved line of occipital bone.	(Portion of complexus.)	Retracts and rotates head.
Brachialis anticus....	Lower half of the shaft of humerus.	Coronoid process of ulna.	Musculocutaneous, musculospiral.	Flexes forearm.
Brachioradialis.....	See *Supinator longus.*			

MUSCLES, TABLE OF PRINCIPAL

NAME.	ORIGIN.	INSERTION.	INNERVATION.	FUNCTION.
Buccinator	Alveolar process of maxillary bones and pterygomaxillary ligament.	Orbicularis oris	Facial, buccal branch.	Compresses cheeks, retracts angle of mouth.
Bulbocavernous	See *Accelerator urinæ*.			
Cervicalis ascendens..	Angles of five upper ribs...	Transverse processes of 4th, 5th, and 6th cervical vertebræ.	Branches of cervical...	Keeps head erect.
Ciliary	*Longitudinal* portion (Brücke's m.), junction of cornea and sclera: *circular* portion (Müller's m.), fibers form a circle.	Outer layers of choroid..	Ciliary	The muscle of visual accommodation.
Coccygeus	Ischial spine	Coccyx, sacrum, and sacrococcygeal ligament.	Sacral	Supports coccyx, and closes pelvic outlet.
Complexus	Transverse processes 7th cervical and 6th upper dorsal, and articular processes of 3d to 6th cervical.	Occipital bone	Suboccipital, great occipital, and branches of cervical.	Retracts and rotates head.
Compressor narium...	Nasal aponeurosis	Fellow muscle and canine fossa.	Facial	Dilates nostril.
Compressor narium minor.	Alar cartilage	Skin at end of nose	Facial	Dilates nostril.
Compressor urethræ..	Ramus of pubes	Fellow muscle	Perineal	Compresses membranous urethra.
Compressor vaginæ....	The analogue of the two bulbocavernosi of the male.		Perineal	Compressor of vagina.
Constrictor of pharynx (inferior).	Cricoid and thyroid cartilages.	Pharyngeal raphe	Glossopharyngeal, pharyngeal plexus and external laryngeal.	Contracts caliber of pharynx.
Constrictor of pharynx (middle).	Cornua of hyoid and stylohyoid ligament.	Pharyngeal raphe	Glossopharyngeal and pharyngeal plexus.	Contracts caliber of pharynx.
Constrictor of pharynx (superior).	Internal pterygoid plate, pterygomax. lig., jaw and side of tongue.	Pharyngeal raphe	Glossopharyngeal and pharyngeal plexus.	Contracts caliber of pharynx.
Coracobrachialis	Coracoid process of scapula.	Inner surface of shaft of humerus.	Musculocutaneous	Adducts and flexes arm.
Corrugator supercilii..	Superciliary ridge of frontal bone.	Orbicularis palpebrarum.	Facial	Draws eyebrow downward and inward.
Cremaster	Upper and deep surface of middle of Poupart's ligament.	Spine and crest of pubic bone and fascia propria.	Genital branch of genitocrural.	Elevates testicle.
Crureus	See *Vastus internus*.			
Deltoid	Clavicle, acromion, and spine of scapula.	Shaft of humerus	Circumflex	Abducts humerus.
Depressor alæ nasi...	Incisive fossa of superior maxillary bone.	Septum and ala of nose...	Facial, buccal branch.	Contracts nostril.
Depressor anguli oris..	External oblique line of inferior maxillary bone.	Angle of mouth	Facial, supramaxillary branch.	Depresses angle of mouth.
Depressor labii inferioris.	External oblique line of the inferior maxillary bone.	Lower lip	Facial, supramaxillary branch.	Depresses lip.
Depressor urethræ....	Ramus of ischium near deep transversus perinei.	Fibers of constrictor vaginæ muscle.		

MUSCLES, TABLE OF PRINCIPAL

NAME.	ORIGIN.	INSERTION.	INNERVATION.	FUNCTION.
Detrusor urinæ.....	Front of pubes.....	Prostate (in male), vagina (in female).	Sympathetic.....	Compresses bladder.
Diaphragm.....	Ensiform cart, 6 or 7 lower ribs, ligamenta arcuata, bodies of lumbar vertebræ.	Central tendon.....	Phrenic and sympathetic.	Respiration and expulsion.
Digastric (anterior belly).	Inner surface of inferior maxillary bone, near symphysis.	Hyoid bone.....	Inferior dental.....	Elevates hyoid and tongue.
Digastric (posterior belly).	Digastric groove of mastoid process.	Hyoid bone.....	Facial.....	Elevates hyoid and tongue.
Dilator naris anterioris.	Alar cartilage.....	Border of ala of nose...	Facial, infraorbital branch.	Dilates nostril.
Dilator naris posterioris.	Nasal notch of superior maxillary bone.	Skin at margin of nostril.	Facial, infraorbital branch.	Dilates nostril.
Dorsal interossei, 4...	Sides of metacarpal bones.	Bases of corresponding phalanges.	Ulnar.....	Abduct fingers from median line.
Dorsal interossei, 4...	Sides of metatarsal bones..	Base of first phalanx of corresponding toe.	External plantar.....	Abduct toes.
Erector clitoridis.....	Tuberosity of ischium. ...	Each side of crus of clitoris.	.....	Erects clitoris.
Erector penis.....	Ischial tuberosity, crus penis, and pubic ramus.	Tunica albuginea of corpus cavernosum.	Perineal	To maintain erection.
Erector spinæ.....	Iliac crest, back of sacrum, lumbar, and three lower dorsal spines.	Divides into sacrolumbalis, longissimus dorsi, and spinalis dorsi.	Lumbar nerves, posterior division.	Extension of lumbar spines on pelvis.
Extensor brevis digitorum pedis.	Os calcis, externally.....	First phalanx of great toe and tendons of extensor longus.	Anterior tibial.....	Extends toes.
Extensor brevis hallucis.	A name applied to that portion of the extensor brevis digitorum that goes to the great toe.			
Extensor brevis pollicis.	See *Extensor primi internodii pollicis.*			
Extensor carpi radialis brevior.	External condyloid ridge of humerus.	Base second and third metacarpal.	Posterior interosseous.	Extends wrist.
Extensor carpi radialis longior.	Lower ⅓ external condyloid ridge of humerus.	Base of second metacarpal.	Musculospiral.....	Extends wrist.
Extensor carpi ulnaris.	1*st head*, external condyle of humerus. 2*d head*, posterior border of ulna.	Base of fifth metacarpal.	Posterior interosseous.	Extends wrist.
Extensor coccygis....	Last bone of sacrum or first of coccyx.	Lower part of coccyx...	Sacral branches.....	Extends coccyx.
Extensor communis digitorum.	External condyle of humerus.	All of the second and third phalanges.	Posterior interosseous.	Extends fingers.
Extensor indicis.....	Back of ulna.	Second and third phalanges of index finger.	Posterior interosseous.	Extends index.
Extensor longus digitorum pedis.	Outer tuberosity of tibia and shaft of fibula.	Second and third phalanges of toes.	Anterior tibial.....	Extends toes.
Extensor longus pollicis.	See *Extensor secundi internodii pollicis.*			
Extensor minimi digiti.	External condyle of humerus.	Second and third phalanges of little finger.	Posterior interosseous.	Extensor of little finger.

MUSCLES, TABLE OF PRINCIPAL

Name.	Origin.	Insertion.	Innervation.	Function.
Extensor ossis metacarpi pollicis.	Back of radius and ulna and interosseous membrane.	Base of metacarpal of thumb and fascia.	Posterior interosseous.	Extends thumb.
Extensor primi internodii pollicis.	Back of radius.....	Base of first phalanx of thumb.	Posterior interosseous.	Extends thumb.
Extensor proprius digiti minimi.	Lower part of ulna, or posterior ligament of wrist-joint.	Base of first phalanx of little finger.		
Extensor proprius hallucis.	Middle of fibula.....	Base of last phalanx of great toe.	Anterior tibial.....	Extends great toe.
Extensor secundi internodii pollicis.	Back of ulna.....	Base of last phalanx of thumb.	Posterior interosseous.	Extends thumb.
Flexor accessorius digitorum pedis (2 *heads*).	1. Inner; 2. Outer surface of os calcis.	Tendon of flexor longus digitorum.	External plantar.....	Accessory flexor of toes.
Flexor accessorius longus digitorum pedis.	Shaft of tibia or fibula ...	Tubercle of os calcis, and joins tendon of long flexor.	External plantar.....	Assists in flexing toes.
Flexor brevis digitorum pedis.	Inner tuberosity of os calcis and plantar fascia.	Second phalanges of the lesser toes.	Internal plantar.....	Flexes lesser toes.
Flexor brevis hallucis.	Under surface of cuboid, plantar ligaments, and external cuneiform.	Base of first phalanx of great toe.	Internal plantar.....	Flexes and slightly adducts first phalanx of great toe.
Flexor brevis minimi digiti manus.	Unciform bone and annular ligament.	First phalanx of little finger.	Ulnar.....	Flexes little finger.
Flexor brevis minimi digiti pedis.	Base of fifth metatarsal...	Base of first phalanx of little toe.	External plantar.....	Flexes little toe.
Flexor brevis pollicis manus.	2 heads—*outer:* lower border of anterior annular ligament; ridge of trapezium; *inner;* os magnum, and bases of first, second, and third metacarpal bones.	Base of first phalanx of thumb.	*Outer head*—median, palmar branch. *Inner head*—deep ulnar.	Flexes metacarpal bone of thumb.
Flexor brevis pollicis pedis.	See *Flexor brevis hallucis.*			
Flexor carpi radialis...	Internal condyle of humerus.	Metacarpal bone of index finger.	Median.....	Flexes wrist.
Flexor carpi ulnaris (2 *heads*).	1. Internal condyle. 2. Olecranon and ulna.	5th metacarpal, annular lig. and pisiform bone.	Ulnar.....	Flexes wrist.
Flexor longus digitorum pedis.	Shaft of tibia.....	Last phalanges of toes...	Posterior tibial.....	Flexes phalanges and extends ankle.
Flexor longus hallucis.	Lower two-thirds of shaft of fibula.	Last phalanx of great toe.	Posterior tibial.....	Flexes great toe.
Flexor longus pollicis..	Shaft of radius and coronoid process of ulna.	Last phalanx of thumb.	Anterior interosseous.	Flexes the thumb.
Flexor profundus digitorum.	Shaft of ulna.....	Last phalanges by four tendons.	Ulnar and anterior interosseous.	Flexes the phalanges.
Flexor sublimis digitorum (3 *heads*).	1. Inner condyle. 2. Coronoid process. 3. Oblique line of radius.	Second phalanges by four tendons.	Median.....	Flexes second phalanges.
Gastrocnemius (2 *heads.*)	Condyles of femur.....	Os calcis by tendo Achillis.	Internal popliteal....	Extends foot.
Gemellus inferior....	Tuberosity of ischium and lesser sacro-sciatic notch.	Great trochanter.....	Sacral.....	External rotator of thigh.

MUSCLES, TABLE OF PRINCIPAL

NAME.	ORIGIN.	INSERTION.	INNERVATION.	FUNCTION.
Gemellus superior....	Ischial spine and lesser sacro-sciatic notch.	Great trochanter.....	Sacral.....	External rotator of thigh.
Geniohyoglossus.....	Superior genial tubercle of inferior maxillary bone.	Hyoid and inferior surface of tongue.	Hypoglossal.....	Retracts and protrudes tongue.
Geniohyoid.....	Inferior genial tubercle of inferior maxillary bone.	Body of hyoid.....	Hypoglossal.....	Elevates and advances hyoid.
Gluteus maximus....	Sup. curved iliac line and crest, sacrum, and coccyx.	Fascia and femur below great trochanter.	Inferior gluteal and sacral plexus.	Extends, abducts and rotates thigh outward,
Gluteus medius.....	Ilium between superior and middle curved lines.	Oblique line of great trochanter.	Superior gluteal.....	Rotates, abducts, and advances thigh.
Gluteus minimus.....	Ilium between middle and inferior curved lines.	Great trochanter.....	Superior gluteal.....	Rotates, abducts, and draws thigh forward.
Gracilis.....	Rami of pubes and ischium.	Tibia, upper and inner part.	Obturator.....	Flexes and abducts leg.
Gubernaculum testis..	See *Cremaster.*			
Hyoglossus.....	Cornua of hyoid.....	Side of tongue.....	Hypoglossal.....	Depresses side of tongue and retracts tongue.
Iliacus.....	Iliac fossa, crest, base of sacrum.	Lesser trochanter, upper part shaft femur.	Anterior crural.....	Flexes and rotates femur outward.
Iliocostal.....	See *Sacrolumbar.*			
Iliopsoas.....	The iliacus and psoas considered as one muscle.			
Infracostals, 10.....	Inner surface of ribs.....	Inner surface of two or three ribs above.	Intercostals.....	Expiration, by depressing ribs.
Infraspinatus.....	Infraspinous fossa.....	Great tuberosity of humerus.	Suprascapular.....	Rotates humerus outward.
Intercostals, external, 11.	Outer lip of inferior costal border.	Superior border of ribs above.	Intercostal.....	Raise ribs in inspiration.
Intercostals, internal, 11.	Inner lip of inferior costal border.	Superior border of ribs below.	Intercostal.....	Depress ribs in expiration.
Interossei of foot, dorsal (4).	Adjacent surfaces of metatarsal bones.	Bases of first phalanges.	External plantar.....	Flex first phalanges and extend 2d and 3d, also abduct 2d, 3d, and 4th toes.
Interossei of foot, plantar (3).	Inner lower surface of 3 outer metatarsal bones.	Bases of first phalanges of three outer toes.	External plantar.....	Abduct first phalanges of three outer toes.
Interossei of hand, dorsal (4).	Five metacarpal bones....	Sides of aponeurosis of extensor communis and adjacent parts of first phalanges.	Ulnar.....	Abduct index, middle, and ring fingers, aid in flexing first phalanges and extending second and third.
Interossei of hand, palmar (3).	Sides of metacarpal bones.	Aponeurosis of extensor tendons, adjacent part of first phalanges.	Ulnar.....	Adduct index, ring, and little fingers, aid in flexing first phalanges and in extending second and third.
Interspinales.....	Upper surface of spines of vertebræ, near tip.	Posterior part of lower surface of spine above.	Internal divisions of posterior branches of spinal nerves.	Extend the vertebra next above.
Intertransversales....	Between transverse proc. of contiguous vertebræ.	.....	Spinal nerves.....	Flex laterally the spinal column.
Ischiocavernosus.....	See *Erector penis.*			

MUSCLES, TABLE OF PRINCIPAL

NAME.	ORIGIN.	INSERTION.	INNERVATION.	FUNCTION.
Latissimus dorsi.....	Spines of 6 lower dorsal and lumbar and sacral vertebræ, crest of ilium, and 3 or 4 lower ribs.	Bicipital groove of humerus.	Long subscapular....	Drawa arm backward and downward and rotates it inward.
Levator anguli oris...	Canine fossa of superior maxillary bone.	Angle of mouth.....	Facial, infraorbital branch.	Elevates angle of mouth.
Levator anguli scapulæ.	Transverse processes of four upper cervical vertebræ.	Posterior border of scapula.	Fifth cervical and cervical plexus.	Elevates upper angle of scapula.
Levator ani.....	Posterior portion of body and ramus of pubes, pelvic fascia, ischial spine.	Rectum, coccyx, and fibrous raphe.	Sacral and perineal...	Supports rectum and vagina.
Levator labii inferioris.	Incisive fossa of inferior maxillary bone.	Skin of lower lip.....	Facial, supramaxillary branch.	Elevates lower lip.
Levator labii superioris.	Lower margin of orbit....	Upper lip.....	Facial, infraorbital branch.	Elevates upper lip.
Levator labii superioris alæque nasi.	Nasal process of superior maxillary bone.	Alar cartilage and upper lip.	Facial, infraorbital branch.	Elevates upper lip, dilates nostril.
Levator menti.....	See *Levator labii inferioris.*			
Levator palati.....	Petrous portion of temporal bone.	Soft palate.....	Sphenopalatine ganglion (facial).	Elevates soft palate.
Levator palpebræ superioris.	Lesser wing of sphenoid...	Upper tarsal cartilage..	Third.....	Lifts upper lid.
Levatores costarum, 12.	Transverse processes of last cervical and dorsal vertebræ.	Each to the rib below..	Intercostal.....	Raise ribs.
Lingualis.....	Under surface of tongue..	.....	Chorda tympani and hypoglossal.....	Elevates middle of tongue.
Longissimus dorsi....	Erector spinæ.....	Transverse process of lumbar and dorsal vertebræ and 7th to 11th ribs.	Branches of lumbar and dorsal.	Erects spine and bends trunk backward.
Longus colli— 1. Superior oblique portion. 2. Inferior oblique portion. 3. Vertical portion..	Transverse processes 3d to 5th cervical. Bodies of 1st to 3d dorsal. Bodies of three dorsal and two cervical.	Anterior tubercle of atlas. Transverse processes 5th to 6th cervical. Bodies of 2d to 4th cervical.	Lower cervical.....	Flexes cervical vertebræ.
Lumbricales, 4, of foot.	Tendons of flexor longus digitorum.	First phalanges of the lesser toes.	Internal and external plantar.	Accessory flexors.
Lumbricales, 4, of hand.	Tendons of flexor profundus digitorum.	Tendons of common extensor.	Median and ulnar....	Flex first phalanges.
Masseter.....	Zygomatic arch.....	Angle and ramus of jaw.	Inferior maxillary....	Muscle of mastication.
Multifidus spinæ.....	Sacrum, iliac spine, articular processes lumbar and cervical vertebræ, and transverse proc. of dorsal and 7th cervical.	Laminæ and spines from last lumbar to second cervical vertebræ.	Posterior spinal branches.	Erects and rotates spinal column.
Mylohyoid.....	Mylohyoid ridge of inferior maxillary bone.	Body of hyoid and raphe.	Inferior dental.....	Elevates and advances hyoid. Forms the floor of the mouth.
Nasolabialis.....	Nasal septum.....	Upper lip.		
Obliquus capitis inferior.	Spinous process of axis....	Transverse process of atlas.	Suboccipital and great occipital.	Rotates altas and cranium.
Obliquus capitis superior.	Transverse process of atlas.	Occipital bone.....	Suboccipital and great occipital.	Draws head backward.

MUSCLES, TABLE OF PRINCIPAL

NAME.	ORIGIN.	INSERTION.	INNERVATION.	FUNCTION.
Obliquus externus....	Eight lower ribs.....	Middle line, iliac crest, Poupart's ligament.	Intercostal, iliohypogastric, ilioinguinal.	Compresses viscera and flexes thorax.
Obliquus inferior.....	Orbital plate of superior maxillary bone.	Sclerotic.....	Third cranial.....	Rotates eyeball upward and outward.
Obliquus internus....	Lumbar fascia, iliac crest, Poupart's ligament.	Three lower ribs, linea alba, pubic crest, pectineal line.	Intercostal, iliohypogastric, ilioinguinal.	Compresses viscera, flexes thorax, and assists in expiration.
Obliquus superior....	Above optic foramen, through pulley.	Sclerotic.....	Fourth cranial.....	Rotates eyeball downward and inward.
Obturator externus...	Obturator foramen and membrane.	Digital fossa, base of great trochanter.	Obturator.....	External rotator of thigh.
Obturator internus...	Obturator foramen and membrane.	Great trochanter.....	Sacral.....	External rotator of thigh.
Occipitofrontalis.....	Superior curved line of occiput and angular process of frontal.	Aponeurosis.....	Posterior auricular, small occipital, facial.	Moves scalp. Facial expression.
Omohyoid.....	Upper border of scapula..	Body of hyoid.....	Descendens and communicans noni (hypoglossi).	Depresses and retracts hyoid.
Opponens minimi digiti.	Unciform bone.....	Fifth metacarpal.....	Ulnar.....	Flexes little finger.
Opponens pollicis....	Trapezium, anterior annular ligament.	Metacarpal bone of thumb.	Median, palmar division.	Flexes thumb.
Orbicularis oris.....	Nasal septum and canine fossa of inferior maxilla, by accessory fibers.	Forms lips and sphincter of mouth.	Facial, buccal and supramaxillary branches.	Closes mouth.
Orbicularis palpebrarum.	Mesal margin of orbit....	Lateral margin of orbit.	Facial.....	Closes eyelids.
Palatoglossus.....	Soft palate.....	Side and dorsum of tongue.	Sphenopalatine ganglion.	Constricts the fauces.
Palatopharyngeus....	Soft palate.....	Thyroid cartilage and pharynx.	Sphenopalatine ganglion.	Closes posterior nares.
Palmaris brevis.....	Annular ligament and palmar fascia.	Skin of palm of hand...	Ulnar.....	Corrugates skin of palm.
Palmaris interossei...	Palmar surfaces second, fourth, and fifth metacarpals.	Bases of first phalanges of corresponding fingers.	Ulnar.....	Adductors of fingers.
Palmaris longus.....	Internal condyle of humerus.	Annular ligament and palmar fascia.	Median.....	Makes tense the palmar fascia.
Pectineus.....	Iliopectineal line and pubes.	Femur below lesser trochanter.	Anterior crural, obturator.	Flexes and rotates outward the thigh.
Pectoralis major.....	Clavicle, sternum, and costal cartilages.	External bicipital ridge of humerus.	Anterior thoracic, external and internal.	Draws arm downward and forward.
Pectoralis minor.....	Third, fourth, and fifth ribs.	Coracoid process.....	Anterior thoracic.....	Depresses point of shoulder.
Peroneus brevis.....	Middle third of shaft of fibula, externally.	Base of fifth metatarsal.	Musculocutaneous....	Extends foot.
Peroneus longus.....	Head and shaft of fibula..	First metatarsal of great toe.	Musculocutaneous ...	Extends and everts foot.
Peroneus tertius.....	Lower fourth of fibula....	Fifth metatarsal bone ..	Anterior tibial.....	Flexes tarsus.
Plantaris.....	Outer bifurcation of linea aspera and posterior ligament of knee-joint.	Os calcis by means of the tendo Achillis.	Internal popliteal....	Extends foot.
Plantaris interossei...	Shafts of 3d, 4th, and 5th metatarsal bones.	Bases of first phalanges of corresponding toes.	External plantar.....	Adducts toes.

MUSCLES, TABLE OF PRINCIPAL

NAME.	ORIGIN.	INSERTION.	INNERVATION.	FUNCTION.
Platysma myoides	Clavicle, acromion, and fascia.	Inferior maxillary bone, angle of mouth.	Facial and superficial cervical.	Wrinkles skin and depresses mouth.
Popliteus	External condyle of femur.	Shaft of tibia above oblique line.	Internal popliteal	Flexes leg.
Pronator quadratus	Lower fourth of ulna	Lower ¼ shaft of radius.	Anterior interosseous	Pronates hand.
Pronator radii teres	Internal condyle and coronoid process.	Outer side of shaft of radius.	Median	Pronates hand.
Psoas magnus	Bodies and transverse processes of last dorsal and all lumbar vertebræ.	Lesser trochanter	Lumbar	Flexes and rotates thigh outward, and flexes trunk on pelvis.
Psoas parvus	Bodies of last dorsal and first lumbar vertebræ.	Iliopectineal eminence and iliac fascia.	Lumbar	Flexes pelvis upon abdomen.
Pterygoid (external)	Two heads: 1. external pterygoid plate of sphenoid bone; 2. great wing.	Neck of condyle	Inferior maxillary	Draws inferior maxillary bone forward.
Pterygoid (internal)	Pterygoid fossa of sphenoid bone.	Inner surface of angle of jaw.	Inferior maxillary	Raises and draws inferior maxilla forward.
Pyramidalis	Pubes	Linea alba	Iliohypogastric	Tenses linea alba.
Pyramidalis nasi	Occipitofrontalis	Compressor naris	Facial nerve, infraorbital branch.	Depresses eyebrow.
Pyriformis	Front of sacrum, through great sciatic foramen.	Great trochanter	Sacral branch	External rotator of thigh.
Quadratus femoris	Tuberosity of the ischium.	Quadrate line of femur.	First sacral and fifth lumbar.	External rotator of thigh
Quadratus lumborum	Crest of ilium, transverse processes of lower three lumbar vertebræ.	Last rib, transverse processes of upper three lumbar vertebræ.	Upper lumbar and twelfth thoracic.	Flexes thorax laterally.
Quadriceps extensor femoris.	Includes the rectus, vastus internus and externus, and crureus muscles. Their common tendon contains the patella.			
Rectus abdominis	Pubic crest and fibrous tissues in front of symphysis.	Cartilages of the fifth to seventh ribs.	Intercostal, iliohypogastric, ilioinguinal.	Compresses viscera and flexes thorax.
Rectus capitis anticus major.	Transverse processes 3d to 6th cervical vertebræ.	Basilar process	First and second cervical.	Flexes head and slightly rotates it.
Rectus capitus anticus minor.	Transverse process and lateral mass of atlas.	Basilar process of occipital bone.	First cervical	Flexes head.
Rectus capitis lateralis.	Ventral cephalic surface of lateral mass of atlas.	Jugular process of occipital bone.	First cervical	Flexes head laterally.
Rectus capitis posticus major.	Spine of axis	Inferior curved line of occipital bone.	Suboccipital and great occipital.	Rotates head.
Rectus capitis posticus minor.	Dorsal arch of atlas	Below inferior curved line of occipital bone.	Suboccipital and great occipital.	Draws head backward.
Rectus externus	Two heads, outer margin of optic foramen.	Sclera	Sixth cranial	Rotates eyeball outward.
Rectus femoris	Anterior inferior iliac spine, brim acetabulum.	Proximal border of patella.	Anterior crural	Extends leg.
Rectus inferior	Lower margin of optic foramen.	Sclera	Third cranial	Rotates eyeball downward.
Rectus internus	Inner margin of optic foramen.	Sclera	Third cranial	Rotates eyeball inward.
Rectus superior	Upper margin of optic foramen.	Sclera	Third cranial	Rotates eyeball upward.
Retrahens aurem	Mastoid process	Concha	Posterior auricular	Retracts pinna.

MUSCLES, TABLE OF PRINCIPAL

Name.	Origin.	Insertion.	Innervation.	Function.
Rhomboideus major..	Spines of first five thoracic vertebræ.	Root of spine of scapula.	Fifth cervical.....	Elevates and retracts scapula.
Rhomboideus minor..	Spines of seventh cervical and first dorsal vertebræ.	Root of spine of scapula.	Fifth cervical.....	Retracts and elevates scapula.
Risorius.....	Fascia over masseter.....	Angle of mouth.....	Facial, buccal branch.	Draws angle laterally.
Rotatores spinæ.....	Transverse processes of from second to twelfth thoracic vertebræ.	Lamina of next vertebra above.	Dorsal branches.....	Rotate spinal column.
Sacrolumbalis.....	Erector spinæ.....	Angle of six lower ribs.	Branches of dorsal...	Erects spine and bends trunk backward.
Sartorius.....	Anterior superior spine of ilium.	Upper internal portion of shaft of tibia.	Anterior crural.....	Flexes and crosses legs.
Scalenus anticus.....	Scalene tubercle on first rib.	Transverse processes 3d to 6th cervical vertebræ.	Lower cervical.....	Flexes neck laterally.
Scalenus medius.....	First rib.....	Transverse processes of six lower cervical vertebræ.	Lower cervical.....	Flexes neck laterally.
Scalenus posticus....	Second rib.....	Transverse processes of three lower cervical vertebræ.	Lower cervical.....	Bends neck laterally.
Semimembranosus...	Tuberosity of ischium....	Inner tuberosity of tibia	Great sciatic.....	Flexes leg and rotates it inward.
Semispinalis coli.....	Transverse processes four upper dorsal and articular processes four lower cervical vertebræ.	Spines of second to fifth cervical vertebræ.	Cervical branches....	Erects spinal column.
Semispinalis dorsi....	Transverse processes 6th to 10th dorsal vertebræ.	Spines last two cervical and first four thoracic.	Branches of dorsal...	Erects spinal column.
Semitendinosus.....	Tuberosity of ischium....	Upper and inner surface of tibia.	Great sciatic.....	Flexes leg on thigh.
Serratus magnus.....	Eight upper ribs.....	Inner margin of dorsal border of scapula.	Posterior thoracic....	Elevates ribs in inspiration.
Serratus posticus inferior.	Spines of last two thoracic and first three lumbar.	Four lower ribs.....	Tenth and eleventh intercostal.	Depresses ribs in expiration.
Serratus posticus superior.	Spines of seventh cervical and first two thoracic vertebræ.	Second, third, fourth, and fifth ribs.	Second and third intercostal.	Raises ribs in inspiration.
Soleus.....	Shaft of fibula, oblique line of tibia.	Os calcis by tendo Achillis.	Internal popliteal and posterior tibial.	Extends foot.
Sphincter ani, external.	Tip of coccyx.....	Tendinous center of perineum.	Perineal, pudic, and fourth sacral.	Closes anus.
Sphincter ani, internal.	A thickening of the circular fibers of the intestine one inch avove the anus.	.....	Hemorrhoidal nerves.	Constricts rectum.
Sphincter vaginæ....	Central tendon of perineum.	Corpora cavernosa of clitoris.	Homologue of accelerator urinæ in male.	
Sphincter vesicæ internus.	Near the urethral orifice of the bladder.	.....	Vesical nerves.....	Constricts internal orifice of urethra.
Spinalis cervicis (*normal, but inconstant*).	Spines 5th, 6th, and 7th cervical and first two thoracic vertebræ.	Spine of axis, sometimes spines of 3d and 4th cervical vertebræ.		
Spinilis colli.....	Spines of fifth and sixth cervical vertebræ.	Spine of axis, or third and fourth cervical spines.	Cervical branches....	Steadies neck.
Spinalis dorsi.....	Last two thoracic and first two lumbar spines.	Remaining thoracic spines.	Dorsal branches.....	Erects spinal column.

MUSCLES, TABLE OF PRINCIPAL

Name.	Origin.	Insertion.	Innervation.	Function.
Splenius capitis.....	Lower two-thirds ligamentum nuchæ, spines of seventh cervical and first two thoracic vertebræ.	Outer third of middle oblique line of occiput and outer surface of mastoid process.	Middle cervical, posterior branches.	Extends head and neck and rotates and flexes laterally.
Splenius colli.....	Spines of third to sixth thoracic vertebræ.	Dorsal tubercles of transverse processes of upper three or four cervical vertebræ.	Posterior divisions of lower cervical.	Extends, flexes laterally, and rotates neck.
Stapedius.....	Interior of pyramid.....	Neck of stapes.....	Facial.....	Depresses base of stapes.
Sternocleidomastoid.	Two heads, sternum and clavicle.	Mastoid process and outer half of superior oblique line of occiput.	Spinal accessory and cervical plexus.	Depresses and rotates head.
Sternohyoid.....	Sternum and clavicle.....	Hyoid bone.....	Descending and communicating branches of the hypoglossal.	Depresses hyoid.
Sternothyroid.....	Sternum and cartilage of first rib.	Side of thyroid cartilage.	Descendens and communicans hypoglossi.	Depresses larynx.
Styloglossus.....	Styloid process.....	Side of tongue.....	Hypoglossal.....	Elevates and retracts tongue.
Stylohyoid.....	Styloid process.....	Body of hyoid.....	Facial.....	Draws hyoid upward and backward.
Stylopharyngeus.....	Styloid process.....	Thyroid cartilage.....	Glossopharyngeal, and pharyngeal plexus.	Elevates pharynx.
Subanconeus.....	Humerus above olecranon fossa.	Posterior ligament of elbow.	Musculospiral.	Tensor of ligament.
Subclavius.....	Cartilage of first rib.....	Inferior surface of clavicle.	Fifth and sixth cervical.	Draws clavicle downward.
Subcrureus.....	Anterior distal part of femur.	Synovial sac behind patella.	Anterior crural.....	Draws sac up.
Subscapularis.....	Subscapular fossa.....	Humerus, lesser tuberosity, and shaft.	Subscapular.....	Chief internal rotator of humerus.
Supinator longus.....	External condylcid ridge of humerus.	Styloid process of radius.	Musculospiral.....	Flexes forearm.
Supinator radii brevis.	External condyle of humerus, oblique line of ulna.	Neck of radius and its bicipital tuberosity.	Posterior interosseous.	Supinates hand.
Supraspinales.....	Lie on spinous processes in cervical region.			
Supraspinatus.....	Supraspinous fossa.....	Great tuberosity of humerus.	Suprascapular.....	Supports shoulder-joint, raises arm.
Temporal.....	Temporal fossa and fascia.	Coronoid process of mandible.	Inferior maxillary....	Closes mandible.
Tensor palati.....	Scaphoid fossa and alar spine of sphenoid.	About hamular process into soft palate.	Otic ganglion.....	Renders palate tense.
Tensor tarsi.....	Crest of lacrimal bone....	Tarsal cartilages.....	Facial, infraorbital branch.	Compresses puncta and lacrimal sac.
Tensor tympani.....	Temporal bone, Eustachian tube and canal, sphenoid bone.	Handle of malleus.....	Otic ganglion.....	Renders tense the membrana tympani.
Tensor vaginæ femoris.	Iliac crest and anterior superior spinous process.	Fascia lata.....	Superior gluteal.....	Tensor of fascia.
Teres major.....	Inferior angle of scapula..	Internal bicipital ridge of humerus.	Subscapular.....	Draws arm downward and backward.

MUSCLES, TABLE OF PRINCIPAL

Name.	Origin.	Insertion.	Innervation.	Function.
Teres minor.....	Axillary border of scapula.	Great tuberosity of humerus.	Circumflex.....	Rotates humerus outward and adducts it.
Thyrohyoid.....	Side of thyroid cartilage...	Body and greater cornu of hyoid bone.	Hypoglossal.....	Elevates larynx.
Tibialis anticus.....	Outer tuberosity and upper part of shaft of tibia.	Internal cuneiform and first metatarsal bone.	Anterior tibial.....	Flexes tarsus and elevates inner border of foot.
Tibialis posticus.....	Shaft of fibula and tibia, interosseous membrane.	Tuberosity of scaphoid, internal cuneiform, and bases of second to fourth metatarsal.	Posterior tibial.....	Extends tarsus and inverts foot.
Trachelomastoid.....	Transverse processes of 3d to 6th thoracic, and articular processes of last 3 or 4 cervical vertebræ.	Mastoid process.....	Branches of cervical..	Steadies head.
Transversalis abdominis.	Poupart's ligament, iliac crest, lower six ribs, lumbar vertebræ.	Linea alba, pubic crest, pectineal line.	Intercostal, iliohypogastric, ilioinguinal.	Compresses viscera and flexes thorax.
Transversalis colli....	Transverse processes of third to sixth thoracic vertebræ.	Transverse processes of five lower cervical vertebræ.	Cervical branches....	Keeps neck erect.
Transversus pedis....	Head 5th metatarsal and plantar ligaments of metatarsophalangeal joints.	First phalanx of great toe.	External plantar.....	Adducts great toe.
Transversus perinei...	Ramus of ischium.....	Central tendon.....	Perineal.....	Tensor of central tendon.
Transversus perinei, deep.	See *Compressor urethræ*.			
Trapezius.....	Superior curved line of occipital bone, spinous processes of last cervical and all the dorsal vertebræ.	Clavicle and spine of scapula, and acromion.	Spinal accessory and cervical plexus.	Draws head backward.
Triangularis sterni...	Ensiform cartilage, costal cartilages of 3 or 4 lower true ribs, and sternum.	Border of inner surfaces 2d, 3d, 4th, and 5th costal cartilages.	Intercostal.....	Expiration.
Triceps (3 *heads*) extensor cubiti.....	*External* and *internal* near musculospiral groove, shaft of humerus; *middle* or *long*, lower margin of glenoid cavity.	Olecranon process of ulna.	Musculospiral.....	Extends forearm.
Vastus externus.....	Anterior border great trochanter and linea aspera.	Tuberosity of tibia.....	Anterior crural.....	Extends leg.....
Vastus internus and crureus.	Inner lip of linea aspera of femur.	Tuberosity of tibia.....	Anterior crural.....	Extends leg.
Zygomaticus major et minor.	Malar bone.....	Angle of mouth.....	Facial, infraorbital branch.	Elevates lip outward.

MUSCLES GROUPED ACCORDING TO FUNCTIONS*

[The exact functions of many of the muscles have not yet been decisively determined. Anatomical studies, the construction of mechanical models, the electrical stimulation of the musculature, and observation of the muscular activities of normal individuals and of individuals in whom given muscles or sets of muscles are absent or paralyzed, have all proved valuable methods of investigation, but each method has its drawbacks, and knowledge of the part actually played by individual muscles in the normal activities of the body is as yet merely approximate. Owing to the influence of gravity, the relations of other muscles to the skeleton, and similar factors, a given muscle may perform functions which would not be deduced from a simple study of the relations of the muscle to the skeleton. Thus the iliacus serves to flex not only the hip, but also the knee, and the hamstring muscles may flex the hip while flexing the knee. The functions ascribed to various muscles in the following tables, although an attempt has been made to base them upon the more recent work on the action of the muscles, must be taken to be merely approximately correct.]

* From Dr. Charles R. Bardeen's article in Morris' Anatomy.

1. Facial muscles.
These serve essentially to contract the various visceral orifices of the head or to retract the tissue surrounding them.
Ear.
Retractors: Attrahens aurem, attollens aurem, and retrahens aurem.
Orbit.
(*a*) *Retractor:* Occipitofrontalis. The levator palpebræ superioris, innervated by the third cranial nerve, serves to raise the upper lid of the eye.
(*b*) *Contractors:* Orbicularis palpebrarum, corrugator supercilii and pyramidalis nasi.
Nasal orifice.
(*a*) *Dilators:* Levator labii superioris alæque nasi, transverse portion of the compressor naris, and the dilatores naris.
(*b*) *Contractors:* Compressor naris and the depressor alæ nasi.
Oral orifice.
(*a*) *Retractors:*
Upward: Zygomaticus major and minor, levator labii superioris, levator labii superioris alæque nasi.
Lateralward: Zygomaticus major, levator anguli oris, risorius, platysma myoides, depressor anguli oris, buccinator.
Downward: Depressor anguli oris, depressor labii inferioris, platysma myoides.
(*b*) *Contractors:* Orbicularis oris.
(*c*) *Protractors of the lips:* Part of the orbicularis oris, levator menti.
Muscles acting on the eyeball.
To adduct the pupil: Internal rectus.
To abduct the pupil: External rectus.
To rotate the pupil upward: Superior rectus, in association with the inferior oblique.
To rotate the pupil downward: Inferior rectus, in association with the superior oblique.

3 Muscles acting on the lower jaw.
(*a*) *To raise it:* Masseter, temporal, internal pterygoid.
(*b*) *To lower it:* External pterygoid, digastric, mylohyoid, geniohyoid, and the infrahyoid muscles. The weight of the jaw also plays a part in this movement.
(*c*) *To protract it:* External pterygoid and internal pterygoid.
(*d*) *To retract it:* The inferior dorsal portion of the temporal, the digastric, mylohyoid, and geniohyoid.
(*e*) *To produce lateral movements:* The external pterygoid acting on one side carries the jaw toward the opposite side. The masseter draws it slightly toward the side on which the muscle lies. This action of the masseter is overcome by the internal pterygoid (Riegner).
Muscles acting on the hyoid bone.
(*a*) *To elevate it:* Digastric, stylohyoid, styloglossus, mylohyoid, geniohyoid, genioglossus, hyoglossus, and the middle constrictor of the pharynx.
(*b*) *To depress it:* Thyrohyoid, sternohyoid, omohyoid, sternothyroid.
(*c*) *To protract it:* Genioglossus (inferior portion), geniohyoid, anterior belly of digastric, and the mylohyoid.
(*d*) *To retract it:* Posterior belly of digastric, stylohyoid, and the middle constrictor of the pharynx.

5. Muscles acting on the larynx.
(*a*) *To elevate it:* Thyrohyoid, stylopharyngeus, palatopharyngeus, the inferior constrictor of the pharynx, and the elevators of the hyoid bone.
(*b*) *To depress it:* Sternothyroid, sternohyoid, and omohyoid.
(*c*) *To approximate the vocal cords:* Lateral cricoarytenoid, posterior cricoarytenoid (in conjunction with the preceding muscle); internal thyroarytenoid, external thyroarytenoid; transverse arytenoid.
(*d*) *To make the vocal cord tense:* Cricothyroid, lateral cricoarytenoid, posterior cricoarytenoid, transverse arytenoid.
(*e*) *To widen the rima glottidis:* Posterior cricoarytenoid.
(*f*) *To relax the vocal cord:* External thyroarytenoid, internal thyroarytenoid.

6. Muscles acting on the tongue.
(*a*) *To elevate it:* Styloglossus (especially along the sides), palatoglossus, glossopharyngeus, and the elevators of the hyoid bone.
(*b*) *To depress it:* Genioglossus (in the center), hyoglossus (at the sides), chondroglossus, and the depressors of the hyoid bone.
(*c*) *To protrude it:* Genioglossus (middle and inferior portions).
(*d*) *To retract it:* Genioglossus (anterior portion), styloglossus, chondroglossus.
(*e*) *To shorten it and make it bulge upward:* Superior and inferior lingual.
(*f*) *To narrow it and make it bulge upward:* Transverse lingual.
(*g*) *To flatten it:* Vertical lingual.
When the muscles work symmetrically, these movements are symmetrical; when they do not work symmetrically, the tongue is moved from side to side, rotated, etc.

7. Muscles acting on the palate and pharynx.
(*a*) *To narrow the pharyngeal opening of the Eustachian tube:* Levator palati.
(*b*) *To widen the isthmus of the Eustachian tube:* Levator palati.
(*c*) *To open the tube:* Tensor palati.
(*d*) *To raise and shorten the uvula:* Azygos uvulæ.
(*e*) *To depress the soft palate:* Palatoglossus, palatopharyngeus.
(*f*) *To make tense the soft palate:* Tensor palati.
(*g*) *To lift the soft palate:* Levator palati.
(*h*) *To approximate the anterior pillars of the fauces:* Palatoglossus.
(*i*) *To approximate the posterior pillars of the fauces:* Palatopharyngeus, superior constrictor of the pharynx.
(*j*) *To constrict the pharynx:* Superior, middle, and inferior constrictors.
(*k*) *To widen the pharynx:* Stylopharyngeus and the muscles which protract the hyoid bone.
(*l*) *To elevate the pharynx:* Stylopharyngeus, palatopharyngeus.

8. Muscles acting on the head.
(*a*) *To flex it:* The supra- and infrahyoid muscles (except the posterior belly of the digastric), rectus capitis anticus major and minor.
(*b*) *To extend it:* Sternocleidomastoid, trapezius, splenius capitis, trachelomastoid, complexus, obliquus capitis superior, rectus capitis posticus major and minor, and the posterior belly of the digastric.
(*c*) *To bend it laterally:* Sternocleidomastoid, rectus capitis lateralis, splenius capitis, trachelomastoid, complexus, obliquus capitis superior.
(*d*) *To rotate it:* Sternocleidomastoid, trapezius, splenius capitis, trachelomastoid, complexus, obliquus capitis superior and inferior, rectus capitis posticus major and minor.

9. Muscles acting on the spinal column.
(*a*) *To flex it:* Sternocleidomastoid, longus colli, rectus capitis anticus major, psoas major and minor, scaleni, rectus abdominis, obliquus abdominis externus and internus, levator ani, coccygeus and sphincter ani.
(*b*) *To extend it:* Splenius capitis, splenius colli, erector spinæ, semispinalis dorsi, semispinalis colli, complexus, multifidus spinæ, rotatores, interspinales, levatores costarum, quadratus lumborum.
(*c*) *To bend it laterally and rotate it:* Sternocleidomastoid, scaleni, longus colli, trapezius, levator anguli scapulæ, splenius capitis and colli, semispinalis dorsi, semispinalis colli, complexus, multifidus spinæ, rotatores, intertransversales, levatores costarum, psoas major and minor, quadratus lumborum, obliquus abdominis externus and internus, and rectus abdominis.

10. Muscles of respiration.
Quiet inspiration: The internal intercostals, anterior portion of internal intercostals, diaphragm.
Enforced inspiration: In addition to the muscles mentioned above, the scaleni, sternocleidomastoid, serratus posticus superior and inferior, rhomboids, serratus anticus, latissimus dorsi, pectoralis major and minor, and the extensors of the spinal column.

Quiet expiration: Posterior part of internal intercostals, subcostals, and triangularis sterni.

Enforced expiration: In addition to the muscles mentioned above, the abdominal muscles, sacrolumbalis, and the quadratus lumborum.

The chief muscles of respiration are the intercostals; the diaphragm plays a minor part (Fick).

11. Muscles acting on the abdomen.
    (*a*) *Constriction of the abdominal cavity:* Obliquus abdominis externus and internus, the transversalis and rectus abdominis, and the diaphragm, levator ani, and coccygeus.
    (*b*) *Reduction of pressure in the abdominal cavity:* The muscles of inspiration, with the exception of the diaphragm, serve to lessen the compression of the abdominal viscera.
12. Action of the muscles of the perineal region.
    (*a*) *To close anal canal:* Sphincter ani externus.
    (*b*) *To constrict the anal portion of the rectum;* Levator ani (pubococcygeal portion).
    (*c*) *To constrict the bulbus urethræ and the corpus cavernosum urethræ* (corpus spongiosum): Bulbocavernosus.
    (*d*) *To elevate the prostate gland:* Levator ani.
    (*e*) *To constrict the vagina:* Bulbocavernosus, levator ani (pubococcygeal portion).
    (*f*) *To cause erection of penis and clitoris:* Ischiocavernosus, bulbocavernosus, and compressor urethræ.
    (*g*) *To compress the urethra and Cowper's gland:* compressor urethræ and the transversus perinei.
    (*h*) *To support and lift the pelvic floor:* Levator ani, coccygeus, transversus perinei.
13. Muscles acting on the shoulder-girdle.
    The two joints acted upon are the sternoclavicular and the acromioclavicular. The movements produced consist in lifting and lowering the shoulder, carrying it forward and backward, and rotating it.
    (*a*) *Elevation:* Levator anguli scapulæ, trapezius (upper portion), sternocleidomastoid, rhomboidei, serratus magnus (middle portion), omohyoid.
    (*b*) *Depression:* Trapezius (lower portion), pectoralis major (lower portion), pectoralis minor, subclavius, latissimus dorsi. The weight of the limb is likewise a factor.
    (*c*) *Forward movement:* Serratus magnus, pectorales major and minor.
    (*d*) *Backward movement:* Trapezius, rhomboidei, latissimus dorsi.
    (*e*) *Rotation:*
    Associated with abduction of the arm: Serratus magnus (inferior portion), trapezius (superior part), levator anguli scapulæ.
    Associated with adduction of the arm: Rhomboidei, trapezius (inferior part), serratus magnus (upper part), pectoralis major (pectoral portion), latissimus dorsi.
14. Muscles acting on the arm at the shoulder-joint.
    (*a*) *To abduct it:* Deltoid, supraspinatus, biceps (long head). The inferior part of the serratus magnus and the superior part of the trapezius are important in the early stages of abduction of the arm; the clavicular portion of the pectoralis major in supraabduction.
    (*b*) *To adduct it:* Pectoralis major, latissimus dorsi, teres major, coracobrachialis, triceps (long head). To these should be added the weight of the limb.
    (*c*) *To flex it:* Pectoralis major, deltoid (anterior portion), subscapularis, coracobrachialis, biceps (short head), and the serratus magnus.
    (*d*) *To extend it:* Deltoid (posterior portion), teres major, latissimus dorsi. The upper and middle portions of trapezius, and the levator anguli scapulæ play an important part in extension of the arm.
    (*e*) *To rotate it outward:* Infraspinatus, teres minor, and possibly the posterior portion of the deltoid.
    (*f*) *To rotate it inward:* Subscapularis, deltoid (anterior fibers), teres major, latissimus dorsi, and pectoralis major.
15. Muscles acting on the forearm at the elbow-joint (arranged in order of force exerted according to W. Grohmann).
    (*a*) *Flexion at elbow:*
    Forearm supinated: Brachialis, long head of biceps, supinator longus, short head of biceps, extensor carpi radialis longus, pronator radii teres, flexor carpi radialis, extensor carpi radialis brevis, palmaris longus.
    Forearm in mid-position or pronated: Brachialis anticus, supinator longus, long head of biceps, short head of biceps, extensor carpi radialis longus, pronator radii teres, flexor carpi radialis, extensor carpi radialis brevis, palmaris longus.
    (*b*) *Extension at elbow:* Triceps, anconeus.
    (*c*) *Pronation of forearm:*
    Forearm extended; Pronator radii teres, flexor carpi radialis, pronator quadratus, palmaris longus.
    Forearm at right angles: Pronator radii teres, supinator longus, flexor carpi radialis, pronator quadratus, extensor carpi radialis longus, palmaris longus.
    Forearm flexed: Pronator radii teres, supinator longus, flexor carpi radialis, pronator quadratus, extensor carpi radialis longus, palmaris longus.
    (*d*) *Supination:*
    Forearm extended: Supinator longus, short head of biceps, long head of biceps, supinator brevis extensor carpi radialis longus, extensor ossis metacarpi pollicis, extensor primi internodii, extensor secundi internodii pollicis, extensor indicis.
    Forearm at right angles; Short head of biceps, long head of biceps, supinator brevis, extensor ossis metacarpi pollicis, extensor primi internodii pollicis, supinator longus (in pronation), extensor secundi internodii pollicis, extensor indicis.
    Forearm flexed; Short head of biceps, long head of biceps, supinator brevis, extensor ossis metacarpi pollicis, extensor primi internodii pollicis, extensor secundi internodii pollicis, extensor indicis.
16. Muscles acting on the hand at the wrist.
    (*a*) *To flex it:* Flexor carpi radialis, palmaris longus, flexor carpi ulnaris, long flexors of the thumb and fingers, extensor ossis metacarpi pollicis.
    (*b*) *To extend it:* Extensor carpi radialis longus and brevis, extensor carpi ulnaris, and the extensors of the thumb and fingers.
    (*c*) *To adduct it:* Extensor carpi radialis brevis and longus, extensor ossis metacarpis pollicis, extensor primi internodii pollicis, flexor carpi radialis.
    (*d*) *To abduct it:* Flexor carpi ulnaris, extensor carpi ulnaris.
17. Muscles acting on the fingers.
    (*a*) *To flex all the joints:* Flexor profundus digitorum; all but the last: flexor sublimis digitorum; the metacarpophalangeal joint only: flexor brevis minimi digiti, the lumbricales, and interossei.
    (*b*) *To extend the fingers*; Extensor communis digitorum, extensor indicis, extensor minimi digiti; to extend the two interphalangeal joints: the lumbricales, interossei, and frequently the flexor brevis minimi digiti.
    (*c*) *To abduct from the axis passing through the center of the middle finger:* Dorsal interossei, first two lumbricals, abductor minimi digiti.
    (*d*) *To adduct toward this axis:* Palmar interossei, last two lumbricals, opponens and flexor minimi digiti.
18. Muscles acting on the thumb.
    (*a*) *To flex all joints:* Flexor longus pollicis; the carpometacarpal and metacarpophalangeal joints: flexor brevis, the adductors, abductor brevis; the carpometacarpal joints: opponens pollicis, extensor ossis metacarpi pollicis.
    (*b*) *To extend all joints:* Extensor longus pollicis; the carpometacarpal and metacarpophalangeal joints: extensor brevis pollicis.
    (*c*) *To adduct:* The adductor, flexor brevis, opponens, first dorsal interosseous, extensor longus.
    (*d*) *To abduct:* The long and short abductors, the extensor brevis.
19. Muscles acting on the pelvis.
    (*a*) *To flex it:* Rectus abdominis, obliquus abdominis externus and internus, psoas major and minor.
    (*b*) *To extend it:* Erector spinæ and multifidus spinæ.
    (*c*) *To bend it laterally and rotate it:* Abdominal muscles, quadratus lumborum, and psoas muscles acting on one side.

20. Muscles acting on the thigh at the hip-joint.
    (a) *To flex it:* Iliopsoas, sartorius, rectus femoris, pectineus, gracilis, adductor longus and brevis, tensor vaginæ femoris.
    (b) *To extend it:* Gluteus maximus, biceps, semitendinosus, semimembranosus, adductor magnus.
    (c) *To adduct it:* Gracilis, pectineus, adductor longus, brevis, and magnus, gluteus maximus (lower portion), quadratus femoris, obturator externus.
    (d) *To abduct it:* Gluteus medius and minimus, tensor vaginæ femoris, gluteus maximus; and when the hip is flexed, the pyriformis, obturator internus, and gemelli.
    (e) *To rotate it inward:* Tensor vaginæ femoris, gluteus medius (anterior portion), gluteus minimus, illopsoas.
    (f) *To rotate it outward:* Pyriformis, obturator internus and gemelli, obturator externus, quadratus femoris, gluteus maximus, gluteus medius (posterior portion), sartorius, pectineus, adductor longus, brevis, and magnus (superior and middle fasciculi), biceps.
21. Muscles acting on the leg at the knee-joint.
    (a) *To flex it:* Sartorius, gracilis, semitendinosus, semimembranosus, biceps, gastrocnemius, popliteus.
    (b) *To extend it:* Quadriceps femoris (the tensor vaginæ femoris and gluteus maximus through the iliotibial band serve to keep the extended leg fixed).
    (c) *To rotate it inward* (when flexed). Sartorius, gracilis, semitendinosus, semimembranosus, popliteus.
    (d) *To rotate it outward* (when flexed): Biceps.
22. Muscles acting on the foot at the ankle-joint (arranged in order of force exerted, according to R. Fick).
    (a) *To flex it:* Tibialis anticus, extensor longus digitorum, extensor longus hallucis, peroneus tertius.
    (b) *To extend it:* Soleus, gastrocnemius, flexor longus hallucis, peroneus longus, tibialis posticus, flexor longus digitorum, peroneus brevis.
    (c) *To invert the foot at the inferior articulation of the talus* (art. talocalcanea and talocalcaneonavicularis): soleus, gastrocnemius, tibialis posticus, flexor longus hallucis, flexor longus digitorum.
    (d) *To evert the foot at the inferior articulation of the talus:* Peroneus longus, peroneus brevis, extensor longus digitorum, peroneus tertius, extensor longus hallucis, tibialis anticus.
    (e) *To invert the foot at Chopart's* (talonavicularcalcaneocuboid) *joint:* Tibialis anticus, tibialis posticus, flexor longus hallucis, flexor longus digitorum, extensor longus hallucis.
    (f) *To evert the foot at Chopart's joint:* Peroneus longus, peroneus brevis, extensor longus digitorum, peroneus tertius.
23. Muscles acting on the toes (arranged in order of force exerted, according to R. Fick).
    (a) *To flex all the joints:* Flexor longus digitorum, flexor accessorius digitorum, and flexor longus hallucis; the first interphalangeal and the metacarpophalangeal joints of the four lateral toes: flexor brevis digitorum; the metacarpophalangeal joints: the lumbricals, interossei, abductor hallucis, adductor hallucis (oblique head), flexor brevis hallucis, abductor minimi digiti, flexor minimi digiti.
    (b) *To extend all joints:* Extensor longus digitorum, extensor longus hallucis, extensor brevis digitorum, the interphalangeal joints; the lumbricales, and the adductors and abductors of the big and little toes.
    (c) *To abduct from an axis passing through the second toe:* Abductor hallucis, dorsal interossei, abductor minimi digiti, first lumbrical.
    (d) *To adduct toward this axis:* Adductores hallucis, plantar interossei, three more lateral lumbricals.
    (e) *To draw together the ends of the metatarsals:* The transverse head of the adductor of the big toe.

MUSCLES, INFLAMMATION.—See Myositis.

MUSCLES, INJURIES.—**Atrophy** of muscles arises from want of use, from continued pressure, from injury, from interference with the blood supply, from disease of the nerves or their centers, or from lead-poisoning. Treatment must be according to the cause, with the use of galvanism, passive motion, friction, massage, etc.

Contractions of muscles result from injury, from joint-disease, from disease of the nervous system, and from malposition of parts. Sudden or gradual extension, tenotomy, and myotomy, are the means of treatment. Nerve stretching is of value when the contraction is spasmodic.

Dislocation of muscles and tendons is more usually the result of accident, associated with chronic joint-disease, or of fracture than of solitary injury. The long head of the biceps is most often displaced. Early in rheumatoid arthritis of the shoulder-joint the long head of this muscle is displaced, and the tendon absorbed. The muscles of the forearm may be dislocated. In treating a dislocated muscle or tendon reduction is generally easy, but the displacement is likely to recur, since the sheath of the muscle or tendon has been lacerated. The limb should be relaxed to reduce a dislocation of this nature, and the tendon manipulated. A splint should be applied, so that pressure is made on the point of injury, but the muscle is relaxed. If firm adhesion of the tendon does not occur in 4 weeks, operation should be performed, incision made, and the edges of the torn sheath freshened and sewed with chromic catgut or kangaroo tendon. Passive movements may begin at the end of the first week. Fibrous tissue forms when the ends of divided muscles are widely separated, but when the ends are closely approximated, this fibrous tissue becomes filled with muscle-fibers resembling true muscle.

Hernia of muscles is treated by incision and stitching of the fascia covering the muscle.

Hypertrophy of muscle arises from excessive use, and in pseudohypertrophic paralysis the muscle bulk is greatly augmented, but there is less muscle structure and more fat and connective tissue.

Rupture of a muscle may be followed by atrophy. A limited rupture is to be treated as a strain, but when it is extensive and the ends widely separated, it should be incised and sutured with chromic catgut, the skin being sewed with silkworm-gut. Rest, relaxation, and other means of combating inflammation are to be employed.

A strain is the name given to the condition in which there is a small amount of rupture with stretching of the muscle. The deltoid, the hamstring, the calf, the back, the biceps, and the great pectoral muscles are those mostly strained. Strain of the pronator radii teres muscle gives rise to the "lawn-tennis" arm. "Rider's leg" is produced by a strain of the adductors of the thigh. Strain of the psoas magnus muscle may suggest appendicitis, but there is no local tenderness, abdominal rigidity, nor constitutional symptoms.

The treatment of strains consists in relaxation by suitable position, rest by the use of splints, and rest in bed, bandages for compression, and the application of hot water, hot lead-water and laudanum, and of ichthyol. Dover's powder or morphin may be used if the pain is excessive.

Wounds and Contusions.—Contusions of mus-

cles vary in severity and in extent, and may be followed by suppuration, inflammation, or atrophy. Wounds of muscles are open or subcutaneous, longitudinal or transverse. When the wound is transverse, it is best to unite the gaping edges of the muscle by catgut stitches. When the wound is longitudinal, drainage should be provided. Rest by means of splints, proper position, and relaxation are to be obtained, and inflammation combated. Bandaging may prevent much swelling, while the early use of cold limits the spread of inflammation. Lead-water and laudanum are useful. Iodin, blue ointment, ichthyol, and intermittent heat are of value when repair is well advanced. As soon as the acute symptoms subside, massage, passive motion, stimulating liniments, and galvanism, if the reaction of degeneration exists, or faradism, if it does not exist, are to be employed.

MUSCLES, PROGRESSIVE ATROPHY.—**Synonyms.**—Wasting palsy; chronic spinal muscular atrophy; chronic anterior poliomyelitis; Duchenne-Aran's disease.

Definition.—A slowly progressive wasting and atrophy of certain groups of muscles, with symptoms varying in accordance with the variations in the pathologic anatomy.

Etiology.—It is most frequent in males between 25 and 50 years of age, and in many instances is hereditary. A predisposing cause seems to exist in those who habitually use one set of muscles (muscular strain). Exposure to cold and damp, lead-poisoning, syphilis, and injuries to the spinal column are other causes. It follows such acute diseases as diphtheria, measles, acute rheumatism, typhoid and typhus fevers.

Pathologic Anatomy.—The morbid alterations are of two groups—spinal and muscular.

The spinal changes consist in the atrophy and degeneration of the anterior columns, wasting and disappearance of the multipolar ganglion cells of the anterior horns, with hyperplasia of the neuroglia; rarely the hyperplasia extends to the lateral columns (amyotrophic lateral sclerosis); also wasting, atrophy, and degeneration of the anterior nerve-roots.

The muscular changes consist of a progressive wasting of the muscular tissue, with increase of the interstitial connective tissue. The final result is that the muscle is converted into a mere fibrous band with numerous fat-cells, the development of this material taking place outside of the muscular elements and in the newly formed connective tissue.

Symptoms.—The invasion is gradual, the disease having been in progress some weeks or months before the patient is aware of its existence. Wasting usually begins in the hand, the first dorsal interosseous being the first to be attacked, then the muscles of the thenar and hypothenar eminences, then the deltoid, and so on from group to group. Often, however, the extension is very erratic in its course, jumping from one group to another at some distance. In the immense majority of cases the disease is permanently limited to one or a few groups of muscles in the upper, or, more rarely, in the lower, extremities. The only muscles not yet known to be attacked are those of mastication and those that move the eyeball (Roberts).

Fibrillary contraction is an early symptom, continuing more or less marked so long as any muscular fibers remain. It consists of wave-like movements of the muscles, excited automatically by drafts of air or percussion. Coincident with the wasting are loss of power, disorders of sensation, coolness and pallor of the surface. The natural roundness and contour of the body and limbs are changed, the bones standing out in unaccustomed distinctness, giving the individual the appearance of a skeleton clothed in skin. The hand is frequently the seat of a very singular deformity—the "claw-shaped" hand. The electrocontractility is preserved so long as muscular fibers remain.

Diagnosis.—When wasting palsy is fully developed, its diagnosis is a simple matter. In its early stages a doubt may exist, but attention to the history, symptoms, and progress will determine the question.

Syringomyelia often begins with muscular atrophy as a marked symptom, and may be confounded with wasting palsy, the chief points of distinction between which are, the loss of power of perceiving heat, or, often, to distinguish between heat and cold, and the appearance of trophic changes, such as a dusky or purplish hue of the hands, with a uniform thickness resembling myxedema, the development of blebs and ulcers, and changes in the nails. Arthropathies are sometimes met with. See MUSCLES (Progressive Dystrophies).

Prognosis is very unfavorable, although the danger to life is often very remote. The disease may be arrested and remain stationary for years.

Treatment.—Internal medication seems to have no effect on the malady, although if mineral poisoning is suspected, potassium iodid should be used, and if syphilis is suspected, a course of potassium iodid and mercury should be administered. Arsenic, strychnin sulphate, and cod-liver oil, with a generous diet, are among the remedies indicated. If the disease is the result of over-working any set of muscles, these must be allowed a rest. A most effective remedy in wasting palsy is, undoubtedly, galvanism. See MOTOR POINTS.

Massage is a valuable adjuvant to the electric treatment, as are hot sponging and rubbing along the spine.

MUSCLES, PROGRESSIVE DYSTROPHIES.—Progressive muscular dystrophy is a term employed to designate all forms of progressive muscular weakness with atrophy, in which the seat of the lesion is in the muscle itself. The dystrophies are to be distinguished on the one hand from progressive spinal muscular atrophy which is due to a chronic progressive degeneration of the gray matter of the spinal cord, and, on the other hand, from chronic multiple neuritis, in which the lesion is in the nerve-fibers. If the lesion of a disease characterized by progressive muscular weakness and atrophy is located in the gray matter of the spinal cord, it is called *amyotrophy;* if it is located in the nerve, it is called *neural atrophy;* if it is located in the muscle itself, it is called *myopathy.* In any case exhibiting progressive muscular weakness and atrophy

it is the physician's first duty to determine whether he has to deal with an amyotrophy, a myopathy, or a neural atrophy. But it is always well to bear in mind that the large multipolar cell in the anterior horn of the cord, with its axis-cylinder process (neuraxon) and the muscle-fibers to which it is distributed, constitutes a trophic unit, and that a disease process may involve more than one portion of this trophic unit. It may begin in one, and spread to an adjoining portion. Indeed, it is questionable whether disease is ever confined strictly to one of these three portions of the trophic unit. Ordinarily, however, they are chiefly confined to one portion, thus affording a basis of classification. There are cases on record which exhibited the symptomatology of amyotrophy and myopathy, or neural atrophy at the same time, and in which two or all three portions of the trophic unit were involved.

Symptoms.—The progressive muscular dystrophies appear before the age of 18, the majority before the age of 10. They are characterized by muscular weakness, and eventually by great muscular atrophy; but in the earlier stages apparent enlargement of certain muscles—pseudohypertrophy—is frequently seen. There are no mental or sensory symptoms, or these are rare or inconspicuous. Fibrillary twitchings, common in the amyotrophic form of progressive muscular atrophy, are, with rare exceptions, absent. The onset of the muscular weakness is insidious, and the shoulder or pelvic girdle or the legs are first affected. Unlike the spinal type of progressive muscular atrophy, the disease almost never begins with weakness and atrophy of the small muscles of the hand. The dystrophies belong to the so-called family diseases. Commonly two or more members of a family are affected. Boys are much more prone to be affected than girls. The hereditary influence is usually derived from the mother. The knee-jerks and the qualitative electric reactions are unaltered save in the late stages of the disease. The disease progresses until a stage of almost complete helplessness is reached. The weakness and atrophy become extreme, and various forms of club-feet and anteroposterior and lateral curvature of the spine are seen late in the disease.

Types.—The different varieties of the muscular dystrophies have been much written about, but they are really unimportant. These different types depend upon the age at which the disease appears, and the parts first or most affected, and the distribution of the atrophy or hypertrophy. These so-called types are merely varieties of the dystrophies exhibiting superficial differences, and are not in any sense distinct diseases.

The fact that these various types run into or overlap each other, and that different types are seen in the same family, offer strong evidence in support of this view. For example, one of the two brothers shown in the accompanying illustrations represents one type, while the other brother represented another type or a mixture of two types.

The most important types commonly described are these:

1. Pseudomuscular hypertrophy.
2. Juvenile type of Erb.
3. Facioscapulohumeral type of Landouzy-Déjérine.
4. The atrophic form.

Pseudomuscular hypertrophy has, of these various types, been longest, and is best, known. It develops slowly, and begins usually before the eighth year. The first symptom noticed is some clumsiness in walking or running and in going upstairs, due to weakness of the muscles of the calves and of the extensors of the knees. The calf-muscles, although weakened, become hypertrophied. The infraspinati, the glutei, and the extensors of the knee also become hypertrophied. The lower half of the pectoralis major and the latissimus dorsi are wasted early in the disease. This hypertrophy may be very marked or only slight. Weakness of the muscles of the back, and of those which fix the pelvis upon the thighs,

Erb's Type of Progressive Muscular Dystrophy.

produce an anterior curvature of the spine (lordosis) which may become extreme, so that a perpendicular line, touching the spine between the shoulders, and striking the ground, passes 2 or 3 inches behind the sacrum. When the child sits down, this anterior curvature disappears and is replaced by a posterior curvature. The gait becomes more and more waddling as the disease progresses. Great difficulty is experienced in going up-stairs, due especially to the weakness of the extensors of the knees. In rising from the floor the child gets upon his hands and knees, then places one foot upon the floor, then one hand upon the knee, the other hand upon the other knee, and then, by successive movements, climbs up his own thighs in the characteristic fashion first described by Gowers. As the disease progresses, the hypertrophied muscles become atrophied. Contractures frequently occur, due to the overaction of

certain groups of muscles which are no longer opposed by their normal antagonists. Thus various forms of club-foot are produced, especially talipes equinus. Contractures of the legs upon the thighs, and of the thighs upon the abdomen, occur, and may become extreme. Sensation remains normal. As a rule, no mental changes take place. Quantitative, but not qualitative, electric changes occur. The knee-jerks are preserved (never exaggerated) until the disease has made considerable progress. They fade out gradually as the disease progresses.

The Juvenile type of Erb begins with weakness in the shoulder girdle. There is atrophy of the thighs and upper arms, while the forearms, hands, legs, and shoulders preserve their natural contour; indeed, there may be some hypertrophy of the deltoids, the calf-muscles, and the infraspinati. The thin upper arms and the thighs, along with the apparently well-developed forearms, deltoids, and calf-muscles constitute the striking picture which this type of dystrophy presents. This variety of dystrophy is well illustrated by the accompanying illustration. Eventually all the muscles become atrophic. Contractures of the legs and curvature of the spine occur, and the child becomes quite helpless. The later stage of this type of the disease differs little from that of pseudomuscular hypertrophy.

The facioscapulohumeral type of Landouzy-Déjérine usually begins in infancy. The distinguishing feature is the wasting and atrophy of the face-muscles, giving rise to the so-called myopathic facies. The face presents a mask-like appearance, and the lips are protruded and thickened, constituting the "Tapir mouth" (*bouche de tapier*). Neither the ocular muscles nor those of mastication or deglutition are affected. The atrophy extends to the shoulder and arm muscles. The features seen in the preceding type develop. It chiefly differs from the Erb type in that the face is involved and that the onset is at an earlier period of life.

The atrophic type presents the chief features of pseudomuscular hypertrophy, differing from that type mainly in that there is no hypertrophy, or apparent hypertrophy, at any stage of the disease. The muscles of the legs and back are first affected. The gait, according to Bramwell, is not so waddling as that of the pseudohypertrophic form; and he has described it as the "spider-crab" gait. This form is so nearly identical with the so-called Leyden type that the latter need not be described.

Course and Duration.—The dystrophies are essentially chronic in their course, which, however, varies greatly within certain limits. Ordinarily, patients live from 10 to 20 years; but a few cases have run a somewhat rapid course in 3 or 4 years. On the other hand, some patients have lived almost to old age. When the affection begins in early infancy, or the onset is rapid, the probabilities are that it will run a comparatively short course. The disease seems to progress more rapidly after the patient has become so weakened as to be practically helpless.

Etiology.—In about one-half the cases heredity has been traced, usually through the mother. The disease is so distinctly a family one that it must be concluded that its potential possibilities are contained in the germ-plasm. This, of course, implies some defect in one or both of the parents of a patient.

In the majority of cases the disease appears before the age of 10 years. Boys are much more frequently affected than girls; but in the Landouzy-Déjérine type boys and girls suffer about equally.

Pathologic Anatomy.—The primary seat of the disease is in the muscles themselves. The term "primary muscular dystrophy" is meant to carry with it this idea. The anatomic changes are practically the same in the different types. Slight changes have been found in the spinal cord, very different in degree and kind from those found in progressive spinal muscular atrophy of the Duchenne-Aran type. Nevertheless, the view is held by some that the dystrophies are nervous in origin, due to damage to the trophic centers which control the nutrition of the muscles. The primary changes are found in the muscle-fibers. Atrophied and hypertrophied fibers are found, the former predominating. There is proliferation of the nuclei, and vacuolation and segmentation of the fibers. Secondarily, there occurs proliferation of the connective tissue, multiplication of its nuclei, and increase of adipose tissue. The apparent increase in size of the muscles is chiefly due to these fatty and connective-tissue deposits.

Diagnosis.—The dystrophies are not difficult of recognition if the features which characterize them are known. In the following little table the chief diagnostic features which separate them from the spinal form of progressive muscular atrophy, with which they are most apt to be confounded, are enumerated, while those which characterize this last-named affection are placed in a parallel column.

Progressive Muscular Dystrophies.	Progressive Spinal Muscular Atrophy.
1. Usually more than one member of a family affected.	1. More than one member of the family affected very rarely.
2. Onset in childhood.	2. Onset in adult years.
3. Small muscles of hand almost never affected first.	3. Small muscles of hand affected first, as a rule.
4. Fibrillary twitchings rare.	4 Fibrillary twitchings usually present.
5. Enlargement of certain muscles very common.	5. No enlargement of muscles.
6. Qualitative electric reactions absent until late in the disease.	6. Qualitative electric reactions present.
7. Waddling gait and peculiar method of rising from floor.	7. Waddling gait not seen.

When only one member of the family is affected, the diagnosis may be difficult or even impossible; but usually the remaining features which characterize the disease are so plain that the diagnosis is

not difficult even in the absence of this very significant feature. The slow onset, together with the features already named, should serve to distinguish the dystrophies from poliomyelitis. From multiple neuritis they are to be recognized by the absence of pain and tenderness, by the normal electric reactions, the presence of pseudohypertrophy, the age and manner of onset, and the family history. The various types of the dystrophies may be distinguished from each other by the points already enumerated. Sometimes this is easy, at other times difficult. These types overlap or run into each other more or less, and it is sometimes difficult or impossible to distinguish them from each other, nor is it especially important to do so.

Prognosis.—The prognosis is grave. The disease is progressive, and a cure is not to be expected. Patients may live 10 to 20 years. Those in whom the disease begins late in childhood or youth are likely to live longer than those in whom it begins in infancy. Rapidity of progress, of course, points to an earlier termination. After patients have become helpless, the progress of the disease becomes more rapid. The patient is likely to die of an intercurrent malady, such as pneumonia or bronchitis.

Treatment.—Members of dystrophic families should be strongly discouraged from marriage. Careful hygiene, with plenty of outdoor life, should be advised for the brothers and sisters of a dystrophic patient. Not a great deal is to be expected from the drugs, but more from a plan of treatment which includes outdoor life, with careful hygiene and measures calculated to promote the nutrition of the affected muscles, such as electricity, massage, and wisely regulated gymnastics. While a cure cannot be affected, the progress of the disease may, for a time at least, be stayed, or even a distinct improvement may be brought about by conscientious, intelligent, and persistent employment of these measures. Weiner has recently reported a case which was very considerably benefited by a systematic course of gymnastics lasting 2 years. While drugs have no special influence upon the disease itself, they may, from time to time, be indicated by the patient's general condition. In the later stages of the disease, after contractures have occurred, the orthopedic surgeon may, by performing tenotomies, produce very gratifying relief.

The Peroneal or Leg Type of Progressive Muscular Atrophy.—This affection, both in its symptomatology and pathologic anatomy, seems to stand midway between the dystrophies and the spinal form of progressive muscular atrophy. Commonly more than one member of a family is affected. The affection is, therefore, a hereditary or family disease. It begins in later childhood or youth by weakness and atrophy of the muscles of the feet and legs, usually in the former first. The atrophy and paralysis slowly and steadily increase, and after 3 or 4 years, the upper limbs become involved, the small muscles of the hands being usually first affected, and then the muscles of the forearms. The supinator longus escapes, as do the muscles of the shoulder, neck and face. The bird-claw hand seen in the spinal type of progressive muscular atrophy may be produced when the hand atrophy has become extreme. Patients rise from the floor by climbing up their own thighs, as do those affected with progressive muscular dystrophies; but as the disease progresses they become unable to rise from the floor at all; and this may occur before the arms have become appreciably involved, as is the case in the patient represented in the accompanying figure. Contractures of the muscles of the legs occur rather early, and produce talipes equinus or equinovarus. Fibrillary twitchings may occur, and slight sensory disturbances with pains are occasionally present. The powers of coordination are not only unimpaired, but rather increased. The patient may be able to walk long after he is unable to rise from the

The Peroneal or Leg Type of Progressive Muscular Atrophy.

Patient aged 20. The legs are greatly wasted, but the arms are unaffected. A sister aged 25 suffers from the same disease in a more advanced form. Neither can rise from the floor unaided.

floor unaided, and when the slightest push suffices to upset him. The knee-jerks are diminished or lost. The affected muscles exhibit the electric reactions of degeneration. The affection has a tendency to follow acute infectious diseases.

Only a few autopsies have been made. Changes in both the peripheral nerves and spinal cord have been found. Whether the disease is due to a neural atrophy or an amyotrophy, or to both, is not yet positively known. The disease is to be recognized by the family history of the patient, by the mode and time of life of onset, the absent knee-jerks, the changes in the electric reactions of the muscles, the fibrillary twitchings, the presence of

club-feet, and, in the late stages, of the bird-claw hands. The course of the disease is slow, chronic, and progressive. Treatment is to be carried out along the lines laid down in cases of progressive muscular dystrophies and progressive spinal muscular atrophies.

MUSCULAR RHEUMATISM.—See RHEUMATISM (Muscular).

MUSCULAR SENSE.—The sensation by which we are aware of the degree of force exerted by contracting muscles. It differs from (1) pain on firm pressure; (2) pain on tetanic contraction (cramp), and (3) the sense of muscular fatigue. Disorders of this sense are those of hyperesthesia and anesthesia. Diminution is most frequent, with or without loss of voluntary power. Muscular anesthesia rarely requires special treatment. A sudden local loss of muscular sense requires rest and counterirritation, and is usually dependent on a local lesion in the cord. Faradization may be useful in some cases. See LOCOMOTOR ATAXIA.

MUSHROOMS, POISONING.—The most common fungus which gives rise to urgent symptoms of poisoning is the fly-fungus, or *Amanita muscaria*, the active principle of which is muscarin. Several other species of fungi possess poisonous properties. Severe cases resemble in their symptoms the algid stage of cholera; collapse, cyanosis, and muscular contractions preceding a fatal termination.

The stomach should be washed out immediately if a siphon-tube or stomach-pump is obtainable; otherwise an emetic of apomorphin hydrochlorid, gr. 1/8, hypodermically; or of zinc sulphate, 20 grains in water, or mustard, 1/2 of an ounce in tepid water, or other emetic, may be administered. The physiologic antagonist of muscarin, which is atropin, should be given at once in the form of the tincture of belladonna, 20 minims in water, or injected hypodermically as atropin, 1/60 to 1/20 of a grain, and it may be repeated, if necessary. Castor oil is the best purgative, and should be given as soon as possible. When depression exists, stimulants in the form of brandy, ether, or ammonia may be administered. External heat is to be employed, and, for some days after symptoms have disappeared, the patient should remain in bed.

MUSK (Moschus).—The dried secretions from the preputial follicles of the musk-deer of Thibet, having an odor of marked penetrating power. It occurs in irregular, unctuous grains, of reddish-brown color and bitter taste. Its odor is destroyed by drying, but returns again on the addition of moisture. Trituration with camphor or hydrocyanic acid also destroys it. There is a variety known as Chinese musk which is very valuable when in pods or sacs, but all varieties are much adulterated. That sold in shops is impure, and if sold for less than 25 cents a grain, it is probably worthless.

It is a diffusible stimulant and supportive, an antispasmodic and nerve sedative. The dose is 2 to 6 grains, and is not to be employed save to carry a patient past a crisis. Rectal injections in starch-water may be used in low fevers, when the strength of a patient is fast failing, and there are nervous symptoms indicative of great depression. It is also of value in nervous excitement or nervous collapse.

Tincture of Musk, 5 percent. Dose, 20 to 80 minims.

A stimulant in croup:

℞. Musk, gr. iv
Powdered white sugar, ʒ j.
Divide into 6 powders; give 1 powder every hour or half-hour.

MUSSEL POISONING.—The toxic effects in man sometimes resulting from eating mussels, especially the *Mytilus edulis*. See FISH-POISONING, PTOMAIN-POISONING.

MUSTARD (Sinapis).—Official under the two following titles but the pharmacopœial preparations are directed to be made from black mustard only.

Sinapis Alba, *White Mustard*—the seed of *Sinapis alba*. Dose, as emetic, 1 to 3 drams.

White mustard contains *myrosin*, a ferment, and *sinalbin*, a crystalline substance, *sinapin*, an alkaloid, *erucic* or *brassic acid*, and a bland, fixed oil.

Sinapis Nigra, *Black Mustard*—the seed of *brassica nigra*. Dose, as emetic, 1 to 2 drams.

Black mustard contains *myrosin*, a ferment, and *sinigrin* (potassium myronate), *sinapin*, an alkaloid, *erucic*, or *brassic acid*, and a bland, fixed oil.

Sinapis is much used locally in the form of the well-known "mustard plaster."

A mustard plaster is a valuable counterirritant in the treatment of pain in the abdomen or chest. It should be made by mixing mustard flour in varying proportions with ordinary flour, and moistened by warm vinegar or water. Half mustard and half wheat flour will suffice if the skin is tender, but for children one-fourth mustard is strong enough. To make a mustard plaster, place a piece of heavy muslin or linen on a newspaper, over which smear the mustard mass. Over this a thin piece of linen should be placed, to prevent adhesions to the skin and to modify the irritant effect. The edges of a newspaper may be folded to resemble a picture-frame, and the plaster placed within this, giving it a support.

Mustard burns are peculiar in their slowness to heal, and in the fact that they are tender and reddened for days. When the burning is excessive, a piece of lint soaked in lime-water and olive oil, or in olive oil alone, may be used to give relief. Vaselin may be smeared over the burn.

Preparations.—Oleum S. Volatile, a colorless or pale yellow liquid, of pungent, acrid odor and taste and neutral reaction, almost insoluble in water but freely soluble in alcohol and in ether. Dose, 1/8 to 1/4 minim. **Charta S.** *Mustard Paper*, consists of black mustard, the fixed oil removed by percolation with benzin, mixed with solution of rubber and spread on paper. Each square inch should contain about 6 grains of mustard. For local use.

MYALGIA.—See RHEUMATISM (Muscular).

MYASTHENIA GRAVIS.—See PARALYSIS (Asthenic Bulbar).

MYCETOMA (Fungus Disease of India; Madura

Foot).—A tropical disease probably due to the vegetable parasitic fungus of the actinomyces group—streptothrix mycetoma. The seat of the disease is usually strictly localized in the foot, which becomes intensely swollen, deformed, and studded with cysts and sinuses which emit an offensive, oily, seropurulent fluid. Prophylaxis probably consists chiefly in the wearing of shoes. Treatment is solely surgical—amputation should be performed well above the diseased part, though in the early stages it may be sufficient to incise or remove with the curette all the diseased tissue.

MYCOSIS FUNGOIDES (Granuloma Fungoides).—A chronic, malignant, infectious disease, characterized primarily by an eruption of an urticarial, eczematoid, or lichenoid appearance, and later by ulcerating fungoid tumors. In the early or "premycotic" stage the affection begins as an urticarial, erythematous, eczematous, or lichenoid eruption, accompanied by itching and burning. After a duration of some months or years this is followed by flat or slightly elevated plaques of a pinkish-red color.

In the second stage there appear pea-sized to fist-sized, reddish or violaceous, shining tumors, which may develop from the above-described plaques or may spring up independently. They at times develop with remarkable rapidity, and spontaneously disappear just as quickly. More commonly they become an abscess, ulcerate, and present the appearance of a mushroom or fungoid growth. The microscopic appearance strongly resembles that of the round cell and lymphosarcoma. The result is almost invariably fatal.

To relieve the itching quinin and antipyrin have been found of value. Recently radium has been used with success.

MYDRIASIS.—See Pupil.

MYDRIATICS AND CYCLOPLEGICS. Definition.—A mydriatic is an agent which produces dilatation of the pupil. A cycloplegic is an agent which produces paralysis of the ciliary muscle of the eye. In ophthalmology these two terms are usually considered interchangeable, as the ordinary drugs possessing the power of producing mydriasis also produce, in a greater or less degree, cycloplegia.

The mydriatics which have been used in the examination of the eye are atropin, belladonna, homatropin, cocain, hyoscyamin, duboisin, daturin, scopolamin, muscarin, mydrin, euphthalmin, and ephedrin. Atropin and homatropin are the drugs usually employed in refraction, and are those to be recommended, as they have been extensively used and their action and dangers are far better understood than those of the newer substances.

Physiologic Action.—Atropin and homatropin produce mydriasis by paralyzing the sphincter of the pupil and stimulating the dilator at the same time. Cocain affects the dilator of the pupil chiefly, stimulating it. Atropin paralyzes the ciliary muscle completely, and leaves the eye adjusted only for the far-point. Homatropin paralyzes it less completely, but sufficiently for the purposes of refraction, when administered in the manner indicated. Cocain has a very slight paralytic action on the ciliary muscle. As usually administered, the effect of atropin lasts from 10 days to 2 weeks; of homatropin, from 1 to 2 days; of cocain, only a few hours.

Indications in Refraction.—In all first refractions of the eyes of persons under 45 or even 50 years of age, in whom there is no suspicion of glaucoma. No absolute diagnosis of the finer grades of astigmatism can be made without a mydriatic in a person possessing the power of accommodation.

Dangers.—These drugs may precipitate an attack of glaucoma in the eye of a person past middle life, or in whom there is already a tendency to increased intraocular tension. It has been said that if a mydriatic ordinarily applied for purposes of diagnosis produces glaucomatous symptoms, the patient would likely have been the subject of insidious glaucoma later in life anyway, and that the early diagnosis by the mydriatic facilitates treatment.

Mydriatics may also cause general toxic symptoms in susceptible patients. The general symptoms are tickling and dryness in the throat, vomiting, diarrhea, redness of the face, and quick and irregular pulse; even fatal cases have been recorded. If there is any history of idiosyncrasy, the patient should always be instructed to press the finger against the lacrimal sac for 10 minutes after using the drops. This danger may also be averted by using minute or divided drops of the solution. Congestion of the conjunctiva is often a temporary result of the instillation of a mydriatic. The systemic effects of a mydriatic may be combated with a full dose of paregoric.

Administration.—The most effective of this class of drugs, and that most frequently used, is the sulphate of atropin. A solution of 1 grain to 2 drams is ordinarily prescribed; 1 drop of this strength solution is placed in each eye 3 times daily for 2 days prior to the examination. An additional drop is generally applied at the office of the oculist before beginning the examination. For the reason of its prompt action and the short duration of its effect, the hydrobromid of homatropin offers a very efficient and necessary substitute for atropin in office practice. It is, however, a much more expensive drug than the sulphate of atropin. The best solution is a mixture of two-thirds hydrobromid of homatropin, 10 grains to the ounce, and one-third hydrochlorid of cocain, 10 grains to the ounce. A drop of the mixed solution is instilled in each eye every 10 minutes for an hour preceding examination. If it is necessary to have repeated examinations of the eye or to have prolonged mydriasis, atropin should invariably be used. Cocain is useful to dilate the pupil, to facilitate ophthalmoscopic or retinoscopic examination, but is valueless as a cycloplegic. The 4 percent solution is generally used. Sufficient dilatation is usually obtained in from 15 to 30 minutes.

Hyoscyamin, duboisin, daturin, and scopolamin are sometimes used, but investigation has not yet definitely established reason why they should be preferred to the older drugs.

MYELITIS.—An inflammation which affects the substance of the spinal cord, and which may be

limited to the gray or white matter, involving the whole or isolated portions of the cord. When the gray matter alone is inflamed, it is termed central myelitis; when the white matter and the meninges, it is termed cortical myelitis. It may be ascending, descending, or transverse in its extension. The disease is characterized by more or less sudden and complete loss of motion and sensation. In the acute form the symptoms appear suddenly; in the subacute they develop in 2 to 6 weeks, in the chronic a longer time elapses.

Etiology.—It follows spinal meningitis; exposure to cold and damp; injuries to the vertebræ; tumors; caries; prolonged functional activity of the cord; typhus fever; rheumatism; syphilis; puerperal fever; or, during the course of the exanthems, arsenical or mercurial poisoning.

Symptoms.—The severity of the symptoms depends upon the extent and location of the inflammation. The onset is usually sudden, with a chill, fever (103° F.), frequent pulse, with alterations in sensibility and motility: pain in the back, aggravated by touch and by heat and cold, with sensations of formication ("pins and needles"), the limb feeling as if asleep, or else complete anesthesia, associated with severe neuralgic pains. The distinction between anesthesia (insensibility to touch) and analgesia (insensibility to pain) must be clearly determined. There is a sensation of constriction around the body and limbs, as if encircled by a tight cord—"the girdle pains"—and rapidly developing paraplegia, complete in a few hours, with involuntary discharges. The reflex functions are usually abolished, as seen by attempting to cause movement of the limbs by tickling the feet or by striking the patella tendon; rarely are they diminished, very rarely exaggerated. The temperature of the affected limbs is lowered 3 or 4 degrees. Sloughs and bed-sores and muscular atrophy result if the anterior cornua—the trophic centers—are affected. The foregoing symptoms, with rectal and vesical paralysis, are associated with more or less pronounced vomiting, hepatic disorders, irregularity of the heart, dyspnea, dysphagia, apnea, and painful priapism. The urine is markedly alkaline in reaction, finally developing cystitis. Among the late manifestations are shooting pains and spasmodic twitchings or contractions of one or all of the muscles of the paralyzed parts. The electrocontractility is abolished in the paralyzed parts.

Diagnosis.—**Acute spinal meningitis** is distinguished from acute myelitis by severe pains, increased by pressure, with muscular contractions, increased by motion, followed by paralysis much less profound than the paraplegia of myelitis; in spinal meningitis there exists cutaneous and muscular hyperesthesia which is absent in myelitis.

Congestion of the spinal cord is characterized by the mild character and short duration of all the symptoms.

Hemorrhage in the spinal canal is abrupt, with irritative symptoms, slight paralysis, preserved reflexes, and electrocontractility.

The principal diagnostic points of acute myelitis are the "girdle" around the limbs or body, rapid and complete paraplegia, loss of sensation, lowered temperature in the affected parts, early and persistent sloughing (bed-sores), and alkaline urine or cystitis.

Hysteric paraplegia shows no trophic changes, no altered reflexes, slight atrophy, irregular anesthesia and the presence of the stigmata of hysteria.

Lithemic paresthesia, tingling and numbness of fingers and toes, might lead to error if the cerebral symptoms of lithemia are overlooked.

The diagnosis of the location of the lesion is made by a study of the height of the anesthesia, the skin reflexes, and the distribution and extent of the paralysis.

The following table by Morton Prince will be helpful in showing what portion of the cord is involved:

	Lumbar Myelitis.	Dorsal Myelitis.	Cervical Myelitis.
aralysis	Paraplegia....	1. Dorsal, abdominal, and intercostal muscles, according to height of lesion. 2. Leg.	Neck muscles, diaphragm, arms, trunk, and legs.
Sensation.	Pains in legs, or girdle pains around loins; hyperesthetic zone around loins; anesthesia of legs, complete or uneven distribution.	Girdle pain and hyperesthetic zone between ensiform cartilage and pubes.	Hyperesthesia and pains in certain nerve distributions of arms; below this, anesthesia of arms, body, and legs.
Atrophy	Of legs.....	Of dorsal and abdominal (and intercostal muscles, not subject to examination) corresponding to height of lesion; sometimes mild and slow of legs.	Atrophy of neck muscles (rare) or more commonly of arms.
Electrical reaction.	Reaction of degeneration in atrophied muscles; or, in mild cases, quantitative diminution.	R. d. in dorsal and abdominal muscles: slight quantitative changes only in legs when wasted.	R. d. in atrophied muscles.
Bladder..	Incontinence from paralysis of sphincter.	Retention, or intermittent incontinence from reflex action; later from overflow. Cystitis common.	Same as in dorsal myelitis
Bowels...	Incontinence from paralysis of sphincter, disguised by constipation.	Involuntary evacuation from reflex spasm, or constipation.	Same as in dorsal myelitis.
Reflexes, superficial.	Lost.....	Temporary loss, then rapid increase,	Same as in dorsal myelitis.
Reflexes, deep.	Lost.....	Temporary loss, then slow increase.	Same as in dorsal myelitis.
Priapism.	.....	Often present...	Often present.

Prognosis varies according to the location of the lesion and the completeness of the symptoms. If the paralysis is of the ascending variety, death occurs within a few days, from paralysis of the muscles of respiration. If the trophic centers are affected, there occur bed-sores, intense pyelonephritis and cystitis, and changes in the joints, with death from exhaustion in several weeks. Central myelitis, or inflammation of the gray matter, is rapid in its progress, death occurring in a week or two. The morbid process may be arrested and the general health restored, but some spinal symptoms will persist.

Treatment.—Absolute rest is essential to secure even a palliation of the symptoms. Locally, considerable relief follows the use of hot-water bags, or sponges dipped in hot water, and applied along the spine every few hours. The remedies most strongly recommended are digitalis, strychnin, iron, mercury, and the iodids. Electricity is of little value. Cystitis and bed-sores must be guarded against.

MYELOCELE.—See Spina Bifida.

MYELOMA.—The myeloid or giant-celled sarcoma. See Sarcoma, and Bone (Tumors).

MYIASIS.—See Parasites (Animal).

MYOCARDITIS.—See Heart-disease (Organic).

MYOCLONIA.—See Paramyoclonus Multiplex.

MYOMA.—A muscular tumor. Also an affection marked by the growth in the skin of small, sessile, freely movable, isolated, reddish tumors consisting of involuntary muscular fibers. If small and multiple, they are called liomyomata; if there is but a single large tumor, it is called a dartoic myoma; if the tumors contain much fibrous tissue, they are called fibromyomata; if vascular and erectile, angiomyomata; if the lymphatics are involved, lymphangiomyomata. See Tumors.

MYOMECTOMY.—The excision of a uterine fibroid without removal of the uterus. This operation is applicable to certain classes of uterine fibroids. When the tumor is pedunculated and subperitoneal, the pedicle may be ligated in two parts and the tumor removed; if it has no pedicle, the capsule may be incised and the tumor enucleated. The uterine wound should then be closed with interrupted sutures.

The operation of myomectomy is of value when the conditions are favorable, since the patient is cured without removal of the uterus. A dangerous complication of myomectomy is hemorrhage. See Uterus (Fibroma).

MYOPIA (Near-sightedness).—A condition of the eye in which parallel rays of light are brought to a focus in an eye at rest in front of the retina. It is most often dependent on the lengthening of the axial diameter of the eye, and such cases are called true or static myopia. A false or functional myopia is produced by spasm of the ciliary muscle, conic cornea, swelling of the lens in incipient cataract, etc. In such cases the sclera is of usual thickness, and the axis of the eyeball is not lengthened; the change is in the refractive media. See Ametropia.

Etiology.—It is rarely congenital, and, when so, it may be hereditary. An anatomic cause is said to be the peculiar construction of the orbit in certain persons. Devitalization and weakened resistance of the ocular tissues are predisposing causes. Scrofulous children are ready victims to myopia. The early necessity for increased convergence and accommodation by the precocious application of hyperopic eyes of childhood to continuous near-work produces a hyperemia of the ocular tissues, which, if of low resisting power, are stretched, the eye gradually becoming lengthened, and, as a result, myopic. Myopia is often seen in persons of intellectual pursuits requiring excessive near-work, such as students, artists, engravers, etc. However, in the congenital and hereditary types, the patients may be of the most ignorant classes of mere manual laborers. In such cases a low-grade choroiditis is an important etiologic factor. Myopia rarely results from an increased refractive power of the lens in the early stages of cataract in old persons, and to this fact may be possibly attributed the cases of so-called "second sight," in which aged persons find themselves able to read again without their convex lenses. However, their distance-vision becomes markedly decreased The entire eyeball is not necessarily involved in myopia: as, for instance, myopia results from the condition known as conic cornea, the relation between the retina and other media being normal.

An occasional and a curious cause of myopia is a marked decrease in weight of an extremely stout emmetrope or a low degree hyperope. In a like manner there has been noticed considerable decrease of myopia in persons who suddenly and markedly increase in weight.

Disadvantages and Dangers.—The axial diameter being too long, the parallel rays of light falling on the eye focus in front of the retina, and hence only a blurred image of external objects, is received on the rods and cones. In moderate hyperopia a similar defect is overcome by the accommodation, but the myopic eye possesses no mechanism adapted to the correction of the refractive error. There is no way of diminishing the refractive power of the dioptric system, and hence distant objects are always blurred. There is false estimation of size and distance, and altogether the myope is at a decided disadvantage in sports or occupations. However, the myope is still able to see near objects distinctly, and, unfortunately, therein lies his greatest danger. Deprived of many outdoor pleasures, he seeks occupation and amusement within his own limited circle of vision. By holding his book or implements close to his eye, he is able to see distinctly; but in so doing he strains his power of convergence excessively, producing ocular congestion and compression of the eyball; and by bending over he affords a favorable position for the distention of the ocular veins. The coats of the eyeball, already of weakened resistance and put upon the stretch, are further pulled and damaged. The eyeball becomes more and more lengthened, and the myopia increases. With the stretching of the ocular coats the nutrition of the eye is seriously disturbed, and, as a result, the choroid becomes diseased, and this causes associate

retinal changes, defective vision, even with proper glasses, resulting. The nutrition of the vitreous and lens is also seriously damaged. The consequences of such denutrition in the highly myopic eye are serious, and these eyes are liable to cataract, vitreous opacities, and retinal detachment. The danger is, of course, greatest in youth.

Contrary to the popular impression, the myopic eye should be considered as a "sick eye." However, if proper glasses are prescribed and constantly worn and excessive near-work interdicted, a moderate degree of myopia unaccompanied by posterior staphyloma is not liable to progress, but will remain more or less stationary through adult life. This again offers another argument for the early correction of myopia.

Another danger of excessive convergence in a myopic child is divergent squint. The strain in excessive convergence, necessitated by the diminished distance for near-work and extra effort to rotate the elongated eyeballs, may be so great that the effort to converge both eyes is finally relinquished, and one eye diverges.

A final danger of myopia is the liability to accidents on account of the inability to see distant objects clearly.

Progressive or malignant myopia is the serious type in which the ocular coats continue to stretch and become devitalized until they ultimately give way. The bulging occurs at the weakest portion, near the posterior pole, to the temporal side of the disc, and constitutes what is known as **posterior staphyloma.** The destruction of the choroid is accompanied by many conditions which are readily recognized through clear media with the ophthalmoscope. The **myopic crescent** is caused by the absence of the pigment of the stretched choroid and retina, usually at the nasal margin of the disc, allowing the sclerotic to show through as a white crescent. Other white spots indicative of chronic choroiditis may be seen scattered throughout the fundus. Hemorrhages and extravasations sometimes produce retinal detachment. In severe cases the vitreous becomes fluid and the eyeball soft. Vitreous opacity and luxation of the lens may result. With such serious sequels we readily see that the ultimate result of unchecked malignant myopia may be disorganization of the whole eye and total blindness; and in all cases of high myopia, whether progressive or stationary, there are pathologic changes of such import as to produce more or less amblyopia.

Symptoms.—The objective symptoms in the lower grades of myopia are of little importance. In the high degrees the eyeballs may be prominent, and when strongly converged, are seen to be elongated. In such cases the pupils are large and inactive. The myopic crescent and the choroidal condition help in forming the diagnosis.

The most noticeable subjective symptom is the interference with vision. In moderate myopia distant objects cannot be seen distinctly. Myopic children complain that they cannot see the clock across the room or distinguish writing on the blackboard at school, although they are able to read at close range with apparent ease. In extreme cases of myopia or in the progressive type the far-point is so close to the eye as to render the eye virtually useless for distant vision. Scotomata, limitation of the visual field, vitreous opacities, photophobia, photopsia, muscæ, and ocular pains are additional symptoms of the higher degree of myopia.

As a rule, the symptoms of accommodative asthenopia and the remote reflex irritations from eye-strain are not complained of in myopia, as the ciliary muscle is passive rather than active. Its radial fibers are better developed, and are greatly in excess of the circular fibers, the opposite of the condition in hyperopia. However, because of the strain on the convergence, evidences of muscular asthenopia, such as headache, weariness and sense of heat in the eye, and chronic conjunctivitis, may follow.

Diagnosis rests upon the diminished acuteness of distant vision, the ophthalmoscopic examination (refraction and fundus changes), the retinoscopic examination, and the acceptance of and visual improvement by a concave lens. Conic cornea is easily differentiated from myopia by the peculiar protruding appearance of the cornea, the depth of the anterior chamber, and the characteristic retinoscopic reflex. Hyperopia with ciliary spasm simulating myopia is readily differentiated under mydriasis. See Retinoscopy.

Treatment.—Prophylactic measures consist in the careful examination of children's eyes, particularly about the time they are to start to school, and in securing the best hygienic conditions for them during their school hours. Good ventilation, properly constructed desks, and sufficient and rightly directed light are requisites for the maintenance of normal vision. There should be a north light coming in over the left shoulder, and not falling directly on the desks. The walls and ceilings should be painted in light colors. There should be 1 foot of window space for every 5 feet of floor space, and small type should be distinctly read in the most remote corner of the school-room on a cloudy day. Books should be printed in large, broad-faced type, and on dull-faced paper. The desks should be sloping and so arranged as to avoid all stooping positions. In young myopes excessive near-work must be interdicted. Such children should be urged to forego studying, reading, and other indoor amusements, and must be encouraged to go out into the open air and take plenty of healthful exercise, meanwhile rigorously wearing their correcting glasses.

In myopia the book, writing, etc., should be placed at a distance of at least 13 inches from the eye, artificial or insufficient light should be avoided, and the eyes should be given frequent intermissions of rest.

In the progressive type of myopia, and in the extremely high degrees, near-work must be virtually excluded from the daily occupation. In such cases the treatment depends upon rest, abstinence from near-work, constitutional and hygienic measures, the relief of any increased ocular tension by the administration of eserin or by iridectomy, attention to the associate choroiditis and other

pathologic changes, and the constant use of correcting lenses.

Prescription of Glasses.—Ordinarily, it is desirable to prescribe spectacles that will give fair distant vision and, at the same time, enable the patient to read easily at the proper working distance. However, in cases of persons doing much near-work, a pair of weak lenses may be ordered for reading, etc., and stronger glasses for outdoor use, theaters, receptions, etc.

In myopia of 3 diopters or over the far-point is inside of the ordinary reading distance, and there is necessarily extra convergence; but, unfortunately, there is no necessity for accommodation; the adductors are deprived of this stimulus, and exophoria results. In order to cause the requisite accommodative stimulus to the adductors, constant use of the full correction of myopia has been urged. The theory of this is plausible, but the strain on the undeveloped accommodation is too severe, and serious asthenopia results. Unfortunately, most myopes complaining of unsatisfactory glasses are wearing not only their full correction, but are, in a majority of cases, over-corrected. A myope will naturally select a strong lens, and caution should be observed in the trial with the test-lenses, accepting as the proper refraction the weakest lens which gives normal vision, and which does not diminish the size of the letters, and, as the patients so often say, makes them appear better but further away.

In prescribing glasses for constant use some deduction from the full correction should be made in cases of children and young adults, in order that compromise lenses may be continually used which give fair distant vision, but which necessitate only a moderate accommodative effort in reading. It must always be remembered that overcorrected myopia may produce as distressing symptoms as uncorrected hyperopia.

At the presbyopic age bifocal lenses should be constantly worn and the full distance-correction ordered in the upper segment. In the high degrees of myopia (above 6 to 8 diopters) the full correction is never tolerated. In the unfortunate cases of extremely high myopia (12 to 20 diopters), with extensive choroidal changes, glasses are often of little service in making a useful working eye, and are so bulky and heavy as to be uncomfortable.

Removal of the Lens for High Myopia.—It is a well-known fact that the removal of the crystalline lens makes an emmetropic eye hyperopic by about 10 or 12 diopters. In the knowledge of this fact it has been suggested that removal of the lens would be an advisable procedure in cases of extremely high myopia: for instance, of from 15 to 20 diopters. Although this operation has been performed a number of times, the actual practical results are not definitely settled; there is great danger of retinal detachment, and, moreover, it is too radical a treatment to be advised to the beginner in ophthalmology. An ideal indication for this operation would be lenticular myopia.

MYOSITIS, INFECTIOUS.—An inflammation of voluntary muscles due to obscure infection; it may be acute or subacute, purulent or nonsuppurative. It is characterized by tenderness, slight edema, and swelling. Frequently an erythema appears over the body. It is differentiated from trichiniasis by examination of the muscle fragments, and by blood examination (eosinophilia being present in trichiniasis).

MYOSITIS OSSIFICANS.—A progressive congenital affection, usually first manifested in boyhood, and seldom seen in females. Masses of bone develop in the muscles, chiefly those of the back, producing deformity, eventually impeding respiration and so causing death in about ten years. It is often associated with irregular epiphyseal ossification, and with the absence or ill-development of the proximal phalanx of the thumb and great toe. It is believed that the connective-tissue of the muscle undergoes ossification while the true muscle fibers atrophy, but the pathology of the disease is quite obscure, and no treatment is of avail. A similar condition known as **myositis ossificans traumatica** may develop after severe injury. It is most common in the quadriceps extensor group in the thigh and in the muscles of the arm. In this form the ultimate prognosis is good. Cases in which operation is done late, after the osteoid tissue has ceased to grow, do well as a rule, but if operation is done early there is a decided tendency toward recurrence (Finney). As a prophylactic measure incision, and evacuation of the effused blood, with drainage of the affected area, is recommended.

MYOTICS.—See Miotics.

MYOTONIA CONGENITA (Thomsen's Disease.)—A rare congenital disease appearing in early childhood and in family groups, characterized by tonic spasms of the muscles when voluntary movements are made. The muscles are developed out of proportion to their power.

The facial, ocular and laryngeal muscles are rarely affected. There is rarely mental defect. The electrical reaction of the muscles involved is slow and associated with vermicular contractions between the poles—the myotonic reaction of Erb. The disease is incurable.

MYRISTICA (Nutmeg).—The kernel of the ripe seed of *M. fragrans*. Its properties are due mainly to the volatile oil. It is an aromatic stomachic and tonic, and in large doses a powerful narcotic. Dose, 5 to 15 grains. The oil is sometimes employed as a rubefacient in paralysis and rheumatism, and is much used as a condiment. **M., Oleum**, the volatile oil. Dose, 1 to 5 minims.

MYRRH.—A gum-resin obtained from the *Commiphora myrrha*, a tree of Arabia. It occurs in dark-colored, brownish-red, irregular shaped tears, having an agreeable aromatic odor and a bitter acrid taste. In medicinal amount it is stimulant to the circulation, and to uterine and bronchial mucous membranes. Dose, 5 to 15 grains. **M., Tinct.**, diluted with water or with potassium chlorate, is used in ulcerative stomatitis, spongy gums, acute pharyngitis, and in ptyalism. It is combined with other remedies for the treatment of chronic bronchitis, and in combination with iron is efficient in functional amenorrhea. In leukorrhea and chronic cystitis it is of service.

The pure tincture is sometimes applied with a small brush to spongy or tender gums, and it is of use as a gargle in ulcerated sore throat. Dose, 10 to 30 minims.

In stomatitis:

℞.	Tincture of myrrh.	gtt. xx
	Potassium chlorate,	ʒ j
	Elixir of calisaya,	ʒ iij.

Give a teaspoonful in water every 4 hours.

MYXEDEMA. Definition.—A disease characterized by the infiltration of the connective tissues of the body with a mucus-like substance and by atrophy of the thyroid gland.

Etiology.—The cause of the disease is the inability of the thyroid gland to perform its function, usually through atrophy. Rarely, it may be observed after removal of the gland. It is more common in women. Heredity is important, particularly in the maternal line.

Morbid Anatomy.—The connective tissue of the skin and subcutaneous tissues are infiltrated with a jelly-like substance containing mucin. The fibrillar and cellular elements of connective tissue are increased. Both of these processes may affect glands, muscles, nervous system, and the outer coats of the arteries. The thyroid gland is usually found to be atrophied.

Pathology.—With the atrophy or degeneration of the thyroid gland a hitherto undetermined something which is necessary for the well-being of the organism fails to be elaborated, and the changes enumerated occur. The secondary changes in organs result from the vascular degeneration.

Symptoms.—The face is swollen, rounded, with features less marked, and expressionless. The hands are spade-like and the feet misshapen; the body is bulky. The skin is thrown into folds, especially around the neck, and is dry, scaly, and thickened. The intellectual processes are sluggish, drowsiness is a quite constant symptom, and insanity often supervenes. The speech is slow. Myxedema in childhood, whether congenital or acquired, is termed cretinism. Subnormal temperatures, particularly in the later stages, are the rule.

Diagnosis.—The edema of chronic cardiac and renal disease is distinguished from this by the pitting and diminished hardness on pressure. The facies is not to be confounded with that of renal and cardiac disease, of which other physical signs are present.

Myxedema is distinguished from akromegaly in the great preponderance of instances in women, its development later in life, the absence of changes in bones, the full-moon face, the swollen and clubbed fingers, and the peculiar pale, waxy, boggy, and shining skin.

Prognosis.—The course of the disease is slow, and death from intercurrent affections is not unusual. Since 1892 the use of thyroid extract has modified the hitherto generally accepted opinion that the disease was of necessity fatal.

Treatment.—The patient should be protected from cold; hot baths, friction, and massage, with subcutaneous injections of pilocarpin, assist in maintaining the action of the skin. Inasmuch as the thyroid gland is found to be atrophied or degenerated in cases of this disease, and total removal of the gland is often followed by cachexia strumipriva (operative myxedema), the logical treatment consists in supplying to the organism that secretion essential to normal metabolism which in health is elaborated by the thyroid gland. The inconvenience of gland implantation, sheep's thyroids beng used, is sufficiently obvious. The injection of minced, raw, or slighty cooked sheep's thyroids, although successful in ameliorating the symptoms of the disease, speedily produced an insurmountable repugnance to them, so that their use was very generally abandoned. At present the glycerin extract, powdered extract, or a presumably active principle of the gland are the only ones employed. The glycerin extract is given by the mouth in daily dose of from 15 to 30 minims, representing from one-eighth to one-fourth of an average sheep's thyroid. If this seems to be ineffective, the amount should be increased until evidence of betterment is obtained. The initial dose should be maintained at semiweekly or weekly intervals until all symptoms of the disease have disappeared. Inasmuch as the substance which the thyroid supplies is essential to the health of the organism, continual administration of the remedy is necessary during the remainder of the patient's life, but at more infrequent intervals. The powdered gland may be given by the mouth in such doses that from one-eighth to one-third of a sheep's thyroid is represented; in amount it is usually 5 grains. Inasmuch as the salts and extractives in the gland have been shown to be useless, attempts have been made to isolate the active principle and at the same time to get rid of the products of decomposition which may be harmful. Fresh thyroid gland contains but one iodin-containing substance —the colloid matter—which consists of a proteid part (possibly a globulin) combined with an organic compound of iodin (crude iodothyrin), and the latter can be separated from the colloid by hydrolysis. Since the specific effects of the thyroid gland can be obtained either from the colloid or the separated iodothyrin, the latter is now chosen for thyroid administration. At present there is no satisfactory way of standardizing the thyroid preparations, but the average dose of colloid matter is 1 1/2 grains.

On the administration of preparations of the thyroid gland in myxedema it has been found that untoward and even poisonous symptoms may arise. If, during its use, cubnormal temperature, slow pulse, and mental hebetude are observed, the dose should be increased. Further, the dose should be larger in cold than in warm or hot weather. If, however, the pulse becomes quicker, evidences of circulatory disturbances arise, febrile reaction is marked, the patient becomes excitable, either the dose is too large or products of decomposition of proteid material are present as impurities. In the first case the dose should be diminished or the remedy stopped for a time; if the second, another preparation must be chosen. Symptoms of

cardiac paralysis and circulatory disorder are more likely to occur in postoperative myxedema (thyroidectomy for goiter). In this instance the heart must be carefully observed, and at the first signs of failure the remedy omitted, while strychnin, strophanthin, or nitroglycerin is employed; a combination of the first and last is the most useful. Since most of the instances of the ill-advised use of thyroid extract have occurred in the practice of surgeons, it is proper that this phase of the treatment should be delegated entirely to physicians. With care in the use of preparations of the thyroid gland their administration may be safely continued during the life of the patient. For other precautions and accidents the reader is referred to THYROID TREATMENT.

MYXOMA.—A connective-tissue tumor the consistency of which is similar to the jelly of Wharton of the umbilical cord. It consists of a gelatinous, mucin-containing intercellular substance, in which are scattered peculiar branched or stellate cells. See TUMORS.

N

NABOTHIAN CYSTS.—See Cervix Uteri (Endocervicitis).

NÆVUS. See Nevus.

NAILS, DISEASES.—Affections of the nail may be divided into those of the nail proper, and those of the soft parts in relation with the nail. Alterations in the texture of nails are not common. Alterations in form result from injury or skin-disease. The general state of health influences the growth of the nails, and after illness a deficient formation of horny matter may result, manifested by the production of a groove across the nail. The breadth of this groove roughly indicates the period and duration of illness.

Onychia is an inflammation of the matrix of a nail. The best-known form is of syphilitic origin, and is either subacute or fully developed. The subacute form is attended with pain, redness, and more or less ulceration of the matrix. The developed form is met with in adults. The nail soon rots and crumbles away at the root, leaving a ragged border attached to the distal portion of the finger. The free edges also suffer, and become broken and fissured.

The treatment includes attention to the primary disease. Hot moist dressings or poultices are suitable in almost all cases of acute inflammations, and may be followed by soothing antiseptic lotions and ointments.

Carbolic acid, 1 dram, with water, 4 ounces, makes a soothing antiseptic lotion, which may be poured on lint and wrapped around the last joint of the finger. Chloral, 5 to 10 grains, with 1 ounce of water, may also be used. Finely powdered lead nitrate makes an excellent remedy. Ointments of boric acid, of tar, of mercury, or red precipitate salve may be used. A free application of a strong solution of silver nitrate at the beginning of the inflammation will often prove curative. When granulations spring up, they may be covered with tannin or alum, or rubbed daily with a crystal of copper sulphate, or strong carbolic acid or the liquor ferri persulphatis applied. In chronic inflammations of parts around the edges, daily painting with a solution of silver nitrate, 10 grains to 1 fluidounce, is useful. These measures failing, removal of the portion of the nail at fault or of the whole nail may be performed. Malignant onychia requires removal of the entire nail, cauterization of the matrix, and dressing with iodoform gauze, and the internal use of tonics and nourishing diet.

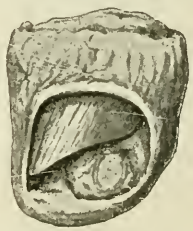
Syphilitic onychia is best treated with black or yellow wash, a weak solution of corrosive sublimate, by dusting with calomel, or by applying calomel ointment. Internal antisyphilitic measures are to be employed coincidently, and in strumous subjects constitutional treatment is also needed.

Paronychia, or whitlow, is an acute inflammation of the tissues around the matrix. It is generally of traumatic origin, and should be incised. In the milder forms the arm may be placed in a sling and the finger kept constantly wet with some weak antiseptic lotion, such as boric acid. Boric acid ointment may be used when the inflammation has subsided. Tonics, especially those containing quinin, are to be given internally. See Paronychia.

Ingrowing Nails.—Though occasionally on the fingers, ingrowing nails are most frequently found on the great toe, as the result of wearing tight boots and of cutting the nails square. A tight boot presses the skin over the sharp corner of the nail on each side, and ulceration ensues. There is lateral hypertrophy of the edge of the nail, or the soft tissues are forced over the margin of the nail. The pain caused by walking is often very severe.

Treatment.—In mild or trivial cases the trimming or clipping of the free margin of the nail, scraping of the dorsal surface with the edge of a bit of glass or with a knife, so as to reduce its thickness and to produce a tendency to curling upward or backward of its lateral margins, and the removal of any cuticle accumulated under the ingrowing edges of the nail are all that is required to give relief and prevent further progress. Pressure must be avoided. When ulceration has occurred, a minute roll of lint shreddings should be neatly packed beneath the tender overhanging skin and

Subungual Exostosis of the Great Toe.—(*Spencer and Gask.*)



The End of a Great Toe to Show the Characteristic Appearance of a Subungual Exostosis.—(*Spencer and Gask.*)

ingrowing edge. Strapping is then so applied as to retain the lint and drag upon the overhanging integument and keep it pulled away from contact with the ingrowing edge. The lint may be removed in a few days and the space filled with boric acid, iodoform, lead nitrate, alum, or zinc oxid. Exuberant granulations may be destroyed by silver nitrate, copper sulphate, perchlorid of iron, or pure carbolic acid. Repeated applications may destroy the sharp ingrowing edge of the nail.

Under local anesthesia the nail may be split, the offending portion removed, together with the soft tissue and the adjacent matrix, and the

wound antiseptically dressed. A somewhat popular operation is to remove a V-shaped piece of the side of the toe in which the nail is ingrown, including in the V the section of offending nail. The cut surfaces are drawn together with sutures, and the wound is dressed antiseptically.

Subungual exostosis forms a painful swelling which raises the middle while the two sides of the nail are unaltered. It generally affects the great toe. Complete removal of the ungual phalanx with the nail and nail-bed is the only satisfactory measure, the plantar surface being turned over as a flap.

NAPHTHALENE, Naphtalin. $C_{10}H_8$.—A hydrocarbon obtained from coal-tar, formed during the manufacture of ordinary coal gas. Chemically, it is one of the benzene derivatives. When redistilled, it crystallizes in colorless, rhomboid plates, of slightly tarry but strong odor, and burning, aromatic taste; insoluble in water, soluble in 15 of alcohol, very soluble in boiling alcohol, ether, chloroform, carbon disulphid, and fixed or volatile oils. It is seen frequently in the form of moulded blocks, under such names as *alabastrin* and *camphylen*, for preserving furs and flannels from moths, and for disinfecting urinals. Dose, 1 to 3 grains, in emulsion, or as a powder with sugar in wafers or capsules.

Naphthalene is employed as an antiseptic for the intestinal canal in typhoid fever, diarrhea, both acute and chronic, tuberculous diarrhea, and dysentery. It renders the urine aseptic and may be employed in vesical catarrh. It is used internally for bronchial asthma, verminous affections, the chronic pulmonary catarrh of the aged, and chronic bronchitis with copious secretion. It is said to be effective as a teniacide, also as a vermifuge for seat-worms given by injection, 15 to 30 grains in 3 ounces of olive oil. Burned in the patient's room it has given excellent results in pertussis, giving force to the belief that the well-known benefit resulting from taking children to gas-works for whooping-cough is due to the naphthalene fumes rather that to those of the gas-tar. Locally, naphthalene has high value as an antiseptic for indolent ulcers, sloughing wounds, open cancers, and pus cavities. Painted over organic remains it effectually prevents the ravages of insects, and has largely supplanted camphor for protecting woolen clothing from moths.

NAPHTHOL (Beta-Naphthol).—A phenol occurring in coal-tar, but usually prepared from naphthalene. It is one of several naphthols, and occurs in colorless, shining, crystalline laminæ, or a whitish, crystalline powder, of faint, phenol-like odor, and sharp taste. Soluble in 3/4 of alcohol, in about 1000 of water, and in 75 of boiling water; very soluble in boiling alcohol, ether, chloroform, olive oil, and petrolatum. Used as ointment, 1 to 5 for adults, but for children it should not be over 2 percent strength. Dose, 3 to 6 grains in cachet or pill.

Beta-naphthol is used in the form of a 2 percent soap in prurigo, herpes, ichthyosis and favus, also in a 1/2 to 5 percent alcoholic solution, or as a 10 percent ointment, for hyperidrosis, scabies, and eczema, but it is a dangerous and irritant application. Internally it has been employed in typhoid fever, dilatation of the stomach, intestinal dyspepsia, diarrhea and dysentery. Its germicidal rank is probably second to many other agents, but it is an efficient internal antiseptic, being practically nontoxic in medicinal doses. Dose, 3 to 6 grains.

NARCOPHIN.—A double salt, being the meconate of morphin and of narcotin. It is mainly used in connection with Twilight Sleep, *q.v.*

NARCOTICS.—See Hypnotics; Lambert Treatment for Narcotic Addiction; Antinarcotic Legislation.

NARCOTIN.—An alkaloid of opium, said to be sudorific and antipyretic, but it has no narcotic or hypnotic effects. Dose, 1 to 2 grains. See Opium.

NARGOL.—A compound of silver and nucleinic acid, containing 10 percent of silver, used in 1 to 5 or 10 percent solutions. It is more stable than protargol and less irritant in solutions of equal strength.

NASAL BONES.—See Nose (Injuries).

NASAL DISEASE.—See Nose (Caries); Rhinitis.

NAUHEIM TREATMENT.—See Heart-disease, Organic.

NAUSEA OF PREGNANCY.—See Pregnancy (Diagnosis, Pernicious Vomiting).

NAVEL.—An oval fossa of variable depth on the median line of the anterior abdominal wall. The cicatricial eminence at its bottom indicates the place where the umbilical cord was detached. See Umbilical Cord.

NEAR-SIGHTEDNESS.—See Myopia.

NECK, INJURIES.—**Burns** are particularly serious on account of the swelling and the edema of the larynx which may complicate them. Even when no deeper than the skin, they result in cicatrices which are most deplorable because of the appearance of the parts and because of the deviations they cause, sometimes binding the chin down to the sternum; for this reason they should be grafted at the earliest possible time. Deep burns extending to the muscles and to the vessels are most serious, even when limited, for obvious reasons. The cicatrices pass into keloids more often than in other regions.

Contusions are not frequent; they are usually produced by falls, blows, hanging, garrotting, throttling, the passage of a wheel over the neck, or by the pressure of the dislocated clavicle. A blow on the side of the neck is a great aim with pugilists, because it is almost a sure knock-down or knock-out; it is often grave in its results, because of the importance of the organs of the neck, and may be accompanied by fractures of the hyoid bone, larynx, and trachea, injuries to muscles, vessels, nerves, pharynx, esophagus, vertebral lesions, concussions, and contusions of the spinal cord; hematoma may form and become large and cause grave pressure-symptoms on all the structures. Death may occur after a few days from edema of the lungs; also from embolism from one of the large vessels of the neck.

Wounds of the neck are comparatively rare in civil practice; sometimes they are accidental and due to a fall on a fragment of glass, a stem of iron or wood; they are most commonly due to attempts at murder or suicide. Suicidal wounds are the

most common and the most interesting. The wounds are penetrating or nonpenetrating according to whether or not they reach the trachea, or the esophagus, or the vessels. **Superficial** or **extrafascial wounds** of the neck—*i. e.*, wounds not extending beyond the superficial cervical fascia—present nothing peculiar. However, a large **incised wound** of the external or anterior jugular, especially if these veins happen to be unusually large, may give entrance to air. In tracheotomy the anterior jugular and the inferior thyroid veins are often wounded. If the parallelism of the lips of the wound has been disturbed, there may be much infiltration of blood; this requires enlargement of the incision and ligation, in preference to pressure; cellulitis spreads rapidly.

Gunshot wounds are rare, yet there are instances when a bullet has traveled under the skin and above the fascia without penetration of the fascia. **Contused** and **lacerated wounds**, if extensive, may be followed by cicatrices and their consequences. **Gunpowder stains** should receive as careful attention as those of the face, especially if in the exposed parts of the neck. Gunshot wounds causing much destruction of skin present the same remarks as the lacerated wounds.

Deep or **subfascial wounds**—that is, wounds extending beyond the cervical fascia, and more or less deeply—are almost all very serious because of the almost invariable injury of some of the large vessels and nerves, or of the special organs of the neck, larynx, trachea, pharynx, and thyroid body, giving passages to air, food, and blood, each of which calls for special treatment.

Complications of the wounds of the neck are the following: Thrombus or extravasation of blood, due to the loss of parallelism of the lips of the wound through the various layers; entrance of air into the veins, more frequent and dangerous here than anywhere else; passage of food through the wound and into the larynx or trachea; hemorrhage, more or less profuse, according to the vessel injured and its accessibility; emphysema, due to injury of some point of the respiratory tract with a gravity greater than in any other region on account of the involvement of the arytenoepiglottic folds and the consequent obstruction of the larynx; aphonia from injury to the vocal cords or to the nerves; emphysema, edema, penetration of blood in larynx, or injury of the pneumogastric or laryngeal nerves; dyspnea due to the same cause, plus injury to the phrenic; dysphagia, due to swelling or pain; erysipelas is a frequent complication, as is pyemia or sepsis; edema of the glottis is very common; spasmodic croup, due to pressure or to nerve injury, is not rare; concussion of the cervical column communicated to the spinal cord, to the pneumogastric, phrenic, cervical plexus, and brachial plexus has been observed in severe wounds.

The symptoms of entrance of air into the veins are a wind-sucking or gurgling sound, immediate pallor of the face, dilatation of the pupil, irregular or tumultuous action of the heart, embarrassed breathing, and death. The wound should be plugged at once with the finger, and all the usual means of resuscitation vigorously and persistently applied. The amount of air introduced is a grave factor. If the wound is small, the operation may be continued by keeping the wound constantly filled with warm sterilized water.

The sequels of the wounds of the neck are: permanent aphonia or dyspnea or dysphagia, necrosis of the cartilages and of the hyoid bone; torticollis due to contraction of cicatrix, to inflammatory adhesions of the muscles, or to nerve injury; fistulous tracts; granulations obstructing the respiratory tract.

Deep punctured wounds striking the large vessels are those which are most commonly followed by deep and extensive extravasation and traumatic aneurysms; they call for the ligation of the two ends of the wounded vessels; it is here that a proximal loop ligature of the main trunk, low down when practicable, will be of the greatest assistance in controlling the hemorrhage during the search for the bleeding ends. They are also more commonly followed by emphysema than the incised wounds. When they involve a nerve, they may cause tetanus or spasmodic croup. **Deep incised wounds** are often rapidly fatal from the extensive hemorrhage, because it is rare that some artery or vein has not been opened; the same remarks apply here as applied to their treatment. **Deep contused and lacerated wounds** present here no special peculiari ies not covered by the foregoing descriptions and the description of these wounds in general.

Gunshot wounds usually cause much hemorrhage; they sometimes recover most unexpectedly; of course, their gravity varies with the injuries inflicted. When the ball is deeply seated, no dissection should be made to extract it until later, if it produces disturbance. See Gunshot Wounds.

Poisoned wounds—*i. e.*, bites, stings—are more frequent on the neck, on account of its exposed condition; also more grave, because no clothing has potected the parts; also because they are usually followed by great swelling, which, reaching the arytenoepiglottic folds, causes obstruction of the larynx. Bites of a rabid animal are more serious, because they have a shorter distance to travel to reach the central organs of innervation, and because no clothing has wiped the animal's teeth.

Foreign bodies in wounds of the neck are common—wadding, pieces of clothing, piece of the weapon or bullet, etc.

Fractures of the neck are rare. See Spine.

Dislocations and **sprains** are the result of injuries in which the head is much stretched, most commonly and especially when violently striking first upon the vertex; they give rise to great pain, particularly when the head is thrown backward. The treatment consists in thorough rest of the part by lying on a bed or by applying a liquid glass bandage.

In all injuries of the neck causing obstruction to the free circulation of the air, from whatever cause, there are great dyspnea, cyanosis, anxiety, rapid pulse, aphonia, dysphagia, and pain. Tracheotomy should be performed in such cases, and it is often advisable to operate before urgent symptoms present themselves, for death may come on

rapidly or suddenly before the patient can be reached.

Peculiarities of the Injuries of the Infrahyoid Region

Burns and the **effects of cold** are only peculiar in the possibility of being followed by cicatrices which bind the neck and chin down to the sternum in a very peculiar manner.

Contusions.—On account of the presence of the larynx and trachea, they may be followed by great concussion effects altogether out of proportion to the severity of the blow. Contusion of the thyroid cartilage by a blow upon and close to it may cause death without any appearance of a lesion. Contusions may cause rupture of the larynx and trachea. In hanging the compression very often bears upon the base of the tongue, and the larynx, with its vessels and nerves, is not injured. In strangulation when the traumatism is applied upon the larynx and the trachea, which may be torn by the fingers and the rope, all the structures are more or less torn. In some cases lesions of the skin of the neck, of the trachea, and of the larynx may cause inhibition of the heart, of the respiratory organs, and of the brain.

It is especially in case of traumatism of the anterior region of the neck that a complete loss of consciousness and a respiratory and cardiac syncope are observed. This takes place in cases of death through incomplete hanging, which does not prevent the passage of air through the respiratory passages. In such cases the red blood of the arteries continues red in the veins, whereas in death by true asphyxia the blood becomes rapidly black in the arteries.

Accidental wounds are rare; the most frequent are punctured wounds, resulting from a fall on a sharp body.

Homicidal wounds are not so rare; they are usually incised wounds, and a cutting instrument is used by the criminal to make believe they are self-inflicted or accidental.

Suicidal wounds are the most frequent; they are seldom punctured; they are usually incised wounds; they are most frequent at the point of the thyrohyoid ligament or below it; they are lacerated, jagged, deeper on the left side; they are usually directed from left to right, and obliquely downward or transversely across the neck; the large vessels are seldom injured. Usually the suicide, throwing his head back, cuts too high; the trachea and the rigidity of the sternomastoid protect the vessels. If the head is bent too much, the larynx, the trachea, and the sternomastoid also protect the vessels. There is usually a single gash. These wounds are more commonly fatal than the other wounds, because the victims are usually intoxicated or are laboring under delirium tremens or insanity. These patients should be watched closely, as they often tear away their dressings and die of hemorrhage. These wounds sometimes present much hemorrhage, although none of the larger vessels are hurt, except the anterior jugular vein; there are cases on record where air has penetrated into it and to the heart, causing death. The edges of these wounds are often much separated, and have a tendency to roll in on account of the action of the fibers of the platysma; coaptation, therefore, needs more care.

Lacerated wounds are very rare.

Gunshot wounds are also rare. Balls may traverse the neck without wounding any important structures, because the tissues are round in form, elastic, and movable.

Bites by dogs are comparatively common; the anterior region of the neck is the favorite aim of dogs, especially the bulldog; they cause all the lesions of strangulation and of incised wounds.

Nonpenetrating wounds—*i. e.*, not involving the larynx, pharynx, esophagus, or recurrent nerves—are not peculiarly serious and should be treated as elsewhere, taking care to secure the divided vessels, etc.

Punctured wounds, especially in duels, may penetrate into the mouth, pharynx, esophagus, larynx, or trachea; it is important to look for such penetrations, and to keep the parts as thoroughly disinfected as possible, because there is often risk of infection of the wound from within. The landmarks are the hyoid bone, the thyroid and cricoid cartilages. The laryngoscope should be used.

Penetrating wounds, due to any cause involving the respiratory or digestive tract and the recurrent nerve, are, of course, severe.

Penetrating wounds above the larynx are less dangerous than those of the larynx and those below it; the lower the wounds, the more dangerous they are.

Wounds through the thyrohyoid membrane penetrate into the pharynx, injure the epiglottis, the arytenoepiglottic folds, the cartilages, and the vocal cords; they are less dangerous than below because they allow feeding; they are more liable to suppuration.

Wounds of the larynx are comparatively frequent because of its prominence; they are usually very dangerous, and may be diagnosed by the rushing sound of the air passing through. They should be treated like those of the trachea.

Wounds of the trachea are commonly followed by severe hemorrhage, because of the large vessels around it, which may also have been wounded by the same cause. When the severance is incomplete, there is slight gaping; when the section is complete, the lower end is drawn in deep at each effort of respiration, and the soft parts cover up the orifice, causing suffocation. In all cases keep the blood and foreign substances out of the respiratory tract until hemorrhage is checked. Rose's position may be of assistance.

In **incomplete wounds** there is slight gaping, and the wound should not be stitched; the head should be flexed on the chest and fixed in that position by a liquid-glass bandage.

In **complete wounds,** when longitudinal, there is little gaping. In complete transverse wounds the retracted lower end should be searched for and a strong thread passed deeply through it; an attempt at stitching should be made; if it fails, a tracheotomy tube should be placed in it and it should be longer than the ordinary one, because the swelling

may lift it out of the trachea; the head should also be kept flexed; a moist cloth should be placed over the tube; the room should be warm—at about 70° —and a vessel with boiling water should keep the atmosphere moist, to avoid bronchitis and pneumonia. Later, we should be mindful of the exuberant granulations which may obliterate the canal.

The sequels of wounds of the air-passages are permanent contractions of these passages, aphonia, fistulous orifices, entire occlusion of larynx, the air passing through the external wound. Fistulæ are hard to cure.

Wounds of the pharynx and esophagus are usually through the side of the neck, by balls, knives, etc.; they cause much pain, spasms, hiccup, dysphagia, and more or less suffocation; there is escape of food through the wound, if this is of a certain size; the thirst is great. The patient should be fed by enema; if the use of the esophageal tube becomes necessary, from insufficiency of the rectal alimentation, it should not be left in place, but introduced each time. In incised wounds stitch immediately; in lacerated wounds let the wound granulate.

Rupture of the esophagus from contusions is rare; the special symptom is hematemesis. When the diagnosis is sure, cut down upon the injured spot along the anterior edge of the sternomastoid; stitch the wound if possible; if not, pack and let it granulate.

The immediate dangers of wounds of the anterior region of the neck are death from hemorrhage—although the hemorrhage stops from syncope, it may start again later—from asphyxia, due to the tongue or epiglottis or a piece of cartilage obstructing the passage, or to blood and clots in the larynx and trachea; from penetration of air in the veins. Penetration of the respiratory tract is recognized by cough, blood expectoration, hissing or boiling sound.

The secondary dangers are inflammation of the larynx, edema of the glottis, bronchitis, pneumonia, abscess and purulent dissections, emphysema, aphonia, more or less complete, and dysphagia; secondary hemorrhages are common and serious complications. In all injuries with solution of continuity of the mucous membrane the most frequent source of death may be mediastinal emphysema and inhalation pneumonia.

Wounds of the neck parallel to the longitudinal fibers of the muscles are more likely to be followed by emphysema. The remote effects and sequels may be exuberant granulations causing dyspnea; cicatrization, producing strictures of the larynx, trachea, and esophagus; persistent fistula; paralysis due to inflammatory thickening, which may disappear later, or to injury of recurrent nerves or the pressure of a bullet. All these complications should be treated here as elsewhere.

Dislocation of the hyoid bone is very rare. The is one case (Gibb) in which the dislocation was muscular; it was accompanied by a peculiar click on the left side of the neck and a sensation of choking; examination showed displacement of the left horn of the hyoid bone; reduction was effected by throwing the head backward toward the right side, so as to stretch the muscles of the neck, and then suddenly depressing the lower jaw, thus bringing the depressors of the hyoid bone into action.

All the following fractures are usually due to violent contusions:

Fracture of the hyoid bone is rare, but it is well known; the site is usually the great horn, near the body; it may be unilateral or bilateral; it is characterized more or less by hoarseness and dysphagia, according as it is without or with displacement and without or with deformity; accompanied by more severe symptoms, especially when swallowing fluids, which pass into the larynx because of the imperfect action of the epiglottis; it is reduced by using the fingers inside the oral cavity.

Fractures of the larynx are less rare than fractures of the hyoid bone; they are due to great violence; they are usually accompanied by much pain and suffocation, often calling for immediate reduction or for tracheotomy. Each cartilage may be fractured by itself; the thyroid is most frequently the site; fractures without displacement are not so grave. Fracture of the thyroid cartilage is more common in old people, because of the ossification of the cartilage. Fracture of the cricoid is more dangerous than the others, perhaps because of its small size, which causes slight displacements to be followed by serious obstruction.

Fractures or subcutaneous ruptures of the trachea without actual wound have been observed after great traumatism; they are less frequent than the others; they present the same symptoms and indications as the fractures of the larynx, but the lesions are lower down. The trachea should be opened below the fracture, and a long tracheotomy tube be introduced; when the fracture is low down, the lower end should be hooked, raised, and sutured to the skin or upper fragment.

Spontaneous ruptures of the trachea due to violent efforts are admitted by some. All these fractures are more serious if accompanied by displacement which obstructs the air-passages. The symptoms are those of obstruction and shock, in addition to those of fractures in general; crepitation, abnormal immobility, and also aphonia, dysphagia, and emphysema. The fragments should be replaced by external and internal manipulations; if necessary, the parts should be incised and the fragments stitched. Tracheotomy is often indicated; it is well to perform the operation before grave symptoms develop, because these sometimes come on so suddenly that the patient may succumb before operation is possible. See LARYNGOTOMY, TRACHEOTOMY.

Peculiarities of the Injuries of the Thyroid Body

Burns and **freezing** are only observed in cases of great and deep destruction of the neck.

Contusions are most common in all cases of much violence to the neck— as has been described —coexisting or not with fractures of the hyoid bone, larynx, and trachea. The peculiar features they present are symptoms of cerebral congestion, and also the fact that they may be followed by myxedema.

Wounds of the thyroid body are likely to be

serious on account of the great vascularity of the organ and its friability; the bleeding is usually great, especially if breathing is obstructed or laborious.

Punctured wounds are rare in the normal thyroid body, but are comparatively frequent in the hypertrophied organ or goiter, and, if deep, give rise to serious hemorrhages.

Incised wounds are usually suicidal; those of the upper angles are the most frequent and the most serious, because of the presence of the superior thyroid artery; in goiters they suppurate, as a rule, and usually run a benign course.

Lacerated wounds are not ordinarily followed by primary hemorrhage, but may present serious secondary hemorrhage.

Gunshot wounds call for the same remarks; the thyroid gland has been carried away by a missile. Treatment of hemorrhage is difficult because of the friability which will not allow a ligature to hold tight enough to arrest the bleeding with safety against secondary hemorrhage. The same remarks apply to the forceps left *in situ*. Deep suturing succeeds best, or a chain ligature or a purse-string ligature. A pin or needle suture, such as is used for harelip, sometimes succeeds; pressure is not borne; it is useless to ligate the nearest trunk because the other vessels will keep up the hemorrhage; when the bleeding is serious, tracheotomy, if practicable, sometimes stops the hemorrhage by relieving its congestion; in spite of all, death is sometimes the result of hemorrhage.

As regards **foreign bodies in wounds**, there is not a case on record where a bullet was found buried in a normal thyroid body. Poisoned wounds, bites, and stings are rare, except in conjunction with such in the infrahyoid region.

Peculiarities of the Injuries of the Suprahyoid or Submental Region

Burns are of peculiar importance, because the resulting cicatrices may draw the skin of the chin and of the lower lip, causing eversion of the lips and its consequences.

Contusions in this region are rare, because of the protection of the chin. In hanging the compression may often bear on the base of the tongue; the vessels, nerves, and larynx are uninjured.

Wounds of the suprahyoid region are very seldom homicidal, but almost always suicidal. **Penetrating wounds** only are of importance; punctured wounds are very rare; they are only observed in the cases of "hooking" of the chin. **Incised wounds**, when transverse, usually gape a great deal, but very little when longitudinal; usually the suicide, throwing his head back, cuts higher than he intends in the suprahyoid region, so that the borders of the stretched sternomastoid protect the vessels. The penetrating wounds open the cavity of the mouth, injure the tongue and epiglottis; there may be suffocation due to the blood or other foreign substances, or to the tongue or epiglottis falling back and occluding the larynx; there is usually much hemorrhage from the wounding of the lingual artery. More than in all injuries of the neck swelling and edema of the arytenoepiglottic folds, which are directly injured, are here met. The gaping is especially great when the head is thrown back; the saliva and food pass out of it during deglutition. Wounds of the epiglottis cause much suffocation, difficulty of speech, of deglutition, and coughing; thirst is a common symptom. **Lacerated wounds** have been observed in several cases of "hooking" of the chin.

Gunshot wounds seldom penetrate posteriorly, because the head, being usually thrown back, the revolver is naturally directed upward and rests under the chin, which is usually carried away by the shot.

Poisoned wounds, bites and stings present nothing peculiar. Foreign bodies in the wound are alimentary matter. The shock is as great as in all injuries to the air-passages, on account of the dyspnea and aphonia and dysphagia.

Peculiarities of the Injuries of the Submaxillary Region (Lateral Suprahyoid or Digastric Triangle)

These injuries present some peculiar interest because they may injure the facial or the lingual artery, or the hypoglossal nerve, and also because they may penetrate into the mouth. In regard to the diseases of the deep parts, it is well to state here at the outset, and to bear in mind, that the overlying lymphatic glands are more often affected than the tissue of the submaxillary salivary gland itself, and that practically it is immaterial which is involved.

Peculiarities of the Injuries of the Parotid Region.

Wounds.—Injuries of the parotid region are rare; they are grave, on account of cicatricial disfigurements and injuries to the facial nerve and to Steno's duct. **Punctured superficial wounds** are of no consequence, nor are the deeper wounds, unless the instrument is large and the great vessels are injured. **Incised superficial wounds** may injure the facial nerve and the duct, and may be followed by paralysis; when large, the divided nerve and duct should be at once stitched. Incised deep wounds are most serious. The diagnosis of the penetration of the gland rests upon the escape of saliva. When the wound is narrow, the hemorrhage and, later, the suppuration prevent the diagnosis; if the pus is very liquid, it is probable the gland is seriously injured. To prevent fistulæ stitch tightly and keep the jaw at rest. **Deep wounds** are more serious, because of the presence of the temporomaxillary vein, which becomes the external jugular; also of the other deep vessels. The bleeding is profuse and sometimes appalling; it should be at once stopped by plugging; then a provisional loop ligature should be applied on the common carotid close to the bifurcation; the bleeding points should then be ligated. If this fails, the source of the hemorrhage should be carefully determined. If it is the external carotid, ligate it; if the internal carotid, ligate it separately or ligate the common carotid at the bifurcation to prevent the return through the collateral circulation. If the jugular vein is injured, ligate

it as high up as possible, at least above the facial and lingual, or ligate there. After the ligation or ligations have been done, the accidental wound should be packed tightly with bits of aseptic sponges to prevent hemorrhage by the distal end of the vessels. This plugging will usually accomplish this, but plugging should never be relied upon if the trunk has not been ligated. The hemorrhage is almost sure to recur, and often the patient thus loses so much blood that when the ligations are at last performed, he succumbs to hemorrhagic anemia. When the hemorrhages are unmistakably venous, the thorough systematic sponge-plugging may suffice, even in wounds of the internal jugular. **Contused and lacerated wounds** call for the same remarks, but it must be remembered that although the primary hemorrhage may not be copious, the secondary hemorrhages are most to be dreaded, and proper instruction in consequence must be given.

Gunshot wounds suggest the same remarks with the aggravation of the presence of the ball in the deeper structures, in the pharynx, in the bones, or in the brain.

Poisoned wounds present nothing peculiar.

Peculiarities of the Injuries of the Lateral Region of the Neck (Region of the Sternomastoid or of the Carotid)

Burns or **frost-bites** present no peculiarity in the region of the sternomastoid, except when deep and reaching the sternomastoid or the underlying vessels and nerves.

Contusions or **blows** on the neck are always severe, but when striking the side of the neck over the jugular they are particularly severe, and are comparatively frequent. They may cause a hematoma in the sheath of the muscle; they may cause paralysis or contracture of the muscle, producing a variety of torticollis; the muscle is sometimes ruptured, also the vessels and the nerves, these have a train of symptoms which will be described further on.

Nonpenetrating wounds—*i. e.*, not extending deeper than the muscles and glands—are not serious unless through infection.

Penetrating punctured wounds of the neck may be deep without injuring the vessels and nerves, owing to the elasticity and mobility of the jugulocarotid vessels. Penetrating wounds of the external jugular, of the internal jugular, and the carotid arteries are more serious injuries. They all may give rise to circumscribed or diffused hematoma. When this is of some size and stationary, it must be aspirated or incised. When it pulsates and grows, it is because a traumatic aneurysm has formed, and the wounded vessel, vein, or artery must be ligated above and below the injured point. When the penetration is comparatively small, the sac may be incised at once, after making as good a pressure above and below as possible. When the puncture is large, and there is risk of the patient bleeding much before the proper ligatures are secured, a provisional loop ligature must be applied below the wounded point. When the wound or swelling is very low down, enough of the sternum must be resected to reach the root of the carotid and the innominate, and the provisional loop ligature applied there. Considering the gravity of a possible terrific hemorrhage, this advice is not too heroic. Never ligate the common or the internal carotid unless it is the wounded artery, because of the possible effects on the cerebral circulation. It is only when the persistent search for the wounded point of the vessel has not succeeded that the vessel itself should be ligated in continuity; below only, if possible. A ligature above, whenever applicable, should be applied to guard against recurrent distal hemorrhage. We must bear in mind that arteriovenous aneurysm often follows punctured wounds which have gone through the vein and the artery. Wounds of the vertebral artery in this part of the neck are more common in the canal of the transverse process. At the base of the neck wounds of the vertebral artery are more grave than those of the carotid.

The diagnosis of this wound will be made only when, upon cutting down through the extravasated blood, it is found that the carotid artery and the jugular vein are intact. When the hemorrhage is profuse, it should be stopped by plugging with the finger or by packing, and a loop ligature should be applied on the subclavian or the innominate before proceeding further; when the wound in the vertebral artery is located, it should be tied above and below; if necessary, the transverse process should be cut away with the bone-nippers. These remarks apply also to the wounds of the deep cervical, the inferior thyroid, the superior thyroid, the lingual, and the pharyngeal arteries.

Punctured penetrating wounds of the base of the neck are almost all fatal, on account of the impossibility of reaching the artery without fatal hemorrhage. Punctured wounds of the nerves of the region (recurrent, phrenic, pneumogastric, sympathetic, spinal accessory, cervical plexus) give rise to the symptoms of irritation of the nerves.

Nonpenetrating incised wounds are only serious if the external jugular vein has been injured, because air may then penetrate into the veins. When the edges of the wounds lose their parallelism, these may form a considerable hematoma. Incised wounds penetrating the sternomastoid and severing it incompletely are not so very serious.

Wounds dividing the sternomastoid muscle may result in curtailing power of the muscle from lengthening, due to the cicatrization. When the muscle has been completely severed and the head is still, it is sometimes brusquely thrown to the other side by the contraction of the intact sternomastoid. In case of division of the muscle from operation this does not take place, because the other muscles have gradually become accustomed, by the presence of the tumor, to keep the head properly balanced. The several ends must be strongly and closely stitched with strong catgut, and the head kept in proper position by a liquid-glass bandage.

Incised penetrating wounds of the internal jugular are perhaps more serious than the wounds of the carotid, because of the danger of penetration of

air. When the respiration becomes embarrassed, the hemorrhage increases, just as in tracheotomy, where, as soon as the tube is introduced, the hemorrhage ceases. These wounds are often due to tearing during the removal of tumors. Whatever be the cause, if the vein alone is wounded, the blood is black and flows continuously. The first thing to do is to plug the opening, to prevent the penetration of air; next make pressure above and below with the fingers, enlarge the wound, and fill it with boiled water to prevent the possible penetration of air; then look for the wounded vein and ligate both ends. The proximal end is the most dangerous, because of the penetration of air and of the abundance of blood coming from the heart. When the compressing fingers are in the way or if their pressure is ineffectual, a provisional loop ligature should be placed around the internal jugular until the wounded ends are ligated. When the wound is low down, it may be necessary to resect the sternum and place a provisional ligature around the innominate vein or the superior cava. Incised wounds of the superior thyroid, lingual, and facial veins close to the internal jugular are almost as severe.

Incised penetrating wounds of the carotids give rise to profuse, even terrific, hemorrhage. When the wound is large, or when the hemorrhage is moderate but does not receive prompt attention, it may be immediately fatal. Death from hemorrhage from the carotid will thus ensue in 4 minutes, it is said. When the larynx or trachea is wounded, the blood penetrating into them causes death also from suffocation. The hemorrhage is sometimes stopped by fainting, if the wound is not too large. Upon reaching such a case, the first thing to be done is to plug the wound with the fingers or to pack it quickly. Packing will stop the hemorrhage temporarily if the vessel is of any size above 1/16 of an inch. It is best and safest to enlarge the wound and attempt to ligate the two ends in the wound; if this causes too much bleeding, a loop ligature must be applied as described. If the bleeding has stopped of itself, it must be borne in mind that it will almost surely return, and that it may do so when proper surgical assistance cannot be procured, and the patient may bleed to death; therefore, the case should be treated as described for punctured wounds. Incised penetrating wounds of the root of the neck are almost all fatal on the spot. The same remarks as above apply here. It is sometimes difficult to recognize which vessel of the neck has been divided; spurting, however, is characteristic of arterial lesion, but the vein may be divided at the same time. When the vein and artery are simultaneously wounded, ligate the ends of both. In all cases when clamping stops the bleeding and a ligature cannot well be substituted, the clamp should be left in place 36 to 48 hours.

Punctured wounds of the nerves of the region (recurrent, phrenic, pneumogastric, sympathetic, spinal accessory, cervical plexus) give rise to the symptoms of the irritation of those nerves. Incised wounds of the nerves of the region (recurrent, phrenic, pneumogastric, sympathetic, spinal accessory, cervical plexus) are followed by the following symptoms:

When the recurrent is wounded, there is aphasia, more or less complete. The section of the phrenic and pneumogastric on one side only is accompanied by respiratory and circulatory irregularities; they are not necessarily fatal, but it is a most serious complication. Park has shown that only about 50 percent of these cases are fatal. Complete wounds of the sympathetic are followed by atresia of the pupil, slight ptosis, congestion of the conjunctiva, headache, congestion of the side of the face (unless only stimulated). It produces mydriasis, pallor of face, and protrusion of eyeball. Injury of the superior laryngeal nerve is sometimes very serious. When possible, the divided ends must be sutured with fine silk.

Penetrating or deep contused and lacerated wounds of the region do not expose so much to primary hemorrhage, but the suturing of the muscles, the ligation of the vessels, and the stitching of the nerves cannot be relied upon as safe, because of the sloughing that usually follows those wounds; for the same reason secondary hemorrhages are much more common and more grave. Penetrating or deep gunshot wounds of the region call for the same treatment, and, in addition, the frequent penetration of the digestive and respiratory tracts and spinal canal with their possible complications; the presence of a ball, or foreign bodies deeply lodged and unremovable in these wounds, injures the vessels more frequently and seriously than the deep punctured wounds. Here, less than anywhere else, should search be made for the bullet. When, however, the wound is larger, the finger may be introduced, and if the ball is felt, it should be removed.

Poisoned wounds, stings, bites, etc., present nothing peculiar in this region.

Foreign bodies, usually bullets, may remain embedded in the tissues without giving rise to any serious trouble; a bullet may thus remain in contact with the large vessels without causing disturbance, but not so with the nerves.

Rupture of the sternomastoid is more common than that of other muscles; it has taken place after falls, sudden twists, and violent muscular contractions. There are great pain, a depression on the course of the muscle, great hematoma; the head is often twisted by the action of the other muscle.

The treatment consists in placing the head in proper position, and immobilizing it in a liquid-glass bandage. The rupture is usually partial; when complete, the ends are far apart; it is well to cut down and stitch; otherwise a kind of torticollis may result from the lengthening of the muscle.

Peculiarities of the Injuries of the Supraclavicular Region

Burns or **frost-bites** are rare, as the region is usually well protected.

Contusions sometimes present hematomata so large as painfully to compress the branches of the brachial plexus. In fractures of the clavicle the brachial plexus may be injured.

Superficial punctured wounds may open the external jugular, the terminal part of the external and anterior jugulars and of the cephalic, but they are seldom serious unless infected. Punctured wounds of the subclavian vein and artery may also give rise to serious hematomata. When persistent, they should be aspirated or incised. We should bear in mind that hematoma may be due to a wound of the vein, and that the connection may still exist. This will surely be the case if, after aspiration, it fills up again. In case of incision the deeper clots should not be disturbed, so as not to open the wound in the vein in case that lesion has occurred.

Injury to the subclavian artery is recognized by the pulsations of the hematoma; it is then a traumatic aneurysm. The artery should be ligated. When the swelling is moderate, the ligation should be made in the supraclavicular region, using, if necessary, an aneurysmal needle with a detachable point. In the majority of cases this simple ligation will suffice to cure the aneurysm; if not, compression of the axillary or its ligation should also be done, then the sac incised, and the injured points ligated above and below. When on the right side, the artery can only be reached and encircled in its second portion after dividing the anterior scalene; no permanent ligature should be applied there; a provisional loop ligature should be placed, the sac incised, and the injured point of the third portion ligated permanently above and below. On the left side the ligation of the second portion can be made permanent at once, as it is as safe on this side as a permanent ligature is unsafe on the second portion of the right side. When the swelling is so great as to cause failure of the procedure outlined, or so as to discourage even the attempt, but only then, a provisional ligature should be applied upon the first portion of the subclavian; the axillary should be compressed or treated in the same way; then the sac is incised and the two ends ligated. In some cases these ends cannot be found; packing with bits of aseptic sponges should then be resorted to, with compression over it. Should the hemorrhage return, the clavicle should be sawed through and the two ends secured. When the artery on the right side is wounded close to the scalene, so as to compel ligation of the second portion, this should be done with double catgut, without rupturing the coats, and with a bloodless space between the ligatures. On the left side the second portion can be ligated with safety after the old method, but the new method should be applied there also in preference. The permanent ligation of the first portion on either side should not be done unless it can be done thoroughly, with double catgut, without rupturing the coats, and with a bloodless space between. As this cannot be safely done, as a rule, without resecting the inner extremity of the clavicle and the corresponding part of the sternum, this should only be done when the ligation of the second portion cannot be performed satisfactorily as described. Arteriovenous aneurysm, due to punctured wounds of both the vein and artery simultaneously, should not be interfered with unless they grow or cause serious pressure-symptoms. Then both the artery and the veins should be ligated above and below, and the sac extirpated, unless too adherent to surrounding structures; if left in place, it should be incised, to diminish its pressure effects; sometimes these continue, although abated.

Punctured wounds of the nerves rarely cause paralysis, but may cause persistent pain, neuralgia, and trophic changes in the area of distribution. Punctured wounds of the lymphatic duct on the right, and of the thoracic duct on the left, may produce a chyloma, which should be treated as a venous hematoma; usually it is only then that it is recognized. Punctured wounds of the apex of the lungs may be followed by emphysema, at first limited and then generalized.

Superficial **incised wounds** are not serious unless infected. Bleeding from the external and anterior jugulars and of the cephalic is easily arrested; however, the wounding of these veins near their point of discharge into the subclavian may be followed by severe hemorrhage and by entrance of air into the veins.

Incised wounds of the third portion of the subclavian artery, when large, are followed by rapid death; when smaller, they often cause traumatic aneurysms; the treatment is the same as indicated for punctured penetrating wounds. Incised wounds of the subclavian vein are most serious because of the amount of bleeding, often causing rapid death, and also because of the quick penetration of air into the vein. The vein should be at once plugged with the finger, or, better, an aseptic packing; then an attempt should be made to enlarge the wounds and to clamp it, then ligate the two ends. When this is impossible, a provisional loop ligature should be applied on the first portion of the vein; also compression should be made on the axilla and the two ends ligated. The ligation of the proximal end is to secure against hemorrhage and also against the entrance of air. But the ligation also of the distal end is, of course, indispensable.

Incised wounds of the lymphatic duct on the right side and of the thoracic duct on the left are diagnosed by the oozing of the peculiar fluid these ducts contain. If possible, the distal end should be ligated, and this usually stops the flow, since there is a valve on the proximal end. There is seldom, if ever, any discharge from it. When ligation is impossible, compression will often suffice. It is very seldom that any further trouble is noticed, because there exist usually two or three branches, and the uninjured ones carry on the circulation. When this fails and a chyle fistula is established, the patient loses flesh and succumbs.

Incised wounds of the brachial plexus are followed by paralysis of the affected area; they should be stitched at once. The lesions, from whatever cause, may affect only one branch. Paralysis never affects the interior, anterior and posterior surfaces of the arm, because there are supplied by the anastomoses of the intercostal filaments with those of the internal brachial cutaneous. They must not be confounded with the anesthesia and paralysis resulting from contusions of the shoulder in hysteric subjects (hysterotraumatism). The

treatment is by electricity. If a callus includes a nerve, it must be resected.

Incised wounds of the phrenic nerve are most serious. However, when the nerve has been pressed upon by a tumor for some time, the wounding of it is not so dangerous. Incised wounds of the apex of the lungs are not so likely to be followed by emphysema as the punctured wounds.

Contused and lacerated wounds are much more serious than clean wounds, because of the impossibility of primary union, and because of greater liability to secondary hemorrhage. Gunshot wounds also are serious, for similar reasons.

Dislocations of the head of the clavicle are a frequent cause of serious contusion of the region.

Fractures of the clavicle sometimes cause wounds of the vein or of the artery or of the brachial plexus. Shock accompanying injuries in this region is sometimes very great, on account of the large nerves implicated.

Peculiarities of the Injuries of the Posterior Region of the Neck

Burns and **frost-bites** are only particularly important here because of the cicatrices which may follow, causing disfigurement in an exposed part. and also possibly causing deviations of the head, from retraction.

Contusions are more frequent than in front; they are particularly painful, because the muscles contused are those which keep the head in balance; they are often accompanied by fracture of the spinous processes and laminæ, contusion and concussion of the spinal cord and even of the brain.

Punctured wounds, nonpenetrating—*i. e.*, not penetrating the vertebral artery and the spinal cord—are simple wounds, and seldom give rise to any trouble. However, should they be large punctured wounds, and strike the deep cervical artery or the posterior jugular veins, they may give rise to serious hematoma. When this persists, it should be aspirated or incised. When it pulsates, it is a traumatic aneurysm of the said artery, and should be treated as such. Punctured wounds of the vertebral artery may give rise to an aneurysm also, which must be treated as such—that is, by ligating above or below, or both, when possible, and then incised. Much hemorrhage must be expected from the untied end, and the surgeon must plug tightly with a septic sponge and make firm pressure with a bandage.

Punctured wounds of the spinal canal through the interlaminar spaces, when the head is flexed forcibly, or through a fracture of the laminæ, are serious only if becoming infected. Incised wounds reaching the spinal cord itself are followed by paralysis of the parts below. If the wound is and remains uninfected, the cicatrization by primary union may take place and the paralysis disappear; if not, it will be permanent. If between the occipital and the atlas or axis the medulla oblongata is severed, death is instantaneous. Infanticide is often effected by a long needle or pin driven between the occiput and the vertebra. If the lesion is above the origin of the phrenic, death follows quickly by paralysis of the diaphragm. Incised wounds of muscles are usually due to sabre cuts; they may include almost all the muscles; they may reach the vertebræ, when the head drops forward; the hemorrhage is great. Incised wound of the vertebral artery give rise to profuse hemorrhage. The peculiarities of the treatment of these wounds are the need of prompt attention, the impossibility of ligating both ends of the artery if it has been wounded high up, the suturing of the large muscles, the difficulty of keeping the head steady, and to secure drainage. A liquid-glass bandage or a jury-mast apparatus will assist materially.

Wounds of the posterior region are said to be followed by sexual impotency when the membranes of the cord are involved; also by paresis and wasting of the lower extremities and of the testicles.

Larrey contends that these results may take place even when the cord is not affected.

Gunshot wounds are usually serious if they reach the membranes or the cord. When pressure-symptoms are present, very extensive and deliberate dissections must be done to remove the ball, the fragments of broken lamellæ, or clots or foreign bodies which cause the pressure. Foreign bodies causing pressure-symptoms on the cord must be removed at almost any cost.

Ruptures of the muscles of the nucha are reported in those who carry heavy loads on the head; the symptoms are those of other muscular ruptures. Ruptures of the attachments of the rhomboid and of the levator anguli scapulæ have been seen in farm-laborers. Shock accompanying injuries of the posterior region is usually great, being often complicated by concussion and contusion of the cord or of the cerebellum or of the whole brain.

NECROSIS.—The death of cells surrounded by living tissues. Necrosis proper refers to death in mass; necrobiosis, to death of individual cells. Among the causes of necrosis are (1) direct injury; (2) obstruction of the circulation; (3) loss of trophic influence. The varieties of necrosis are: (1) Coagulative necrosis; (2) liquefactive necrosis; (3) cheesy necrosis; (4) dry and moist gangrene. See GANGRENE. Necrosed tissues may be absorbed, retained, or thrown off. The dead tissue is called *sequestrum* in case of bone and *sphacelus* in case of soft parts. In surgery the term necrosis is often applied specifically to the death of bone. See BONE (Diseases).

NELAVAN.—See SLEEPING SICKNESS.

NEPHRECTOMY.—See KIDNEY (Surgery).

NEPHRITIS (Bright's Disease; Inflammation of the kidney).—Marvelously accurate as were Bright's descriptions of many of the forms of renal disease which have since received his name, it is clearly unreasonable to limit the name to the conditions literally described by him, since others, evidently a part of the same process, were not included in his descriptions, while other additions, in turn, had to be made to fill out these. Naturally, too, all are not agreed, even to-day, as to what should be included under the term. On the other hand, it would be futile to attempt to eliminate the

words "Bright's disease" from the nosology. Under the term will be considered: (1) *Acute parenchymatous* or *acute diffuse nephritis;* (2) *chronic parenchymatous* or *chronic diffuse nephritis,* with a second or indurated stage of the latter; and (3) *chronic interstitial nephritis.* The *amyloid* or waxy kidney is not, strictly speaking, a variety of Bright's disease. Amyloid disease of the kidney occurs in two forms—first, as a part of general amyloid disease, shared by the kidney in common with the liver, spleen, and other organs; and, second, as amyloid infiltration of certain portions of kidney previously invaded by inflammation. See URINE (Examination).

Acute Parenchymatous Nephritis

The peculiarity of this form of Bright's disease is that, in the majority of cases, the cells lining the uriniferous tubules are the primary seat of attack. As such, the cells enlarge, proliferate, and degenerate, choking up the tubules and interfering with the proper elimination of excrementitious matters usually separated from the blood by the kidneys.

Etiology.—Most cases of acute parenchymatous nephritis are caused by the infectious diseases, especially scarlet fever and diphtheria, though cold, and especially cold combined with moisture, is an acknowledged cause.

Symptoms.—The first symptom to attract attention is generally a puffiness about the face (see FACE IN DIAGNOSIS), which usually extends to the extremities and, in extreme cases, to the trunk, producing in a word, general anasarca. Thus, attention is attracted to the urine, which often appears "smoky" to the naked eye, an appearance due to the presence of small quantities of blood in acid urine. The same urine, if made alkaline, will exhibit a brighter red hue. It contains albumin, commonly in large amount, and the microscope shows numerous blood discs, also blood casts, epithelial casts, and free renal epithelium. This may be regarded as the distinctive sediment of acute nephritis. Hyaline casts, which are not characteristic of any form of renal disease, are also present. To these are soon added, in all cases of prolonged duration, dark granular casts and dark granular cells representing degenerated renal cells. Pus-cells and pus-casts are sometimes present.

The urine of acute Bright's disease is also scanty, of correspondingly high specific gravity, and disposed to deposit uric acid crystals and mixed urates when in the fresh state. At the beginning the specific gravity of the urine is high. Complete suppression of urine is not infrequent. Various degrees of inconvenience result from the dropsy. It may involve the penis and scrotum, invade the serous cavities, especially the pleuræ and peritoneum. Positive fever is seldom present; neither is severe pain in the kidney region, although it is more frequent in this than in any other form of Bright's disease. The pulse is moderately accelerated. Nausea and vomiting sometimes usher in the disease.

The serious danger of acute Bright's disease is uremia, a toxic condition due to retention of excrementitious substances, of which urea is the type. Uremia possesses its own symptomatology. Headache and drowsiness may be initial symptoms. At other times sudden vomiting is the first sign. Not infrequently epileptoid convulsions, without previous warning, are the earliest manifestations; at all times an alarming and dangerous symptom. The convulsions usually alternate with periods of drowsiness, though sometimes also with lucid intervals. The onset of convulsions is sometimes preceded by sudden blindness and amaurosis. Sometimes the pulse is abnormally slow. If the condition does not pass away, exhaustion supervenes, and Cheyne-Stokes breathing may be the final symptom. Rarer symptoms of actue nephritis are an intense itching of the skin; shortness of breath, due to edema of the lungs or a feeble dilated heart; delusional insanity as a part of the uremic symptomatology; and palsies, monoplegic or hemiplegic.

Complications and sequels of acute nephritis are not numerous. They include pleurisy, pneumonia, bronchitis, and pulmonary edema. Hypertrophy of the left ventricle is a possible, but very rare, result.

Diagnosis.—The diagnosis is easy. Dropsy, beginning in the face, albuminuria, blood discs, blood casts, and epthelial casts in the urine point unmistakably to acute Bright's disease.

ACUTE PARENCHYMATOUS NEPHRITIS.	CHRONIC PARENCHYMATOUS NEPHRITIS.	CHRONIC INTERSTITIAL NEPHRITIS.
1. Most common in children, from exposure or infectious fevers.	1. Later life; often the consequence of acute attack.	1. Later life; often results from alcoholism, gout, lead-poisoning.
2. Edema of lower eyelids; then of upper extremities, trunk, and, lastly, lower extremities.	2. In early stage same as acute form; later, dropsy may diminish.	2. Dropsy slight or entirely absent.
3. Urine scanty, dark or smoky color, high specific gravity, 1025 or over.	3. Urine normal or increased amount; specific gravity may fall to 1010; urine pale.	3. Urine greatly increased; specific gravity low, 1005; urine pale in color.
4. Large amount of albumin.	4. Late in attack, greatly diminished; occasionally absent.	4. Albumin greatly diminished, often absent.
4. Variety of casts, such as hyaline, blood, epithelial, and waxy casts, also free red blood globules, and epithelial cells.	5. Large and small granular casts; compound granule cells, and fatty epithelium.	5. Hyaline or finely granular casts, occasionally dark in color; infrequently blood casts and oil droplets.
6. Urea diminished.	6. Urea diminished.	6. Urea diminished.
7. Recoveries frequent.	7. Recoveries rare.	7. Indefinite duration, but never cured.

Prognosis.—This is usually favorable if treatment is promptly instituted. Sometimes the disease is overlooked for a time, when it is more intractable. In fatal cases uremic convulsions often end the scene.

Treatmen .—Many cases recover withou other

treatment than rest in bed, warmth, and milk diet. These are all essential to a successful treatment. In severe cases dry cups, followed by fomentations, should be applied to the loins. In all cases brisk purgation should be produced, especially by the salines, including bitartrate of potassium and compound jalap powder. Calomel and jalap are good preliminary purges. Action of the skin should be favored by sweet spirit of niter, neutral mixture, warm applications and warm baths, and, if necessary, by the vapor bath.

Having secured a free action of the bowels, digitalis, 5 to 20 minims of the tincture every 4 hours, is the best diuretic, but it may be substituted by the tincture of strophanthus in the same dose, or by spartein in 1/4 to 1/2 of a grain doses every 4 hours. When spartein cannot be obtained, broom tea may be used. It is an efficient but nauseous diuretic. Infusion of cream of tartar and juniper berries is at once a good diuretic and aperient, or the cream of tartar may be used alone, making a drink which is pleasant when cool.

Fisher's Alkaline Treatment of Acute Nephritis.—Prof. Martin H. Fisher premising that all the changes that characterize nephritis, viz., the albuminuria, the specific morphological changes noted in the kidneys, the associated production of casts, the qualitative variations in the dissolved solids are due to a common cause—the abnormal production or accumulation of acid in the cells of the kidney—concludes that the entire purpose of our therapy must be to get alkali into the patient to neutralize the acids present. To this end he recommends administration by the rectum of sodium bicarbonate crystallized, 20 grams, sodium chlorid, 14 grams, and water enough to make 1000 c.c. This is administered high up in the bowel by the drop (Murphy) method at the body temperature.

Should uremic convulsions supervene, the most prompt and energetic measures must be used. Immediate elimination should be secured by active purgation by croton oil or elaterium, vapor baths, and, if necessary, pilocarpin should be employed to promote sweating. Pilocarpin hydrochlorid should be given hypodermically in doses of 1/12 to 1/3 grain, according to the age of the patient. Its action should be favored by warm covering and hot applications. The convulsions should be controlled by chloroform or chloral.

Chronic Parenchymatous Nephritis

In this form of chronic Bright's disease, beside the tubal involvement, the interstitial tissue becomes infiltrated with cells, which are later di erentiated into fibroid tissue, resulting in more or less induration. The tubular involvement is still a conspicuous part of the process. The tubules are distended by proliferated and degenerated cells, which include fatty cells as well as cells less advanced in degeneration. Certain white specks are resolvable by the microscope into coils of fattily degenerated tubules. Its typical macroscopic product is the large white kidney. An indurated form sometimes results, which is regarded by some as a further stage of the large white kidney—stage of secondary contraction—but probably also occurs as a direct result of the diffuse nephritis.

It may be a continuation of the acute form, or it may originate *de novo*, or it may arise insidiously, more frequently, perhaps, favored by a vulnerability due to a previous acute parenchymatous nephritis.

The symptoms include edema in various degrees, which in an advanced stage of the disease equals that described in acute nephritis. Less advanced stages exhibit slighter degrees of dropsy, while in some cases there is no edema. In many cases there is no dropsy in the initial stage.

The urine is albuminous, and the quantity of albumin is variously large. The sediment ncludes hyaline casts, oil casts, dark granular casts, and casts containing fatty renal cells. In addition are found free fatty renal cells, granular fatty cells (compound granule cells). More rarely blood-corpuscles are present, and in a few instances there is more or less constantly present blood—constituting chronic hemorrhagic nephritis. See URINE (Examination).

There are few other distinctive symptoms. Edema is not always present. A peculiar waxy appearance of the skin often betrays the disease, with a yellowish tinge, as contrasted with the opaque white of the edema of acute Bright's disease. Cardiac symptoms are more frequent than in the acute form. Hence weakness and shortness of breath are often symptoms. The same complications are liable to occur as in the acute form. There are no symptoms by which the onset of the stage of secondary contraction may certainly be recognized. Long duration of the illness is presumptive evidence that contraction has set in, and when there is superadded hypertrophy of the left ventricle and accentuation of the aortic second sound, with polyuria and lowered specific gravity of the urine, its occurrence is rendered more likely.

The diagnosis is usually easy. High albuminuria, with dropsy and fatty casts, free fatty renal cells, and granular fatty cells point easily to chronic parenchymatous nephritis. There are, however, intermediate forms, when the albumin is less copious and the distinctive forms of casts are wanting, when the distinction between chronic parenchymatous nephritis and chronic interstitial nephritis only becomes possible by prolonged study of the case.

Amyloid degeneration often invades chronic nephritis, but no additions are made to the symptoms by which such a state of affairs can be recognized. In the purer forms of amyloid disease the kidney shares the process with the spleen and liver, and enlargement of these, associated with the causes of such degeneration, come to our aid in diagnosis. See PHENOLSULPHONEPHTHALEIN TEST.

The prognosis is unfavorable as to cure, but if the cases are brought under proper management as to diet, habits of life, and some treatment by medi cine, much can be done to prolong life.

The treatment is, however, more difficult than in acute nephritis. More discrimination is required and results are more difficult of attainment. Spontaneous recovery is probably impossible.

The indications are, first, to improve nutrition, restrain the accumulation of toxic matters in the blood, and second, to combat symptoms and complications. The first indication is fulfilled by suitable food and tonics, including iron. The food should be easily assimilable, in which proteins are kept at a minimum. The careful regulation of the diet is exceedingly important and its selection is based upon the functional efficiency of the kidney, non-protein nitrogen of the blood, condition of the heart and blood pressure, the digestion and weight of the patient. The excretion of salt and of nitrogen is impaired, hence these substances must be restricted in the diet and in some instances, the salt must be entirely withheld. "It has not been shown that fresh fish, poultry and meat (not rich in purins, as kidneys, sweet-breads, liver and shad roe) are any more harmful to the nephritic patient than are vegetable proteins, such as nuts, peas, beans and oatmeal; but some patients may tolerate vegetable proteins better. There is no special difference between red and white meat, though the latter may be more easily digested. Boiled meats are better than those cooked in other ways because some of the extractives have been lost. For this reason meat soups should not be allowed to patients with nephritis, as they contain mostly meat extractives." The Karell treatment may be carried out as follows: "The patient receives 200 mils of milk, in 4 doses, at 4-hour intervals during the day, beginning early in the morning. This treatment is continued for about a week. The milk may be taken hot or cold, as the patient desires, but he is allowed no other fluid and no solid food. After this period of limited diet he is allowed one egg and a slice of dry toast a day, for 2 or 3 days; the food is then gradually increased during the next 2 weeks by adding an egg, more bread, rice or other cereal, so that at the end of this period he is back to his ordinary diet, that is, the diet considered correct for one in his condition. Whether or not a little meat should be allowed depends on the character of the nephritis and on the absence or presence of uremic symptoms. During this starvation period an enema or some vegetable cathartic should be used. If the patient suffers from extreme thirst, the amount of water allowed may be slightly increased, or if hunger becomes unendurable, he may be allowed a little more toast. If the edema is largely cardiac, he may be allowed a small amount of salt" (J. A. M. A., April 7, 1917).

Iron, quinin, and strychnin are excellent tonics, yet iron is too often indiscriminately given, and sometimes more harm is done with it than good by locking up secretions, causing headache and constipation. Large doses should be avoided. A few drops of the tincture of the chlorid of iron and a dram or two of Basham's mixture should suffice for a dose. Rest, bathing, and massage are advisable hygienic measures. The clothing should always include wool next the skin in winter and summer. Elimination by the skin is facilitated by such clothing. The urine should be tested by frequent analysis, and if the quantity of urea eliminated is small compared with that ingested, its excretion should be stimulated by warm baths, warm packs, or vapor baths. The urine elimination should be aided by aperient remedies, including salines. Edema is to be treated by the same measures as acute nephritis. Sometimes it is very helpful to scarify the legs. Enormous quantities of fluid are thus liberated, with great relief to the patient. Uremia should be treated as described under acute nephritis.

Chronic Interstitial Nephritis (Contracted Kidney)

In this form of Bright's disease the resultant is a small kidney in which the interstitial connective tissue predominates, but whether this is the result of a primary overgrowth of connective tissue at the expense of the tubular structure, or whether the latter slowly disintegrates to be as gradually replaced by fibroid tissue, is a question more unsettled of late than it formerly was.

The cause often cannot be traced. Overfeeding, gout, lead, alcohol, and syphilis causes a certain number of cases. Grief and anxiety have been assigned to rather an undue portion of responsibility by some authors. Hereditary influence must be admitted. Arteriosclerosis is a cause and a consequence.

Symptoms.—The characteristic of its symptomatology is insidiousness of onset. Often the disease is discovered accidentally in a routine examination of urine, or by the ophthalmologist in the eye clinic, when least suspected by the patient—an examination suggested by a dimness of vision or more or less blindness. As often the discovery of hypertrophy of the left ventricle without explainable cause leads to an examination of the urine, and the discovery of a small amount of albumin and a few casts. More rarely a sudden outburst of uremic convulsions is the first intimation of the presence of the disease, and may also be the concluding symptom. Headache is a frequent symptom, with unpleasant throbbing in the temples. Occipital headache is said to be especially characteristic, but this symptom occurs under so many conditions that it can scarcely be allowed any diagnostic value. Never, except sometimes toward the close of the disease, is there dropsy in a marked degree, though at times a tightness of the shoe or a swelling about the ankle toward evening first attracts the attention of the patient.

The changes in the urine are more or less characteristic. The quantity is always copious; its specific gravity is low, and in it are found usually only a few hyaline casts, occasionally containing an oil drop or two. Casts are often not found, though less frequently with the use of the centrifuge. Albumin is sometimes totally absent, and there is a prealbuminuric stage, rarely recognized, in which there is neither albumin nor casts. See URINE (Examination).

Arterial sclerosis, recognizable commonly only in the radials, sometimes in the temporals, is more or less characteristic. Its exact relation to the renal disease is perhaps not precisely determined. Sometimes found early, and even preceding other symptoms, it may then be regarded as a cause. At others, occurring later, it is perhaps a conse-

quence. The changes are chiefly in the intima and media, inflammatory and degenerative rather than hypertrophic in the muscular coat, as once supposed.

The diagnosis is commonly easy. The absence of dropsy, small amount of albumin, few hyaline casts, hypertrophy of the left ventricle, and albuminuric retinitis point rarely to anything else except the contracted kidney. Only in those cases of chronic parenchymatous nephritis referred to in the stage of secondary contraction or in the undeterminate and imperfectly developed first stage is there sometimes difficulty, which time and a careful study will remove. See PHENOLSULPHONEPHTHALEIN TEST.

The prognosis of contracted kidney is unfavorable as to recovery. No kidney in which the characteristic interstitial change has been wrought probably ever returns to its normal state. Something may be done to arrest further development of the disease, so far as it is possible to counteract the causes which favor its spread. Sooner or later the disease advances slowly or rapidly to an ultimate unfavorable termination.

Treatment.—As has been intimated, treatment must consist mainly in measures calculated to arrest the spread of the disease from localized foci in the kidney to larger areas. The uric acid of the gouty diathesis must be kept in solution or eliminated, lead must be dissolved out of the blood, alcohol and excessive eating, especially of protein foods, must be cut down, and the patient put upon a diet of milk, vegetables, and fruits. High arterial pressure should be reduced by full doses of nitroglycerin and aconite. If uremia threatens, milk and Vichy or milk and water should be given in lieu of all other nourishment for a time. The bowels should at all times be kept free, and medicines calculated to lock up secretions, such as iron and other astringents, should be avoided. The occasional use of mercurial aperients is helpful, and the free ingestion of liquids between meals should be encouraged. Diuretics are not indicated in the earlier stages so long as the secretion is free. The same hygienic measures described as necessary in chronic parenchymatous nephritis are essential in this form of disease. The treatment of uremia is identical with that described under acute and chronic parenchymatous nephritis.

Drugs are not likely to be serviceable in clearing away the interstitial overgrowth. Theoretically, iodin and mercury should do this, but biniodid and bichlorid of mercury in suitable doses have been given for months without result. The gold preparations are not recommended. There are, however, men of experience who claim to have had good results from all of these remedies, and there is no reason why their use should not be continued until their true value is determined. The use of opium in interstitial nephritis, especially for the control of uremic convulsions, is dangerous, and likely to prolong the condition it is purposed to relieve.

Amyloid Disease

There are two ways in which amyloid disease may invade the kidneys: first, as a complication of chronic diffuse nephritis; and, second, as a part of general amyloid disease when the kidneys share the process with the spleen, liver and other organs of the body. The first is not recognizable by any means at our disposal; the second may be inferred from the presence of the causes of amyloid disease: viz., syphilis, suppuration, and exhausting drains on the system, along with enlargement of the liver and spleen, albuminuria, and casts. The so-called waxy cast is probably more frequent in this form of chronic disease, but is not peculiar to it, or even to chronic disease at all, as it is found also in acute nephritis. In addition to these, the other varieties of casts more or less characteristic of chronic nephritis are also found: viz., oil casts, dark granular casts, and fatty renal cells. The albuminuria is not commonly so large as in the typical forms of chronic parenchymatous nephritis.

The treatment of the first of these forms is that of chronic parenchymatous nephritis; of the second, that of the condition causing the amyloid disease, aided by the tonic and restorative measures needed in the treatment of chronic parenchymatous nephritis.

NEPHRITIS OF PREGNANCY.—Kidney insufficiency occurs in about 6 percent of all pregnant women, and is the result of the kidney of pregnancy, or true nephritis.

The kidney of pregnancy is a peculiar noninflammatory condition in which the kidney becomes anemic and the epithelial cells become infiltrated with fat.

The cause is probably some condition which interferes with the blood supply to the kidney, such as compression of the kidney by the gravid uterus, spasmodic contraction of the renal arteries, and an exaggerated hydremia of pregnancy.

The symptoms usually manifest themselves during the latter months of pregnancy. These are albuminuria, more or less pronounced, and probably some hyaline and granular casts. Desquamated epithelial cells filled with fat may also be found. The condition becomes more marked as pregnancy advances, and it not infrequently terminates in an outbreak of eclampsia. It disappears spontaneously after labor.

Nephritis may manifest itself as an acute or chronic condition, the latter being the more common.

The symptoms are the same as in uncomplicated Bright's disease.

The differential diagnosis between chronic nephritis and the kidney of pregnancy may be determined by the following:

CHRONIC NEPHRITIS.	NEPHRITIS OF PREGNANCY.
1. There may be a history of previous kidney disturbance.	1. There is no such history.
2. There may be albuminuric retinitis.	2. There is no albuminuric retinitis.
3. Symptoms appear in the first half of pregnancy.	3. Symptoms appear in the latter half of pregnancy.

Chronic Nephritis.	Nephritis of Pregnancy.
4. Casts are usually present in large number—hyaline, granular, waxy, and fatty.	4. Hyaline and granular casts may appear, but are usually few in number.
5. Symptoms persist after delivery.	5. Symptoms disappear after delivery.

The prognosis is grave; eclampsia may occur at any time.

The treatment of kidney insufficiency during pregnancy should be prophylactic and curative. Every pregnant woman's urine should be regularly examined; during the first 6 months, once every 3 weeks; later, once every week or 10 days. Should albumin appear, daily quantitative examinations should be made. This is most conveniently done by the use of an Esbach's albuminometer. If the amount of albumin is slight, if there are no casts, and if there are no general symptoms, such as edema; dietetic and hygienic treatment is sufficient.

The patient should avoid exposure to cold and wet; the skin should be kept active by frequent bathing, followed by brisk rubbing; the bowels should be moved at least once daily; and the diet should be light and easily digested. No meat should be allowed. Milk, milk-broths, and the lighter vegetables are appropriate. Should the albumin increase in amount; should casts appear in abundance; and should there be edema of the face or extremities, thorough and active treatment is indicated. The patient should be confined to bed; the diet should be exclusively milk; the bowels should be moved 2 to 4 times daily by the use of salines; and diaphoresis should be encouraged by the use of hot baths. Diuretics are indicated, such as digitalis, caffein, strophanthus, and Basham's mixture. If, in spite of this treatment, the symptoms become progressively worse, the induction of abortion or premature labor is indicated. This is particularly urged if there are serious eye symptoms, or if there is persistent headache, since they are the premonitory symptoms of eclampsia. See Eclampsia.

NEPHRECTOMY.—See Kidney (Surgery).

NEPHROLITHIASIS.—See Kidney (Stone).

NEPHROLITHOTOMY.—See Kidney (Surgery).

NEPHRORRHAPHY.—See Kidney (Surgery).

NEPHROTOMY.—See Kidney (Surgery).

NERVES, TABLE OF PRINCIPAL

Name.	Function.	Origin.	Distribution.	Branches.
Abducens (sixth cranial).	Motion	Fourth ventricle	External rectus of eye	Filaments.
Alveolar	Sensation	Inferior dental	Molar and bicuspid teeth, and adjacent gums.	Gingivales.
Articular	Trophic, sensory (?)	Anterior crural	Knee-joint	Capsular, synovial.
Articular, 2	Trophic, sensory (?)	Ulnar	Elbow-joint	Filaments.
Articular, recurrent	Motion	External popliteal	Knee-joint and anterior tibial muscle.	Filaments.
Auditory (eighth cranial).	Hearing	Restiform body	Internal ear	Vestibular, cochlear.
Auricular (*posterior*)	Motion	Facial	Retrahens aurem, attollens aurem, occipitofrontalis.	Auricular, occipital.
Auricularis magnus	Sensation	Cervical plexus, 2d and 3d cervical.	Parotid gland, face, ear	Facial, mastoid and auricular.
Auriculotemporal	Sensation	Inferior maxillary	Pinna and temple	Articular, two branches to meatus, parotid, anterior auricular, superficial temporal.
Buccal	Motion	Facial	Buccinator and orbicularis oris muscles.	Filaments.
Buccal, long	Sensation, motion (?)	Inferior maxillary	Cheek	Superior and inferior buccinator and external pterygoid.
Calcanean, internal	Sensation	Posterior tibial	Fascia and integument of heel and sole.	Several small filaments.
Cardiac (cervical and thoracic).	Inhibition	Vagus	Heart	Branches to cardiac plexuses.
Cavernous	Sensation	Prostatic plexus	Erectile structures of penis.	Filaments.

NERVES, TABLE OF PRINCIPAL

Name.	Function.	Origin.	Distribution.	Branches.
Cervical, eight.....	Motion and sensation...	Cord.....	Trunk and upper extremities.	Ventral and dorsal divisions. See *Plexus.*
Cervical, 1st (anterior division).	Motion and sensation...	Cord.....	Rectus lateralis and two anterior recti.	Filaments and communicating to vagus, hypoglossal, sympathetic.
Cervical, 1st (posterior division).	Motion and sensation...	Cord.....	Recti, obliqui, complexus.	Communicating and cutaneous filaments.
Cervical, 2d (anterior division).	Motion and sensation...	Cord.....	Communicating.....	Ascending, descending, communicating and filaments.
Cervical, 2d (posterior division).	Motion and sensation...	Cord.....	Obliquus inferior, scalp, ear, complexus, splenius, trachelomastoid.	Internal or occipitalis major, and external.
Cervical, 3d (anterior division).	Motion and sensation...	Cord.....	Communicating.....	Ascending, descending, and communicating filaments.
Cervical, 3d (posterior division).	Motion and sensation...	Cord.....	Occiput, splenius, complexus.	Internal, external, and filaments.
Cervical, 4th (anterior division).	Motion and sensation...	Cord.....	Shoulder and communicating.	Communicating filaments, muscular, etc.
Cervicals, 5th to 8th (anterior divisions).	Motion and sensation...	Cord.....	Brachial plexus.....	Communicating.
Cervicals, 4th to 8th (posterior divisions).	Motion and sensation...	Cord.....	Muscles and skin of neck..	Internal and external branches.
Cervicofacial.....	Motion.....	Facial.....	Lower part of face and part of neck.	Buccal, supramaxillary, inframaxillary.
Chorda tympani.....	Motion.....	Facial.....	Tongue, tympanum, submaxillary gland.	Filaments.
Ciliary.....	Sensation, nutrition, motion.	Ciliary ganglion.....	Eyeball.....	Filaments.
Circumflex.....	Motion and sensation...	Brachial plexus.....	Teres minor, deltoid and skin.	Anterior, posterior and articular.
Coccygeal.....	Motion.....	Coccygeal plexus.....	Coccygeus and gluteus maximus.	Filaments.
Colli, superficialis....	Sensation.....	Cervical plexus.....	Platysma myoides and ventrolateral parts of neck.	Ascending and descending branches, filaments.
Communicans hypoglossi.	See *Communicans noni.*			
Communicans noni...	Motion and sensation...	Second cervical, third cervical.	Descendens noni, depressor muscles of hyoid bone.	Omohyoid and filament, ansa hypoglossi.
Communicating.....	Motion and sensation...	Cervical plexus.....	Spinal accessory.....	Branches.
Communicating.....	Sensation and motion...	First and second cervical	Vagus, hypoglossal, sympathetic.	Three branches and filaments.
Crural.....	Sensation.....	Genitocrural.....	Skin, upper and central part ant. aspect of thigh.	Filaments.
Crural, anterior.....	Motion and sensation...	Lumbar plexus, second, third and fourth lumbar nerves.	Thigh.....	Middle and internal cutaneous, long saphenous, muscular, articular
Cutaneous.....	Sensation.....	Musculospiral.....	Skin of arm, radial side of forearm.	One internal, two external.
Cutaneous.....	Sensation.....	Ulnar.....	Wrist and palm.....	1st and palmar cutaneous.

NERVES, TABLE OF PRINCIPAL

NAME.	FUNCTION.	ORIGIN.	DISTRIBUTION.	BRANCHES.
Cutaneous (dorsal)...	Sensation.....	Ulnar.....	Little and ring fingers.....	Filaments and communicating branches.
Cutaneous (external)	Sensation.....	2d and 3d lumbar....	Skin of thigh.....	Anterior, posterior.
Cutaneous (internal)	Sensation.....	Brachial plexus.....	Forearm.....	Anterior and posterior branches and filaments.
Cutaneous (lesser internal) (*of Wrisberg*)	Sensation.....	Brachial plexus.....	Inner side of arm.....	Filaments.
Cutaneous (middle and internal).	Sensation. Motion (?).	Anterior crural.....	Thigh and communicating.	Communicating and filaments.
Cutaneous, perforating.	Sensation.....	Fourth sacral.....	Integument covering gluteus maximus.	Filaments.
Dental (inferior or mandibular).	Sensation.....	Inferior maxillary....	Teeth, muscles.....	Mylohyoid, incisor, mental, dental.
Dental, superior.....	See *Dentals* (*posterior* and *anterior*).			
Dentals (post. and ant.).	Sensation.....	Superior maxillary...	Teeth.....	Filaments.
Descendens hypoglossi.	Motor.....	Cervical plexus.....	Omohyoid, sternohyoid, sternothyroid, thyrohyoid, geniohyoid, hyoglossus and muscles of tongue.	Muscular, tongue.
Descendens noni.....	See *Descendens hypoglossi.*			
Digastric.....	Motion.....	Facial.....	Posterior belly of digastric.	Filaments.
Dorsal, 12 (anterior and posterior divisions).	Motion and sensation..	Cord.....	Muscles and skin of chest and trunk.	External, internal, cutaneous.
Dorsal (of clitoris)...	Homologue of dorsal of penis.....		.....	Filaments.
Dorsal (of penis).....	Sensation.....	Pudic.....	Penis.....	Filaments.
Facial (seventh cranial, portio dura).	Motion.....	Floor of fourth ventricle.	Face, ear, palate, tongue..	Petrosals, tympanic, chorda tympani, communicating, post. auricular, digastric, stylohyoid, lingual, temporal, malar, infraorbital, buccal, superior and inferior maxillary.
Frontal.....	Sensation.....	Ophthalmic.....	Forehead and eyelids.....	Supraorbital, supratrochlear.
Genital.....	Motion and sensation...	Genitocrural.....	Cremaster muscle.....	Filaments.
Genitocrural.....	Motion and sensation...	First and second lumbar.	Cremaster and thigh.....	Genital, crural, communicating.
Glossopharyngeal (ninth cranial).	Sensation and taste.....	Fourth ventricle.....	Tongue, middle ear, tonsils, pharynx, meninges.	Tympanic, carotid, pharyngeal, muscular, tonsillar, lingual.
Gluteal (inferior).....	Motion.....	Sacral plexus (2d and 3d sacral nerves).	Gluteus maximus.....	Filaments.
Gluteal (superior)....	Motion.....	Sacral plexus.....	Glutei, tensor vaginæ fem.	Filaments.
Gustatory.....	See *Lingual.*			
Hemorrhoidal (inferior).	Sensation and motion...	Pudic.....	External sphincter ani, and adjacent integument.	Filaments.
Hypogastric.....	Sensation.....	Iliohypogastric.....	Skin about external abdominal ring.	Filaments.

NERVES, TABLE OF PRINCIPAL

Name.	Function.	Origin.	Distribution.	Branches.
Hypoglossal (twelfth cranial).	Motion	Floor of fourth ventricle.	Hyoglossus and hyoid muscles.	Descendens noni or hypoglossi, muscular, thyrohyoid, genichyoid and meningeal.
Iliac	Sensation	Iliohypogastric	Integument covering fore part of gluteal region.	Filaments.
Iliac	Sensation	Last dorsal	Integument covering fore part of gluteal region.	Filaments.
Iliohypogastric	Motion and sensation	First lumbar	Abdominal and gluteal regions.	Iliac, hypogastric, communicating.
Ilioinguinal	Motion and sensation	First lumbar	Inguinal region and scrotum.	Muscular, cutaneous and communicating.
Inframaxillary	Motion	Facial	Platysma myoides	Filaments.
Infraorbital	Sensation and motion	Facial	Nose and lip	Palpebral, nasal, labial.
Infratrochlear	Sensation	Nasal	Skin and conjunctiva of inner part of eye, lacrimal sac.	Filaments.
Intercostal	Motion and sensation	Spinal cord	Muscles and integument of thorax.	Muscular, anterior and lateral cutaneous.
Intercostohumeral	Sensation	Second intercostal	Integument of upper two-thirds of inner and posterior part of arm.	Filaments.
Interosseous (anterior).	Motion	Median	Deep muscles of forearm	Filaments.
Interosseous (posterior).	Motion and sensation	Musculospiral	Carpus and radial and posterior brachial regions.	Filaments.
Labial	Motion and sensation	Superior maxillary	Muscles and mucous membrane of lips.	Filaments.
Lacrimal	Sensation	Ophthalmic	Gland and conjunctiva	Filaments.
Laryngeal (recurrent or inferior).	Motion	Vagus	Larynx	Branches to all laryngeal mus. except cricothyroid.
Laryngeal (superior)	Sensation and motion	Vagus	Larynx	External — cricothyroid muscle and thyroid gland. Internal—mucous membrane of larynx.
Lingual	Motion and sensation	Facial	Mucous membrane of tongue, palatoglossus and styloglossus muscles.	Filaments.
Lingual	Sensation	Glossopharyngeal	Circumvallate papillæ and glands of tongue.	Filaments.
Lingual	Taste and sensation	Inferior maxillary	Tongue and mouth	Filaments.
Lumbar (5)	Motion and sensation	Cord	Lumbar and genital tissues.	Anterior and posterior divisions, lumbar plexus.
Malar	Motion	Facial	Lower part of orbicularis palpebrarum, and eyelids.	Filaments.
Malar	Sensation	Orbital	Skin over malar bone	Filaments.
Mandibular	See *Maxillary, inferior.*			
Masseteric	Motor	Inferior maxillary	Masseter muscle (and temporal?).	Filaments.
Maxillary (inferior)	Sensation, motion, and taste.	Trigeminus	Muscles of mastication, ear, cheek, tongue, teeth.	Masseteric, auriculotemporal, buccal, gustatory, inferior dental.

NERVES, TABLE OF PRINCIPAL

Name.	Function.	Origin.	Distribution.	Branches.
Maxillary (superior).	Sensation	Trigeminus	Cheek, face, teeth	Orbital, sphenopalatine, dentals, infraorbital.
Median	Motion and sensation	Brachial plexus	Pronator radii teres, flexors, two lumbricales, fingers, palms.	Muscular, anterior interosseous, palmar cutaneous.
Meningeal	Sensation	Glossopharyngeal	Pia and arachnoid	Filaments.
Meningeal	Sensation	Hypoglossal	Dura mater	Filaments.
Meningeal	Sensation	Vagus	Dura around lateral sinus.	Filaments.
Meningeal, recurrent.	Sensation	Inferior maxillary	Dura and mastoid cells	Filaments.
Mental	Motion and sensation	Inferior maxillary	Mucous membrane of lower lip and chin.	Filaments.
Motor oculi (third cranial).	Motion	Floor of aqueduct of Sylvius.	All muscles of the eye, except external rectus, superior oblique, and orbicularis palpebrarum.	Filaments.
Muscular	Motion and sensation	First and second cervical.	Rec. cap. lat., rec., anterior major et minor	Filaments.
Muscular	Motion and sensation	Cervical plexus	Sternomastoid, lev. ang. scap., scal. med., trapez.	Filaments.
Muscular	Motion	Brachial plexus	Longus colli, scaleni, rhomboidei, subclavius.	Filaments.
Muscular	Motion	Musculospiral	Triceps, anconeus, supinat. long., extens. carpi rad. long., brach. antic.	Internal, posterior, external.
Muscular	Motion	Median	Superficial muscles of forearm.	Filaments.
Muscular	Motion	Ulnar	Flexor carpi ulnaris, flexor profundus digitorum.	Two branches.
Muscular	Motion	Great sciatic	Biceps, semimembranosus, semitendinosus, adductor magnus.	Filaments.
Muscular	Motion	Sacral plexus	Pyriformis, obturator int., gemelli, quad. femoris.	Filaments.
Muscular	Motion	Anterior crural	Pectineus and muscles of thigh.	Filaments.
Musculocutaneous	Motion and sensation	Brachial plexus	Coracobrach., biceps, brach. anticus, forearm.	Anterior and posterior.
Musculocutanéous	Motion and sensation	External popliteal	Muscles of fibular side of leg, skin of dorsum of foot,	Internal, external.
Musculospiral	Motion and sensation	Brachial plexus	Back of arm and forearm, skin of back of hand.	Musculocutaneous, radial, posterior interosseous.
Mylohyoid	Motion	Inferior maxillary	Mylohyoid and digastric muscles.	Filaments.
Nasal	Sensation	Dental, anterior	Mucous membrane of inferior meatus.	Filaments.
Nasal	Sensation	Maxillary, superior	ntegument of lateral aspect of nose.	Filaments.
Nasal	Sensation	Ophthalmic	Iris, ciliary ganglion, nose.	Ganglionic, ciliary, infratrochlear.
Obturator	Motion and sensation	Lumbar plexus, third and fourth nerves.	Obturator externus, adductors, joint and skin	Ant. and post. articulating and communicating.

NERVES, TABLE OF PRINCIPAL

Name.	Function.	Origin.	Distribution.	Branches.
Obturator (accessory).	Motion and sensation..	Lumbar plexus.....	Pectineus and hip-joint ...	Filaments.
Occipital, smallest or 3d.	Sensation.....	Third cervical.....	Integument of occiput...	Filaments
Occipitalis, lesser or minor.	Sensation.....	Second cervical.....	Occipitofrontalis, ear, etc.	Communicating, auricular, filaments.
Occipitalis magnus....	Motion and sensation...	Second cervical.....	Complexus, trap. and scalp.	Filaments.
Oculomotor.....	See *Motor oculi.*			
Olfactory (first cranial).	Smell.....	Frontal lobe, optic thalamus and insula.	Schneiderian membrane of nose.	Twenty branches.
Ophthalmic.....	Sensation.....	Trigeminus.....	Forehead, eyes, nose.....	Frontal, lacrimal, nasal.
Optic (second cranial).	Sight.....	Cortical center in occipital lobe.	Retina.....	None.
Orbital.....	Sensation.....	Superior maxillary....	Temple and cheek.....	Temporal and malar.
Palmar cutaneous....	Sensation.....	Median.....	Thumb and palm.....	Outer and inner.
Palmar (deep).....	Motion.....	Ulnar.....	Little finger, dorsal and palmar interosseous, two inner lumbricales, abductor pollicis.	Filaments.
Palmar (superficial)..	Sensation and motion..	Ulnar.....	Palmaris brevis, inner side of hand and little finger.	Filaments and two digital branches.
Palpebral.....	Motor.....	Superior maxillary...	Integument of lower lid...	Filaments.
Parotid.....	Sensation.....	Auriculotemporal....	Parotid gland.....	Filaments.
Patheticus (4th cranial).	Motion.....	Valve of Vieussens...	Superior oblique of eye.....	None.
Pectineus.....	Motion.....	Anterior crural.....	Pectineus muscle.....	Filaments.
Perineal.....	Motion and sensation...	Pudic.....	Perineum, genitalia and skin of perineal region.	Cutaneous and muscular.
Perineal.....	Motion and sensation...	Fourth sacral.....	External sphincter ani and integument of anus.	Filaments.
Peroneal communicating.	Sensation.....	External popliteal....	Connecting external popliteal with short saphenous.	None.
Phrenic.....	Motion and sensation...	Third, fourth, and fifth cervical.	Diaphragm, pericardium, pleura.	Filaments.
Plantar (external)....	Motion and sensation..	Posterior tibial.....	Little toe and deep muscles of foot.	Superficial and deep.
Plantar (internal)....	Sensation and motion...	Posterior tibial.....	Sole of foot, adduct. pollic., flexor brev. digi., toes.	Cutaneous, muscular, articular, digital.
Pneumogastric (tenth cranial ("par vagum").	Sensation and motion...	Floor of fourth ventricle.	Ear, pharynx, larynx, heart, lungs, esophagus, stomach.	Auricular, pharyngeal, superior and inferior laryngeal, recurrent laryngeal, cardiac, pulmonary, esophageal, gastric, hepatic, communicating, meningeal.
Popliteal (external)..	Sensation and motion...	Great sciatic.....	Extensors of foot, skin, and fascia.	Anterior tibial, musculocutaneous, articular, cutaneous.
Popliteal (internal)...	Motion and sensation...	Great sciatic.....	Knee, gastrocnemius, tibialis posticus, plantaris, soleus, popliteus, skin of foot.	Articular, muscular, cutaneous, external saphenous, plantar, external or short saphenous.

NERVES, TABLE OF PRINCIPAL

Name.	Function.	Origin.	Distribution.	Branches.
Pudendal, long (nerve of Soemmering).	Sensation	Small sciatic	Integument of genitalia and inner and proximal part of thigh.	Filaments.
Pudic	Motion and sensation	Sacral plexus	Perineum, anus, genitalia.	Inferior hemorrhoidal, perineal, cutaneous, dorsal of penis.
Radial	Sensation.	Musculocutaneous	Thumb and three fingers	External and internal.
Sacral (five)	Motion and sensation	Cord	Multifidus spinæ, skin, gluteal region.	Filaments and sacral plexus.
Saphenous (external or short).	Sensation	Internal popliteal	Integument of foot and little toe.	Filaments.
Saphenous (long or internal).	Sensation	Anterior crural	Knee, ankle	Cutaneous, patellar, communicating, filaments.
Sciatic (great)	Motion and sensation	Sacral plexus	Skin of leg, muscles of back of thigh and those of leg and foot.	Articular, muscular, popliteals.
Sciatic (small)	Sensation and motion	Sacral plexus	Perineum, back of thigh and leg, gluteus maximus.	Muscular, cutaneous, long pudendal.
Spinal accessory (eleventh cranial)	Motion	Floor of fourth ventricle.	Sternocleidomastoid, trapezius.	Filaments.
Splanchnic (great)	Sympathetic	Thoracic ganglia	Semilunar ganglion, renal and suprarenal plexuses.	Communicating and filaments.
Splanchnic (lesser)	Sympathetic	Tenth and eleventh thoracic ganglia, great splanchnic.	Celiac plexus and great splanchnic.	Communicating and filaments.
Splanchnic (renal or smallest).	Sympathetic	Last thoracic ganglion.	Renal and celiac plexus	Communicating and filaments.
Stylohyoid	Motion	Facial	Stylohyoid muscle	Filaments.
Subscapular (three)	Motion	Brachial plexus	Subscapular, teres major, and latissimus dorsi.	Filaments.
Supraacromial	Sensation	Cervical plexus	Skin over deltoid	Filaments.
Supraclavicular (descending).	Sensation	Third and fourth cervical.	Skin of neck, breast and shoulder.	Sternal, clavicular, acromial.
Supramandibular	See *Maxillary, superior.*			
Supramaxillary	See *Maxillary, superior.*			
Supraorbital	Sensation	Ophthalmic	Upper lid, forehead	Muscular, cutaneous and pericranial branches.
Suprascapular	Motion and sensation	Brachial plexus	Scapular muscles	Filaments.
Supratrochlear	Sensation	Ophthalmic	Forehead and upper eyelid.	Muscular and cutaneous.
Temporal	Motion	Inferior maxillary	Temporal muscle	Filaments.
Temporal	Sensation	Orbital	Integument over temporal muscle.	Filaments.
Temporal	Motion	Temporofacial	Orbicularis palpebrarum, occipitofrontalis, attrahens and attollens aurem, corrugator supercilii.	Muscular.
Temporal, superficial.	Sensation	Auriculotemporal	Integument over temporal fascia.	Filaments.
Temporofacial	Motion	Facial	Upper part of face	Temporal, malar, infraorbital.

NERVES, TABLE OF PRINCIPAL

Name.	Function.	Origin.	Distribution.	Branches.
Thoracic (ant. and ext.).	Motion.....	Brachial plexus.....	Pectoralis major et minor.	Filaments.
Thoracic (posterior or long). External respiratory nerve of Bell.	Motion.....	Brachial plexus.....	Serratus magnus.....	Filaments.
Tibial (anterior).....	Motion and sensation...	External popliteal....	Tibialis antic., extensor long. digit., peroneus ter. joints of foot, skin of great toe.	Muscular, external, internal.
Tibial (posterior)....	Motion and sensation...	Internal popliteal....	Tibialis post., flexor long. digit., flexor long. pollic., skin of heel and sole, knee-joint.	Plantars, muscular, calcaneoplantar, cutaneous or internal calcanean, articular.
Tonsillar.....	Sensation.....	Glossopharyngeal....	Tonsil, soft palate, and fauces.	Filaments.
Trigeminus or trifacial (fifth cranial).	Motion and sensation (taste).	Medulla and floor of fourth ventricle.	Skin and structures of face, tongue and teeth.	Ophthalmic, superior and inferior max. divisions.
Trochlear.....	See *Patheticus*.			
Ulnar.....	Motion and sensation...	Brachial plexus.....	Muscles, shoulder-joint and wrist-joint, and skin of little finger.	Two articular, muscular, palmar cutaneous, dorsal, superior palmar, deep palmar.
Vagus.....	See *Pneumogastric*.			
Vidian.....	Sensation.....	Union of large superficial and deep petrosal.	Sphenomaxillary fossa, and posterior part of upper nasal meatus.	Filaments, nasal.

NERVES, DISEASES.—See Neuralgia, Neuritis, Neuroma, etc.

NERVES, INJURIES. Wounds.—A nerve may be completely or partially divided, and the wound may be incised, lacerated, contused, or punctured.

The effects of wounds of nerves, in addition to the degeneration of the portion below the wound, are: (1) Paralysis of motion and sensation of the parts supplied by the nerve; (2) subsequent wasting, atrophy, and fatty degeneration of the paralyzed muscles; (3) certain trophic changes in the tissues whose nutrition is presided over by the injured nerve, such as a glazed, smooth, cold, and bluish-red condition of the skin, falling off of the hair, cracking and deformity of the nails, local ulcerations and gangrene of the fingers, etc.; (4) a marked diminution in the temperature of the part, which may be preceded for a few days or even a few weeks by a slight increase of 2 or 3 degrees; (5) affections of the joints resembling rheumatism, and apt to terminate in more or less complete ankylosis; (6) ascending neuritis, which is attended by severe pain in the cicatrix and shooting up the nerve, and pain in the area of its distribution; and (7), very rarely, changes in the nerve-centers of a functional or of an organic nature (Walsham).

Symptoms.—The immediate symptoms are loss of function in the parts supplied by the nerve—viz., muscular paralysis, local anesthesia, or loss of special sense—according as a motor, sensory, or nerve of special sense is injured. In the case of a mixed nerve, both motion and sensation will be lost; but sensation in some instances may be partially restored in a few days through anastomosing branches from other nerves. The remoter symptoms are wasting of the muscles, and the trophic changes of the skin, nails, etc., already alluded to, and sometimes pain in the cicatrix, and in the course of the nerve and its peripheral distribution. The muscles exhibit to electric tests the *reaction of degeneration—i. e.*, they do not respond to the faradic current, but contract on the application of a continuous current of less strength than that necessary to cause the contraction of normal muscles; the contraction elicited, moreover, is slow, long, and tetanic; and the sequence of polar reaction is altered ($ACC. > CCC.$ instead of $CCC. > ACC.$). Their response, however, to the continuous current becomes feebler until they finally cease to contract. As a consequence of the degeneration of the affected muscles, their opponents undergo adaptive shortening, thus producing various deformities: as, for example, the hammer fingers (*main en griffe*) seen after division of the ulnar nerve.

The treatment varies according as the wound of the nerve is recent or of long standing. In the former case the nerve should be sought in the wound, the divided end sutured, the limb placed at rest on a splint in such a position that the united ends are not subjected to tension, and every effort subsequently made to obtain healing of the wound of the soft parts by first intention. If the divided ends of the nerve are lacerated or contused,

the injured portions should be cleanly cut away before applying the sutures. If the nerve is only partially divided, the divided parts should be sutured. The sutures, consisting of fine China-silk twist, should be passed with a small curved needle through the sheath of the nerve in 4 or 5 places. In every recent wound it should be as much a matter of routine to suture large nerves, if divided. as to tie wounded arteries. If the nerve does not unite, an attempt may be made to procure union after the wound is healed, as may also be done in long-standing cases of nonunion, though many months or even a year or two may have elapsed. An incision over the ununited ends should be made parallel to the nerve, the bulbous upper end of which can generally be felt through the soft tissues. The ends, which may have retracted so as to be an inch or more apart, should be sought, the bulbous ends shaved away little by little with a sharp scalpel until plenty of nerve-fibers are seen on the surface of the section, the lower end also refreshed, and the two united in the manner described above. When the ends are embedded in much cicatricial tissue, they should be freed by careful dissection, and when much separated, stretched so as to bring them into apposition. If the nerve is only partially divided, and the divided portions are bound down by cicatricial tissue, the injured segment of nerve, in its entire thickness, should be cut away before applying the sutures. In some instances sensation may return within 24 hours of suture; but it may be more than a year in long-standing cases before the function of the nerve is restored. In the meanwhile the nutrition of the parts supplied by it should be promoted by warmth, and the muscles prevented as much as possible from degenerating by galvanism, massage, friction, and passive movements (Walsham).

Transplantation of nerves, or **nerve-grafting,** has become a recognized surgical procedure. In some cases, also, a piece of nerve has been taken from an animal for the purpose. An attempt to restore the function of the nerve in this way may be made when the proximal and the distal ends of a divided nerve cannot be brought into apposition: as, for instance, after a portion of nerve has been destroyed in a compound fracture, or after a portion of nerve, damaged by the contraction of cicatricial tissue, by the formation of callus, or by the growth of a tumor in its substance, has been removed. The conditions for success are: great care in dissecting out and handling the nerve, its immediate transference, the employment of a single suture at each end, the avoidance of all tension, strict asepsis, and immediate union of the wound of the soft parts.

Subcutaneous rupture of a nerve is rare, but is occasionally met with as the result of a severe twist or wrench. It is attended with severe pain at the time of injury, perhaps also referred to the periphery of the nerve, and the gradual formation of a bulbous swelling on the nerve immediately above the rupture. The same effects follow as in division of a nerve in an open wound. The treatment is also similar.

Compression of a nerve occasions numbness and tingling, and, if severe and prolonged, partial or complete paralysis of the parts supplied by it, and the series of changes already described. As examples may be mentioned crutch-palsy, due to the pressure of a crutch upon the large nerves in the axilla; the dropped wrist, from the involvement of the musculospiral nerve in the callus in fracture of the humerus; the tingling, numbness, and partial paralysis sometimes following dislocations of the shoulder from the pressure of the head of the displaced bone on the brachial plexus; the pain caused by the pressure of a tumor on a nerve; the "pins and needles" felt in the feet, after sitting on the edge of a chair, from compression of the sciatic nerve, etc.

The treatment consists in releasing, if practicable, the nerve from the compressing agent. If a wound of the soft tissues is necessary to accomplish this object, healing without suppuration should be obtained, if possible, as otherwise the nerve may again become compressed by the resulting scar-tissue.

Contusions.—A familiar example of this injury is a blow on the ulnar nerve, as it lies behind the internal condyle. There is intense pain at the spot struck, and shooting and "pins-and-needles" pains in the parts supplied by the nerve. These symptoms pass off shortly, but occasionally they may be more severe and last for several weeks, in which case there is probably some effusion of blood in the nerve. In rare instances ascending neuritis, persistent neuralgia, or even paralysis, and changes similar to those observed after complete division of a nerve, may follow.

Foreign Bodies.—A portion of a needle broken off in a nerve, the lodgment of small shot from a gun accident, etc., may give rise to inflammation of the nerve, persistent irritation and pain at the injured spot, spasm in the muscles, and pain or tingling in the parts supplied by the nerve. Such accidents have occasionally been followed by epileptiform convulsions. The treatment is to cut down upon and remove the foreign body.

NERVOUS DISEASES, EXAMINATION

Mode of Procedure in Diagnosing Diseases of the Nervous System

In making a diagnosis of diseases of the nervous system it is frequently advisable to resort to the plan of exclusion, and in this manner to eliminate such disorders as rheumatism, gout, and diseases of the joints, affections which disturb sensation or motion, or both. As syphilis is a very common cause, in diseases of the nervous system the possibility of such infection, even many years before the onset of the nervous symptoms, should be determined. For a full discussion of the diagnosis of syphilis, see Syphilis.

In all lesions of the nervous system there is either a disturbance of motion or of sensation, or of both. In some there is a disturbance of the special senses or of consciousness. It is necessary then to separate diseases of the brain,

diseases of the cord, and diseases of the peripheral nervous system. The elimination of eyestrain is of paramount importance in all nervous disorders.

A careful history will eliminate such conditions as gout, rheumatism, and joint affections. After these factors have been eliminated, it is determined whether or not the lesion is within the brain, in the spinal cord, or in the peripheral nerves. Spinal curvature may be found to be the cause.

Symptoms of Diseases of Brain, Spinal Cord, and Peripheral Nerves

Lesions of Brain.	Lesions of Cord.	Lesions of Peripheral Nerves.
1. Disturbances of consciousness.	1. Consciousness usually preserved.	1. Consciousness preserved.
2. Disturbances of special sense, as hearing, smelling, tasting, feeling.	2. No disturbance of nerves of special sense.	2. No disturbance of nerves of special sense except feeling.
3. Delusions and hallucinations.	3. No delusions or hallucinations.	3. Mind usually normal.
4. Paralysis frequently involves arms.	4. Paralysis frequently involves legs.	4. Paralysis may involve arm or leg, most frequently the latter.
5. Convulsions common.	5. Convulsions rare.	5. Convulsions rare.
6. Vomiting common.	6. Vomiting not common, except in tabes dorsalis.	6. Vomiting uncommon.
7. Sphincters frequently involved.	7. Sphincters frequently involved.	7. Usually control of sphincters.

Systematic Study of Diseases of the Nervous System

(1) Disturbances of motion; (2) disturbances of sensation; (3) disturbances of nutrition; (4) disturbances of consciousness; (5) disturbances of special sense; (6) psychic disturbances.

Paralysis

Varieties.—1. **Irregular paralysis,** arising from various regions of brain, giving rise to optic neuritis, vomiting, strabismus; or, if in the cord or peripheral nervous system, giving rise to paraplegia, neuritis, etc.

2. **Monoplegia,** arising from brain, as seen in small hemorrhage into cortical layer; or may arise from disease of peripheral nerve, as from traumatism.

3. **Hemiplegia.**—Hemorrhage into the cerebrum is the most common cause. Hemorrhages into cerebellum and crus cerebri are very rare.

Paraplegia may arise from hemorrhage into brain or cord, or it may arise from disease of peripheral nerves, as in multiple neuritis.

Convulsions

Varieties.—(1) Epileptiform; (2) tetanic; (3) hysteroid; (4) local.

In **epileptiform convulsion** consciousness is lost, and there are clonic spasms.

Tetanic convulsions are usually accompanied by consciousness, and the muscles most frequently affected are the muscles of the jaws and of deglutition. They occur in tetanus, strychnin-poisoning, tetany and spinal meningitis.

Hysteroid convulsions occur in hysteria; consciousness may or may not be present.

Local convulsions or **spasms** frequently affect the face, causing momentary spasms, as is seen in tic douloureux, which results from neuralgia of the fifth nerve.

Saltatory Spasm.—A transient or permanent condition allied to hysteria in which the attempt to stand results in a sudden violent contraction of the leg muscles.

Tremors

Tremors are involuntary vibratory movements and are produced by alternate contraction and relaxation of antagonistic muscles. They are observed most often in the arms, head, face, tongue, and hands. They may be *coarse* or *fine*. Tremors occur in chronic alcoholism, delirium tremens, paralysis agitans, and in poisoning by lead, mercury, arsenic, chloral and opium. Neurasthenia, debility from various causes, senility, hysteria, disseminated sclerosis, and paresis are accompanied by tremors. In *disseminated sclerosis,* the tremor is irregular, jerky, and increased by voluntary efforts to restrain it. The tremor is absent during rest but is brought about by movement. In *paralysis agitans,* it is regular and rhythmic, occurring both during rest and movement. The tremor of *senility* is exceedingly fine and begins in the hands, often extending to the face. It occurs at first only during motion, disappearing during rest. When age is far advanced it may occur during both rest and movement.

Choreiform movements are coarse, incoordinated, involuntary movements of a jerky and irregular character usually separated by short intervals. They may simulate, to some extent, purposeful movements. Among the causes may be mentioned idiopathic chorea, Huntingdon's chorea, posthemiplegic chorea, organic brain disease, habit, hysteria, reflex irritation, etc.

Athetoid movements are slow, more or less rhythmic twisting movements of the fingers and toes. They are observed in cerebral palsies of children, after hemiplegia in adults, and polioencephalitis.

The Gait

The Ataxic Gait.—In locomotor ataxia the characteristic development of incoordination of movements comes on slowly. It is frequently observed by the patient from the inability to walk after dark. The characteristic gait is manifested by the fact that the foot is raised high in the air with a rotatory motion, and is dropped quickly so that the whole of the sole strikes the floor at the same time.

The Spastic Gait.—In spastic paraplegia or lateral sclerosis, the gait is manifested by the legs being dragged behind the patient, the toes frequently scraping the ground; the knees seem to come together, and the limbs may shake from the clonus which may be present.

Festination is observed in paralysis agitans. In this movement the patient appears to be in the act

of falling forward, when the steps become faster and faster, then suddenly cease, and the patient may fall backward or on the side, should he receive no support from in front.

The Gait of Pseudomuscular Hypertrophy.—The limbs are generally well nourished, frequently greatly enlarged, and in walking the feet are thrown outward straddling; the abdomen is greatly enlarged, and the body movements are slow and awkward.

Titubation is observed in diseases of cerebellum. It may be mistaken for the gait of locomotor ataxia, except that it is more irregular. If the patient is put in the reclining attitude, the motions may be perfectly controlled, while in locomotor ataxia there is partial loss of voluntary motion, as is seen when the patient tries to touch the tip of the nose when the eyes are closed.

In *myotonia* (*q. v.*) any muscular action such as walking is begun with difficulty. The stiffness gradually, however, disappears and progression is easy.

In *intermittent claudication* (*q. v.*) walking is associated with rigidity, numbness, cramps, weakness and disorders of sensation.

The Reflexes

As a rule, when the "reflexes" are spoken of in diseases of the nervous system, the tendon or patellar reflex of the knee-joint is meant: this is probably due to the contraction of the muscle itself, brought about by its normal irritability. As the impulse communicated to the muscle is transmitted through the medium of the spinal cord, it may be said that the reflexes are governed by this portion of the nervous system.

The Knee-jerk or Patellar Reflex.—This symptom is elicited by having patient cross the knees while in a sitting posture, and after distracting attention, gentle taps are made over quadriceps tendon immediately below the patella.

The knee-jerk is increased in lateral sclerosis, disseminated sclerosis, incomplete lesions of the cord above the lumbar segment, irritability of the spinal cord such as occurs in spinal meningitis, strychnin poisoning, hysteria, etc., and in some cases of organic cerebral disease.

The knee-jerk is decreased in locomotor ataxia, neuritis, pseudomuscular hypertrophy, poliomyelitis, myelitis, and in poisoning by spinal depressant drugs. Pronounced physical exhaustion also serves to lessen the tendon reflexes.

Ankle-clonus.—This symptom is elicited by allowing patient to cross the knees, and by elevating the foot so that the entire limb is on the same plane, then, by a sudden push upward, there is a tremulous movement or vibration communicated to the hand, frequently lasting for many seconds.

The *Babinski reflex* is the extension of the great toe which follows tickling the sole of the foot. Normally flexion follows such a procedure. The reflex occurs most often in hemiplegia, diplegia, and diseases of the motor tract of the cord.

Arm-jerk and jaw-jerk are also frequently elicited.

Paradoxic contraction, a peculiar phenomenon allied to the reflexes, first studied by Westphal, is occasionally noted. Its cause is unknown. In the *tibialis anticus* muscle it is induced by forcibly flexing the foot on the leg. As a result, the foot remains thus flexed for a considerable time, then slowly relaxes. On repeating the flexion, the tetanic contraction recurs, but the response gradually diminishes in intensity. Contractions induced by faradism may similarly persist. More rarely it may be induced in the flexors of the leg and forearms. It has been observed in early tabes dorsalis, multiple sclerosis, hysteria, and paralysis agitans.

Vasomotor Disturbances

Paralysis of the vasomotor system occurs as a symptom of hysteria, neurasthenia, and other functional neuroses, and follows injuries of the sympathetic nerve. It is manifested by abnormal redness of the skin with a sensation of heat and a rise in the dermal temperature. Vasomotor spasm is indicated by pallor and coolness of the skin with formication and stiffness. It is observed with functional disturbances of the sympathetic system and may be followed by trophic disturbances such as occur in scleroderma and symmetric gangrene.

Disturbances of Sensation

Loss of sensation is most common. This is called **anesthesia. Hyperesthesia** is a condition in which the sensation is increased above the normal. **Paresthesia** consists of abnormal sensations, such as "pins-and-needles" pains. Subjective painful sensations or nerve ache is known as **neuralgia.**

Areas of anesthesia may be determined by the prick of a pin, by the finger stroke, by the application of heat (flame or coal) or cold (ice), and by the faradic current. **Monanesthesia** is a condition in which the sensation is lost in but one member. **Hemianesthesia** means loss of sensation over the lateral half of the body. **Analgesia** means insensibility to pain. It is met with in hysteria and syringomyelia especially.

Disturbances of Consciousness

The principal alterations to which consciousness is subject in nervous diseases are coma, trance, somnambulism, ecstasy, and catalepsy.

Coma is an abnormally deep and prolonged sleep in which the cerebral functions are in abeyance, characterized by stertorous breathing, relaxation of the sphincters, lividity of the face, loss of parallelism of the optic axes, and an inability to respond to external stimuli. It may be gradual or sudden in its onset; complete or partial, transient or permanent. It may be due to organic brain disease, traumatism, cerebral anemia, epilepsy, sunstroke, hysteria, various convulsive states, and various toxic agents in the blood, introduced either from without or produced within the body.

Trance is an hysteric manifestation characterized by a prolonged abnormal sleep from which the patient cannot be aroused and in which the vital functions are reduced to a minimum.

Somnambulism is a condition of half-sleep in which the senses are but partially suspended and

the patient is able to perform various feats automatically. Ordinary sleep-walking may occur in health but the more pronounced varieties of this condition are observed in hysteria and in hypnotized subjects.

Ecstasy is a peculiar state of the mind in which a delusion so governs the mental functions that the entire nervous system is held in a condition of subjection or apparent insensibility. It is usually an hysteric manifestation.

Catalepsy is characterized by loss of will and by muscular rigidity. It occurs in paroxysms with loss of consciousness, the limbs remaining for long periods in any position in which they are placed. It occurs in hysteria, various psychoses, hypnotic states, and organic brain disease.

Disturbances of the Special Senses

Miosis, or contraction of the pupil, frequently occurs in opium-poisoning, locomotor ataxia, paretic dementia, and uremia.

Inequality of the pupils may be found in such conditions as organic brain-disease, locomotor ataxia, and paretic dementia.

The Argyll Robertson pupil occurs in locomotor ataxia. In this phenomenon the pupil fails to respond to light, but accommodates for distance. See PUPIL.

Nystagmus.—A peculiar condition of the eyeball in which an outward and an inward oscillation occurs. It may be observed in disseminated sclerosis and diseases at the base of the brain.

Ocular movements are often impaired or paralyzed, and the muscles involved give evidence of the nervous lesion. See EYE-MUSCLES.

The Ear

Tinnitus aurium is a peculiar ringing or buzzing sound in the ear observed in middle-ear or Ménière's disease. It may be produced by administering large doses of quinin or salicylic acid. See EAR.

Psychic Disturbances

Delusion.—By this is meant a faulty belief concerning a subject of physical demonstration, out of which the person cannot be reasoned by adequate methods for the time being (Wood).

Illusion means a perverted conception, attributing life and motion to inanimate things.

Hallucination.—A false perception. Frequently occurs in the insane, and is one in which the patient appears to hear voices and to see faces where none exist.

Morbid Impulse.—An irresistible desire to commit an act which the patient knows to be wrong (Stevens).

Disturbances of Nutrition. (*Trophic Derangements*)

By this term is meant changes in the nerves and muscles of a part, giving rise to a change in the contractility when a galvanic battery is applied and resulting also in muscular atrophy, arthropathies, ulcerations, and trophic affections of the skin, nails and hair. These trophic or nutritive phenomena are closely related to vasomotor phenomena.

Reaction of Degeneration

To determine this reaction, a galvanic battery of moderate strength should be used. The battery should always be tested by dipping the sponges in a weak saline solution or in water. In the galvanic battery there are what are termed the *anode*, or positive pole, and the *kathode*, or negative pole. By placing the kathode over a normal muscle and closing the circuit, a strong contraction occurs; when the anode is placed over the normal muscle, the contraction is greatly lessened. There is no contraction in either case when the circuit is broken. With a strong galvanic current contractions of the normal muscle occur, and the anodal is greater than the kathodal. In the reaction of degeneration all these reactions are altered or even reversed.

Another simple degenerative reaction is given by Gowers, who states that the faradic irritability is lost, while the galvanic irritability is increased, and often changed in quality.

The circuit of a galvanic battery is said to be *closed*, *made*, or *complete* when the elements are connected outside of the fluid.

NEURALGIA.—A severe paroxysmal pain in the area of distribution of a nerve or along its course.

Etiology.—Age, sex, heredity, and anemia are important predisposing causes. The true nature of neuralgia is obscure; it is possible that in many cases the cause is an inflammatory or circulatory disturbance in the nerve-trunk. Among exciting causes, cold and traumatism play an important rôle. Certain disease-poisons, as those of typhoid fever, variola, malaria, and *metallic* poisons, such as lead, arsenic, copper, mercury, in addition to alcohol and nicotin, are sometimes causative agents of neuralgia. Gout and diabetes also occasionally give rise to neuralgia. Finally, there is a class of so-called reflex neuralgias, such as those due to eye-strain and those met with in connection with uterine and ovarian disease and occurring in remote organs. Lesions of the central nervous system also give rise to attacks of neuralgic pain.

Varieties.—According to the nerves involved, the following varieties occur: Trifacial, or tic douloureux (prosopalgia); cervicooccipital, cervicobrachial, and brachial neuralgias; neuralgia of the phrenic nerve; neuralgias of the trunk, such as dorsointercostal, lumboabdominal, and possibly pleurodynia; neuralgia of the spinal column, sacral neuralgia, and coccygodynia; neuralgia of the feet; and visceral neuralgia. The fifth nerve is a favorite seat for reflex neuralgias.

Symptoms.—Pain is the most important symptom. It is of a spontaneous nature; occurs in paroxysms; runs along the course of the nerve by the nervi nervorum; and is of a darting, burning character. These paroxysms, lasting from a few moments to some hours, may return at regular intervals. Certain tender points exist along the course of the nerve, usually where the nerve passes from a deeper to a more superficial position. These pains are supposed to be caused by sudden explosions in the ganglionic cells in the gray matter of the cerebrum, where all nerve-fibers terminate. Other symptoms of neuralgia are

numbness, transient hyperesthesia, vomiting and various vasomotor disturbances.

Diagnosis is usually easy. Neuralgia may be distinguished from organic disease of a part by the presence of great superficial tenderness, by a hysteric temperament, and by the absence of all the other symptoms of organic disease; from neuritis, by the intermittent nature of the pain, by its occurring in hysteric subjects, and by the absence of the constitutional symptoms of inflammation. When neuritis and neuralgia exist together, the diagnosis may be difficult. Here the presence of superficial tenderness and a relief of the pain by deep pressure points to neuralgia, while in neuritis, on deep pressure the pain is extreme. The severe forms of neuritis are followed by anesthesia and muscular wasting, with changes in muscular irritability. In compression of nerves the pain is continuous, and the symptoms and consequences of neuritis will sooner or later ensue. Muscular rheumatism differs in its localization in muscles and groups of muscles. It is continuous, and the pain increases on motion.

The treatment of pain during the paroxysm calls for the administration of powerful anodynes. Morphin and opium and their preparations are foremost, and should be given in full doses by the mouth or hypodermically. Acupuncture and hypodermic medication may be combined. In sciatica this is probably the best treatment. Cocain hypodermically (1/4 of a grain) may be preferred to morphin.

Ammonium chlorid, 20 grains in solution, may be given every 4 hours. Quinin is to be used when a malarial origin is suspected. Antipyrin, acetanilid, acetphenetidin, and salol sometimes act with rapidity. Exalgin gives relief, but without diminishing the tendency to future paroxysms.

The following may be administered.

℞. Acetanilid, gr. xx
Citrated caffein, gr. x
Camphor monobromate, gr. v.
Make 10 pills; give 1 pill every 2 hours.

Cannabis indica, in doses of 1/2 grain of the extract, is efficacious in neuralgias of the pelvic region and in neuralgia in migraine sufferers. Gelsemium and its alkaloids are valuable for the affection confined to the dental branches of the fifth nerve. Chloral has been recommended, but almost always fails. Croton-chloral or butyl-chloral has been recommended for neuralgia of the fifth nerve. It may be administered to advantage in combination with cannabis indica, as follows:

℞. Butyl-chloral hydrate, gr. c
Extract of cannabis indica, gr. ijss.
Divide into 20 pills. Give 1 pill every 3 hours.

Chloroform and ether may be used as inhalations, to give speedy relief in desperate attacks of neuralgia, while amyl nitrite, nitroglycerin, and other nitrites give the best chance of relief in cardiac neuralgic conditions. Recently, castor oil has been highly recommended. It is given before breakfast in doses of from 1 to 2 ounces.

Belladonna and atropin are drugs long employed in the treatment of neuralgia. They are probably of more benefit in the abdominal and pelvic varieties than in facial neuralgia. Belladonna is used locally, moreover, often with relief. Hyoscyamus, hyoscin, and stramonium are employed in much the same way as belladonna.
The following may be tried:

℞. Tincture of hyoscyamus,
Tincture of stramonium,
Tincture of belladonna, } each, ℥ iv.
Give 25 drops in a tablespoonful of water every 4 hours.

Of local applications, pressure may relieve mild cases. Menthol, ointments of veratrin and aconite, the tincture of aconite painted over an involved area, the extract of belladonna, thinned with glycerin, and the oleate of morphin are of service. Blisters, (by chloroform, either pure or diluted) sinapisms and camphor may be used. Cocain will act on mucous surfaces, but not on the skin. Acupuncture and aquapuncture are employed. Chloroform, osmic acid, and phenol have been injected hypodermically.

Freezing the part with ether spray often proves useful. The continuous electric current may be used, placing the positive sponge near the seat of pain, and with the negative gently rubbing the neuralgic spot until the skin is slightly reddened, and until it causes a faint tingling or burning, but not pain.

In the most intractable cases the surgical means that may be tried are nerve stretching or excision of a portion of the nerve. Of the two operations the latter is to be preferred, but too often the pain returns after it. In fact, the operation can only be of use when the pain is peripheral, due to some irritation existing between the part cut and the ends of the nerve. If the neuralgia depends upon any central cause, or if the irritations exists higher up than the point divided, the operation has always eventually failed, although at times a temporary cessation of pain for a few weeks has occurred. See Lumbago, Sciatica, etc.

NEURASTHENIA.—Neurasthenia is a nervous state or condition marked by irritable weakness. It is commonly known as nervous prostration or nervous exhaustion, and presents a great many variable and inconstant subjective symptoms and a few significant objective phenomena. All forms of nervous energy—mental, motor, and organic—are disturbed, so that fatigue in these various spheres is more quickly occasioned than in health.

Etiology.—The majority of cases occur during the age of reproductive activity, and the disorder is rare after the age of 50. It sometimes occurs in childhood and during adolescence in individuals of a pronounced neuropathic tendency. Both sexes are about equally subject to it. High altitude and extremes of climatic conditions favor its development. Hebrews, Slavs, and Scandinavians are especially subject to it. A neuropathic heredity commonly furnishes the field in

which it develops. Debilitating conditions in the antecedents are very common; gout, rheumatism, tuberculosis, syphilis, excesses, malaria, and all the various cachexias in parents are likely to be followed by neurasthenia in the offspring.

Among the inciting causes, overwork or overstrain of any kind is the most potent. Anxiety, worry, disappointment, excesses, deprivation of sleep, and anything that makes continuous and exacting demands upon the endurance of patients may induce this condition of nervous exhaustion. Traumatism, especially when attended by fright and shock, and mental shocks of all varieties may induce it with great readiness and sometimes suddenly. It may be symptomatic of or secondary to all sorts of chronic diseases and various toxic states, such as lithemia, alcoholism, and syphilis. Most cases present a multiplicity of predisposing exciting causes.

Dana sums up the leading causes of neurasthenia as follows:

1. Hereditary nerve instability.
2. Overwork and worry.
3. Severe shocks, with or without injury.
4. Infections.
5. Abuse of stimulants and narcotics.
6. Abuse of sexual functions.
7. Disorder of digestive functions and autotoxemia.

This means that the causes are most often a bad heredity and foolish living.

Pathology.—The pathologic anatomy of neurasthenia is not known. The best conception of the development of this disorder is obtained from a consideration of the changes which take place in motor cells when subjected to natural fatigue, as demonstrated by Hodge. It seems probable that when cells are continually overtaxed, recuperation and a full restoration of their potential energy do not take place except after a prolonged rest, and it is conceivable that in certain instances restoration may be impossible.

Symptoms.—The most important and commonly encountered symptoms in neurasthenia are headache, backache, gastrointestinal atony, neuromuscular weakness, cerebral depression, mental irritability, and insomnia. To these may be added an almost infinite number of subjective complaints, which vary in different cases, and even in the same case. They may all be considered systematically, as follows:

Motor Disorders.—Muscular weakness is constantly found. This is commonly demonstrated by the ready fatigue upon exertion. Often the patient is able to put forth an ordinary amount of strength for one or two efforts, and thereafter is left weak and trembling. Constant effort is impossible. Tremor is frequently present, and is easily provoked by muscular effort. It may be present in any of the extremities, and is often seen in the face and lips, especially when the patient is embarrassed or mentally disturbed. The tendon reflexes are generally intensified. This is particularly true of the knee-jerk. It sometimes happens that if the knee-jerk is repeatedly elicited, the exaggeration becomes less and less, showing the ready fatigue of the reflex arc. Irritability in muscles and nerve-trunks is sometimes demonstrable by sharply tapping the parts.

Sensory Disturbances.—Neurasthenics complain of many subjective sensory disturbances. A tired feeling is almost invariably present, and headache is one of the most common symptoms. It may be slight and constant, but more often is produced by muscular, and especially by mental, effort or by any disturbing emotion. Commonly occipital, it may be frontal, temporal, or vertical, and often is attended by a feeling of drawing in the back of the neck. The sensation as of a weight upon the head, a binding band around the brows, the leadcap headache, are extremely common. Backache is usually present in neurasthenics, and is probably a fatigue symptom, though sometimes referable to a disturbance in the stomach and hypersensitiveness along the spine. Its common location is the small of the back, between the shoulders, and at the nape of the neck. It frequently results in the patients padding their chairs or retaining the recumbent position, and is usually intensified by any effort or disturbing circumstance. Tenderness of a superficial character is usually found over the spine, but sometimes is intensified by deep pressure. The spine may be sensitive its whole length, but usually presents a number of hypersensitive points. Near the occiput, over the seventh cervical spine, at the lower end of the scapula, at the waist, at the tip of the sacrum, and over the coccyx are favorable locations for these sensitive areas. Sensitiveness and spontaneous pain in various portions of the trunk and limbs are frequently present, but the outlines of these sensitive and painful areas are not sharply defined, and are likely to shift position and intensity within a period of a few minutes or hours. Various vague sensations of heat, cold, prickling, tightness, numbness, stiffness, weakness, fatigue, soreness upon pressure, etc., referred to various portions of the body and limbs, or to the internal organs, particularly the cardiac region, are constantly encountered. Those having reference to the pelvic and generative organs have in some cases a special prominence.

Visual Disturbance.—Neurasthenics find reading more or less irksome and often impossible. Headache, ocular distress, blurring of the letters, and other indications of eye-strain are readily induced. Another difficulty is furnished by inability to concentrate attention. Appropriate investigation usually demonstrates ready fatigue of the muscular apparatus of accommodation and a ready retinal exhaustion. In taking the chart of the visual fields it is a common experience to find them rapidly reduced within the course of a few minutes, and the fields for colors are usually concentrically contracted. Varying degrees of asthenopia mark a case of neurasthenia the same day, or even within the same hour. Heterophoric disturbances may be commonly encountered, but they are usually inconstant in their manifestations, and tend to disappear when the physical and nervous state of the patient is reestablished. Sometimes

there is intense photophobia, keeping the patient within darkened rooms, due apparently to retinal hyperesthesia. Other patients complain of obscurities of vision. Hearing and smell may be intensified and irritable or weakened, but are never lost as a part of the neurasthenic symptom-group. Tinnitus and hyperacusia are sometimes encountered, and most neurasthenics are readily startled by sudden, slight, and insignificant noises. Complaints of disagreeable and peculiar odors and tastes are analogous disturbances.

Gastrointestinal Disorders.—Nervous indigestion is commonly encountered. The appetite is often capricious, but may be excessive or diminished. Sometimes the mere thought of food is repugnant. Gaseous eructations, borborygmi, gastric distention and dilatation, often attended by cardiac palpitation and precordial pain, are generally encountered in pronounced neurasthenia. Hydrochloric acid may disappear from the gastric secretion, and digestion is usually retarded and inefficient, with alternating constipation and diarrhea.

Circulatory Disorders.—Cardiac palpitation, due to gastric disturbance or provoked by slight mental or muscular activity, is commonly encountered, in some instances reaching an intense degree, attended by precordial pain, tumultuous heart action, throbbing and general distress, strongly suggestive of a stenocardial attack. The pulse ordinarily is rapid, and may range from 100 to 140, being promptly accelerated by any disturbing element. Anemic cases are likely to present exaggerated hemic murmurs, while the feebleness of the circulation is manifested in the cold extremities that are usually encountered. Vasomotor storms, sweating, flushing, and blushing are the rule, and these may be general, localized, or unilateral.

Secretory Disorders.—The urine is ordinarily scant and of high specific gravity, with a relative increase of uric acid or urea and a great abundance of phosphates and oxalates. In other instances the urine may be neutral or alkaline, and commonly at intervals neurasthenics pass a large quantity of limpid urine of a low specific gravity. Secretions—as the perspiration, saliva, and gastric, intestinal, and synovial fluids—are commonly deficient, but may be increased, or may increase and decrease from time to time.

Genital Disorders.—The average male neurasthenic complains of lessened sexual power, which is often at first attended by nocturnal emissions, and if the urine shows a little cloudiness, he is at once convinced that he has spermatorrhea. Any early indiscretions are likely to be recalled, and the patient may become extremely morbid regarding his genital tract. Impotence may actually exist. Women have analogous conditions.

Mental Disorders.—The mental state of neurasthenia is one of its most important features. All the mental activites show the element of irritable weakness. The capacity for mental work is abridged, yet at times neurasthenics have moments of great mental activity. Protracted mental effort, however, is irksome or impossible, the power of attention is reduced, memory for recent events becomes defective, and there is general mental asthenia. Active spontaneous mentation and the flow of ideas to which the patient has been accustomed do not take place so readily, sometimes leading them to fear that they are losing their minds, and they frequently state that they cannot think. Self-reliance and courage are frequently completely lost, so that the patient becomes suspicious of himself, apprehensive, introspective, and usually more or less hypochondriacal. Whatever feature of the disease strongly fixes his attention is dwelt upon, and he is likely to develop some one of the numerous nosophobias. The morbid self-watchfulness naturally leads to depression, and neurasthenics are always lacking in cheerfulness. Fears are their common portion. These usually are incited by some incident or have reference to some physical condition, and often become well-formulated delusions, which all but dominate the patient, and in certain instances become fixed insane delusions, then carrying the patient over the boundary into the field of alienism. In the lowered physical and mental state the patient has not the same interest in and affection for his friends and family; he becomes exacting, peevish, fretful, and despondent. The emotions are unstable; neurasthenics, from their fears and loss of courage, are easily moved to tears, and sometimes become markedly hysteric.

Sleep.—Disorder of sleep is one of the earliest features of neurasthenia, and frequently for a long time precedes other marked indications of the nervous state. As a rule, neurasthenics have difficulty in getting to sleep, ideas of one sort or another, usually unpleasant, pursue them to their beds, and even if they fall asleep, they are troubled by dreams of an unpleasant and often of an exciting, worrisome, and depressing character. Nightmares and formulated dreams of a disturbing sort are common in neurasthenia, and the patient, as a rule, awakes unrefreshed in the morning, being more despondent and hopeless than at night.

The Physical Condition.—In neurasthenia of long standing general nutrition is almost invariably affected, and all degrees of anemia and emaciation may be encountered. But neurasthenia of moderate degree and character is consistent with fair nutrition, and often with a certain amount of fatness. Some of the most inveterate neurasthenics become quite stout, but, as a rule, neurasthenics are nutritionally defective.

Forms.—Various forms of neurasthenia have been described, apparently depending upon the prominence of certain groups of symptoms. Spinal, cerebral, and sexual neurasthenias have been described, but neurasthenia is one and indivisible, and all portions of the nervous apparatus show the disorder to some degree. In proportion, however, as head, spine, or pelvic symptoms preponderate, the particular case is modified in a corresponding way, and most cases of so-called nervous dyspepsia are merely cases of neurasthenia with prominence of the gastric features. Very many neurasthenics, especially women, develop hysteria, and a combination, indicated by the

term hysteroneurasthenia, is frequently encountered. It is very difficult to say when the disorders of neurasthenia become the defects of hysteria, and as a matter of clinical fact nearly all hysterics present some neurasthenia.

Course.—Neurasthenia is essentially chronic. Ordinarily its onset is insidious, but great moral, physical, or mental shocks may suddenly induce it. Once established, it tends to persist, and ordinarily the conditions which led to its development cannot be easily modified. Frequent remissions are presented, and patients once affected with neurasthenia are subject to relapses, even after long periods of freedom. In patients under adult years the disease is likely to improve spontaneously and to recur with readiness.

Diagnosis.—The diagnosis of neurasthenia is easy; the story of the neurasthenic usually suffices to make the diagnosis. The difficulty lies in overlooking some organic disease of which the neurasthenia may be symptomatic. A diagnosis of simple neurasthenia is never justified until all organic conditions have been investigated. Actual hypochondriasis and melancholia are to be differentiated.

Prognosis.—The prospects in neurasthenia are commonly good if the patient is below the age of 40 years and can be properly controlled and managed. This, however, is sometimes very difficult to accomplish, as circumstances may preclude that avoidance of fatigue and interruption of occupation usually necessary. If of a psychopathic stock, pronounced mental enfeeblement may occur, and should be apprehended. Occurring in patients before the age of 20, nervous prostration is likely to yield more or less readily, and to relapse frequently. After 40 the prognosis is less hopeful, as the neurasthenic exhaustion appears to have taken place in tissues that have lost their elasticity and recuperative powers, and complete recovery after this age is very exceptional. Cases of extreme emaciation often respond admirably to treatment, while some of the most inveterate instances do not present any considerable physical disorder. The presence of organic disease modifies the outlook in proportion as it is or is not manageable.

Treatment.—There is but one treatment for neurasthenia, and that is rest. Whatever function or quality of the individual has been overtaxed must be allowed an opportunity for recuperation. This is more easily said than accomplished. In cases of simple neurasthenia in women the Weir Mitchell rest cure usually is well advised, and oftentimes secures brilliant results. In men it is scarcely practicable, and usually fails when attempted. A change of scene, of atmosphere, freedom from suggestive surroundings, undue sympathy, and of well-meant but harmful solicitude, are generally of the first importance. The patient needs encouragement and all the hopeful suggestions that can in any way be brought to bear. In proper sanitariums this can be provided for the severe cases. In milder cases one should give up half his daily work, lie abed late in the morning, go to bed early at night, take a nap in the middle of the day, receive small quantities of readily digested food at frequent intervals, strengthening applications of water in the form of cold spinal douches in the morning, and quieting applications of water at bedtime in the form of warm baths or packs. In addition the patient should drink a considerable quantity of water. Neurasthenics, as a rule, shun drinking-water. Elimination from the skin, bowels, and kidneys is greatly increased by these simple measures. Massage, salt baths, alcohol rubs, and general frictions serve a very good purpose in some cases, being refreshing and strengthening. Many patients who are greatly troubled with insomnia promptly drop off to sleep after a half-hour's gentle massage. Many of these patients need to see the physician frequently; the reiterated encouragement of the trusted adviser is often of more benefit than all other measures combined.

Office treatment in mild cases, by the use of one form or another of electricity, hypodermic injections of small doses of strychnin or of plain water, the use of dry cups, or any other means which serves to fix the attention of neurasthenics and give a helpful turn to their thoughts, may be properly used with the full understanding on the part of the physician of its suggestive value. Patients should not be allowed to constantly discuss their symptoms and fears with members of their family or any one else, and it is essential to provide for them a certain amount of recreation, which is not at the same time fatiguing. It is highly injudicious to advise a neurasthenic to ride horseback or a bicycle, or to attempt to turn the mind from his ailments by a course of reading or study. A vacation, with a change of air and scene, or a sea voyage, often answers perfectly in mild cases.

In the anemic and emaciated and severe cases the scale is the best index as to the success of treatment. A gain of a pound or so is most encouraging. The question of diet is, therefore, of extreme importance. Keeping in mind the gastrointestinal atony, it is necessary to supply food in a form that is easily assimilated and least liable to fermentation. Many of these patients will digest a small amount of food thoroughly, while double the amount will cause extreme distress. Therefore small quantities of food, particularly of the sorts that are easily digested, should be frequently administered.

The drug treatment of neurasthenia may be practically dismissed with a word. Large doses of strychnin should be condemned. Occasionally a hypnotic to reestablish the sleep habit may be given with decided advantage. The hypnotic should be selected with a view to its being in force at the time the restlessness is most prominent. If the warm bath and a glass of hot milk or of malted milk, or even of hot water, does not suffice to put the patient to sleep, a pint of beer, with hot bath, may have the desired result. Should this fail, 10 grains of trional 2 hours before bedtime may be given. If the patient goes to sleep readily but wakes up after midnight, trional may be given in a dry powder at bedtime. Bromids, chloral, and opiates are to be avoided. Gastric disturbance

may sometimes be relieved by subgallate to bismuth, small doses of calomel, beta-naphthol, or other antiseptic preparations which inhibit fermentation. Constipation must be controlled. As a rule, the physician will best succeed in managing cases of neurasthenia in proportion as he understands their mental requirements and can, by a vigorous personality, override their fears and control their actions, thereby securing for them the curative rest which is partial or absolute in proportion to the severity of the disorder.

NEURITIS.—An inflammation of the nerve-trunks; characterized by pain and paresis of the parts supplied by the affected nerve-trunk.

Etiology.—Wounds and injuries or compression of nerves; cold and damp; syphilis; lead.

Symptoms.—The onset may be accompanied by febrile reaction. The most decided symptom is pain along the course of the nerve-trunk and its peripheral distribution, of a burning, tingling, tearing, intense character, increased by pressure or motion. If the affected nerve is a mixed one—sensory and motor—spasmodic contractions and muscular cramps occur, followed by impaired motion, terminating in paresis of the muscles innervated by the affected trunk. If the inflammation proceeds to the destruction of the nerve-trunk, wasting and degeneration of the muscular tissue ensue. Various trophic changes also occur, such as cutaneous eruptions and clubbing of the nails. The electrocontractility is impaired or lost.

Diagnosis.—Myalgia or muscular pain is not associated with paralysis, nor does the pain follow the course of a nerve-trunk. In neuralgia there is pain, but, as a rule, no tenderness. In fact, it is relieved by pressure. See NEURALGIA.

Prognosis is generally favorable with proper treatment.

Treatment.—Repeated blistering along the course of the nerve, with full doses of potassium iodid, are usually successful. Sodium salicylate, phenacetin, and antifebrin are each of utility. As the more acute symptoms subside, the use of galvanism or a feeble, slowly interrupted faradic current restores the disordered function of nerve and muscle.

NEURITIS, MULTIPLE. (Polyneuritis, Korsakow's Psychosis, Peripheral Neuritis).—A parenchymatous inflammation of a number of symmetric nerves, simultaneously or in rapid succession; characterized by pain, numbness, loss of power, or ataxia, with muscular atrophy. Mental symptoms are often associated.

Etiology.—Alcoholism; syphilis; malaria; lead, arsenic, or silver; following diphtheria, typhoid fever, and rheumatism. Beri-beri and kakké are epidemic varieties of multiple neuritis and the result of a special poison. See BERI-BERI.

It is likely that the various causes named develop in the blood a poison, having a particular susceptibility or selective action for nerve-fibers.

Symptoms.—The affection is generally bilateral and symmetric. An important characteristic is its peripheral distribution, the inflammation being most intense at the extremities of the nerves, lessening progressively toward the center, usually terminating before the nerve-roots are reached. The inflammatory process affects the nerve-fibers primarily and the sheath and connective tissue secondarily—a parenchymatous inflammation. The affected muscles are paler and smaller than normal, the fibers reduced in size and undergoing granular changes.

All plans suggested for classifying the varieties of multiple neuritis are imperfect. The onset may be sudden, even overwhelming, causing rapid death, but is usually subacute or chronic in its course, the symptoms being wide-spread in proportion to the acuteness, intensity, and cause of the malady. The symptoms may be described under three forms—a motor, a sensory, and an ataxic form.

The motor form shows motor weakness, chiefly involving the flexors of the ankles, the extensors of the toes, and the extensors of the wrist and fingers in the forearms. Inflammation of the anterior tibial or peroneal nerve in the leg, and the radial branch of the musculo-spiral in the arm, results in the double "wrist-drop" and "foot-drop" so characteristic of this disease. Any nerves of the body may be affected, the symptoms varying with the particular nerves.

The sensory form shows pains, tenderness, tingling, and numbness, with loss of cutaneous sensibility.

The ataxic form shows incoordination with or without sensory disturbances, but with loss of the muscular sense.

The forms may all be associated, in greater or less extent, in any one case. Muscular atrophy begins early and progresses with the disease. The knee-jerk is feeble or absent. The electrocontractility is feeble or lost. In alcoholic cases there may be delirium, mania, and delusions, associated with tremors. Trophic changes may occur in the nails, hair, and skin. The characteristic glossy condition of the skin, with some edema, is due to involvement of the vasomotor nerves. Rarely the vagus, optic, and laryngeal nerves are involved. The disease may be ushered in with fever, 101° to 103° F., rapid, feeble pulse, headache, nausea, vomiting, with delirium or confusion.

The alcoholic variety affects chiefly all the limbs; the malarial, the legs; diphtheritic, the pharyngeal and motors of the eye; rheumatic, the face; and lead, the arms.

Diagnosis.—Early diagnosis is most important, as prompt treatment may prevent idleness and months of suffering. Since the symptoms of this wide-spread affection have been properly separated from diseases of the spinal cord, with which they were formerly always associated, the diagnosis is very readily determined. The distinctive features are symmetric localization of the sensory and motor symptoms first and mainly in the extremities, and the tenderness of the skin, nerve-trunks, and muscles. The disease may be confused with rheumatism, neuralgia, tabes dorsalis, poliomyelitis, and other spinal diseases, and hysteric palsy.

Prognosis.—The earlier the treatment is insti-

tuted, the better the prognosis. At best, months are required for recovery and even years may be necessary. Involvement of spinal cord precludes total recovery. The return of faradic irritability in nerve and muscle is favorable. To sum up with Gowers: "The prognosis is better in the sensory than in the motor form; better when the arm escapes than when all the limbs are involved; better in cases of chronic than acute onset; and better if a case of apparently acute onset is really such than if it succeeds slight symptoms of longer duration."

Treatment.—The removal of the cause, if possible, is a primary step in treatment. Along with this, rest is most important, and the rest should be complete—in bed. Alcohol should not be allowed, although in cases of great debility its gradual withdrawal may be justified. The patient should, on the other hand, be fed on the most nutritious food. Local anodyne applications may be resorted to to relieve the pain, and may be varied according to effect. Dry heat, moist heat, applications of lead-water and laudanum, and ointments of aconite and veratrin are some of those which may be employed. Wrapping the parts in cotton or wool is sometimes beneficial. Warm baths are soothing; sometimes very hot ones give relief. Postures assumed because of the relief they give to pain should not be too long permitted, lest deformity result by contractions and adhesion difficult or impossible to overcome. Dropping of the feet should be prevented by splints or by the support of sand-bags. The same is true of flexion at the knee and hip.

As to drugs, they are of little use; the salicylates, phenacetin, antifebrin, and antipyrin may be useful in mild cases, and should be tried in doses of 5 to 15 grains. They are more particularly useful in cases due to cold. Extreme pain may demand the cautious use of morphin hypodermically in doses of 1/6 to 1/3 of a grain combined with 1/150 of a grain of atropin, which modifies and improves the action of morphin most happily. For the mental symptoms, the hydrobromid of hyoscin in doses of 1/200 to 1/100 of a grain hypodermically, or hyoscin in doses of 1/400 to 1/150 of a grain may be tried. Mercurials, so highly approved of in simple neuritis, are useless here. The iodids are sometimes beneficial in chronic cases. Roborant medicines, such as iron and cod-liver oil, are indicated to build up the patient, who is generally broken down. Electricity and massage are very useful after convalescence has set in (Tyson).

NEUROMA.—A tumor of or on a nerve. Many a neuroma is really a fibroma. See Tumors.

NEVUS (or Nævus).—A mark or blemish due to dilatation of the blood-vessels near the surface of the skin or within its texture.

Nævi often grow with marked rapidity, and, though rarely causing fatal hemorrhage, occasion serious inconvenience and great disfigurement. Sometimes they spontaneously disappear, but more often remain stationary. Cystic degeneration or suppuration may occur. Microscopically, a nævus is composed of large capillaries, arterial and venous trunks of larger size, connective tissue, fat, and sometimes sweat- or sebaceous glands. Inflammation of a nævus generally leads to a spontaneous cure. Hence, the injection of carbolic acid is used in the treatment of nævi. But there is danger of an irritating fluid entering a large vessel and passing to the heart, setting up a coagulation causing instant death. Ligation, pressure, application of caustics, such as fuming nitric acid, electrolysis, puncture with the actual cautery, and complete excision of the mass, are also employed in removal. A capillary nævus may quickly be cured by touching it once or twice with fuming nitric acid. A knitting-needle at a dull red heat or the galvanocautery may be employed. Sodium ethylate, in 5 percent solution, applied by a glass rod on 2 or 3 successive days, has been used to destroy the growth. The best plan for the cure of the cavernous variety is excision. Astringent injections are not advised.

Nævus Pigmentosus (Pigmentary Mole).—Circumscribed pigmentary deposit, usually congenital, with or without associated hypertrophy of other cutaneous structures. A "mole" may consist merely of a circumscribed deposit of pigment, or there may be, in addition, hypertrophy of the papillæ, of the hairs, and of the connective tissue. Nævi vary in size from a pea to the palm of the hand or larger, are rough or smooth, elevated or nonelevated, and of a brownish or blackish color.

According to the cutaneous structures involved, various forms of pigmentary nævi are distinguished.

Nævus spilus is a term given to a smooth, flat, pigmented nævus devoid of hair.

Nævus pilosus is a pigmented nævus covered with a growth of downy or stiff hairs.

Nævus verrucosus is a pigmented nævus with an irregular or wart-like surface.

Nævus lipomatodes is an elevated pigmented nævus with connective tissue and fat hypertrophy.

The etiology is obscure. Hairy moles are usually congenital; nonhairy ones acquired. There is increased pigment deposit in the cells of the rete mucosum and also in the corium. In nævus verrucosus the papillæ are greatly hypertrophied. There is often more or less connective-tissue hypertrophy.

Treatment.—The growths may be removed by means of the knife, caustics, or electrolysis. The last named is particularly useful in the treatment of hairy moles.

NEW-BORN INFANT.—As soon as the child is born it should be held by the feet, with the head down, and, with the little finger introduced into the mouth, any foreign material that may obstruct the air-passages should be removed.

As soon as pulsations in the cord cease, it should be ligated with an aseptic ligature, about two fingers' breadth from the abdominal wall. An ordinary surgeon's knot, reinforced by a double bow-knot to permit tightening after the child has had its bath, should be used for this purpose. The cord should now be cut, the free end being allowed to drain into some convenient receptacle.

Asphyxia Neonatorum.—If the child is born

asphyxiated, the cord should be ligated and cut immediately, and all mucus extracted from the throat and fauces.

If the case is of minor degree, *stimulation of the reflexes* will be sufficient to establish normal respiration. This is best accomplished by slapping the buttocks and back of the child with the end of a wet towel, by pouring a few drops of ether on its abdomen, or by immersing its back and extremities in warm water and pouring ice-water on its epigastrium. The faradic current, if it can be obtained, is a very powerful stimulant. Inasmuch as shock is a factor of considerable importance in this condition hot saline infusion into the rectum or hypodermics of strychnin (1/200 grain) or brandy (5 to 6 drops) are indicated. In advanced asphyxia artificial respiration should be resorted to immediately. The best methods are *Schultze's* and *mouth-to-mouth insufflation.*

Schultze's Method.—The child is seized by the shoulders from behind with both hands, in such a way that the right index-finger of the operator is in the right axilla of the child from behind forward, and the left index-finger in the left axilla, the thumbs hanging loosely over the clavicles. The other 3 fingers hang diagonally downward along the back of the thorax. The operator stands with his feet apart, and holds the child as described, practically hanging on the index-fingers in the first position, with the feet downward, the whole weight resting on the index-fingers in the axillæ, the head being supported by the ulnar borders of the hands. This is the first inspiratory position. At once the operator swings the child gently forward and upward. When the operator's hands are somewhat above the horizontal the child is moved gently, so that the lower end of the body falls forward toward its head. The body is not flung over, but moved gently until the lower end rests on the chest. In this position the chest and upper end of the abdomen are compressed tightly. The child's thorax rests on the tips of the thumbs of the operator. As a result of this forcible expiration, the fluids usually pour out of the nose and mouth of the infant. The child is allowed to rest in this position (the first expiratory position) about 1 or 2 seconds. The operator gradually lowers his arms, the child's body bends back, and he again holds the infant hanging on his index-fingers with its feet downward; this is the second inspiratory position. The movements are repeated 15 to 20 times in the minute.

Mouth-to-mouth insufflation is performed as follows: Wrap the child in a towel and lay it upon its back on a table or chair, with the head well extended. This is best accomplished by placing a drinking-mug or similar article under the child's neck. Place a piece of clean gauze over its mouth; take a quick inspiration and blow lightly through the gauze. The lungs will immediately become inflated. Secure expiration by compressing the chest and flexing the head. This should be repeated 15 or 20 times to the minute until the child breathes naturally. A very good plan is to alternate the foregoing methods, using one for 3 or 4 minutes and then substituting the other. Efforts at resuscitation should be continued until the child breathes freely or until the heart stops beating.

Other methods are as follows:

Byrd's (H. L.) Method.—The physician's hands are placed under the middle portion of the child's back, with their ulnar borders in contact and at right angles to the spine. With the thumbs extended, the two extremities of the trunk are carried forward by gentle but firm pressure, so that they form an angle of 45 degrees with each other in the diaphragmatic region. Then the angle is reversed by carrying backward the shoulders and the nates.

Laborde's Method.—Rhythmic tractions are made upon the tongue in order to excite the respiratory center. The tongue, covered with gauze, is drawn out by the fingers and allowed to fall back again 15 to 30 times a minute.

Dew's Method.—The infant is grasped in the left hand, allowing the neck to rest between the thumb and forefinger, the head falling far over backward. The upper portion of the back and scapulæ rest in the palm of the hand, the other 3 fingers being inserted in the axilla of the babe's left arm, raising it upward and outward. The right hand grasps the babe's knees, and the lower portion of the body is depressed to favor inspiration. The movement is reversed to favor expiration, the head, shoulders, and chest being brought forward, and the thighs pressed upon the abdomen.

Forest's Method.—The child is placed on its face and quick, violent pressure is made on the back; then it is placed in a pail of hot water, and the hands carried upward until the child is suspended by its arms, and mouth-to-mouth insufflation is practised; the arms are then lowered and the body doubled forward; these movements are repeated at the rate of 40 a minute.

Pacini's Method.—The child lying on its back, the operator stands at its head and grasps the axillæ, pulling the shoulders forward and upward to compress the thorax, and allowing them to fall in order to expand the chest.

Schroeder's Method.—The babe, while in a bath, is supported by the operator on the back, its head, arms, and pelvis being allowed to fall backward; a forceful expiration is then effected by bending up the babe over its belly, thereby compressing the thorax.

Sylvester's method may be used, the head being supported and the feet held firmly by an assistant.

Recently, the pulmotor has been modified so as to be of service in cases of asphyxia neonatorum. See Artificial Respiration; Pulmotor.

Eyes.—Wash the eyes with clean warm water, and drop on the cornea of each eye one drop of a one or two per cent solution of silver nitrate. See Conjunctivitis (Ophthalmia Neonatorum).

Bathing.—As soon as the third stage of labor is completed and the mother has been made comfortable, the child should be cleansed. It should first be anointed freely with sweet oil to remove the vernix caseosa, and then washed with soap and warm water. The nurse should avoid the eyes during this procedure, since the slightest amount of soap or dirty water coming in contact with them may produce an ophthalmia. Subsequently the

child should receive a daily bath. The temperature of the bath should be about 90° F. Appropriate precautions should be made to prevent the child from being chilled when it is removed from the bath.

Cord.—The cord should now be examined closely. If the ligature has become loosened, the bow-knot should be undone, and a firm surgeon's knot substituted. The cut end of the cord should be dusted freely with a powder composed of salicylic acid and starch—1 part of the former to 5 of the latter. It should then be dressed with salicylated or borated absorbent cotton and kept as dry as possible, and the binder applied. At its subsequent daily baths the cord should be closely inspected and fresh powder and dressing applied.

Clothing.—An infant should be clothed as follows: A binder of soft flannel, a diaper, a knit shirt, and knit woolen shoes. Over these should go 2 skirts. These should be suspended from the shoulders. Finally should come its dress. During the winter a knit jacket may be worn over the dress, and, particularly if the child is subject to attacks of coryza, a cap is desirable to protect it from drafts.

The child should have an abundance of diapers, which must be changed from 16 to 24 times daily. To prevent chafing, perfect cleanliness must be maintained and some dusting-powder, like lycopodium or compound talcum, used.

Nursing.—During the first 48 hours the child should be put to the breast regularly every 4 hours. The colostrum that it receives from the breast acts as a mild laxative and secures free evacuation of the meconium in the child's intestinal tract. After the milk appears, it should be put to the breast every 2 hours during the day, and 2 or 3 times at night. This interval should gradually be lengthened until at the end of about the third month it is nursed every 3 hours during the day and once or twice at night. See Infant (Care), Infant Feeding, etc.

NICOTIN.—$C_{10}H_{14}N_2$. A poisonous alkaloid found in the leaves of the tobacco plant; a colorless, oily fluid, of acrid taste and penetrating odor, readily soluble in water, and forming soluble salts with acids. In tetanus and strychnin poisoning the dose is 1/20 to 1/10 minim in 2 hours. The proportion of nicotin in tobacco is about 1 : 1700. Turkish tobacco contains little or none. It is an open question whether or not there is more nicotin in tobacco before or after curing. Nicotin, even in minute doses (1/7 of a grain), causes symptoms of gastric irritation, with an extreme degree of collapse, abolishing the function of motor nerves and paralyzing respiration. A dose of 1/15 grain has caused death in a human being. For the depression due to excessive smoking, 1 to 2 drams of Hoffmann's anodyne, or the spirit of nitrous ether, is effective. Strychnin is the best physiologic antidote to nicotin.

The treatment of poisoning by nicotin consists in the use of strychnin, the employment of cardiac stimulants, external heat, and atropin, while the stomach should be evacuated, tannin, the iodids, and artificial respiration employed. See Tobacco; and Lambert's Treatment for Narcotic Addiction.

NICTITATION.—Clonic spasm of the orbicularis; and is really frequently repeated involuntary winking. It may be associated with hysteria, chorea, or general neurasthenia; in fact, it may be a symptom of nearly any reflex neurosis. It often becomes a habit. Clonic spasms of the orbicularis sometimes appear after the use of eserin. In persons doing considerable eye-work, there is doubtless some uncorrected error of refraction. The treatment of this condition consists in administering remedies alleviating the nervous condition, or in correcting the ametropia.

NIGHT-BLINDNESS.—See Hemeralopia.

NIGHTMARE.—A feeling of distress or suffocation during sleep, attended by fright, hideous dreams, and often by inability to stimulate muscular contraction, except in the slightest degree. A heavy meal or indigestible food has generally been taken before the sleep, and this is especially so in those of a nervous temperament, whose digestion is weak. Eye-strain sometimes causes night-terrors. A closely allied condition occurs as a consequence of brain-exhaustion, and in those whose sleep has continually been broken in consequence of overwork, by application to study, business details, or literary pursuits. Certain forms of incipient delirium are akin to it, such as occur in various febrile diseases or as a result of alcoholic excesses.

Treatment.—The diet should be light, and late meals and indigestible food avoided. A teaspoonful of camphor water, repeated if necessary, may be the best remedy. For the nightmare of adults potassium bromid in small doses may be administered. In the attacks of night-screaming of children the digestive organs are frequently at fault, although they are sometimes associated with worms and delayed dentition. The moral surroundings of children so affected should be closely studied. Ghost stories and appalling tales should be discontinued. Indigestion is to be treated by a few grains of sodium bicarbonate and powdered rhubarb. Forbidding potatoes, candies, puddings, fruit, and cake may have a salutary effect. Potassium, sodium, and ammonium bromids are probably the best means of preventing future attacks. Sulphonal, chloral, or trional may also be given. Punishment, cold douches, or treatment adding to the distress are to be condemned. During the attack, efforts should be made to soothe the child and calm its fears by assurances of present safety.

The following mixture may be given every night at bedtime to a child of 1 year:

℞. Ammonium bromid, Sodium bromid, Wine or antimony, each, ʒ ss
Simple syrup, ʒ j
Peppermint water, enough for ʒ ij.

Give a teaspoonful at bedtime.

NIGHT-SWEATS.—The profuse nocturnal sweating often observed in pulmonary tuberculosis and other wasting disorders. In tubercu-

osis of the lung they are one of the most distressing features, and may come on early in the disease, although they are more persistent and frequent after cavities have formed.

Treatment.—Belladonna, or its alkaloid, atropin, is one of the best remedies. It may be given internally, or externally as a liniment. It is especially beneficial when applied externally to children. Atropin, 1/200 to 1/100 grain hypodermically, or 1/60 to 1/20 grain by the mouth, is useful when given about 1 hour before the usual or expected time of beginning of sweating; duboisin may be used instead. Aromatic sulphuric acid may be used alone, or with belladonna or morphin, to check night-sweats, but it creates indigestion. Camphoric acid, given dry on the tongue, not over 2 hours before the expected sweating, is considered one of the very best remedies against sweating from various causes, but especially that from phthisis when it is very profuse. The dose is 10 to 30 grains. Pilocarpin, 1/20 grain hypodermically, or given in the same dose thrice daily by the mouth, may be used to check profuse perspiration, even when atropin fails. Dover's powder will often check a profuse colliquative sweating. Agaricin, muscarin, and zinc oxid at bedtime are useful for the night-sweats of phthisis.

℞. Zinc oxid, gr. xxx
Extract of belladonna, gr. iij.
Make into 10 pills. Give 1 pill before going to bed.

Tannic and gallic acids, salicin, and ergot are all employed.

Acetic acid, diluted one-half with water, alum dissolved in weak alcohol, and naphthol in a 5 percent alcoholic solution are used locally. Oleate of zinc and of aluminum may also be used. See Tuberculosis.

NIPPLE.—See Breast (Diseases).

NITER.—See Ether, Nitrates.

NITRATES.—The salts of nitric acid. All nitrates are soluble in water. A solution called acid phenylsulphate, and composed of 46 1/2 grains of phenol in 5 1/2 drams of strong sulphuric acid, is used for the detection of nitrates in water. See Water.

Potassium nitrate, or saltpeter, sodium nitrate, and silver nitrate are the most commonly used nitrates in medicine. These and the other nitrates are described under the metallic titles. They are poisonous, and are often taken with suicidal intent. Emetics and the stomach-tube should be used, and soap in quantity administered. Demulcent drinks should follow, and emollient enemata used to protect the lining membranes of the intestines. Milk may be used with benefit. Of antagonists, opium in small doses may be administered for the subsequent depression, and aromatics and brandy are of value.

NITRIC ACID.—A colorless, fuming liquid, very caustic and corrosive, of strong acid reaction, used only externally as a caustic. Its preparations are: **Diluted Nitric Acid,** 10 percent nitric acid, given in the dose of 3 to 40 minims, well diluted. **Nitrohydrochloric Acid** or **Nitromuriatic Acid** (aqua regia), a golden-yellow, fuming, corrosive liquid, having 18 volumes of nitric acid and 82 volumes of hydrochloric acid, a drop of which, added to a test-solution of potassium iodid, will liberate iodin in abundance. Dose, 1 to 8 minims, well diluted. **Diluted Nitrohydrochloric Acid.** Consists of nitric acid 4, hydrochloric acid 18, water 78. Dose, 5 to 20 minims, well diluted.

Therapeutics.—Nitric acid does not tend to relax the bowels, as does nitrohydrochloric acid. It coagulates, but does not redissolve, the albumin of the tissues, and thus soon makes a barrier for itself. It is used externally to destroy warts, chancres, hemorrhoids, phagedenic ulcers, in gangrene, etc. For indolent ulcers a solution of from 5 to 30 drops to the ounce is of use. In oxaluria nitric acid is preferable to the nitromuriatic acid. Three-drop doses of nitric acid are beneficial when small ulcers in the mouth or stomatitis exist. In gastric indigestion, intestinal dyspepsia, the green summer diarrhea of children, and combined with pepsin in the chronic diarrhea of children, it is stimulant and astringent. A lotion of nitric acid, 1/2 to 1 dram to a pint of water, is of service in bleeding hemorrhoids. The dilute acid should be taken through a glass tube to protect the teeth.

In cholera morbus:

℞. Nitric acid, ʒ j
Tincture of opium, gtt. xl
Camphor water, ʒ viij.
Give one-fourth part every 3 or 4 hours.

Nitrohydrochloric acid is an efficient cholagog, and is employed with benefit in jaundice, dyspepsia, the so-called bilious condition, and also in acidity of the stomach. The official dilute acid rapidly deteriorates, and the strong acid also is unstable. It is best to use only the strong acid freshly prepared, which is of an orange-red color. This should be constantly protected from light and taken well diluted.

NITRITES.—The salts of nitrous acid, HNO_2. The term is also applied to certain combinations with organic radicles, as nitroglycerin, $C_2H_5(NO_2)_3$, nitrobenzol, amyl nitrite, and other compounds.

Physiologic Action.—Amyl nitrite and the other nitrites agree closely in their general action, producing great vascular dilatation by paralyzing the sympathetic system, the vasomotor center, or the muscular coat of the arterioles—which, is yet undecided. They cause tumultuous action of the heart by relaxing its inhibition; lowered respiration, from paralysis of the respiratory muscles and impairment of the ozonizing function of the blood; diminution of sensation, motility, and reflexes; a sense of heat, but lowered body-temperature; also throbbing pain in the head, beating carotids, quickened pulse, flushed face, and vertigo. Sodium nitrite is slower in action than amyl nitrite, and does not cause so much throbbing headache as nitroglycerin. It may be given in solution with water. The action of all these agents is

probably due to the nitrous acid contained in them. Nitroglycerin acts similarly to the nitrites, but less promptly, and its action is more enduring. The headache it produces is of intensely frontal character, and persists for hours after the other effects have passed off. It is more suitable than amyl nitrite for internal administration.

Therapeutics.—Amyl nitrite possesses a peculiar fruity odor. It is useful in attacks of angina pectoris, asthma, epileptiform convulsions, transient hemianopsia, and occasionally in sea-sickness. Dose, internally, 1/4 to 1 minim, dissolved in alcohol; by inhalation 2 to 5 minims, generally put up in glass beads.

Nitroglycerin is sometimes of benefit in neuralgic dysmenorrhea and in sea-sickness; in chronic interstitial nephritis; and in hiccup and migraine of spasmodic character, and has given immediate relief in neuralgia of the fifth nerve and in sciatica. In angina pectoris it gives more lasting effects than amyl nitrite. In the weak heart of the aged, or in that from fatty degeneration, or when, as in Bright's disease, arterial tension is above the normal, and in irritable and overacting heart, it is of service. It is a dangerous explosive, and should not be kept in stronger solution than 1 percent. Dose, 1/200 to 1/50 minim or more, according to susceptibility.

Sodium nitrite may be used in hemicrania, angina pectoris, and in asthma of purely bronchial and neurotic origin. In chronic desquamative nephritis, with a weak and dilated heart, it is useful. By prescribing it with spirit of chloroform or ammonia water, and small doses of morphin, disagreeable symptoms may be avoided. Dose, 1/2 to 3 grains.

Poisoning.—Ergot, belladonna, strychnin, brucin, digitalis, picrotoxin, and all other agents which increase the functional activity of the spinal cord and sympathetic, are antagonistic, though by reason of their slower rate of diffusion the antagonism may not always be available. Stimulants, artificial respiration, the alternate cold and hot douche, with cold to the head, and ergotin or atropin subcutaneously, are the best means to be used in cases of poisoning by the nitrites.

NITROGLYCERIN.—See Nitrites.

NITROUS ETHER.—See Ether.

NITROUS OXID.—N_2O. Nitrogen Monoxide. A gaseous compound known also as laughing gas, devoid of odor, but with a slightly sweetish taste, which, when inhaled, produces mental exaltation and cerebral excitement, followed by anesthesia. It is the safest of all anesthetics, but ought not to be given to those far advanced in age or having atheromatous arteries. It rarely produces any disagreeable after-effects, save a slight dizziness for a few hours. It is much used in dentistry. Its preparation requires apparatus too cumbersome for the ordinary practitioner of medicine. When first inhaled, the face becomes flushed, then of deadly pallor, and the lower jaw may drop; at this time anesthesia is complete, and the operation should be quickly performed. The gas should be administered without access of air, and if so, insensibility is usually attained in from 50 to 80 seconds from the commencement of inhalation. The following points are to be studied in the administration of nitrous oxid as an anesthetic:

1. The patient should have a full and free expansion of the chest. To obtain this all impediments to free chest movement should be removed. The head should not be thrown back nor flexed in any direction, and the feet should be so placed that if violently extended, they cannot come in contact with a wall or other fixed point of resistance. Two hours after a moderate meal is not too soon for administration. It may be reinspired with safety, when necessary.

2. The apparatus employed should be of modern description, and in good working order. Nitrous oxid is supplied in a liquid form, condensed by its manufacturers into wrought-iron bottles, whence it is liberated into bags from which it is to be inhaled. The bag should not be filled within the patient's sight, never overfilled, and should rest in the patient's lap during inhalation. The bottles should be small, duplex, and should both be connected with the air-bag, so that one may be drawn from if the other is exhausted, without delay. The screw-plugs in bottles should be turned loose, and away from the operator or surrounding persons. The mask may be of celluloid, and its rubber pad should be inflated immediately before use.

3. During administration the mask should fit so closely as to allow no admission of air. If it is wished to prolong unconsciousness, the mask should be lifted up after 6 or 8 full breaths of gas have been taken, or signs of anesthetization are apparent, so that air may be once more inhaled, and more gas then administered, etc.

4. During and immediately after operation care is to be exercised against a vigorous inspiratory effort drawing materials—blood-clots, portions of extracted teeth, or other substances—into the larynx. The mouth is to be washed out while the head is turned to one side.

5. If possible, a qualified assistant should be on hand to administer the gas, and to guard against complications from the possible occurrence of erotic delusions in female patients.

For description of nitrous oxid and oxygen anesthesia in major surgery, see Anesthetics (General).

NOCTURNAL EMISSIONS.—Too frequent emissions reduce the strength, make the patient irritable and weak, and gradually prey upon his mind. When masturbation is practised, extreme mental depression ensues. Nocturnal emissions occurring in normal males who are continent and chaste are not to be interfered with unless excessive.

Treatment.—Unchaste literature and lascivious thoughts are to be avoided. A hard mattress and light covering is advisable. Sleeping on the back is undesirable. A spool is sometimes tied around the loins so that when the sleeper rolls on his back, he is awakened by the pressure. Of drugs used to prevent the nocturnal emissions, potassium bromid, in doses of 20 grains at bedtime, or the same amount of chloral, may be taken. Hyoscin

hydrobromid, 1/100 grain, has been recommended. Cold sponging of the perineum and loins night and morning has been of great benefit. All irritations of the bladder or genitourinary system should be corrected. Potassium citrate, in doses of 20 grains in water 3 times daily, will render the urine unirritating and alkaline, and allay a provocative cause of emissions. Arsenic alone or in combination with strychnin is often of service when given in full dose. Stimulating foods and drinks are to be avoided.

NOCTURNAL ENURESIS.—See Urine (Incontinence).

NOMA.—See Stomatitis (Gangrenous).

NOGUCHI'S TEST.—See Syphilis.

NOSE-BLEED.—See Epistaxis.

NOSE, CARIES AND NECROSIS.—Inflammation of the bones of the nose, leading to caries and necrosis, is usually the result of syphilis, hereditary or acquired; but it may be due to tubercle or glanders, to injury, the presence of foreign bodies, septic decomposition, mercury, and occasionally the fumes of bichromate of potassium. The septum may be attacked, so that the bridge of the nose sinks in (although, in an adult, a great deal may be lost without any apparent alteration in shape), or the turbinate bones, or the roof, and in the latter case there is always the risk of meningitis.

The symptoms are those of inflammation of the mucous membrane, but the discharge is always profuse and fetid, the breath exceedingly foul, and nothing, so long as any dead bone exists, gives more than temporary relief. In many cases the diagnosis is clear at once; either there is a perforation of the hard plate, or a probe introduced into the nasal cavity strikes the sequestrum at once; but sometimes, especially when it lies toward the upper and back part, detection is a matter of very great difficulty.

Treatment.—The dead bone must be removed as soon as it is loose, careful attention being paid at the same time to any constitutional taint that is present. In most cases it can be extracted, under an anesthetic, through the anterior nares; sometimes it is easier to push it back into the pharynx (the two forefingers can usually be made to meet in the inferior meatus of the nose, the one introduced from the front, the other from behind, when the patient is anesthetized), but the operator must be prepared for free, though not usually serious, hemorrhage. When, owing to the size of the fragment, this cannot be done, Rouge's operation may be performed—*i. e.*, an incision made through the mucous membrane, where it is reflected from the under surface of the upper lip on to the gum, the cartilaginous septum detached from the anterior nasal spine, and, if necessary, from the maxillary crest; the alæ detached at the margins, and the upper lip with the nose lifted up and reflected on to the forehead. The nasal cavities are thoroughly opened up to view by this, the whole interior can be examined, and then the nose and lip replaced without a suture being required or a mark left. If the dead bone, without being loose, is fairly accessible, as frequently happens in hereditary syphilis, it may be partially dissolved away by a sulphurous acid spray (which also helps to check the fetor), and occasionally can be chipped off in little pieces with a fine chisel, but care must be taken that the instrument does not slip and penetrate the roof. See Rhinitis (Chronic).

NOSE, CATARRH.—See Rhinitis.

NOSE, DEFORMITIES.—**Congenital malformations** are rare; deformities, on the other hand, resulting from injury, lupus, or syphilis, are very common.

Deviations of the septum, if causing severe symptoms, may be straightened by means of forceps or operation, but the tendency to return is often so great that either the process must be repeated again and again, or an intranasal splint must be worn for some time.

Extensive destruction of the soft parts can sometimes be remedied by means of a plastic operation; but in cases in which it is due to disease, this should never be attempted until the stump is perfectly sound.

The two best known methods of **rhinoplasty** are the Indian, and that first carried out by Tagliacozzi (the Italian). In the former a flap of suitable shape is marked out upon the forehead, having its pedicle immediately over the root of the nose, or slightly to one side, so that it can be twisted down more easily. This is carefully dissected up [Langenbeck recommends that the periosteum should be brought away with it], adjusted in a bed prepared for it by cutting away the old scar-tissue around the margins of the orifice, and secured with sutures, hollow plugs being inserted into the nostril, so that it may retain its shape. To avoid the sinking inward of the tip, Langenbeck reflected some of the bony margin of the nostril, fashioning a flap from each side, so that they should meet like the rafters of a roof in the middle; but when the nose has been destroyed by inflammation, this proceeding is rarely practicable. In the Italian method the skin is taken from the arm over the biceps. In the original plan the flap was raised by an incision down each side and left to granulate; then the upper end was separated; and, after the skin, detached now on 3 sides, had begun to shrink, it was carefully fixed by sutures in the freshly cut margins of the defect. The arm is fixed with plaster bandages in a suitable position, and must be so retained without the slightest traction for at least 8 days. The treatment has since been shortened by detaching the flap at an earlier date, but naturally with some risk. Of these two methods there is no doubt that the former is the better when it is practicable, in spite of the scar it leaves. In the latter the transplanted flap sinks into a shapeless mass. Neither, however, is really satisfactory, and it is probable that in most cases the deformity would be better concealed by an artificial nose made from vulcanite or enameled silver and fastened on to the spectacle-frame.

In cases in which one ala only is defective, Langenbeck's plan of reflecting a flap from the other on the opposite side (leaving it attached by a bridge upon the dorsum) tends to diminish, or at least equalize, the deformity. There is, however, some

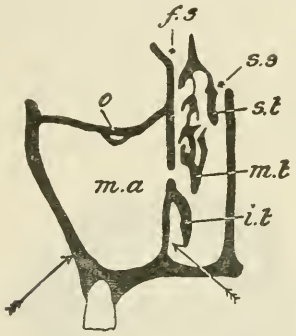
difficulty in separating the skin from the cartilage without cutting or bruising it, owing to the very close connection that exists between the two. See PLASTIC SURGERY.

NOSE, DISEASE OF THE ACCESSORY SINUSES

Empyema of the Maxillary Antrum

This sinus is an air space in the upper jaw lined with thin mucous membrane and communicating with the middle meatus of the nose by an opening about one inch above its floor. Into the floor project the roots of the molar teeth, which are separated by only a very thin plate of bone; but the roots of any of the teeth in the upper jaw may communicate with it.

Empyema of the antrum is a collection of mucopus prevented from escaping into the nose owing to the orifice being obstructed, or owing to the fact that it is above the level of the floor. The empyema may form in course of an acute inflammation, especially during influenza, or may occur



THE MAXILLARY ANTRUM.

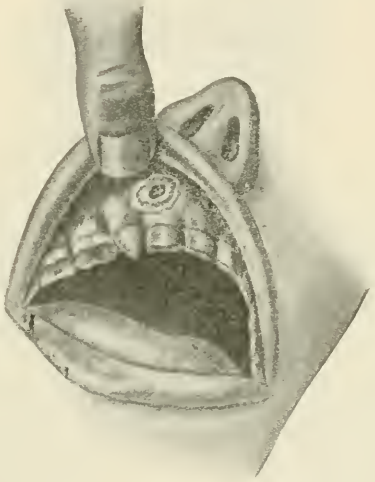
i.t, *m.t*, *s.t*. Inferior, middle and superior turbinals. *m.a*, Maxillary antrum opening into middle turbinal fossa. *f.s*, Frontal sinus and infundibulum, into which open anterior ethmoidal cells. *s.s*, Orifice of sphenoidal sinus. *o*, Infraorbital canal. Arrows show the points at which the antrum is punctured.—(*Spencer and Gask.*)

as a subacute affection by extension from a dental alveolus, and less commonly from necrosis of bone; or it may be a mere chronic retention, owing to the orifice being blocked by nasal polypi. An empyema may rarely be the result of an acute osteomyelitis of the walls of the maxillary antrum, set up by septic inflammation in the mouth, such as cancrum oris, or it may follow gonorrheal conjunctivitis.

The **signs** are neuralgic pain and inflammatory swelling of the cheek, with fever. Pus may escape from the nose, pale yellow, intermittent in its flow, and its odor will then be perceived, especially by the patient; whereas in atrophic ozena the patient may be unconscious of the foul odor, so evident to bystanders. It flows when the patient's head is bent forward, or may be directed backward into the pharynx and disturb the patient's appetite. The interior of the nose should be wiped free of pus, and the patient's head bent, after which the meatus will be again full. When it does not escape the signs of tension are more marked.

Transillumination of the upper jaw serves to confirm this. The patient is seated in a dark room, or is examined under a photographer's cloth, supported by an umbrella. A small electric lamp is placed in the mouth and the lips closed, when a dull glare will illuminate the sound cheek and pupil, leaving the pupil on the diseased side and the infraorbital region partly in shadow. With eyes closed the patient experiences a dull red glow in the eye of the sound side, which is absent on the diseased side. It is this unequal illumination of the two sides which is important for diagnosis.

If neglected, the empyema may burst on the cheek or lead to necrosis of the upper jaw, or there may be septic absorption resulting in pyemia; or septic thrombosis of the orbital veins may occur, producing proptosis or acute optic neuritis; or the



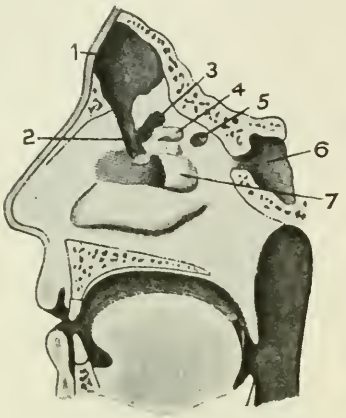
PUNCTURE OF THE MAXILLARY ANTRUM THROUGH THE CANINE FOSSA.—(*Spencer and Gask.*)

thrombosis may extend further back to the cavernous sinus and brain, setting up meningitis.

Treatment.—Cocain is applied to the inferior meatus and then a trocar and cannula is pushed through the wall into the antrum. If pus escapes the cannula can be kept in or it is replaced by a tube and the antrum frequently irrigated. Or the hole may be enlarged under gas at the same time that the anterior end of the inferior turbinal is removed. This provides an opening level with the floor of the antrum which shows no tendency to close, and through which the antrum can be easily irrigated or by passing a catheter like a eustachian, or female urethral catheter. If there are polypi to be removed from the antrum, the aperture as above is further enlarged by raising the lip from the gum so as to expose the lateral nasal wall of the superior maxilla which is chipped away until

a finger and a sharp spoon can be inserted. Polypi and dead bone are scraped away, but healthy mucous membrane is left. After this a plug of iodoform gauze is inserted and brought out through the nostril, while the communication with the mouth is closed by suture. Blood is prevented from running back by temporarily plugging the posterior nares before cutting away the turbinal.

If the disease is dental in origin the antrum may be perforated through the canine fossa, and a counter-opening made into the inferior meatus



Sinuses Opening into the Upper Part of the Nose.

1. Frontal sinus. 2. Infundibulum. 3. Opening of anterior ethmoidal cells. 4. Superior turbinal. 5. Opening of posterior ethmoidal cells. 6. Sphenoidal sinus. 7. Middle turbinal partly cut away. (*Spencer and Gask.*)

of the nose as above; for then the communication with the mouth will soon close spontaneously. Dental surgeons, instead of making the counter-opening, pass a short cannula through the perforated socket of an extracted tooth, the lower end of the cannula being fixed in a dental plate and closed by a split plug with a knob to facilitate withdrawal. This is retained until the mucous membrane of the antrum has returned to the normal. But the objection is that dead bone, polypi, or food materials from the mouth may keep up the discharge indefinitely.

Mucocele and Empyema of the Frontal Sinuses. **Mucocele.**—Retention of mucus may occur in the frontal sinus owing to swelling and hypertrophy of the nasal mucous membrane over the middle turbinal, or to the formation or polypi in that region. The anterior wall of the sinus after a time becomes thinned and a fluctuating swelling forms on the forehead to one or both sides of the middle line. An acute inflammation of the nasal mucous membrane, such as may be set up by influenza, may spread up the infundibulum to the frontal sinuses, giving rise to an *empyema* with or without an intermittent discharge of pus into the nose.

The **symptoms** are frontal headache, and when there is suppuration, severe frontal pain, also redness and edema of the forehead and eyelids, and later fluctuation and pointing. With this is a continuous discharge of pus through the infundibulum, or the passage of a probe into the infundibulum may push aside polypoid granulations, and be followed by a flow of pus.

An X-ray examination shows the size of the frontal sinus, which varies from a small dilatation of the upper end of the infundibulum to one extending upward on the forehead and outward to the outer angle of the orbit, the sinus of the two sides freely communicating.

Treatment.—A *mucocele* may be relieved by excising the anterior end of the middle turbinal bone and also any polypi, then the frontal sinus is washed out by passing a cannula.

An *empyema*, when the mucous membrane is still healthy, may be relieved in the same way. If it is of some standing and there is a polypoid degeneration of the mucous lining, an incision is required. This is an angular one about 1 1/2 inches in length, through the inner margin of the eyebrow down to the bone. The periosteum along with the pulley of the superior oblique muscle is pushed toward the orbit. Then the floor of the frontal sinus is entered at its lowest level through the roof of the orbit just behind the inner angle. The whole sinus is scraped out including the infundibulum, and a free communication with the nose reestablished. A rubber tube is now cut off the length to reach from the upper end of the infundibulum to the free margin of the anterior nares. To hold it in place a temporary suture is

Frontal Sinus Operation.

On the right side is shown the line of the incision; on the left side, the opening made into the sinus. (*Spencer and Gask.*)

inserted at each end of the tube. This enables the skin wound to be entirely closed, and so a fistula and puckered scar is avoided.

In the case of a very large frontal sinus some of the anterior and inferior wall must be clipped away, and the nan iodoform plug is required to stop the hemorrhage, after the removal of which a secondary suturing of the skin can be done.

Disease of the Ethmoidal and Sphenoidal Sinuses. —The ethmoidal sinuses lie along the inner wall of the orbit, and a mucocele produces a swelling on the inner side of the orbit, which pushes the eye outward and causes squint.

The sphenoidal sinus lies behind in the base

of the skull. The orifice of the sphenoidal sinus can be reached by first applying cocain, then passing a probe backward and upward across the center of the middle turbinal, while the shank of the probe is kept in contact with the lower margin of the anterior nares.

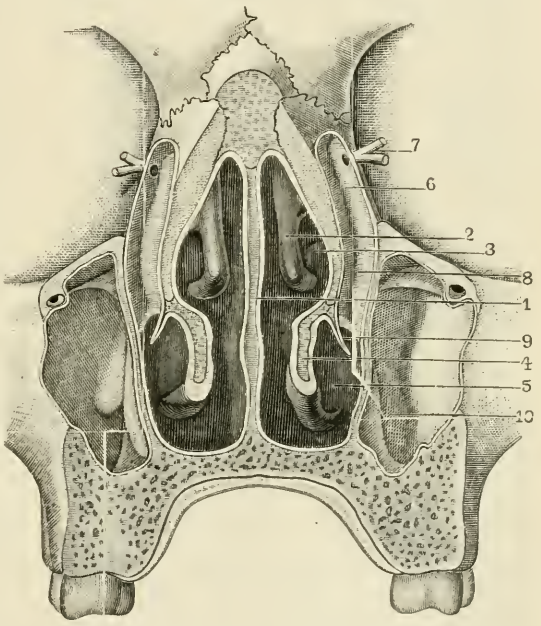
Ethmoidal and sphenoidal empyemas give rise to deep-seated pain in the orbit and back of the nose, with a discharge into the nasopharynx. The dangerous complications are septic basal meningitis and thrombosis of the cavernous sinus. Exophthalmos, ptosis, strabismus, retrobulbar neuritis, and blindness occur when the nerves at the back of the orbit become involved. **Treatment.**—Removal of the anterior end of the middle turbinal may relieve simple retention. The ethmoidal cells may be curetted from the nose, regard being had to the nearness of the meninges and cavernous sinus. The anterior ethmoidal cells are reached through the inner side of the orbit, by extending the incision for the frontal sinus a little downward. The sphenoidal sinus opening is enlarged under the guidance of the probe passed as above. A general anesthetic may be given, a speculum inserted, and a fine cutting hook is passed in and the orifice enlarged, or fine punch forceps may be employed for the purpose. (Spencer and Gask.)

NOSE, EXAMINATION.—This organ consists of two parts: the external, made up of skin, cartilage, and bone; and the internal, or nasal fossæ, which communicate with the pharnyx posteriorly through the medium of the posterior nares. The anterior nares form the entrance to the nostrils. Each nostril contains 3 turbinated bones—the superior, middle, and inferior—thus dividing it into the superior, middle and inferior meatuses. The whole of the internal surface is covered with mucous membrane, that on the turbinated bodies being easily congested and highly erectile. The portion covering the lower and anterior portions of the middle and inferior turbinated bodies frequently gives rise to catarrhal inflammation with obstruction of the nasal chamber. Thick, viscid mucus is constantly secreted from muciparous and serous glands lining the internal surface of the nostrils, which catches foreign particles that have been inhaled and also warms the air before it reaches the lungs. The nasal cavities (choanæ) communicate with the ethmoid, frontal, and sphenoid sinuses and the antrum of Highmore, all of which are lined by a prolongation of the nasal mucous membrane. The superior portion of each nasal chamber is supplied by filaments from the olfactory nerve and controls the sense of smell, while that portion below the lower border of the middle turbinated bone may be termed the respiratory portion.

Anterior Rhinoscopy.—The essentials are: A good light, a nasal speculum, a nasal probe, and a head-mirror with a central opening.

The patient should be seated facing the examiner, and with the light behind or on each side of head, and on a level with the eye of the operator. After anesthetizing the anterior nares with a few drops of a 10 percent solution of cocain, the nasal speculum is introduced, and at the same time the light is reflected into the nares by means of the head-mirror. It is essential for the examiner to always look through the central opening of the head-mirror rather than from above or below. It is best to examine the nares anteriorly, gradually going backward until the whole anterior chamber has been surveyed. A hypertrophic condition can be quickly determined by applying a few drops of a solution of cocain (10 percent) to a suspected spot by means of a pledget of cotton wrapped around the probe, when, if no organic change has taken place, the erectile tissue quickly contracts and the enlargement disappears. Care should be exercised at all times against cocain poisoning.

Posterior Rhinoscopy.—For this are needed a tongue-depressor, head-reflector, throat-mirror, palate-hook, and throat-applicator. The patient should be seated in the same position as for anterior rhinoscopy. A few drops of a solution of cocain (5 percent) are then applied to the upper and posterior vault of the pharynx and the palatine folds (care being exercised to prevent swallowing the fluid), and, after waiting a minute or two, the tongue-depressor is inserted in the mouth to a sufficient distance to hold the organ down, but not sufficiently to cause gagging. The light is then directed toward the pharynx, and the mirror, after being slightly heated (to prevent it becoming



Transverse Section of Nasal Fossæ.

1. Nasal septum. 2. Anterior extremity of middle turbinated bone. 3. Middle meatus. 4. Section of inferior turbinated bone. 5. Inferior meatus. 6. Lacrimal canal. 7. Canaliculi. 8. Nasal canal. 9. Section of reflected mucous membrane. 10. Maxillary sinus or antrum of Highmore.

cloudy from the moisture during respiration), is introduced well back into the pharynx, and, by rotating it slightly, the choanæ are surveyed thoroughly. Subsequently the lower portions of the posterior nares are examined. Directions should be given to the patient to breathe naturally during the examination, otherwise the soft palate retracts and closes the posterior orifices. In some cases the tongue-depressor causes gagging, and in these cases the organ may be held out of the way by grasping it within the folds of a napkin. The examination is often an educative one on the part of the patient, and the first trial may fail.

NOSE, FOREIGN BODIES.—Peas, beads, pebbles, beans, marbles, and the like are sometimes pushed up the nose by children, and sooner or later lead to inflammation and nasal discharge. Foreign bodies may enter the nose from vomiting. Insects may fly or crawl into the nose.

In cases in which it is difficult to grasp the foreign body with a small blunt hook, scoop, or properly curved forceps, or to push it back into the pharynx, the following device may be employed: A small sized Nélaton catheter, to the distal end of which a long silk ligature is attached, is carefully and slowly passed into the nares until it reaches the pharynx; the gagging induced forces the catheter out of the mouth; it is then seized and the ligature pulled through, about 8 inches being allowed to remain outside of the nose. A small wad of absorbent cotton fastened to the buccal end is slowly drawn upward into the posterior nares and along the inferior meatus. The foreign body, particularly if it is a tack or an object with jagged edges, is generally caught and dragged out of the anterior nares with the cotton.

The appearance of the nasal mucous membrane after the removal of the offending body is apparently one of severe ulceration. Under simple instillation of lukewarm salt-water (0.75 per cent), or weak boric acid solution, the parts readily and quickly assume their normal appearance.

NOSE, FRACTURE.—The nasal bones often suffer from direct violence; the fracture may be compound, either externally or internally, or both, or it may be comminuted, and the injury may be limited to the bones themselves, or the septum may be bent or crushed in, or the other bones that surround the nasal cavities may be involved as well. Hemorrhage is always profuse; emphysema is occasionally present from the escape of air into the tissues, and deformity and swelling are generally very considerable.

Treatment.—No pains should be spared to effect reduction as early as possible. Manipulation is exceedingly painful, so that, if the displacement is at all extensive, it is advisable to give an anesthetic. The bleeding, which is sure to be profuse, must be checked afterward by injecting ice-cold water, or by the application of an ice-bag. Elevation from within with a steel director, or a pair of dressing-forceps, may be tried first, but they are not of much service in really bad cases. In some instances it is necessary to grasp the fragments with smooth-bladed forceps, bent so as not to pinch the soft tissues near the nostril, and twist them into position. Later on a great deal may be done to correct any deformity that is left by means of pressure. A spring truss may be used, especially at night, outside the face, or, as Erichsen suggests, india-rubber bags may be introduced into the nostril and inflated. Spectacle- or eye-glass splints have also been used with success. Suppuration is not uncommon, but it is rarely serious; ozena and necrosis, however, occasionally occur, and when the fracture extends on to the face so as to involve the nasal process of the superior maxilla, stricture of the lacrimal duct generally follows.

NOSE, POLYPS.—Polyps of the nasal passages form soft, gelatinous, semitranslucent masses, pale pink or yellow in color, projecting from the surface of the mucous membrane, and sometimes reaching far into the anterior and posterior nares. At first they are small and sessile, and in any advanced case numbers in this stage can be seen between the larger ones. Those that project toward the front may usually be seen at once (or if the patient expires forcibly) forming smooth, pedunculated masses very soft to the touch, and moving up and down with each breath. The deeper ones may require a speculum, and those that grow into the posterior nares can only be detected by introducing the finger round the margin of the soft palate. Occasionally, when one has been exposed to the air for any time, the surface becomes dry and rough, and then it may possibly be mistaken for an overgrowth of the mucous membrane over the inferior turbinated bone; otherwise it is difficult to see how such an error can arise.

Symptoms.—Chronic catarrh is always present. The breathing is obstructed (especially in wet weather, when the polyp swells up); the mouth is held open; the voice is altered and becomes muffled; the sense of smell, and often that of hearing, is lost; and nearly always there is constant frontal headache. In severe cases the shape of the nose may become altered by the internal pressure; the lacrimal duct obstructed; the septum displaced to one side; and the eustachian tube occluded. As a rule, there are no bleeding and no offensive discharge, both of which symptoms are common in the case of malignant growths.

Treatment.—There are various ways of removing polyps. The simplest is to grasp the neck as high up as possible with a pair of slightly curved forceps, having long serrated blades, and twist it round and round until it comes away. If there is a very distinct pedicle, the ordinary wire écraseur may be employed, or the galvanocautery, cocain being used to allay the pain and prevent sneezing. Polyps that lie far back, in or near the posterior nares, can only be snared if the forefinger of the other hand is carried around the back of the soft palate to guide the loop. The bleeding is free, but ceases at once upon the application of ice-cold water. The chief difficulty is to make the removal thorough; and the operator should not be satisfied until the passage between the two nares is completely freed. Even then many small growths

must be left behind, and these, released from the pressure of the larger ones and stimulated by the inflammation that follows the operation, are almost sure to spring up rapidly. To prevent this, tannic acid or sulphate of zinc may be used as snuff, or the cavity may be washed out with boric acid and alcohol, or with other astringents; but constant care is needed. In the worst cases it may be necessary to perform Rouge's operation.

After removal, true polyps return rapidly, hence it is necessary to have the case under observation; the base of each polyp should be cauterized with trichloracetic acid or the galvanocautery. Should a young polyp be detected, it should be removed at once, and its base treated accordingly. The nasal passages should be kept cleansed with some simple collunarium, such as chlorate of potassium and bicarbonate of sodium in water at 95° F., followed by a spray of some bland protective, such as albolin or vaselin, to the cauterized surfaces and mucous membrane. This local treatment should be conjoined with such drugs as will improve the constitutional condition of the patient, as arsenic, syrup of the iodid of iron, or the hypophosphites. See Adenoid Vegetations.

NOSTALGIA(Home-sickness).—An abnormally exaggerated longing for home, relatives, or friends. It is most frequent among the Swiss mountaineers and other persons who have always led an isolated life, and have been more or less dependent upon a small circle of relatives and friends for companionship and diversion. Nostalgia represents a combination of psychic and bodily disturbances, and must be defined as a disease, and may become the object of medical treatment. It is most troublesome when it occurs in new military recruits, and may lead to melancholia and even death. Often the only cure is to allow a return home. Nostalgia must not be confounded with disappointment or moroseness produced by illness, bad temper, or discontent with the temporary position abroad. Compulsory absence from home has great influence in causing nostalgia, and in these cases there is more liability to nostalgia than in those in which the patients are at liberty to go where they please.

NOVARGAN.—Silver proteinate. An organic silver-albumin compound containing 10 percent of silver. As a bactericide, it is claimed to be more effective and less irritating than other protein-silver compounds. In the form of a 15 percent solution it is said to be useful for the treatment of gonorrhea, especially as an abortive in the first stage.

NOVASPIRIN.—Methylene-citrylsalicylic acid. It is decomposed in the intestines into methylene-citric acid and salicylic acid after passing through the stomach unchanged. Its diaphoretic action is slight, and it is said to be devoid of unpleasant effects. It is recommended in influenza, neuralgia, gouty and rheumatic conditions. Dose, 8 to 15 grains.

NOVOCAIN.—A local anesthetic similar to cocain. It is recommended as a substitute for the latter and is claimed to be far less toxic than any of the cocain substitutes.

NUCLEIN.—Nuclein is that constituent of the cell by virtue of which it grows, develops, and reproduces itself. It is the chemic basis of the nucleus. Nuclein is contained in the cellular envelope of the tubercle bacillus, and it is the nuclein which takes the stain. It has been obtained from the thymus and thyroid glands, spleen, testicle, white of egg, and from brewers' yeast. It is abundant in the polymorphonuclear leukocyte, and is set free upon the destruction of those corpuscles. When glandular activity is at its highest, leukocytosis occurs, hence an increased amount of nuclein, and concurrently an increase in the germicidal property of blood-serum. The number of kinds of nuclein is limited only by the different varieties of cells.

While Vaughan and other authors look upon nuclein as the essential element that gives the blood-serum its specific germicidal properties, there are others (probably the majority) who maintain that the ductless glands—thyroid, thymus, suprarenal and pituitary bodies—all secrete certain essential principles, which not only are used for the general body nutrition, but also aid in protecting the system against attacks by pathogenic microorganisms.

Many look upon nuclein as the prototype which gives rise, by decomposition, to alloxin bodies, of which uric acid is a member, and it is believed that the latter product in great part depends upon the amount of nuclein destroyed in the system, and that it rises or falls concurrently with the destruction of nuclein.

Chemically, nuclein consists of a complex proteid base and nucleinic acid, containing from 5 to 9 percent of phosphorus. The terms "nuclein" and "nucleinic acid" are often used interchangeably, as it is generally impossible to obtain nucleinic acid from the albuminous base. Physiologically, nuclein acts by stimulating glandular activity with increase in the number of polymorphonuclear leukocytes, and therefore as increase in the germicidal action of blood-serum. By some authors nuclein is supposed to be the "natural antitoxin."

Nuclein has a selective action and is not germicidal to certain varieties of bacteria. It, however, kills the tubercle bacillus. Introduced into the system hypodermically, it causes, within 3 to 5 hours, an increased frequency of the pulse, a rise of 1 degree or more in the temperature of the body and an increase in the number of multinuclear leukocytes (leukocytosis). In 76 cases of tuberculosis in all stages and with no exclusions, Vaughan reports recovery in 24 percent. King reports 30 similar cases with 22 percent recoveries. The remedy to be effective must be given hypodermically, once daily, over long periods (frequently months), selecting a slightly alkaline solution. Vaughan employed the 1 percent solution in doses of 60 to 80 minims, while King used the 5 percent solution in doses of 50 minims.

Nuclein has been successfully used in diphtheria, suppurative tonsillitis and other suppurative disorders, also in chronic rheumatism and malaria, chronic bronchial catarrh and neurasthenia.

Experience goes to show, however, that in cases in which there is rapid destruction of living tissue

and great depression the remedy is of no benefit and may do harm.

NUCLEOALBUMIN.—One of the series of nucleins obtainable from cell protoplasm, poorer in nucleinic acid than the plastins of the nucleus. It appears to be the most constant of the proteids obtainable from cell protoplasm, but is not confined to cells, being the chief constituent of tissue-fibrinogen. The chief proteid of milk (*caseinogen*), the so-called mucin of bile, and the mucinoid substance in the mucus of urine, are nucleoalbumins. Nucleoalbumin is insoluble in acetic acid, precipitable by magnesium sulphate, not reducible by prolonged heat in the presence of an acid. It is formed by the combination of nuclein and albumin in the process of digestion. It contains phosphorus. The presence of nucleoalbumin in the urine has been observed in leukemia, icterus, diphtheria, and in scarlatina and other varieties of nephritis.

NURSING.—See Infant Feeding, New-born Infant.

NUTMEG.—See Myristica.

NUTMEG LIVER.—A mottled appearance of the liver, the center of the acini being dark, while the periphery is lighter in color. The condition is seen especially in passive congestion and in fatty infiltration. See Liver.

NUX VOMICA (Poison Nut, Quaker Button, Dogbutton).—The dried, ripe seed of *Strychnos nux-vomica*, containing not less than 1.25 percent of strychnin. Its properties are due mainly to two alkaloids—strychnin and brucin—with the properties of which its own properties are identical. In small doses it is a bitter tonic, exciting the secretions and stimulating the functions of the body. In larger doses it exalts the function of the spinal cord, causing tetanic spasms of the extensor muscles. In toxic doses it paralyzes the functions of the spinal cord, arrests respiration, and causes death by suffocation. It is valuable as a general tonic in cardiac failure, in hemiplegia, dyspnea, and in certain forms of amblyopia. Strychnin is now the acknowledged remedy for inebriety. The tincture of nux vomica is excellent in atonic dyspepsia and gastric catarrh, especially in drunkards and in constipation from atony. It is valuable in neuralgia, in the condition known as torpid liver, and, through its influence on the pneumogastric, in many kinds of coughs. Dose, 1/2 to 1 1/2 grains.

The alkaloid strychnin is also contained in the St. Ignatius' bean, or ignatia in the proportion of 1 percent, and in the bark of the tropical blind-weed, a creeping vine found in the mountains of Tonquin and Cochin China.

Poisoning by strychnin has some points in common with tetanus. In the latter affection the lower jaw first manifests stiffness, and is affected throughout the attack, while in poisoning by strychnin the jaw is not affected until late, and then only during the paroxysm. The diagnosis of strychnin poisoning from hysteria requires attention only for a short time.

Treatment.—Vomiting should be encouraged if convulsions have not already set in; in such case the stomach-pump may be used. Quiet and absolute rest are to be obtained as soon as possible, and the patient removed from every irritation, as a mere touch may set up a convulsion. Large doses of chloral hydrate may be given in doses of 1/2 dram, repeated in a half-hour. Potassium permanganate given in large doses may be antidotal. Tannic acid forms an insoluble tannate, and iodin in dilute solution and soluble iodids are antidotes. Butylchloral hydrate is a very active antagonist. Potassium bromid is too slow in action for practical use. Chloroform or ether may be used to bring about muscular relaxation. Hydrastin hydrochlorid, in doses of 1 grain hypodermically, has been successfully employed, and amyl nitrite has been given by inhalation with good result.

Incompatible with *nux vomica* and *strychnin* are alkalies and their carbonates, bromids, iodids, chlorids, and all other alkaloidal precipitants. Oils and fats retard the absorption of strychnin salts. Physiologically incompatible are aconite, alcohol, amyl nitrite, atropin, chloral hydrate, chloroform, curarin, digitalis, hydrocyanic acid, morphin, nicotin, paraldehyd, physostigmin, potassium bromid, urethane.

Preparations.—**Extract Nucis Vomicæ** should contain 5 percent of strychnin. Dose, 1/8 to 3/4 grain up to a maximum in 24 hours of 2 grains. **Fluidextract Nucis Vomicæ** should contain 1 percent of strychnin. Dose, 1/2 to 1 1/2 minims. **Tinct. Nucis Vomicæ** should contain 1/10 percent of strychnin. Dose, 5 to 15 minims. **Strychnin,** an alkaloid obtained from nux vomica, ignatia, and other plants, crystalline, intensely bitter even in 1 to 700,000 solution, of alkaline reaction, soluble in 7 of chloroform, 110 of alcohol, 6700 of water. It is a constituent of ferri et strychninæ citras, pil. laxativæ comp., and the elixir, glyceritum and syrupus ferri quininæ et strychninæ phosphatum. Dose, 1/100 to 1/30 grain. **Strychninæ Sulphas,** crystalline, efflorescent, odorless, of intensely bitter taste, even in 1 to 700,000 solution, neutral reaction, soluble in 50 of water, in 109 of alcohol, and in 2 of boiling water, insoluble in ether. It contains 75 percent of strychnin. Dose, 1/100 to 1/20 grain, but after tolerance is attained much larger doses may be safely used. **Strychninæ Nitras,** soluble in 90 parts of cold water, 3 of boiling water, in 70 of alcohol, and in 26 of glycerin, insoluble in ether. It contains 84 percent of strychnin, and is preferred to the sulphate for hypodermic use, being less irritant. Dose, 1/100 to 1/20 grain, or more after tolerance is attained. The nitrate in doses of gr. 1/30 to 1/20, hypodermically three or four times daily for a week, and less frequently for two weeks longer, removes the craving for stimulants, counteracts the vasomotor paralysis to which most of the injurious effects of alcohol are due, and is probably in other respects a true antagonist to the action of that narcotic poison on the human organism.

NYCTALOPIA.—Nyctalopia etymologically means night-blindness, but the general usage making the term mean night-vision is so strongly intrenched that it is useless and confusing to

reinstate the old significance. The condition in which one sees better at night, relatively speaking, than by day, is due to some lesion in the macular region rendering it blind; at night the pupil dilates more than in the daytime, and hence vision with the extramacular or peripheral portions of the retina is correspondingly better. Nyctalopia is a symptom of serious retinal disease, and not a disease in itself. All night-prowling animals have widely-dilated pupils, and in addition to this they have in the retina a special organ called the *tapetum lucidum*, the function of which is to reflect to a focus in front of them the relatively few rays of light that enter the widely dilated pupil, and thus enable them the better to see their way. Hence, the luminous appearance of the eyes of such animals in the dark.

NYMPHÆ.—See Vulva.

NYMPHOMANIA.—See Mania.

NYSTAGMUS.—Involuntary oscillation of the eyeball due to spasmodic jerking movements of the eye, not interfering with the voluntary movements, but accompanying them. It is the result of defective coordination, inadequate light, and errors of refraction. The involuntary movements may be horizontal or vertical, oblique, or rotations about the visual axis. Internal squint is a frequent accompaniment, and there may be simultaneous shaking of the head.

The commonest form of nystagmus is that coming from some deficiency of vision in both eyes, beginning in childhood, particularly in amblyopia, the result of the destructive changes after ophthalmia neonatorum and in retinitis pigmentosa. It also exists in microphthalmos, albinism, and some varieties of congenital cataract. Miners who constantly strain their eyes in the darkness sometimes develop the disease. Nystagmus from cerebral disease is only of symptomatic significance. It is especially important in the diagnosis of multiple sclerosis.

Treatment, beyond simple rest and the relief of the distressing symptoms, is of little value. It must always be remembered that there is a possibility of improving the visual acuity and modifying the disease by correcting lenses. The prognosis of the nystagmus is never encouraging, even under the most favorable circumstances.

O

OAK.—See Quercus.

OBESITY.—Obesity may be defined as an excessive development of fat throughout the body. There are two forms, the anemic and the plethoric.

Etiology.—Heredity is a potent factor. Over-indulgence in carbohydrates, fats, and albumins is a frequent cause. Diseases marked by defective oxidation, as chlorosis and sexual continence, are often the exciting conditions of this disease; so, too, is lack of exercise or muscular inactivity.

Morbid Anatomy.—Increased subcutaneous fat, rounded face, pendulous cheeks, protuberant abdomen, and gross legs and buttocks are evident. There is an accumulation of fat over the chest and in the mediastinum, and enlarged liver and increased intraabdominal fat. In the later stages there is a fatty infiltration of the heart-muscle.

Pathology.—Although corpulent individuals may eat but little fatty foods, they are frequently hearty eaters of all classes of foods. The carbohydrates are not only directly productive of fat-increase, but by saving the stored fat, indirectly aid in the development of this condition; hence sugars, starches, and alcohol (beer in particular) are productive of corpulence. Alcohol, by hastening the metabolism of albumin, sets free fat-producing substances which may be stored. Diminished oxidation from anemia, for example, or lack of muscular exercise, favors this condition.

Symptoms.—The increased bulk of the patient renders his movements sluggish and may interfere with locomotion, producing a waddling gait. Dyspnea, from mechanic interference with respiration, fatty chest-wall, mediastinal fat, or enlarged liver, are early symptoms. Later, a true cardiac dyspnea from fatty infiltration of the heart-muscle, secondary to arteriosclerosis, may arise. A late symptom is the effusion which takes place, showing itself as anasarca, ascites, hydropericardium, and hydrothorax. Eczema, secondary to intertrigo, adds much to the discomfort of the patient.

Prognosis.—Marked corpulence is not incompatible with long life and considerable comfort. When excessive, the conditions mentioned are likely to supervene, and death, often sudden, results. The prospect of recovery is lessened by the fact that most patients find the treatment irksome, and are induced with great difficulty to continue it.

Complications.—The obese are especially prone to contract heart, disease, diabetes, asthma, gallstones apoplexy, gout, disturbances of secretory organs. They stand major operations poorly and can make little resistance when attacked by severe acute infections.

Treatment.—Two indications present themselves: (1) Diminish the food-supply, and (2) oxdize the fat already stored. For the first, 3 prominent systems are those of Banting, Ebstein, and Oertel.

The Banting system nearly excludes fats, forbids the largest possible amount of sugar and starches, and limits the daily amount of fluids taken to 35 ounces. The patients are practically starved, in that they are allowed only 20 to 25 ounces of dry food daily, about one-half of this being meat. The fault of this method lies in its failure to secure elimination of waste products, and it is likely to result in serious malnutrition.

The Ebstein method allows fat on the theory that it does not produce stored fat and clogs the appetite. Sugar- and starch-containing vegetables, as potatoes and all farinaceous foods—3 1/2 ounces of bread each day being excepted—are forbidden. The quantity of fluids is limited. Black tea, without milk or sugar, and light wines are allowed. A moderate amount of meat is permitted.

The Oertel system not only regulated the diet, but pays especial attention to the heart and circulation. For convenience, these patients are divided into 2 classes: (1) Those in whom there are no marked respiratory and circulatory disturbances, and (2) those in whom the oxygen intake is diminished, so that dyspnea is readily excited. For the first class double the amount of fat and carbohydrates, with much larger amount of albuminates, is allowed, as compared with the second class. In the latter class the amount of liquid ingested is markedly reduced. As compared with the Ebstein and Banting systems, it gives nearly the same amount of albuminates as the Banting, and one-half to three-quarters more than the Ebstein. It allows from 3 to 4 times as much fat as the Banting, and from one-third to one-half as much as the Ebstein. For the carbohydrates, the same to one-third more than the Banting, and one-half more to double that of Ebstein. When exercise can be taken, the more generous diet of Oertel should be chosen. Other systems have been employed, and may be adapted to individual patients, but that of Oertel has a wider application than any other, especially when combined with systematic exercise to strengthen the heart-muscle and massage to stimulate the circulation. In detail, the diet should consist chiefly of albuminates—lean of roast or boiled beef, veal, mutton, game, and eggs. Green vegetables, as cabbage and spinach, are allowed; fat and carbohydrates only in small quantities, and 4 to 6 ounces of bread a day. The liquid drunk must be limited to 6 ounces of coffee, tea, or milk, morning and evening, with 12 ounces of wine, and 8 to 16 ounces of water during the 24 hours. In warm weather this amount may be slightly increased, but beer is

absolutely prohibited. To prevent formation of fat, the following diet table should be observed:

Morning.—One cup of coffee or tea, with a little milk, altogether about 6 ounces. Bread, 3 ounces.

Noon.—Three to 4 ounces of soup; 7 to 8 ounces of roast or boiled beef, veal, game, or not too fat poultry; salad or a light vegetable; a little fish (cooked without fat); 1 ounce of bread or farinaceous pudding (never more than 3 ounces), and 3 to 6 ounces of fresh fruit. In hot weather, or in absence of fresh fruits, 6 to 8 ounces of light wine may be taken.

Afternoon.—Coffee or tea with milk to 6 ounces, with at most 6 ounces of water; exceptionally, 1 ounce of bread.

Evening.—One or 2 soft-boiled eggs, 1 ounce of bread, perhaps a small quantity of cheese, salad and fruit; 6 to 8 ounces of wine with 4 or 5 ounces of water. Thus far the indication has been to furnish less food for the patient to oxidize, and at the same time sufficient for purposes of nutrition.

The second indication is to increase the oxidation of fat in the body. This is accomplished by massage, exercise in the gymnasium, or, preferably, in the open air. The latter comprises walking, mountain-climbing, cycling, and, what is of great value when possible, horseback exercise. Turkish baths are useful to remove surplus fluids from the body, but should be employed with great hesitation if any circulatory disturbances are present. Of health resorts Carlsbad and Marienbad are most frequently chosen. Here the restricted diet, systematic exercise, and purgative waters combine to give relief. The regimen must be continued after the return of the patient to his home, else the betterment will not be permanent.

Of the drugs in popular use most are inefficient and many are harmful. It is not likely that any one drug will meet the various conditions arising from the complex processes which result in fat production and fat storage. Should these be mentioned individually, it would be merely to give their contraindications. The one which has given the best results is thyroid extract, and this must be administered with the precautions enumerated under THYROID TREATMENT (*q. v.*).

OCCUPATION NEUROSES.—A group of affections of the nervous system, characterized by the occurrence of spasm (cramp) and pain in groups of muscles in consequence of overuse or frequently repeated muscular acts. It has been noticed that many persons suffering from occupation neuroses have a family history of nervous affections.

Varieties.—Writers' cramp; piano-players' cramp; telegraphers' cramp; violin-players' cramp; dancers' cramp, etc.

The symptoms of any of the varieties named generally develop gradually and slowly, by a feeling of stiffness in the used member; the part feels fatigued and heavy, until it is impossible to use it, from the occurrence of spasmodic contractions; there is pain on using the affected muscles, often associated with tremor, and in many cases with an actual paralysis. Associated with the loss of power to follow the usual occupation are nervousness, mental worry, and often depression. There is often the sensation of prickling, and numbness in the crippled member. The electro-contractility is preserved until the atrophy of nonuse develops.

Prognosis is often unfavorable, although some recoveries are reported.

Treatment consists of rest to the part and mental quiet, with tonics and other means to improve the general nutrition. Faradism in weak applications once or twice weekly seems useful. The following combination may be of value (Hughes):

℞.	Zinc phosphid,	gr. ij
	Extract of nux vomica,	gr. x
	Iron albuminate,	gr. xxx.

Make 30 pills. One after meals.

OCULOMOTOR PARALYSIS.—See EYE-MUSCLES (Paralysis).

OINTMENTS (Unguenta).—Soft, fatty mixtures of medicinal agents with a basis of lard, petrolatum, or fixed oils, with a solid fat, such as wax or spermaceti. They are intended for application to the skin by inunction, and have a melting-point which is below the ordinary temperature of the human body. The official unguentum is prepared by fusing together 80 parts of benzoinated lard and 20 parts of white wax, and is the basis of 2 other ointments, while 9 have benzoinated lard, and 3 have lard as their basis. There are 24 official ointments.

TITLE.	PERCENT OF ACTIVE CONSTITUENT.	BASE.
Unguentum.....	White wax, 20; benzoinated lard, 80.	.....
UNGUENTUM:		
Acidi borici.....	Boric acid, 10.....	Paraffin, 10; white petrolatum, 80.
Acidi tannici....	Glycerin and ointment.	Tannic acid, 20.
Aquæ rosæ.....	Stronger rose water, 19.	Spermaceti, 12.5; white wax, 12; almond oil, 56; borax, 5.
Belladonnæ.....	Extract belladonna leaves, 10.	Diluted alcohol, 5; wool-fat, 20; Benzoinated lard, 65.
Chrysarobini....	Chrysarobin, 6.....	Benzoinated lard, 94.
Diachylon.....	Lead plaster, 50....	Olive oil, 49; oil of lavender flowers, 1.
Gallæ.....	Nutgall, 20.....	Ointment, 80.
Hydrargyri.....	Mercury, 50; oleate of mercury, 2.	Prepared suet, 23; benzoinated lard, 25.
Hydrargyri ammoniati.	Ammoniated mercury, 10.	White petrolatum, 50; hydrous wool-fat, 40.
Hydrargyri dilutum.	Mercurial ointment, 67.	Petrolatum, 33.
Hydrargyri nitratis.	Nitrate of mercury, abt., 12.5.	Lard.
Hydrargyri oxidi flavi.	Yellow oxid of mercury, 10.	Water, 10; hydrous wool-fat, 40; petrolatum, 40.
Hydrargyri oxidi rubri.	Red oxid of mercury, 10.	Water, 10; hydrous wool-fat, 40; petrolatum, 40.
Iodi.....	Iodin, 4; potassium iodid, 4.	Benzoinated lard 80; glycerin, 12.
Iodoformi.....	Iodoform, 10.....	Lard, 90.
Phenolis.....	Phenol, 3.....	White petrolatum, 97.

Title.	Percent of Active Constituent.	Base.
Unguentum:		
Picis liquidæ....	Tar, 50.....	Lard, 35; yellow wax, 15.
Potassii iodidi...	Potassium iodid, 10; potassium carbonate, 0.6.	Benzoinated lard, 80; water, 10.
Stramonii.....	Extract of stramonium, 10.	Hydrous wool-fat, 20; benzoinated lard, 65; diluted alcohol, 5.
Sulphuris.....	Washed sulphur, 15.	Benzoinated lard, 85.
Veratrinæ.....	Veratrin, 4.....	Benzoinated lard, 90; almond oil, 6.
Zinci oxidi.....	Zinc oxid, 20.....	Benzoinated lard, 80.
Zinci steratis....	Zinc stearate, 50...	White petrolatum,50.

The process of compounding an ointment or a cerate is sufficiently simple, being generally a mere matter of triturating the ingredients together in a mortar, or of their incorporation on a slab by means of a spatula. When extracts, powders, or gritty substances are ordered, the ingredients should first be pulverized into a fine powder, then triturated with a small quantity of the basis into a smooth, impalpable paste, the remainder of the basis being added gradually, until the whole is thoroughly incorporated. A warm mortar may be required for hard extracts. Soluble salts should be triturated with a little water before adding the excipient. Camphor needs a little alcohol to enable it to be pulverized, and iodin should be rubbed to a fine powder, a little alcohol then added, and finally the excipient by degrees. Sulphur iodid requires persevering work with a small portion of olive oil. Borax should be triturated with glycerin, and red mercuric oxid with distilled water. A bone or horn spatula should be used for all ointments, as steel or iron blades will injure many substances, particularly alkaloids, free acids, tannin or iodin, and several of the mercurial salts. Volatile substances should be added last, and quickly worked in, so that their evaporation may be as slight as possible.

OLD AGE.—The period of life in which the degenerative changes that set in after middle life become apparent. It does not correspond to any definite term of years, but is hastened by want, confinement, hardship, and mental anxiety, by exposure to mercurial and nitrous fumes, and the habitual use of alcohol and poisonous drugs. Some persons are old at 40, and some hardly so at 70. The normal anatomic and physiologic changes are well seen in the bones, which become more brittle and lighter, but without reduction in size, and hence fractures more readily produced, especially in the spongy portions of the bones, in the neck and trochanteric region of the femur. The cartilaginous portions of the body are thinned, slightly lessening the height. The alveolar processes of the jaw are absorbed, the teeth loosening and falling out, and the angle of the jaw is enlarged. The face is shortened and the chin protrudes. Voluntary muscles waste with ensuing loss of power and increasing difficulty in maintaining an erect carriage. The cardiac muscle shares in the general change, the heart-beat becoming weakened and often intermittent, the rate not being materially altered. The activity of the involuntary muscles diminishes. The powers of digestion become lessened, inducing constipation. The accommodation of the eyes fails; and the expulsive force of the bladder diminishes. The skin becomes wrinkled. There is shrinkage of the elastic tissues, and adipose tissue is absorbed and the cutis thinned; the hair-roots undergo atrophy, and the color of the hair is lost. The lungs, spleen, lymphatic glands, uterus, and ovaries become more or less atrophied, and the functional powers of testes diminish or cease. The brain and spinal cord shrink in size, reflex action becomes sluggish, and mental concentration and energy lessen.

Other morbid changes peculiar to old age are thickening of the walls of the arteries, atheroma, and calcification thereof. Thrombosis and embolism are not infrequent results, and cerebral hemorrhage is an imminent danger. The heart-valves are often atheromatous or calcified. Costal cartilages may calcify and impede respiratory movement. "Arcus senilis," a ring of degeneration, is often seen near the margin of the cornea, and cataract is common. The atrophy of mind may become actual dementia, and the lungs become emphysematous. Deafness and paralysis agitans are common, and joint-affections appear. Cirrhosis of the liver is seldom delayed to old age, while granular degeneration of the liver commences in old age. The prostate is liable to fibroid enlargement, causing retention of urine and the train of results dependent upon it.

Catarrhs of the air-passages are very prone to persist and extend, and to set up a form of lobular pneumonia. Wounds are liable to slough, but heal most readily. Fatality ensues in old age often from gradual enfeeblement of the powers without predominant lesion of any organ. Cerebral hemorrhage and cardiac failure are frequent modes of death, but pneumonia gives greatest mortality.

Moderate and continuous activity of mind and body, moderate and regular hours of sleep, a spare diet, little or no indulgence in alcoholic liquors, and particularly a guarded use of flesh food, are the most salient points conducing to length of life. The very aged have seldom been addicted to the use of drugs. A robust frame, a bodily and mental stature above the average, the power of sound sleep, of speedy recovery after fatigue, good reproductive power, and long retention of the hair of the scalp are criteria of capacity for prolonged life.

Serious illness lessens the prospect. The very aged are seldom found to be the offspring of immature marriages, or to have contracted such themselves. Elder children appear to have an advantage over the younger.

In the treatment of illnesses of the aged, the failing powers of digestion, of repair, and of vasomotor accommodation must be kept constantly in mind. The dietary should contain less meat and more milk and farinaceous foods than that of the young or middle-aged. Fatty matters are less

easily tolerated. Malted and predigested aliments may supplement the diet as age advances. Changes of temperature must be guarded against, and the liability to bronchitis should dictate caution in exposure to cold or damp air.

OLEATES.—Liquid solutions of metallic salts or alkaloids in oleic acid, intended for external administration. They are not definite chemical compounds, though the term is also employed in trade to designate certain solid preparations which are claimed to be chemical compounds of the same acid with various bases. There are 5 official oleates, three of which have olive oil, as well as oleic acid.

Title.	Composition.
Oleatum:	
Atropinæ.....	Atropin, 2 grams; oleic acid, 50 grams; olive oil to 100 grams.
Cocainæ.....	Cocain, 5 grams; oleic acid, 50 grams; olive oil to 100 grams.
Hydrargyri...	Yellow mercuric oxid, 25 grams; oleic acid to 100 grams.
Quininæ.....	Quinin, 25 grams; oleic acid, 75 grams.
Veratrinæ....	Veratrin, 2 grams; oleic acid, 50 grams; olive oil to 100 grams.

OLEORESINS (Oleoresinæ).—Liquid preparations consisting principally of natural oils and resins extracted from vegetable substances by percolation with acetone. They differ from fluidextracts in not bearing any uniform relation of c.c. to the gram of drug, in containing principles which though soluble in acetone are not so in alcohol, and in some instances being devoid of principles which are insoluble in acetone but soluble in alcohol. They are the most concentrated liquid preparations of drugs which can be produced. The official oleoresins are 6 in number.

Title.	Average Yield and Properties.	Dose.
Oleoresina:		
Aspidii.....	10 to 15 percent. Tæniacide.	30 grains.
Capsici.....	5 percent. Stimulant, rubefacient.	1/2 grain.
Cubebæ.....	18 to 25 percent. Diuretic, expectorant.	7 1/2 grains.
Lupulini.....	50 percent. Tonic sedative.	3 grains.
Piperis.....	5 percent. Stimulant.....	1/2 grain.
Zingiberis....	6 to 8 percent. Stimulant..	1/2 grain.

OLIGOHYDRAMNIOS.—See Amnii, Liquor.

OLIVE OIL (Sweet Oil, Salad Oil).—"A fixed oil expressed from the ripe fruit of *Olea europæa*" (U. S. P.). Cotton-seed oil, poppy oil, colza oil, ground-nut oil, and lard oil are used in immense quantities as substitutions for olive oil, since, with the exception of the common adulterant, cotton-seed oil, which is slightly irritating, all these varieties of oil have many of the properties in common with olive oil. By exposure to the air, olive oil soon becomes rancid. Olive oil enters into the composition of several cerates, ointments, and plasters, notably emplastrum plumbi and unguentum diachylon. Olive oil is emollient and protectant.

Carbolized oil, consisting of a 5 to 10 percent solution of carbolic acid in sweet oil, was at one time extensively used in the treatment of wounds. Since it has been shown that the amount of acid employed is ineffective, so far as any antiseptic properties are concerned, the practice has been abandoned. Sweet oil was in extensive use as a wound dressing, especially after amputation, by the older surgeons. It had the advantage of being bland and unirritating and not allowing the dressing to adhere to the cut surfaces. Olive oil forms one of the substances in repute for the preparation of instruments used in the surgery of the mucous cavities. In the treatment of unusually tight strictures of the urethra, the injection of a little sweet oil with a syringe will often prove more serviceable than anointing the instrument. As an emollient, sweet oil is largely employed in enemata. It has a special tendency to soften scybala and assist in their removal. It also serves to reduce the irritation which accompanies the presence of seat-worms. It is also used in large and frequently repeated doses in cases of biliary colic. Olive oil enters into the composition of a number of preparations employed in the local treatment of skin-diseases. Employed alone, it is useful to soften crusts and scales and to remove epithelial débris as a preliminary to more active treatment.

OMENTOPEXY.—See Liver, Cirrhosis.

OMENTUM.—The omentum forms an extremely mobile covering to the intestines, and it may glide into any part of the abdominal cavity, or communicating pouch, or hernial sac, and readily prolapses into a wound. Its displacement may be caused by the peristaltic movements of the intestines, by movements of the chest, or of the abdominal wall, or be due to gravity. At any point the omentum may become adherent, which in some cases may have a beneficial result: (1) by closing a threatened or actual intestinal perforation; (2) by encysting an infectious mass such as a diseased appendix; (3) by confining a septic peritonitis to a limited region of the abdomen. Advantage is taken of the omentum for grafting over a weak line of suture, and for establishing a venous anastomosis. On the other hand harm arises from omental adhesions; a band may be formed under which a coil of intestine slips and becomes strangulated, whether in the abdominal cavity, or in a hernial pouch; one end of the omentum being fixed, the peristaltic movement of the intestine may induce torsion of the omentum, and so gangrene; omental adhesions may furnish additional blood supply to a uterine fibroma and encourage the rapid growth of the tumor.

A **tumor of the omentum** is movable and not covered by intestine. It may consist of rolled up or matted omentum, the result of inflammation, or it may be a cyst or of a vascular, fibrous, or sarcomatous nature. *Treatment.*—An exploratory in-

cision should be made, and if the tumor is found movable the whole of the omentum should, as a rule, be excised up to the transverse colon (Spencer and Gask).

OMPHALORRHAGIA.—See UMBILICAL CORD.

ONOMATOMANIA.—Functional derangement of speech, of which 5 varieties are described: (1) A powerful effort to recall some word; (2) an irresistible impulse continually to repeat a word, by which the patient seems perplexed; (3) the patient attaches some peculiar and dreadful meaning to a commonplace word; (4) the patient attaches talismanic significance to certain words, which he repeats as a safe guard; (5) the patient is impelled to spit out some word, like a disgusting morsel. A word is a complexus of images, localized in certain centers of the cerebral cortex, the images being partly auditive, partly visual, partly motor. "Onomatomania is characterized by irregular action of one or several verbal images, resulting from some functional disturbance of the corresponding center." In *simple onomatomania* the patient is possessed with the idea of recovering a word that escapes him. The word is familiar; its significance can be given; the place where read or the time when heard can be given, but the word cannot be recalled. Articulate speech may be at fault. The patient knows the word, sees it written before him but cannot articulate it. He may utter a synonym or a similar word. In *associated onomatomania* words acquire a peculiar or preponderant meaning. See APHASIA, SPEECH DEFECTS, etc.

ONYCHIA.—See NAILS (Diseases).

OPEN-AIR TREATMENT.—In conjunction with vaccine therapy open air is advocated in empyema. It is efficacious in burns, lobar pneumonia, bronchopneumonia, inoperable cancer, pulmonary and surgical tuberculosis. It is used conjointly with X-rays to prevent recurrence after operation for carcinoma of the breast. See BURNS, TUBERCULOSIS, etc.

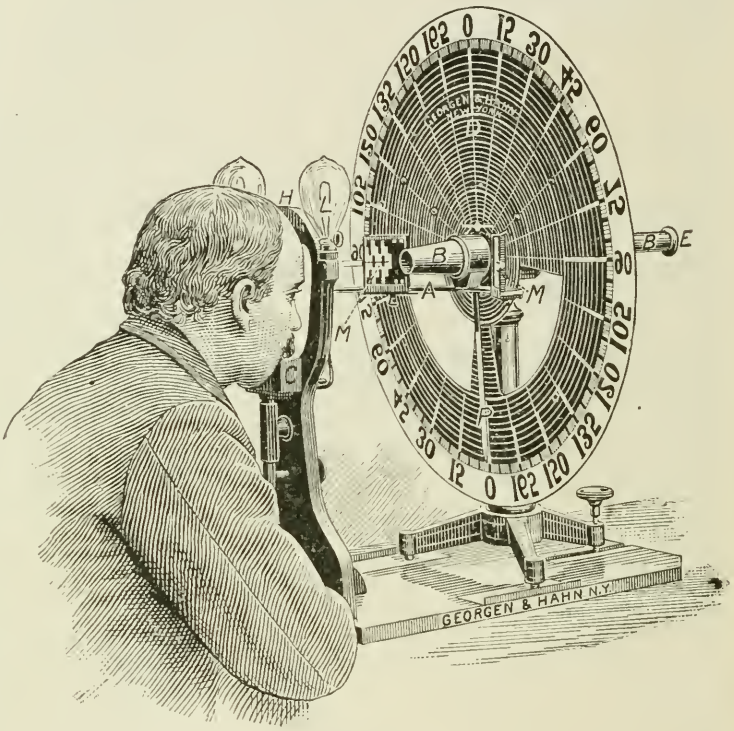
OPERATIONS IN GENERAL.—See ABDOMINAL SECTION.

OPHTHALMIA NEONATORUM.—See CONJUNCTIVITIS (Purulent).

OPHTHALMIA, SYMPATHETIC.—See SYMPATHETIC OPHTHALMIA.

OPHTHALMIC REACTION OF TUBERCULOSIS.—See TUBERCULIN.

OPHTHALMOMETER.—An instrument used for the determination of the kind and amount of corneal astigmatism. It is less exact than the retinoscope, and, moreover, it is very expensive. That of Javal and Schiötz consists of a telescope attached to a graduated arc, upon which are two objects called mires, the left one being fixed, while the right is movable. These mires are of white enamel, one quadrilateral in shape and the other the same size, except that on one side it is cut out into 5 steps. The observer looks through the tube, which contains a combination of convex lenses and a bi-refracting prism, and sees 4 magnified images in a line on the cornea under examination. He first finds the meridian of least refraction by moving the semicircular arm to the position in which the 2 central images are furthest apart. The mires are then moved together until the 2 central images on the observed cornea touch and their central black lines coincide—the lowest step of one image with the side of the other. The arm is now turned at right angles to this meridian, and the overlapping of the 2 central images is noticed; for each step overlapping there is a difference of 1 diopter between the meridians. In higher degrees of astigmatism we add 5 diopters to the number of steps protruded on the other side. At 5 diopters of astigmatism the steps exactly cover the plain quadrangular mire.



THE OPHTHALMOMETER OF JAVAL AND SCHIÖTZ.

A. The perimeter-bar. *B, B*. Telescope. *C*. Chin-rest. *D*. Disc of radiating lines and concentric circles. *E*. Eyepiece at which the observer sits. *H*. Head-rest. *L*. Lights. *M, M*. The mires, or targets. *P*. Pointer, indicating the axis by the degree numbers on the peripheral border of the disc.

The meridian of least curvature corresponds to

the axis of astigmatism. The findings of the ophthalmometer are not exact. No account is taken of the lenticular astigmatism, and even though the cornea is at fault, no rules for adapting the ophthalmometric results can be formulated. Speaking broadly, the total astigmatism is approximately equal to the amount indicated by the ophthalmometer, expressed as myopic astigmatism, combined with an *inverse* myopic astigmatism of 0.75 D; or, in other words, when there is no corneal astigmatism by the ophthalmometer, the test-lens will likely show about 0.75 D of inverse astigmatism (Bull).

Mires Exactly Approximated.

Mires Overlapping One Diopter.

OPHTHALMOPLEGIA.—See Eye Muscles (Paralysis).

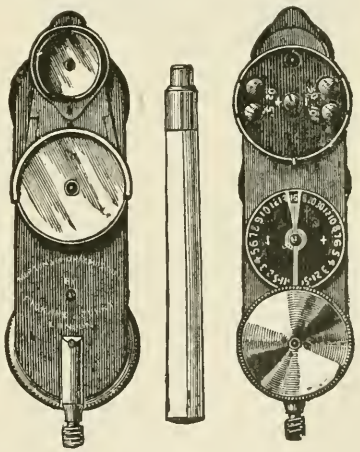
OPHTHALMOSCOPY. Theory.—It is self-evident that rays reflected from the fundus of the eye emerge from the eye in the same direction as that in which they enter it, the refractive media of the eye having the same action on light whether passing in or out. However, as ordinarily seen, the pupil is black. There is no light reflected from the patient's eye into ours, because our own eyes are not a source of light. Now, if the observer's eye is artificially made the source of light, and if he looks in the same direction as that in which the luminous rays enter the observed eye—as, for instance, through the sight-hole of a mirror—illumination renders the interior of the eye visible. This is the fundamental principle of the ophthalmoscope, and it was first explained and made practical by Helmholtz in 1851.

Description.—The simplest form of ophthalmoscope is a mirror with a hole in the center, which is held close to the patient's eye in such a manner as to reflect light from a luminous point near by into it, illuminating the interior of the eye, and revealing the details of the fundus. The ophthalmoscopes in use to-day are of more intricate mechanism, and render the examination much easier and more satisfactory. The mirror most used in this country is small, concave, oblong or round in shape, with a central aperture of from 2 to 4 mm. in diameter, and so arranged that it can be tilted or rotated from side to side, thus saving the trouble of inclining the whole instrument to reflect the light properly. By means of various ingenious appliances, a series of lenses are incorporated with the instrument in such a manner that, by turning a wheel with the finger, the convex or concave lens of the strength desired can be brought before the sight-hole in the mirror. By arranging the lenses so that they can be combined, the range may be extended from a fraction of a diopter to a lens of as high power as is ever required. The large mirrors are more useful in the indirect method, in retinoscopy, and for illuminating a large surface of the eye. In the direct method a very small mirror is as good or better than a large one. A small sight-hole gives a more distinct image, and does not necessitate so much accommodation or optic aid in examining slightly ametropic eyes. The large sight-hole is better for the accurate estimation of refraction. As the direct method is more generally employed, and refraction is not ordinarily estimated by ophthalmoscopy, and retinoscopy is usually performed with a special plane retinoscopic mirror, for all practical purposes it is better to use a small mirror with a small sight-hole.

There are many forms of ophthalmoscopes, for all of which some advantage is claimed. The model of Loring is cheap, and answers all practical purposes, but it is awkward to use, and necessitates removal from the eye and a combination of lenses to secure the higher powers. More expensive and, at the same time, more convenient are the models of Morton, Harlan, Gould, Pyle, and others.

Use of the Ophthalmoscope.—The ophthalmoscope may be used in 2 ways—by the direct and indirect methods.

Direct Method.—The patient is placed in front of the source of illumination, and to the side of the eye to be examined, the light behind him so that it shines on his temple, just touching the tips of the outer lashes. He is then told to look straight ahead to an object on a level with his eyes across the room. To examine the patient's right eye, the surgeon sits or stands, and holds his ophthalmoscope in his right hand before his own right eye.



Morton's Ophthalmoscope.

To examine the patient's left eye, he places himself to the left of the patient and holds the ophthalmoscope in his left hand before his own left eye. The ophthalmoscope is brought close to the eye under examination, the mirror of the ophthalmoscope having been inclined, and the instrument held in such position that the light from the source of illumination will be reflected directly into the patient's pupil; then, if the media are clear, a red glare, called the **fundus reflex,** is seen through the hole in the mirror. If the examiner wears glasses, he need not remove them; in fact,

if he is astigmatic, he had better accustom himself to working with his correcting lenses on.

Examination of the Media.—The reaction and form of the pupil are noticed. If a foreign body or opacity is present in the pupillary area, it appears as a dark spot on a red background. A slight corneal opacity appears only as a mere shadow. It must be remembered that spots on the cornea and lens always maintain their same relative position and are immovable, while opacities in the vitreous are usually freely movable, and can be diagnosed by their change of position as the patient turns the eye quickly in various directions and then looks straight forward. To **locate corneal or lenticular opacities,** in addition to focal illumination advantage is taken of the phenomenon of **parallactic displacement,** which is governed by the rule that opacities lying in front of the pupil move in the same direction as the patient's eye, while opacities behind the pupil move in the opposite direction to the patient's eye, and the extent of this apparent movement enables one approximatley to determine the distance of the opacity either in front or behind the pupillary plane. After having observed any anomaly of the pupil or media at a distance of from 12 to 16 inches, a strong convex lens (10 D. to 16 D., according to its location) is then wheeled before the sight-hole of the ophthalmoscope, which allows the observer to approach closer to the patient's eye, and greatly magnifies the conditions present.

Direct Method.

Examination of the Fundus.—If the media are clear, the surgeon approaches close to the patient's eye, and at once the details of the eye-ground become visible. The refractive media of the eye magnify the details of the fundus about 14 times, and by this fortunate circumstance the minute details of the eye-ground are plainly visible. Probably the first distinct object will be a retinal vessel which can be easily traced to the most prominent part of the fundus, the **optic disc.** At this point a bright whitish or pinkish reflex is seen, standing out in sharp distinction to the surrounding red fundus. By adjusting the proper lens before the sight-hole in the mirror the outlines of the disc may be brought sharply into view. The average size of the normal disc, as seen by the direct method, is nearly that of a 25-cent piece or a shilling, while to the naked eye it measures only 1.5 mm. Emerging from the disc is seen the central retinal artery and vein, dividing into inferior and superior branches. The veins may readily be distinguished from the arteries by their darker color and their size—about one-fourth larger. Pulsation of the veins is observed under normal circumstances, while pulsation of the arteries indicates a pathologic condition—either rise of intraocular tension or decrease of blood-pressure. Reflexes consisting of bright lines in the middle of the blood-vessels are seen. Frequently a depression may be seen in the disc called the **physiologic cupping,** caused by the branching of the internal fibers of the optic nerve at a lower level than the more external ones. This is white, with a surrounding zone of pink. **Pathologic cupping** includes the whole of the disc, and is characteristic of glaucoma. The form, the size, the color, and other appearances of the disc must be further studied. At the external border of the disc is often seen a black, circular *pigment ring,* bounding the opening in the choroid through which the optic nerve enters. To the outer side of this is the *white scleral ring,* which is not always distinctly circular. A white conus, or even a crescent, may be seen at the edge of the disc if there is choroidal atrophy. In high myopia this condition is noticeable. If there is distinct sign of cupping, the extent may be approximately estimated by the refractive conditions of 2 points lying at different elevations. The difference in diopters in the lenses required to distinctly focus the 2 points multiplied by 0.35 of a mm. will give the difference in depth. It is usual to select one point at the bottom of the cup, and the other near the surface.

The parallax test is based on the fact that in the indirect method, while the whole fundus seems to move along with the lateral movements of the convex lens, the floor of the excavation apparently moves in the same direction, but at a slower rate. This parallax is more marked the deeper the excavation.

The general aspect of the eye-ground is then studied, and any abnormalities in the retina, choroid, or sclera should be noted. If there is absence or deficiency of pigment between the retina and choroid, the larger choroidal vessels are seen through it, and the eye-ground is streaked with well-defined interspaces. At any portion of the fundus in which both the retina and choroid are lacking, the white, glistening sclera is seen shining through. To examine the **macular region** the patient is told to look into the light coming from the mirror, or, better, beyond it in the same direction, which movement of the eye generally brings the macula into view. This appears as a dark spot isolated in the fundus, with a small, bright spot in the center, called the *fovea centralis.* There are usually no vessels to be seen in this vicinity. The macular region should always be studied carefully, as any lesion or hemorrhage in this location has an important bearing on the vision of the patient.

Refraction by the ophthalmoscope is usually accomplished by the direct method. Refraction of the macular region is desirable, but as the intense

dazzling produced by light makes it almost impossible, the disc is usually the objective point selected. The observer first corrects his own ametropia, and as much as possible relaxes his accommodation. It is this inability to regulate the relaxation of accommodation that makes this test unreliable in simple errors of refraction, and in the lower degree of astigmatism it is comparatively worthless even in the most skilful hands. The retinoscope is a more important and more scientific instrument for the objective method of refraction. Having relaxed the accommodation and corrected his own error, the surgeon moves before the eye the lens which gives him the best outlines of the disc, and subtracts his own correcting lens from the result. In cases of astigmatism the disc is usually oval, its long diameter corresponding to the axis of astigmatism. Two vessels at right angles to each other in the principal meridians are refracted separately, and the results noted. Glasses should not be prescribed from the ophthalmoscopic refraction alone.

Indirect Method.—The indirect method is less valuable than the direct. The image is inverted and less magnified (3 or 4 diameters), but one is able to see a larger part of the fundus at a glance and is not compelled to approach so near the patient's face. It also enables the surgeon to intensify his illumination in cases of very small pupil or of cloudy media. In this country the indirect method is being less and less used. The method of procedure is usually the same as in the direct method, except that the surgeon keeps his eye a foot or more away from the patient's face and holds in front of the patient's eye a strong convex lens. However, the surgeon need use but one eye, and may stand directly in front of the patient. The lens is usually held at such a distance from the eye that the iris just disappears from view; a plus spheric 4 D. lens may be held before the opening in the mirror to enlarge the image and to replace the observer's strain of accommodation. By directing the light from the mirror through the lens into the eye, an inverted aerial image is formed in front of the lens, and it is this image that the surgeon sees. In high degrees of myopia it is easy to examine the inverted aerial image without a convex lens.

Indirect Method.

The satisfactory use of the ophthalmoscope, both in examining the fundus and approximately estimating the kind and degree of ametropia, can only be obtained after considerable practice. A normal fundus in both a light-complexioned and dark-complexioned person should be repeatedly studied, as abnormal conditions are not recognized until one is thoroughly familiar with the normal healthy fundus.

OPISTHOTONOS.—A tetanic condition of the muscles, particularly of the back, whereby there is an arching backward of the trunk, which may rest upon the head and heels. The condition is seen in poisoning from strychnin, in tetanus, hydrophobia, hysteria, and other tetanic conditions. In rare instances the muscles in front of the spine are affected, when **emprosthotonos** is the term used to describe the condition, the patient's body being arched forward. **Pleurothotonos** is the term used when the body is bent to one side or the other.

OPIUM.—The inspissated juice of the unripe capsules of the *Papaver somniferum*, or poppy, obtained by incising the capsules and collecting the milky juice which is exuded. Most of the opium in the American market comes from Smyrna, Asia Minor. Opium is a very complex substance, and contains, besides morphin and codein, a large number of less important alkaloids—narcein, narcotin, thebain, laudanin, papaverin, cryptopin, and meconin, opianin, paramorphin, and meconic, thebolactic, and sulphuric acids, in addition to a variety of extractives. Good opium should yield at least 9 percent of morphin. The dominant physiologic action of opium is the relief of pain. It also causes slowing of the respiration and pulse, contraction of the pupils, diaphoresis, and constipation; more rarely, nausea and vomiting, headache, itching of the skin, erythema; occasionally, instead of sleep, wakefulness, delirium, even convulsions.

Therapeutics.—The chief indications for the use of opium are: (1) To relieve pain from any cause except acute inflammation of the brain; (2) to produce sleep, particularly in the insomnia of low fevers with delirium, in which the combination of morphin and chloral is very efficient; (3) to allay irritation in the various forms of acute nervous erethism; (4) to check excessive secretion, as in diarrheas, dysentery, diabetes, ptyalism, etc.; (5) to support the system in low fevers and other adynamic conditions, when sufficient food cannot be retained; (6) as a sudorific, to produce sweating in coryza, etc. It is considered of especial value in any irritation of the stomach, bladder, or bronchi, in severe vomiting, both forms of diabetes, gastralgia, colic, and muscular spasm.

Superficial pain is often alleviated by the plaster or by liniments containing laudanum or some other fluid preparation. The oleate of morphin is said to be very penetrating.

Intense pain, as from the passage of calculi, is best met by the hypodermic injection of morphin sulphate in full doses (1/4 to 1/2 of a grain) with atropin sulphate (1/100 of a grain). Either the solution of morphin or the liquid preparations of opium may be given by the mouth in corresponding doses for the same purpose.

Sedative action is obtained by different preparations for different organs. The stomach is best affected by the solution of morphin in effervescing solution. The intestines may be influenced by laudanum in a starch enema, or internally by Dover's powder, powdered opium, or the pill of opium, especially the latter, with or without calomel, as an astringent when the bowel must be paralyzed, as in peritonitis, hernia, intussusception, etc. The rectum and other pelvic organs are promptly affected by a suppository of the extract of opium, 1/4 of a grain, with 1/12 of a grain of the extract of belladonna. The ovaries and the abdominal and pelvic organs generally are markedly susceptible to the analgesic action of codein in doses of 1 to 2 grains for an adult in severe pain.

To produce sleep, the most efficient preparations are the tinctures, the solution of morphin, pill of opium, and Dover's powder, in doses corresponding to the degree of insomnia and restlessness present.

Cough is relieved by the troches, the tinctures, and by the solution of morphin in small doses with the syrup of wild cherry or syrup of tolu; also by codein in the last-named syrup.

Diaphoresis is obtained by the use of Dover's powder in either of its forms.

Children bear opium badly, and for them its proportionate dosage should be much smaller than for other agents. Morphin should not be given to children less than 10 years of age, and never hypodermically to those under the age of 15. Opium given to a nursing mother will effect the child, being partly excreted in the milk.

Poisoning.—In a child 1 day old 1 minim of laudanum has caused death. A medicinal dose given to a nursing mother proved fatal to the infant. A few drops of paregoric have killed a child of 9 months. In the adult 1/6 of a grain of morphin in one case, and 4 grains of crude opium in another, have proved fatal.

A toxic dose produces at first restlessness, increased mental activity with a feeling of exhilaration, cardiac stimulation and flushed face. Then follows the stage of stupor, when the patient feels drowsy, and falls into a deep sleep. The pulse is slow and full; respirations are slow and labored; pupils are contracted ("pin-point"); the skin is warm and dry. During this stage, the patient can be aroused, but quickly goes to sleep again. The patient passes insensibly into the third stage in which coma is absolute, and which is characterized by cyanosis; respirations feeble and irregular; muscular relaxation; pulse weak and rapid; relaxed, cold, clammy skin; the pupils dilate just before death which occurs from paralysis of the respiratory center due to direct action on the medulla. Postmortem shows only congestion of the brain, congested lungs, and engorgement of the venous trunks and of the right heart.

The coma produced by opium-narcosis, when deep and when a history of the case cannot be obtained, is almost impossible of differential diagnosis from that due to alcohol, apoplexy, uremia, epilepsy, etc. The odor of breath may point to laudanum or some other preparation of opium. The pupils are very much contracted in opium poisoning. See COMA.

Treatment.—Potassium permanganate is the best antidote to opium or morphin in the stomach, given in dose about one-half greater than the quantity of morphin present, and repeated in less quantity from time to time in cases where the poison has been administered hypodermically, so as to neutralize the morphin excreted by the gastric mucous membrane. If an opium preparation has been taken, or the alkaloid morphin itself, vinegar should be added to the permanganate solution. Atropin antagonizes the cerebral action of morphin, also its action on the pupils, respiration, heart, and arterial tension; but if given too freely, it will endanger the case by substituting belladonna-narcosis for opium-narcosis; 1/120 of a grain hypodermically every 15 minutes for 3 doses is generally sufficient. It is unsafe to be guided in this respect by the pupils. Caffein is also physiologically antagonistic, and is generally used in the form of strong black coffee, frequently administered.

The chief indications in opium- or morphin-poisoning are to antidote any of the poison in the stomach and to wash out that viscus repeatedly at short intervals; to maintain respiration and keep up the circulation; and to prevent sleep by noises, flagellation, or electricity. Strychnin is an efficient antagonist to the respiratory paralysis, and may be used in lieu of atropin, or in connection therewith. Amyl nitrite should also be used when the heart shows signs of failure. Capsicum, the tincture, 1/2 to 1 ounce, by injection into the rectum, is said to give almost instantaneous results in antagonizing the stupor of opium-poisoning. For further directions, see under POISONING.

Preparations.—**O. Acetum** (*black drop*), opium-strength 10 percent, with nutmeg and sugar in dilute acetic acid. Is now 1/3 weaker than formerly, having the same strength and dose as tincture of opium. **O. Deodoratum** (*denarcotized opium*) is powdered opium free from narcotin and the odorous principles, which are supposed to cause the unpleasant after-effects of the drug. It should yield 12 to 12 1/2 percent of morphin, and is a good preparation, being a purified opium with a fixed morphin standard. The proprietary article named *Svapnia* is a similar preparation. Dose, 1/2 to 3 grains. **O. Emplastrum**—contains of extract of opium 6 parts, adhesive plaster to 100. **O. Extractum,** an aqueous extract containing 20 percent of morphin, and freed from principles insoluble in water. Dose, 1/4 to 2 grains. **O. Granulatum,** opium dried and reduced to a coarse powder. It should yield from 12 to 12 1/2 percent of morphin. Dose, 1/2 to 3 grains. **O. Pilulæ,** each pill contains about 1 grain of powdered opium incorporated with soap. Dose, 1 to 3 pills. **O. Pulvis**—opium dried at a temperature not exceeding 185° F., and reduced to a very fine powder. It should contain not less than 12 nor more than 12 1/2 percent of crystallized morphin, when assayed by the official process. Dose, 1/2 to 3 grains. **Pulvis Ipecacuanhæ et Opii** (*Dover's*

powder)—has of ipecac 10, powdered opium 10, sugar of milk 80, rubbed together into a very fine powder. Dose, 5 to 15 grains. **O. Tinctura,** *laudanum*, opium-strength 10 percent, or 48 grains to the ounce. Morphin-strength about 6 grains (equal to 7 1/2 grains of morphin sulphate) to the ounce. Ten minims equal 1 grain of opium or 1/8 grain of morphin. Sixty minims equal on the average about 120 drops. Dose, 5 to 30 minims, according to the effect desired. **O. Tinctura Camphorata,** *paregoric*, has of powdered opium 4, benzoic acid 4, camphor 4, oil of anise 4, glycerin 40, diluted alcohol to 1000. Half an ounce contains nearly 1 grain of powdered opium. It is about 1/20 of the strength of laudanum. Dose, for an infant 5 to 20 drops; for an adult 1 to 4 drams. It is an ingredient of mistura glycyrrhizæ composita. **O. Tinctura Deodorati,** an excellent liquid preparation, being freed from all the noxious and useless ingredients soluble in alcohol and ether. Opium-strength 10 percent, average morphin-strength 6 grains to the ounce. Dose, as of tincture of opium. Drops of this preparation nearly equal minims. *McMunn's elixir* is a similar preparation, so also is another proprietary nostrum named *papine*. **Tinctura Ipecacuanhæ et Opii,** has of tincture of deodorized opium 100 evaporated to 80, fluidextract of ipecac 10, diluted alcohol to 100. Is intended to represent Dover's powder in liquid form. Dose, 5 to 15 minims. **Trochisci Glycyrrhizæ et Opii,** each troche contains of powdered opium 1/12 of a grain, with extract of glycyrrhiza, acacia, sugar and oil of anise. Dose, 1 to 4 troches. **O. Vinum** (*Sydenham's laudanum*), opium-strength 10 percent, with the aromatics cinnamon and cloves of each 1 percent, in alcohol and white wine. A vinous tincture decreased somewhat in strength from the wine of 1870. Dose, as of tincture of opium. Drops of this preparation are larger than those of the tincture. See Morphin; Antinarcotic Legislation; Harrison Law.

OPIUM HABIT.—An irresistible craving for opium or its alkaloid, morphin. It is most frequently acquired as the result of long-continued administration of morphin, to relieve some suffering caused by a painful or incurable malady, or for insomnia. Heredity and a neurotic tendency are predisposing factors. Alcoholics often become morphin fiends. The chief symptom is the craving for the drug. Among other symptoms are irresolution, loss of self-control, moral obliquity, and untruthfulness. Epigastric pain or nausea, or both, are frequently complained of toward the time when another dose is due, though whether this is actual or feigned is not always easily determined. Mental depression is a more constant and characteristic symptom, associated with insomnia, intense anxiety, restlessness, and a sense of impending evil, all relieved for a time by the dose. Diarrhea rather than constipation is not infrequent.

Treatment.—Successful treatment is scarcely possible outside an institution, and even within one serious difficulties beset the way, chief of which is the deception practised by the patient. Patients should be divested of their own clothing and put to bed in hospital garb, because in this way alone can we be sure that morphin is not concealed about the person. In the case of women, whenever possible, a separate nurse should be assigned to each case. The latest testimony favors complete and sudden withdrawal of the drug as furnishing a short struggle, though a severe one. Such treatment is usually followed by diarrhea, vomiting, and insomnia. Some counsel even that no adjuncts should be employed, but certainly there can be no harm in the employment of general tonic treatment and remedies directed to the irritability of the stomach and torpor of the liver. A calomel purge is useful at the start. It is a well-established fact that, as in alcoholism, the patient should be well nourished, given such food as milk, cream, beef-juice, or beef peptonoids, rich broths, and beef-teas. When there is great asthenia, aromatic spirit of ammonia, strychnin, and digitalis may be given as directed under Alcoholism (*q. v.*). If possible, an occupation of an absorbing kind should be furnished. In most cases it is impossible to secure the consent of the patient to sudden and complete withdrawal, when the gradual plan must be adopted. The success of either plan depends on securing effectual control of the patient, and if this cannot be obtained, all efforts fail (Tyson).

Chloralamid is probably the best hypnotic. It is not easy of administration, because of pungent taste and difficult solubility. Ten or twenty grains are a moderate dose, and are easily soluble in a fluidram of a mixture of 2 parts alcohol and 1 part glycerin. Of this solution 2 teaspoonfuls should be given in a glass of sherry wine or 4 tablespoonfuls of milk at the ordinary temperature. Trional and sulphonal or somnal may be given in 15- to 20-grain doses dissolved in hot water. Hyoscin in doses of 1/96 of a grain may also be tried. Chloral itself may be used in doses of from 10 to 30 grains. If there is cardiac weakness, the dose should not exceed 10 grains. Chloralose may be given in 5-grain doses in wafers or in hot milk. See Lambert Treatment for Narcotic Addiction.

OPOTHERAPY.—See Organotherapy.

OPSONINS. OPSONIC INDEX.—See Serum Therapy and Vaccine Therapy.

OPTIC NERVE ATROPHY. Causes.—The vast majority of cases are postneuritic—that is, following some inflammation of the optic nerve. Most cases are due to some disease of the brain or spinal cord, especially of syphilitic origin. Of the cerebral diseases might be mentioned disseminated sclerosis, progressive paralysis, and general paralysis; of the diseases of the spinal cord, locomotor ataxia is a prominent cause. Mechanic pressure from tumors, traumatism, embolus in the central artery, cutting off the blood supply, and the toxic agents, causing retrobulbar neuritis, lead to optic atrophy. Blindness, or amblyopia following severe hemorrhages, is supposed to be due to atrophy of the optic nerve. Sexual abuse, "catching cold," physical and mental excesses, have all been set down as causes.

Symptoms and Diagnosis.—The patient notices an early disturbance of vision, consisting of diminution of the central acuity, concentric contraction

of the visual field, both for white and colors, and irregular scotomas. There is no pain, and seldom photophobia. Of the colors, green is first lost, and blue last; light-sense is longest retained. The ophthalmoscopic appearances vary with the cause. If the atrophy is subsequent to papillitis, the disc is increased in size, and there is more or less obliteration of its outline and distention of the veins. In simple atrophy instead of the rosy, healthy hue of the normal disc, the papilla may be grayish-blue or quite white. The outlines have a striking sharpness, which give the shining disc its characteristic appearance. The disc appears sunken and excavated, and allows the network of the lamina cribrosa to be seen through the spaces left open by the disappearance of the nerve-fibers. The vessels diminish in size, and the capillaries of the papilla are no longer visible.

Prognosis is serious. The probability of retaining the vision yet left is small, and the result is usually total blindness.

Treatment should be directed to the cause; constant, increasing doses of strychnin should be given, orally or hypodermically, and the continuous electric current should be applied until it is found to be of no avail. Good results have recently been reported from the combined use of mercuric chlorid and nitroglycerin.

OPTIC NEURITIS. Synonyms.—Choked disc, papillitis, neuroretinitis. **Choked disc** is so called on account of the interference of return of blood through retinal veins by pressure from swelling at this point. **Papillitis** generally describes an inflammation limited to the intraocular head of the optic nerve, although in all probability, in the majority of cases, the nerve is affected throughout its entire length. There is less swelling than in choked disc, the visual disturbance appears earlier, and the disease leads to atrophy and blindness more frequently than does choked disc. **Neuroretinitis** and **papilloretinitis** are terms used to describe an inflammation which involves the retina as well as the optic nerve. It is characterized by hemorrhages, patches of fatty degeneration that appear as white spots, deposition of pigment, etc., similar to the changes in albuminuric retinitis.

Causes.—The condition often called choked disc may be due to traumatism, but is usually the result of a brain tumor, and is commonly bilateral. Tumors of the cerebellum and those at the base of the brain pressing upon the sinuses are most likely to be followed by choked disc. Some form of optic neuritis is said to accompany 90 percent of all cases of brain tumor. If unilateral, the disease is probably caused by a tumor in the orbit. Other intracranial diseases causing inflammation of the optic nerve are: Tuberculous basilar meningitis of children, epidemic cerebrospinal meningitis—in fact, meningitis from other infectious diseases or from any suppurative origin. Infectious diseases, syphilis, lead-poisoning, and other systemic affections may directly cause optic neuritis. Tumors or diseases of the orbit may have the same effect. Traumatism and inflammation of surrounding tissues are also causes.

Pathologic Anatomy.—Cerebral tumors interfere with the circulation and distribution of subarachnoid fluid in the lymph-spaces. The sheath of the optic nerve becomes much swollen and pyriform. It is supposed that the bacilli of the causative meningitis act directly upon the nerve-head.

The line of distinction between retinitis and neuroretinitis is so slight that we can probably associate closely the causes of the former with those of the latter; however, in albuminuric neuroretinitis the greatest changes are in the retina rather than in the nerve-head, and the urinary tests are quite indicative. Cases of inflammation of the optic nerve in which the cause is unknown are sometimes seen. Occasionally, several members of a family—the males particularly—and of apparently healthy parents, are attacked between the eighteenth and twenty-fourth years by a bilateral optic neuritis. In other cases, "catching cold," suppression of the menses, lactation, etc., are given as causes. In such cases there must be a suspicion that there was latent inflammation which became prominent under the conditions mentioned, and was not directly due to them.

Symptoms and Diagnosis.—The systemic condition is often simultaneously affected. The principal ocular symptom is impairment of vision, gradually passing into total blindness. In the early stages of choked disc vision is not markedly impaired. Particularly typical are diminution of central visual acuity, unsymmetric contraction of the visual field, and impaired color-sense. The ophthalmoscopic appearance of choked disc is a swelling and opacity in the disc and its immediate neighborhood. That the papilla is larger than normal and projects into the vitreous may be proved by the parallax test. The papilla, while undergoing inflammation, has what has been called a woolly appearance, together with swelling and congestion. The same vessels of the disc are dilated, so that many of them are visible, unless masked by excessive edema. There may be numerous capillary hemorrhages in the nerve-head. The retinal arteries are diminished in size, and the veins are swollen and tortuous. The edges of the disc are lost, and a striated flame-like or grayish haziness spreads over the disc into the adjoining retina, nearly equal on all sides. In severe forms there are diffuse retinal hemorrhages and, perhaps, macular changes resembling albuminuric retinitis. In addition to the presence of choked disc, the discovery of hemianopsia and the use of Wernicke's sign will aid in the diagnosis of cerebral growth.

In the interstitial or descending neuritis the disc is not swollen as in choked disc; it is dull and edematous looking. Vision is usually more and sooner affected, owing to the greater length of nerve structure involved.

Prognosis.—The course is usually chronic, finally ending in optic nerve atrophy. Of course, the prognosis is affected by the cause. Cerebral tumors are usually fatal in a short time. The various forms of meningitis are always serious. Restoration of vision is doubtful; there is little hope of regaining lost visual power. However, cures, with restoration of normal visual acuity,

and cures of amblyopia of every degree, have been reported.

Treatment is naturally directed to the cause. If the cerebral tumor can be located, surgical interference may be of value. A syphilitic gumma will yield to mercury and potassium iodid. If no cause is discernible, diaphoresis, the mercurials and iodids, and tonics may be tried. Blood-letting from the temporal region has been reported of value. Possibly mild cases recover spontaneously. If there is reason to suspect that the neuritis is orbital in origin, systemic treatment will prove of little value; and in well-defined malignant orbital disease immediate enucleation is imperative.

OPTIC NEURITIS, RETROBULBAR.—Inflammation of the optic nerve beyond the eyeball, in which the disc is not involved at first, papillitis arising in the advanced stage.

Causes.—Acute retrobulbar neuritis is caused by exposure to cold, acute infectious diseases, sudden cessation of the menses, and any condition which leads to a sudden exudation into the sheath of the optic nerve. The most common cause of the chronic form is excessive use of tobacco and alcohol, although lead-poisoning, syphilis, quinin, and other toxic agents may produce it. As a rule, both tobacco and alcohol are simultaneously used to excess, and act conjointly. The disease is often called *tobacco* or *alcohol amblyopia*, or *toxic* or *intoxication amblyopia*, although many authors distinguish between intoxication amblyopia and retrobulbar neuritis from other causes. It has recently been suggested that the central amblyopia is due to primary rather than to secondary macular disease—that is, that the disease starts in the macula and ascends the central fibers of the optic nerve.

Symptoms.—In the acute disease total blindness results in a few days, and there is often pain in the eye, increased by movement or pressure. The ophthalmoscope reveals a papillitis of moderate severity. In the more common chronic disease the chief symptom is slowly diminishing central vision. The patient complains that he sees indistinctly, especially in bright light, and that his vision improves at sundown. This is explained by the dilatation of the pupil as day light fades, and consequent stimulation of the unaffected perimacular region by the increased illumination. Examination with the perimeter shows a central scotoma, at first for color, and finally for light. At the onset the field of vision remains nearly normal, and only begins to be obliterated when fixation becomes impossible, and nystagmus results. With the ophthalmoscope there is first seen slight hyperemia of the disc, and later a grayish-white discoloration of the temporal halves of the papillæ. The outlines are obscured, the veins are enlarged, and the arteries are diminished in size.

Prognosis may be considered favorable if the disease has not progressed to atrophy, and if the patient can be made to stop drinking and smoking; but relapses are likely to occur whenever the abstinence is suspended.

Treatment.—In the acute form general blood-letting, active diaphoresis, and other antiphlogistic measures are indicated. In chronic cases abstinence from tobacco and alcohol must be enforced, and strychnin administered in increasing doses. If syphilitic, the disease yields to the mercurials and iodids. Any other discoverable cause should be treated according to the indications.

OPTOCHIN.—This is ethyl-hydrocuprein, and is a derivative of quinin. It is used in pneumococcus infections, chiefly of the conjunctiva.

ORANGE.—See Aurantium.

ORBIT, DISEASES.—**Periostitis** is an inflammation of the periosteal lining of the orbit, particularly prevalent in scrofulous and syphilitic patients. The inflammation may be so extensive as to involve the frontal sinuses and produce necrosis of the underlying bones. A blow or a fall is usually the exciting cause.

The symptoms are dull pain, swelling and edema of the skin surrounding the orbital edge, and, if necrosis has taken place, a fistula discharging foul pus and bony débris. Cicatrization of the fistula may lead to ectropion. The eyeball is rarely involved.

Treatment consists of leeches to the temple, cold compresses, and, if the patient is syphilitic, the administration of mercurials and iodids. If the disease reaches a suppurative stage, antiseptic poultices, incision, and drainage are indicated.

Orbital cellulitis, or inflammation of the connective tissue of the orbit, is due to periostitis or to any suppurative or inflammatory process in the vicinity of the eye; even inflammation about the roots of the teeth may cause it. Erysipelas, anthrax, and pyemia may result in metastatic orbital abscess; and, finally, infection after injury to the orbit or its contents is a cause.

The symptoms are pain, fever, general prostration, swelling and redness of the lids, edema and increased tension of the conjunctiva and lids, exophthalmos, fixation of the eyeball in a straight or deviating position, causing visual disturbance, and, after the pus escapes, a discharge from the orbit. In unfavorable cases panophthalmitis may ensue. Metastatic abscesses generally lead to death. Extension into the cranium is always to be feared.

Treatment consists in prompt incision—preferably at a spot showing signs of pointing—drainage, and antiseptic irrigation.

Injuries to the orbit may cause fracture of the bony wall or laceration of the soft parts. Foreign bodies may be received and retained in the orbit for varying periods of time. They may escape into the nasal cavities, or they may cause orbital inflammation, and even death. Luxation of the globe is generally produced by a wedge-shaped foreign body crowding between the eyeball and the orbit. Formerly, what was called "gouging" was resorted to by contestants in brutal fights, the object being to dislocate the eyeball from its socket with the point of the thumb. The danger is blindness from laceration or overstretching of the optic nerve.

Fracture of the orbit may be detected by palpation. If the neighboring sinuses are opened, there will be much emphysema about the lids, made

worse by blowing the nose. There is late appearance (2 or 3 days) of extravasation and ecchymosis of the lids. If the optic foramen is involved, there is, sooner or later, blindness from pressure or injury of the optic nerve. When fracture of the orbit produces enough hemorrhage to cause exophthalmos, the prognosis is grave.

Treatment.—After orbital injuries the affected parts should be thoroughly disinfected and foreign bodies removed. The proximity of the brain to the orbit renders the prognosis doubtful in extensive fractures or infected wounds. Rest and cooling compresses are indicated. In luxation vision may be lost through stretching of the optic nerve, but may return after reposition of the eyeball and retention with a pressure-bandage. If the lids are closed tightly behind the globe, preventing replacement, the external canthus should be divided at once. The longer the eyeball is dislocated, the worse the effect upon vision.

Tumors of the orbit cause exophthalmos in the direction of pressure. The other symptoms are disturbance of motility and vision and pain, all of which vary according to the size and malignancy of the tumor. The chief tumors are osteoma and encephalocele of the orbital wall; tumors of the optic nerve; and sarcoma, cysts, and vascular tumors arising in the neighboring cellular tissue. A genuine orbital sarcoma is extremely rare, and carcinoma never originates in the orbit proper. All orbital tumors of any considerable size or malignancy should be removed after enucleation of the eye. There is little hope of cure of encephalocele.

ORCHITIC EXTRACT.—See TESTICULAR EXTRACT.

ORCHITIS.—See TESTICLE (Inflammation).

ORGANOTHERAPY.—The treatment of diseases by the administration of animal organs, or extracts prepared from them. Although organotherapy has existed in some form since the most ancient times, the method as now practised is of recent origin. Brown-Séquard, in 1889, suggested the employment of testicular juice in the treatment of the mental and physical deterioration incident to old age. Experiments which he had made upon himself had, he reported, yielded the most brilliant results. Physicians in different parts of France subsequently tested the properties of Brown-Séquard's extract, and found its dynamogenic action beneficial in diseases attended with debility, especially in senile changes, in pulmonary tuberculosis, leprosy, locomotor ataxia, general paralysis, and anemia. Paul, in 1892, under the name of "nervous transfusion," advocated the hypodermic use of an extract of sheep's brains in conditions of neurasthenia. The method of preparation of the various extracts as employed in France is that suggested by d'Arsonval. The organ is removed, with all possible antiseptic precautions, and is cut into small pieces of about 1 c.c. The segments are covered with pure glycerin and allowed to macerate for 24 hours. Before filtering, 2 or 3 parts of distilled water are added. Sterilization is accomplished by means of carbonic acid gas under pressure. The first step toward a rational application of the method of organotherapy was the subcutaneous transplantation of pieces of thyroid gland in cases of myxedema and cachexia strumipriva by Horsley and Kocher, and later the employment of extract of sheep's thyroid in myxedema, the credit of which belongs to G. R. Murray, of Newcastle, England. Since Murray's announcement, in 1891, the method has been extensively tested in England and elsewhere; many cases of myxedema have been reported as improved, and not a few cured. Gratifying results have also been achieved in sporadic cretinism, and in psoriasis and other chronic affections of the skin. Various preparations of the thyroid gland have been employed—*e. g.*, glycerin extracts, dry extracts in powder, and, finally, the uncooked or partially cooked gland has been used. In the particular case of myxedema neither the kind of preparation nor the mode of administration seems to be of much importance. The results have been practically the same whether a liquid extract was given by hypodermic injection, or a dry extract was administered by the mouth. The fresh gland, slightly fried and seasoned, has also been used, and at present is preferred by many. The success attending thyroid therapy in myxedema has led to the employment of many other organic extracts in diseases of corresponding organs. Extracts have been prepared from nearly every organ in the animal body; thus there are on the market: *Cerebrin*, from the brain; *medullin* or *myelin*, from the cord; *cardin*, from the heart; *musculin*, from muscles; *ossin*, from bones; *renin*, from the kidneys; *gastrin*, from the stomach; *pancreatin*, from the pancreas; *ovarin*, from the ovary, and *testin*, from the testis. Pituitary extract has sometimes proved beneficial in acromegaly. Splenic extract has been used with some success in exophthalmic goiter, and in insanity due to physical exhaustion. Thymus extract appears beneficial in leukocythemia, chlorosis, anemia, pernicious anemia, "status thymicus." Brain-extract has been reported as beneficial in various organic and functional diseases of the nervous system, such as locomotor ataxia, bulbar palsy, general paralysis of the insane; also in epilepsy, neurasthenia, migraine, hysteria, hebephrenia, and other conditions. Heart-extract is recommended for cases of nervous prostration. It is said to raise the blood-pressure, augment the quantity of urine, and increase the number of red blood-corpuscles. In diseases of the muscular system muscle-extract is also reported as of value. Extract of pancreas, containing the active ferments of the gland, has been administered with doubtful success in certain cases of diabetes mellitus, which disease, as is well known, is sometimes dependent upon morbid changes in the pancreas. Of all the extracts, that of the thyroid gland is still the one most successfully employed. Its use is not confined to the two diseases mentioned—myxedema and cretinism; it seems to be an efficient galactagog and is useful in promoting consolidation of obstinate fractures; it has also proved useful in diseases of the skin, in leukemia, and affections of the nervous system, both organic and functional,

endometritis, menorrhagia, uterine fibroma and carcinoma, lupus, ozena, obstinate leg ulcers, progressive myopathy, simple goiter; in exophthalmic goiter, and diabetes mellitus and cases presenting much emaciation it is contraindicated. See THYROID TREATMENT.

ORPHOL.—Bismuth beta-naphtholate. An intestinal antiseptic. Dose, 5 to 20 grains in honey or milk. See BISMUTH.

ORRHOTHERAPY.—See SERUM THERAPY.

ORTHOFORM.—It has no chemical relation to cocain which it resembles only in its action on the sensory nerve terminations. It occurs as a white, crystalline, odorless and tasteless powder, almost insoluble in water. It is efficient as a local anesthetic only when it comes in contact with exposed sensory nerves, and has been used chiefly as a dusting powder or ointment for painful abrasions, ulcers or burns. Applied in powder to raw surfaces, as burns, and excoriated nipples, it has frequently produced local gangrene. Internally it has been given in doses of 8 to 15 grains for the pain of gastric ulcer and cancer. It does not relieve the pain of simple gastralgia, and hence it has been employed as a test for gastric ulcer. A saturated solution in collodion may be used as a paint, and an emulsion in glycerin is employed during operations within the uterus. The hydrochlorid is more soluble in water and may be used for internal administration or urethral injection, but is too acid for hypodermic injection or eye application. Its *incompatibles* are antipyrin, bismuth subnitrate, and silver nitrate.

ORTHOPEDIC SURGERY.—See GENU, HIP-JOINT DISEASE, TALIPES, etc.

OSLER'S DISEASE.—See ERYTHREMIA.

OSMIDROSIS.—See BROMIDROSIS; SWEAT-GLAND.

OSMIUM TETROXID (Osmic Acid).—Obtained by the action of nitrohydrochloric acid on osmium. In persistent neuralgia it is injected into the nerve in doses of 1/2 to 1 c.c. of a fresh 1 to 2 percent solution. The cure is rarely permanent. It is contraindicated in renal disease.

OSTEOARTHRITIS.—See JOINTS (Diseases).

OSTEOARTHROPATHY, HYPERTROPHIC PULMONARY.—A disease first described by Marie, characterized by a bulbous enlargement of the terminal phalanges of the fingers and toes, a thickening of the articular ends of the bones, a peculiar curvation of the nails, and an enlargement of the lower jaw. According to Marie, the condition is usually associated with disease of the lungs or pleura, and results from the absorption of toxic products from the diseased foci. The disease is not allied to akromegaly. See BONE (Diseases), JOINTS (Diseases).

OSTEOCLASIS.—See GENU VALGUM.

OSTEOMA.—A bony tumor; exostosis. See TUMORS, BONE (Diseases).

OSTEOMALACIA.—Softening of bone from loss of its earthy constituents, occurring in adults, especially in females and in the course of pregnancy. The true cause of the disease is not known; by some it is considered to be infectious, but this view is not proved. See BONE (Diseases).

OSTEOMYELITIS.—See BONE (Diseases).

OSTEOPERIOSTITIS.—See BONE (Diseases).

OSTEOSARCOMA.—See BONE (Diseases).

OSTITIS.—See BONE (Diseases).

OSTITIS DEFORMANS (Paget's Disease).—A rare senile disease characterized by kyphosis of the spine, marked enlargement of the cranial part of the head, enlargement and deformity of the clavicles, and of the long bones of the extremities due to a rarefying ostitis. The abdomen protrudes; the ribs fall in and cause dyspnea; neuralgic pains are present; and there is some muscular atrophy, but the bones of the face, hands, and feet remain practically normal.

OTITIS.—See EAR (Diseases).

OTOSCOPE.—An instrument for examining the ear. What is ordinarily called and used as an otoscope is a rubber tube, one extremity of which is inserted into the ear of the subject, and the other extremity into the ear of the examiner, a current of air being passed by means of a Politzer bag and a eustachian catheter through the middle ear. In case of tympanic perforation the rushing sound made by the passing air is audible to the examiner. See EAR (Examination).

OVARIAN EXTRACT.—The substance of the ovaries has been administered with some benefit in the nervous manifestations and pathologic conditions which occur when the ovarian functions are partially or wholly arrested, as in cirrhosis or malignant disease thereof, or after the operation of ovariotomy. It is said to be of use in cases of depression or other mental disturbance coincident with the climacteric, to relieve ovarian congestion and neuralgia, and to be efficient in the treatment of delayed or scanty menstruation. See ORGANOTHERAPY.

OVARIOTOMY.—The removal of the ovaries and Fallopian tubes. This operation is usually effected through an incision in the abdominal wall. Some operators, under certain circumstances, prefer the vaginal route.

The operation is performed for diseased conditions of the tubes and ovaries; for extrauterine pregnancy; for cysts and tumors of the ovary; and for cysts of the parovarium. See FALLOPIAN TUBES; OVARY (Diseases).

The removal of the tubes and ovaries was formerly advised in certain cases of fibroid tumors of the uterus to bring about a premature menopause, but at present the operation is rarely if ever done for that purpose. See UTERUS (Fibroid Tumors).

OVARY, DISEASES. Hernia.—Descent of the ovary into the inguinal canal, or even into the labium majus, has been noted occasionally. There may be no symptoms present, or there may be pain, which is much increased at the menstrual period. The characteristic sickening pain on pressure, the increase in size at the menstrual period, and bimanual examination will confirm the diagnosis.

Treatment should consist in replacing the ovary and sac, after which it should be kept in place by a properly applied truss. If the ovary is diseased, it should be removed.

Prolapse.—Downward displacement of the ovary without displacement of the uterus and

tubes. For displacement of the ovary accompanying displacement of the uterus, see Uterus.

The principal **cause** of prolapse of the ovary is some condition which increases its weight, such as prolonged congestion, inflammation, and subinvolution. Elongation and stretching of the ligaments of the ovary may result in prolapse. It sometimes occurs as the result of a violent strain or sudden effort.

The symptoms of ovarian prolapse are usually well marked and occasionally severe. Pain is the most constant symptom. It is increased by any movement or straining effort, such as walking or defecation. It is always more severe at the menstrual periods. The pain is dull and aching in character, and usually extends down the thigh. Associated with the pain are frequently found such symptoms as nausea and indigestion, headache, and nervous disturbances. Bimanual examination will usually reveal the ovary in its abnormal position. It is enlarged and excessively tender, the slightest touch causing intense pain. Occasionally it may be pushed in place by the examining finger, when it will remain there until the patient assumes the erect posture, or until she coughs or strains.

The treatment of ovarian prolapse will depend upon the condition which causes it. Prolapse of the ovary accompanying displacement or subinvolution of the uterus will usually be cured by restoring the uterus to a normal condition. In uncomplicated cases of ovarian prolapse the patient should be advised to assume the knee-chest position 2 or 3 times daily; the vaginal orifice should be opened so that its walls may be distended by air, and the woman should remain in this position for 5 or 10 minutes if possible, after which she should lie in the lateroabdominal position for a time. This restores the ovary to its normal position, and, in time, if efforts are made to reduce the size of the ovary and to secure contraction of its ligaments, it may remain there.

Return of the ovary to its normal size may be secured by relieving pelvic congestion. This is best accomplished by the use of saline laxatives; by frequent vaginal douches of hot water; by painting the vaginal vaults and cervix with tincture of iodin, and by the use of glycerin or glycerin and ichthyol tampons. If the ovary is diseased, or if it is bound down in its abnormal position by extensive adhesions, it will have to be removed. Occasionally, if the ovary is healthy, the abdomen should be opened and the ovary fixed in its proper position. Sometimes this may be accomplished by shortening the round ligaments or by ventrofixation. In other cases the infundibulopelvic ligaments should be shortened or the outer end of the ovary should be attached to the broad ligament at its upper posterior part. However, the ovary is ordinarily diseased.

Acute inflammation of the ovary (oophoritis) is usually the result of extension of inflammation from the tube. It is particularly apt to occur as the result of gonorrheal salpingitis or puerperal sepsis. It may occur as a complication of the eruptive fevers.

The symptoms of acute oophoritis are pain in the ovarian region, accompanied by rise of temperature and rapid pulse. There may be nausea and vomiting. Bimanual examination will reveal the enlarged tender ovaries.

The treatment consists of rest in bed, vaginal douches of hot water, hot fomentations over the lower abdomen, and free purgation. If the symptoms increase in severity and if suppuration occurs, laparotomy must be performed and the diseased structures removed.

Chronic inflammation of the ovary occurs in two forms. The follicular part of the ovary may be particularly involved, giving rise to the formation of numerous little cysts underneath the capsule, when it is called cystic oophoritis; or there may be an increase in the connective-tissue element of the ovary, diminishing its size and rendering it paler and harder, when it is called cirrhotic oophoritis. Chronic oophoritis is usually bilateral. The condition may persist after an acute attack, or it may be chronic from the beginning as the result of a mild form of infection transmitted from the tubes. Prolapse of the ovary, excessive sexual connection, and celibacy may be mentioned as less important causes.

Symptoms.—The most important symptom of chronic oophoritis is pain. It is worse just before the menstrual period, and is usually relieved after the flow is well established. The pain is exaggerated by the erect posture and by exercise or movement of any kind. Associated with the pain are commonly menorrhagia and reflex nervous disturbances. Bimanual examination will reveal the altered condition of the ovary. Accompanying it there will usually be found displacement of the uterus and disease of the tubes.

The treatment of chronic oophoritis is palliative or operative. Palliative treatment may prove successful when there is no accompanying disease of the tubes or uterus. It consists of prolonged rest in bed, mild purgation, hot vaginal injections, applications of tincture of iodin to the vaginal vaults and cervix, and the use of glycerin tampons. It may be necessary to begin the treatment by the repair of a lacerated cervix or perineum, or by a thorough curettage. Sexual connection must be prohibited during the treatment. If there is accompanying disease of the uterus and tubes, or if, after the foregoing treatment, the pain should persist or return, oophorectomy should be performed.

The relief afforded by palliative treatment is rarely permanent when this plan is pursued to tide the woman over the menopause. Palliative treatment is only applicable to women who can afford to be chronic invalids.

Cystic Tumors.—There are 3 classes of cystic tumors of the ovary:

1. *Oophoritic cysts*, which arise from the parenchyma of the ovary—the oophoron.

2. *Paroophoritic cysts*, which arise from the hilum of the ovary—the paroophoron.

3. *Parovarian cysts*, which arise from the parovarium.

Cysts of this last class while they do not arise

directly from the ovary, have so close a connection with it that they may properly be classed as ovarian cysts.

Oophoritic cysts may be subdivided into (1) cysts of the Graafian follicles, (2) cysts of the corpus luteum, and (3) multilocular cysts.

Cysts of the Graafian follicles arise from distention and coalescence of the ovarian follicles. Such cysts may consist of a number of distended follicles or of one large follicle. They rarely attain a large size, usually ranging from that of a walnut to an egg. The wall of the cyst is thin and smooth, and is lined with epithelium, either columnar or stratified. It is filled with a straw-colored serum, having a specific gravity from about 1005 to 1020.

The condition is usually due to thickening of the capsule of the ovary, which prevents rupture and discharge of the Graafian follicle. These cysts are, therefore, retention cysts. Occasionally hemorrhage will take place in the cyst, when it will be found filled with a dark, chocolate-colored fluid.

Cysts of the corpus luteum are a variety of follicular cysts. They have a peculiar light-yellow color, and almost never exceed a walnut in size. They are caused by degeneration and distention of a corpus luteum.

The symptoms of the two varieties of cysts just described are not marked. There is usually some ovarian pain, and there may be menorrhagia or metrorrhagia.

The diagnosis must be made by a bimanual examination, which will reveal the enlargement of the ovary.

Unless the pain is intense, palliative *treatment* is indicated. Should the patient suffer severely, the ovary and probably the corresponding tube should be removed. If there is but one cystic cavity in the ovary, it should be incised, its contents evacuated, and the severed edges whipped over with fine catgut. It should be remembered that these cysts are limited in growth, and will never give rise to dangerous symptoms.

Multilocular cysts are cysts of unlimited growth. They are supposed to originate in a degeneration of the ducts of Pflüger. The wall of these cysts is thick and strong, and is composed mainly of fibrous connective tissue. It has usually 3 layers, which are most distinct in the neighborhood of the pedicle. These cysts are intraperitoneal in growth, and are attached to the ovary by a distinct pedicle, through which it obtains its nourishment. As these cysts increase in size, the septums between the loculi may be absorbed, so that, although the cyst is always multilocular at first, it may finally become unilocular. Traces of these septums are, however, always visible.

These cysts may vary in size from that of a fetal head to a tumor weighing as much as 200 pounds. The contents are usually syrupy in consistency and light in color, and may be dark brown or black. The specific gravity is always above 1010. If the lining membrane is epithelium, the tumors are known as simple multilocular cysts; if mucous membrane, they are called glandular cysts; if presenting the characteristics of the skin and its appendages, they are known as dermoid cysts.

Paroophoritic cysts are also called papillary cysts of the ovary. They arise from the hilum of the ovary, and probably originate in the remains of the Wolffian body. Since they grow from the hilum, or attached portion of the ovary, they are usually extraperitoneal, forcing their way between the layers of the broad ligament. As a rule, these cysts are not attached by a distinct pedicle.

The lining membrane is cylindrical epithelium, sometimes ciliated. Upon the interior of the cyst are scattered warty or papillary growths, from which it derives its name. These growths are usually pink in color and are very vascular, bleeding upon the slightest touch. They show a marked tendency to perforate the cyst wall, causing secondary papillary growths to appear on any organ with which they come in contact. The contents are usually a clear, watery serum, with a specific gravity of from 1005 to 1040.

These cysts are rarer than the multilocular cysts; they do not grow so rapidly, nor do they become so large; and they are frequently bilateral.

Parovarian cysts may be subdivided into (1) cysts of Kobelt's tubes and (2) cysts of the vertical tubes. They originate in the parovarium, the remains of a fetal structure lying in the mesosalpinx between the tube and ovary. Cysts of Kobelt's tubes are small pedunculated cysts about the size of a pea. They originate in the outer series of tubules of the parovarium. They are not important pathologically, since they cause no disturbance. They resemble very much the hydatid of Morgagni.

Cysts of the vertical tubes are of unlimited growth. They develop between the layers of the broad ligament, and are therefore extraperitoneal. The layers of the broad ligament are widely separated, and the fallopian tube is greatly elongated. The ovary is not affected unless the cyst becomes large. Cysts of the vertical tubes may be either simple or papillary. The papillary varieties are rare, and present the same characteristics as the cysts of the paroophoron. The wall of the parovarian cyst is thin, and its contents are a clear serum with a specific gravity below 1010.

These cysts are small in size, slow in growth, and are almost invariably unilocular and unilateral. The following tables will recall the classification and characteristics of the cystic tumors of the ovaries:

CYSTIC TUMORS OF THE OVARY

I. Cysts of the oophoron.	1. Cysts of the Graafian follicle.	Blood cysts.
	2. Cysts of the corpus luteum.	
	3. Multilocular cysts.	(*a*) Simple. (*b*) Glandular. (*c*) Dermoid.
II. Cysts of the paroophoron; Papillary cysts of the ovary.		
III. Cysts of the parovarium.	1. Cysts of Kobelt's tubes.	
	2. Cysts of the vertical tubes.	(*a*) Simple. (*b*) Papillary.

Multilocular Cysts of the Ovary.	Papillary Cysts of the Ovary.	Cysts of the Vertical Tubes.
1. Intraperitoneal.	1. Extraperitoneal.	1. Extraperitoneal.
2. Pedunculated.	2. No pedicle.	2. No pedicle.
3. Multilocular.	3. Unilocular.	3. Unilocular.
4. Ovary destroyed.	4. Ovary normal.	4. Ovary normal.
5. Tube normal.	5. Tube normal.	5. Tube elongated.
6. Unilateral.	6. Bilateral.	6. Unilateral.
7. Specific gravity of contents above 1010.	7. Specific gravity of contents not diagnostic.	7. Specific gravity of contents below 1010.
8. No papillary growths.	8. Papillary growths.	8. Rarely papillary growths.

The symptoms of ovarian cysts are not at all diagnostic. There may be some menstrual disturbance, usually menorrhagia; pain may or may not be present. The pain of ovarian cysts is due to pressure, and is largely dependent upon the direction of growth of the tumor. Cysts growing into the pelvis between the layers of the broad ligament usually cause the greatest disturbance. Most frequently, if the cyst is intraperitoneal, the patient complains of no symptoms until the tumor has grown to sufficient size to distend the abdomen. Later she loses weight and strength, the general health fails, and her features assume a characteristic pinched expression, which has been called *facies ovariana*.

The physical signs of ovarian cysts are usually more distinct. Inspection may reveal a localized or general enlargement of the abdomen. Palpation will reveal a tense resisting tumor, usually smooth and regular in outline, which will give a distinct wave of fluctuation. Percussion shows dulness over the face of the tumor, with resonance above it and in the loins. The dulness does not change when the position of the patient is changed.

Bimanual examination will reveal the uterus normal in size, and usually displaced by the weight of the tumor. The lower segment of the tumor can generally be felt by the vaginal finger. Ovarian cysts may be mistaken for ascites, pregnancy, fibroid tumors of the uterus, and a fat abdominal wall with tympanitic distention of the intestines.

The prognosis is favorable if operation is performed. Ovarian cysts are not malignant in character, yet they frequently cause death by their rapid growth and great size. Pressure upon the uterus, with resulting kidney-disease, is another frequent cause of death. Other causes of death may be the various complications to which cysts are liable, such as inflammation and suppuration, torsion of the pedicle, hemorrhage, and rupture. Papillary cysts are particularly dangerous on account of their liability to rupture, with the formation of secondary papillary growths.

The treatment of ovarian cysts is operative. Even though the tumor has given no symptoms, it should be removed. Serious complications may arise at any time which will render its removal difficult, or which will destroy the patient in a few days. Tapping should not be resorted to on account of the many dangers which attend it.

Solid Tumors.—Solid tumors of the ovary are rare. They are found in about 5 percent of all cases of ovarian tumors. The most important are fibroma, myoma, sarcoma, carcinoma, and papilloma.

The treatment is removal as soon as diagnosed.

OVERLYING.—An accident which not infrequently happens to young children, and in which they are suffocated. It is usually the fault of drunken parents who, in sleep, roll over their infants. Evidence that a child has really died from this cause is afforded by (1) the postmortem appearance of death from asphyxia; (2) the absence of any other mortal disease, and (3) absence of evidence of any cause of asyphxia other than overlying. The statement that a child has been overlain should be received with caution. It is reasonable to suppose a child would escape from a suffocating position beneath bedclothes, or the body of another, or succeed by crying or struggling in awaking the nurse or another. A medical witness must consider all points before charging carelessness in this, or, on the other hand, allowing an act of wilful murder to pass under the guise of accidental death.

OXALIC ACID $(COOH)_2$.—A colorless, crystalline solid, occurring in many plants as potassium oxalate. It is soluble in 9 parts of water and more soluble in alcohol. It is a respiratory depressant in 1/2 grain dose, and is a violent poison in large dose. It is serviceable in amenorrhea, in 1/2 to 3/4 grain dose, and it is classified as a direct emmenagog. It is commonly known as "salts of lemon" or of "sorrel," and is used for removing ink-stains; when taken internally, it results in poisoning. If a person immediately after swallowing a solution of a crystalline salt which tasted purely and strongly acid is attacked with burning sensation in the throat and then in the stomach, vomiting, particularly of bloody matter, imperceptible pulse, and excessive languor, and dies in half an hour, or still more in 20, 15, or 10 minutes, there is strong reason to believe that oxalic acid has been taken. The antidotes are the calcium carbonate or hydrate in such forms as lime-water, chalk, whiting or wall-plaster in water, or magnesia. Potassium and sodium carbonates and bicarbonates are to be avoided. Bland mucilaginous drinks should be given, and warm poultices should be applied to the abdomen. Cerium oxalate is official. See Cerium.

OXALURIA.—A term used to indicate the presence of calcium oxalate in the urine in an undue amount. There is a white deposit on standing. It occurs in the urine of hypochondriac and depressed patients, and in that of gouty patients. Excessive venery and masturbation will produce it, as will the ingestion of certain foods, as rhubarb. See Urine (Examination).

OX-GALL.—See Fel Bovis.

OXYGEN.—Oxygen is inhaled as a therapeutic agent in diseases of the respiratory organs and blood. It is essential to respiration, blood-formation, nutrition and tissue change, in fact to life itself; its combination with the tissues yields heat and other energy. Combustion is also dependent upon it, consisting of a rapid oxidation, with the

evolution of heat and light. It exists also in an allotropic form known as Ozone (*q. v.*). See also Hydrogen Dioxid.

OXYTOCICS or ECBOLICS, agents which stimulate the muscular fibers of the gravid uterus to contraction, and may therefore produce abortion. In small doses the same remedies are as a rule **emmenagog** (*q. v.*). Their mode of action has not been clearly made known, but it is generally believed to be due in some cases to direct stimulation of the uterine center in the cord, in others to congestion of the uterus producing reflex stimulation. The principal are: Ergot, ustilago, savin, potassium permanganate, hydrastis, borax, cotton-root bark, oil of rue, pilocarpin, viscum flavescens, strong purgatives.

Any drastic purgative, or gastrointestinal irritant, may produce abortion by reflex action. The *volatile oils* act in this manner, also *colocynth* and many other agents used by women to produce abortion, as *tansy, pennyroyal,* etc., all of which are dangerous to life in doses sufficient to excite the action of the gravid uterus.

OXYURIS.—See Worms (Round-).

OZENA.—A chronic inflammation, with subsequent atrophy, of the mucous membrane of the nose, accompanied by the formation of dry crusts and by a very offensive odor. The great difficulty in dealing with ozena is the removal of the crusts and thickened secretions upon which the fetor depends. While the secretions remain, decomposition is present, and the diseased surface is never in condition for healing. The treatment, therefore, may be summed up in the words absolute cleanliness. The persistent use of the nasal douche should be continued until every trace of thickened secretion is removed. At first, or in neglected cases, hot fomentations and steam inhalations may assist in the removal. When the dried discharge adheres to the roof of the nasal cavity, a syringe may be used to wash it out, or it may be mopped out by pledgets of cotton-wool twisted around a probe. A solution of sodium bicarbonate may be used at first, and when crusts are removed, an antiseptic solution should be substituted. Potassium permanganate, zinc chlorid, zinc sulphate, carbolic acid, solution of chlorinated soda, potassium chlorate, silver nitrate, sulphurous acid, powdered alum, boroglycerin, glycerite of tannin, tincture of iodin, boric acid, chloral hydrate, and perchlorid of mercury may all be used locally in aqueous solution.

Cotton tampons may be saturated with:

℞.	Beta-naphthol or naphthol,	gr. xij
	Tincture of quillaja,	ʒ jss
	Distilled water, enough for	℥ j.

The interior of the nose may be painted with balsam of Peru, and tampons, saturated with the same drug, may be left in contact with the deeper parts of the cavity. This effectually destroys all fetor. Powders of boric acid, bismuth, camphor, tannin, calomel, and iodoform have been used, but they are less satisfactory than liquid applications. As a rule, ulcers heal readily under constant irrigation by weak saline or antiseptic solutions. When diseased bone is present, it must be removed before healing can begin. Curettage is often very successful. Syphilitic ozena requires local treatment with mercuric chlorid in solution of 1:5000 to 1:10,000. Calomel may be insufflated with advantage. Constitutional treatment is of great importance in ozena, and is especially required in strumous and syphilitic cases. See Nose (Caries), Rhinitis (Chronic).

OZONE.—An allotropic form of oxygen, its molecule having the structure O_3. It is present in the atmosphere in small quantities, being produced constantly by the evaporation of water, by electric discharges, and in the growth of chlorophyll-containing plants. It is also formed during the slow oxidation of phosphorus, turpentine, and other essential oils. In the sickroom it may be produced by dissolving in water a mixture of manganese dioxid, potassium permanganate and oxalic acid. It is an active oxidizing agent, possessing bleaching and antiseptic properties. It has been recommended in cases similar to those in which oxygen is used; also in infectious diseases, as diphtheria. See Oxygen.

P

PACHYMENINGITIS.—See Meningitis.

PACK.—A blanket wrapped about the body. A **cold pack** is a blanket wrapped about the body after having been wrung out of cold water. A **half pack** is one limited to the trunk. A **hot pack** is a blanket wrung out of hot water and wrapped around the body. A **wet pack** is a blanket wrung out of warm or cold water, and wrapped about the body or a part, and surrounded by dry blankets. It may be used as a means of reducing temperature (cold pack), or to produce sweating (hot pack).

PAGET'S DISEASE.—See Breast (Diseases); Ostitis Deformans.

PAIN.—Bodily or mental suffering. Distressing or agonizing sensation. It is usually due to irritation of sensory nerves, although there are said to be pains of central origin.

The qualifying terms applied to pain are: **P., Boring,** severe pain in bones of a boring character. **P., Electric.** See Pain (Fulgurant). **P., Fulgurant, P., Fulgurating,** the intense shooting, cutting pains affecting principally the limbs of patients suffering from locomotor ataxia. **P., Girdle,** a painful sensation as of a cord tied about the waist; it is a symptom of organic spinal-cord disease. **P., Growing,** a popular term for the soreness about the joints in young persons at puberty. Some attribute these pains to increased vascularity of the epiphyses of long bones; others believe them to be rheumatic. **P., Jumping,** the pain peculiar to disease of joints when the bone is exposed by ulceration of the cartilage. **P., Lancinating.** See Pain (Fulgurant). **P., Lightning.** See Pain (Fulgurant). **P., Osteocopic,** bone-tiring pains; a symptom of ostitis, periostitis, and secondary syphilis. **P., Shooting.** See Pain (Fulgurant). **P., Starting.** Synonym of Pain (Jumping).

General Diagnosis.—As an aid to diagnosis, the kind of pain and its location are often of higher value than any other symptoms. Thomson divides pain into 6 different forms: (1) That due to inflammation; (2) that due to pressure; (3) that due to stretching; (4) neuralgic pain; (5) subjective pain; (6) cutaneous reflex pain.

An investigation should begin with a request that the patient describe just where the pain is felt most, and where it first began. While he is doing so, the gestures which he uses should be carefully noted.

When the pain is due to inflammation, if external, as in a joint, the patient will avoid pressure upon the most painful part. If deeper seated, the gestures are often expressive of the varying kinds and distribution of the pain, according to the texture inflamed. Thus, the diffused soreness of a mucous-membrane inflammation causes the gesture of bronchitis to be made with the whole hand laid on the sternum, and then passed over and across the chest. A similar movement of the hand across the abdomen never implies peritonitis, but catarrhal intestinal inflammation. With pleurisy and peritonitis, on the other hand, the tips of the straightened fingers are used to indicate the stabbing nature of the pain. In the localized pain of commencing appendicitis the open hand is used, as with an inflamed joint. In pleurodynia the whole hand is pressed firmly to the side to prevent movement of the ribs. In rheumatic fever the pointing by the patient to the epigastrium or to the xiphoid cartilage, especially if followed by a movement from the precordium up the neck or into the left arm, is significant of cardiac inflammation. So also the gesture in gastritis, whether acute or chronic, is wholly different from that in colic. Inflammatory pains about the head may have very characteristic gestures. The use of one finger-tip to localize it on the scalp is strongly significant of intracranial syphilis. The finger-tips passing up the side of the face and stopping on the scalp an inch below the sagittal suture indicates pain ascending from a tooth, and should not be mistaken for trigeminal neuralgia. In conjunctivitis the hand is laid over the eye. In iritis the finger is pointed toward it, not touching it, and then passed up the forehead to the inner side of the nose or to the malar process. In glaucoma the gesture may be reversed, as if the pain were emerging from the orbit. All these gestures differ entirely from those of head pains not inflammatory. Meningitis, whether cerebral or spinal, is significantly indicated by absence or suppression of gesture, for reasons to be noted further on. There are exceptions to this in some cases of tubercular meningitis. But the gesture of myelitis, with both hands passed from the back across the abdomen to describe the cord- or band-like sense of constriction, is almost pathognomonic.

On the other hand, the gestures indicating the seat of greatest pain produced by pressure, as by tumors, abscesses, etc., or cramps, markedly contrast with those of inflammatory pains in showing no apprehension in touching or in moving the part. Here the locality indicated at first by the gesture is of importance to note, and whether, on repeating the question, the same place is again started from, because the patient's hand then moves in a fashion expressive of the extension or radiation of the pain from the original focus, although he may describe the pain as equally present at some distance from the spot first pointed out. Hence his unconscious repetition of the sign with which he commenced is of much significance. Thus, a patient with a growth springing from the lumbar vertebræ always first pressed the point of two fingers deeply into the abdomen below the umbilicus, while the fingers of the other hand moved over the sacrum, where he insisted his pain was chiefly. A fixed pain in the back caused by an aneurysm is often indicated by the extended thumb, and likewise the

pain preceding herpes zoster, but no spinal inflammatory pain will elicit such a gesture, nor will the pains of so-called spinal irritation. In stretching pains, such as in biliary or renal colic, or cramps, as in lead colic, the contrast to inflammatory pains is shown by the forcible grasp or pressure which the patient makes on the abdomen, while the characteristic radiations of the different varieties may be very plainly represented. Even when the pain has ceased, the gestures descriptive of what he has experienced may be equally conclusive as to their nature (Thomson).

Inflammatory pains have three great characteristics. The first is that pain is elicited by pressure upon, or by handling, the inflamed part; and the rule is that pressure produces the maximum amount of pain at the site of the inflammation. This fact is useful in diagnosis, both positively and negatively. Thus, an inflammatory pain in the leg may be due to peripheral neuritis, to sciatica, to hip-joint disease, to gouty arthritis, to rheumatic arthritis, to muscular rheumatism, or to spinal meningitis, and each one of these may be distinguished from the others by appropriate palpation. In peripheral neuritis pain is most complained of on pressure upon the skin and superficial structures much more than when one lifts the whole limb in the hands or moves its joints. Sciatica is diagnosed by the special tenderness on pressure at the sciatic notch, along the course of the nerve down the back of the thigh, or deep in the popliteal space, or between the heads of the soleus in the calf; hip-joint disease by pressing the head of the bone against the acetabulum.

The second great characteristic of inflammatory pain is that it is increased by any form of movement of the inflamed part, not excepting its own proper functional movements. The inflamed part, therefore, is both voluntarily and involuntarily kept at rest as much as possible. This is done by muscular action, the afferent impression of this pain being reflected to all the associated muscles of the part to restrain their action, and even to muscles which, though not usually connected with the function of the part inflamed, may yet disturb it by their movements. Examples of the first kind are seen in the fixity of joints by the contraction of their muscles whenever and as long as the joints are inflamed, while the latter is shown by both the local or general rigidity of the abdominal muscles, according to the local or general state of inflammation underneath. Thus, comparative palpation made by both hands in the iliac fossæ is of help in the early diagnosis of typhoid fever. In appendicitis, from the commencement of the irritation, the muscular resistance over the cecum may give the impression of a solid tumor much before there has been time for exudation or pus-formation.

The third great characteristic of inflammatory pain is that it is accompanied by disturbance of the normal function of the injured part. This does not happen with the other varieties of pain—at least, as a characteristic of them. Neuralgic headache, for example, is not accompanied by delirium, or, ordinarily, by intolerance of light or of sound, as the headache of meningitis is. Neuralgic pains in the spine, in the arms, or in the legs do not produce stiffness nor fetter the movements of those parts whose chief functions are to execute movements, as do inflammatory pains. So the diagnosis between pleurisy and pleurodynia lies in the fact that the pain on movement of the ribs in pleurisy causes the functional symptom of cough, while that of pleurodynia does not, for the seat of the pain is not in the pleura at all.

Besides these three great characteristics of inflammatory pains, the sensation itself often varies in kind, according to the tissue involved. The rule is, the softer the texture, the more acute the pain; so that it may be described as only dull and heavy, as in inflammation of the liver or in pneumonia which has not involved the pleura. In inflammations of mucous membranes the pain, if moderate in degree, is more like a diffused soreness; if severe, it may be termed burning. Whenever griping or bearing-down sensations develop, it is because the inflammatory irritation has extended from the mucous membrane to the muscular coat of the wall of the canal or viscus which the membrane lines. Pain of inflamed serous membranes is much more acute than in the case of mucous membranes, and is likely to be lancinating or stabbing, as is indicated by the patient's gesture. Pain of inflamed fibrous tissues, such as muscular fascia, nerve-sheaths, periosteum, dura, etc., if moderate, is of a dull, aching character; but if severe, is very violent on account of the unyielding nature of the tissue. A serviceable indication of the seat of the inflammatory process is afforded by the susceptibility of patients with any form of fibrous-tissue inflammation to changes in the weather. In health there is a perfect adjustment between the centrifugal pressure of the circulation and the centripetal pressure of the weight of the atmosphere. Changes in the latter, as indicated by the fall in the barometer on the approach of a storm, are promptly compensated for by the nerve-fibrils being readily removed in the softer tissues from unbalanced intravascular pressure, but not so in the denser fibrous tissues. Hence the good, but inconvenient, barometers which a gouty man has in his toes, that may ache worse while the sky is yet clear, but which he knows, from experience, means that the clouds are on their way. It is well, therefore, to ask whether a headache complained of grows worse just before a storm, when you have reason to suspect that it is no mere functional trouble, but a cephalalgia of syphilitic origin (Thomson).

Referred Pains.—These are made clear by the illustrations, the following sections, and the table at the end of the article.

Local Significance.—**Pain in the head,** when continuous, dull, aching, and increased on lowering the head, may be due to rheumatism. When of like character and limited to the forehead, it may be dependent on gastric derangement or eye-strain. It is likely to be neuralgic when limited to one spot of the head or face, and darting from spot to spot and sharp and paroxysmal. When accompanied by nausea, vomiting, and giddiness, it is called migraine, but is probably due to eye-strain. Cerebral

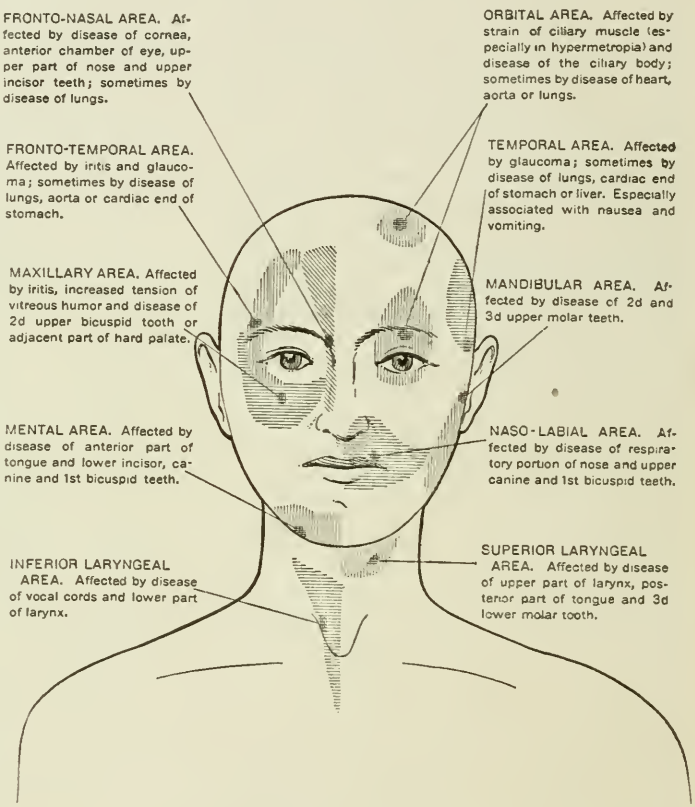
disturbance may be productive of like pains, but in this case they are continued for more than a day or two. The ophthalmoscope may help to differentiate here between migraine and cerebral trouble or Bright's disease. Tumor, aneurysm, abscess, hemorrhage, or meningitis are forms of intracranial disease accompanied by pain in the head, vomiting, giddiness, squint, or some other evidence of localized paralysis of a cranial nerve. A more or less variable amount of pain in the head will remain after recovery from hemiplegia. The pain in the head from Bright's disease is likely to attack the back of the head. The pain in the head from glycosuria is more or less continuous, with violent exacerbations. Generally speaking, persistent pain in the head, in one unaccustomed to it, should call for the use of the ophthalmoscope and urine analysis, particularly in females. Lead-poisoning may also be responsible for headaches. When chlorosis exists, the pain in the head is fixed in one spot, and is piercing. The pain of hysteria often simulates it. Pains in the head are often due to ocular disturbance other than abnormalities of refraction: as, for instance, weaknesses or imbalance of certain eye-muscles. The pains in the head in locomotor ataxia are of a darting, shooting character. See HEADACHE.

Pain in the neck may be due to rheumatism, which generally affects the large muscles; to uric acid excess, or some equivalent, which excites a subacute inflammation of severe type; to neuralgia; to caries of the spine; to rheumatoid arthritis of the cervical vertebræ; or to herpes zoster.

Pain in the chest may be referred to the chest-wall or to the interior of the cavities. When due to muscular rheumatism, syphilitic periostitis, intercostal neuralgia, or to the encroachment of aneurysm or tumor, the pain is probably superficial. The first cause would probably be indicated by an absence of febrile action and the dependence of the pain upon movement. Syphilitic periostitis would be distinguished by the finger outlining a node upon the clavicle, sternum, or ribs, and by the history or other symptoms. The character of the pain would indicate an intercostal neuralgia, especially when coupled with the history of previous neuralgic attacks in other portions of the body.

Physical examination will detect or exclude aneurysmal tumor. Pleurisy causes particularly well marked pain or coughing. It may be confounded with intercostal neuralgia or muscular rheumatism. Continued deep and dull pain in the chest points to intrathoracic growth, aneurysm, or abscess. See CHEST.

Pain about the heart may be caused by beginning pericarditis or endocarditis. Purely nervous debility is often attended by a dull and more or less constant pain about the heart, and cardiac palpitation and hysteria are often accompanied by a somewhat sharp pain just under the mamma. The pain of angina pectoris is not confined to the heart, but extends to the left arm and various parts of the chest. Pains in the chest also accompany the various diseases of the lungs and pulmonary tubes. See HEART (Pain).

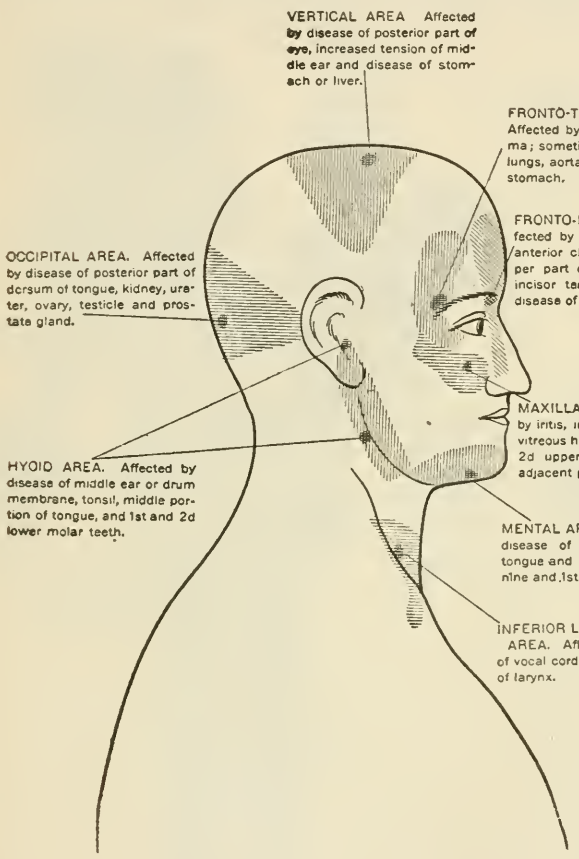


AREAS OF REFERRED PAIN.—(*From Head.*)

Pain in the spinal column is commonly indicative of a state of nervous exhaustion, rather than of disease of the spinal cord. Diseases of the cord do not usually give rise to such pain, unless attended by disease of the spinal vertebræ. Spinal meningitis gives pain only on movement. Myelitis is attended by an encircling pain—as of a band in the wall of the chest or abdomen—and when accompanied by a "bloated feeling," is a serious symptom. Aneurysm and malignant growth resemble this condition, but the pain in the two last instances is often constant and excessive, with a good deal of tenderness of the surface of the spine. A "stinging" pain of the chest is often

complained of in beginning caries of the vertebræ. Heavy pressure on the spine will cause a like pain, and the acts of stooping, or of lifting weights, or of jumping to the ground will cause complaint of pain in the spinal column in this disease. See Locomotor Ataxia, Spinal Cord.

Pain in the abdomen may be in the wall or cavity. Inflammation, abscess, neuralgia, herpes, overstrain, or fatigue may be responsible for pain in the wall. Pain in the cavity of the abdomen may be dependent on internal strangulation of the bowel, strangulated hernia, peritonitis, the false pains of labor, enteritis, appendicitis, tympanites, fecal accumulations, colic, biliary or renal calculi, and on hysteria. See Abdomen (Pain).



Areas of Referred Pain.—(*From Head.*)

Pain in the loins and back may arise from congestion of the kidneys or nephritis, renal calculus, abscess or morbid growth, flatulent distention of the bowels or retained feces, tumor of the bowel, abscess of the rectum, an undiscovered hernia, flexions and morbid growths of the uterus, ulcerations of the cervix, the approach of the catamenial period, retention and overdistention of the bladder (which also gives pain in the hypogastric region), or to Lumbago (*q. v.*). Lumbago depends upon rheumatism of the muscles, or subacute inflammation of the connective tissue between the muscles. When the pain in the back is stabbing, paroxysmal, or independent of muscular movement, it is probably neuralgic in character. Contrary to the popular idea, chronic nephritis is not usually associated with pain over the kidneys.

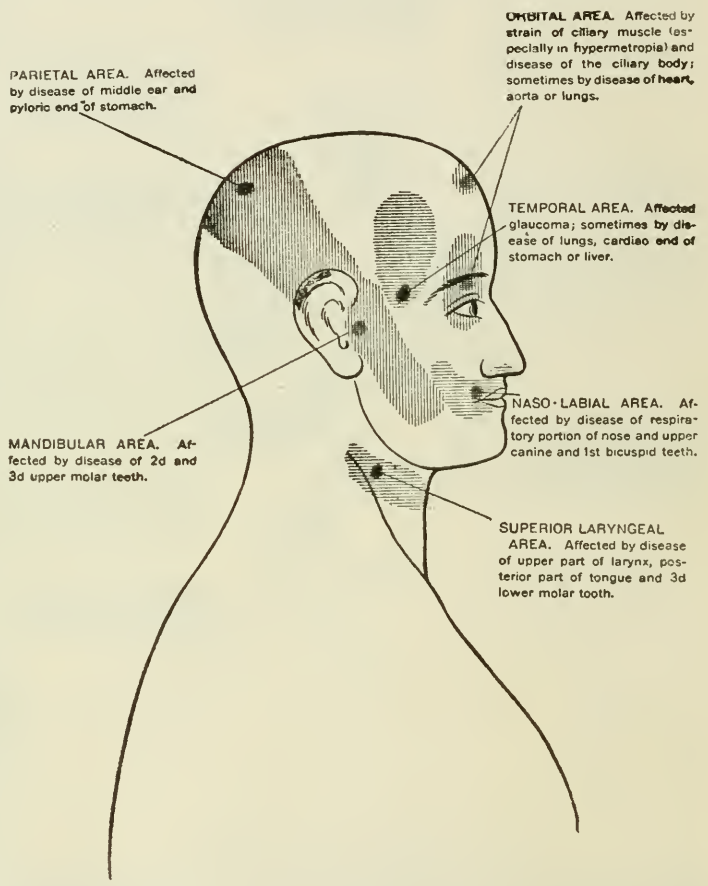
Pain in the extremities may be due to neuralgia. When paroxysmal in character—sudden, sharp, lightning-like, darting through one or more limbs and severe enough to make one cry out—the pains are probably due to the early stage of locomotor ataxia. They will occur in paroxysms, lasting hours, days, or weeks, and subside as quickly as they came. Rheumatic pains, gnawing and aching pains occupying the joints in acute inflammations, also affect the extremities.

The treatment of pain is always primarily directed to its causation. As a rule, pain should be relieved temporarily, since its continuance is exhausting and mischievous to the nervous system. However, when it constitutes a vital point in diagnosis, the administration of narcotics is ill-advised. Rest is essential, while local applications, as counterirritants, poultices, sinapisms, or anodyne liniments are most ready means in many cases. Superficial pain is often relieved by a plaster or extemporaneous liniments containing laudanum or some other fluid preparation. The oleate of morphin alone is said to be penetrating, but it is doubtful whether such applications are of direct value. Intense pain, as from the passage of a calculus, is best treated by the hypodermic injection of morphin sulphate (1/4 to 1/2 grain) with atropin sulphate (1/100 grain), while the preparations of opium may be given by the mouth for the same purposes. Severe pain enables the system to resist the action of opium. Opium is the most efficient and universally used drug for relieving pain, and morphin is its most analgesic alkaloid. A single injection is sometimes curative in sciatica and other neuralgias. In combination with antipyrin it is more efficient than when used alone. Codein is another opium derivative, having special action over abdominal and ovarian pain, and is not liable to give rise to the drug-habit.

The treatment of inflammatory pains is that of the inflammation itself, and, hence, often different from, if not the reverse of, the treatment of other kinds of pain. The first indication is rest, including the position which assures most complete rest

After rheumatic carditis the patient had better stay in bed 3 or 4 months if he still has cardiac pains and a quickened pulse. Nothing is more serviceable sometimes in the later stages of pleurisy than to limit, as much as possible, the movements of the ribs by firmly strapping the whole affected side of the chest. But the instances in which this principle can be applied are too numerous to mention here. In many acute inflammations the vascular sedative action of topical blood-letting is often remarkably effective in relieving the pain. On the other hand, with the pains of chronic inflammations the stimulant effect of counter-irritation is preferable, according to the rule that the indications in the treatment of chronic inflammations are the opposite of those for acute inflammations. In traumatic lesions both the pain and the inflammation are generally treated best by local application of ice-bags, but cold is useless when the inflammation is due to a general cause in the blood, as in rheumatic and gouty arthritis. Cold applications should be discontinued at once if they cause a neuralgic pain to take the place of an inflammatory pain. Many internal inflammatory pains are best relieved by the sedative properties of moist heat applied to the surface, as by poultices, etc., according to the general law that the cutaneous sensory nerves are always in association with the vascular nerves of the parts underneath. The best drug for inflammatory pain is opium. Next comes aconite, especially in serous membrane and cardiac inflammations. The coal-tar analgesics, so valuable in the other kinds of pain, are comparatively useless in inflammatory pains.

The following list, taken from Potter's "Therapeutics, Materia Medica and Pharmacy," contains the agents most employed in the treatment of pain: **Opium** is the most efficient of all analgesics and is universally used to relieve pain from any cause except acute inflammation of the brain; opiates soon lose their power in any particular dose, and require increasing dosage to sustain their analgesic influence, hence in chronic cases all other means should be exhausted before resorting to them. **Morphin** is the most analgesic alkaloid of opium; hypodermically in the vicinity of the nerve it is efficient when not so by the stomach; the morphin-habit must be kept in mind; a single injection thereof is sometimes curative in sciatica and other neuralgias; the conjoined administration of morphin and antipyrin is much more efficient in pain than the use of either agent alone. **Codein** has a special influence over abdominal pain and that of the ovaries, and is not liable to give rise to a drug habit. **Dionin** in 4 to 7 percent solution locally is the best analgesic for the eye. **Belladonna** is the best remedy for every kind of pain in the pelvic viscera. **Atropin,** hypodermically in local pain, neuralgia, sciatica, glaucoma; when it succeeds, has more lasting effect than morphin; for sciatica, tic douloureux; has little value unless the pain be due to spasm or some cause situated so that the remedy can be brought into direct contact with sensory nerve-endings. **Duboisin** may be used instead of atropin. **Cocain,** as a local anesthetic to mucous surfaces, or hypodermically for minor operations involving a small area, as circumcision, eye operations, has no equal; a 4 percent solution is generally employed; also as a general anesthetic by spinal subarachnoid injection. **Eucain** is fully as efficient as cocain and much less toxic; in medicinal doses is harmless and does not affect the heart. **Antipyrin** is a most efficient analgesic in doses of 10 to 15 grains, being



Areas of Referred Pain.—(*From Head.*)

especially adapted to neuralgia, migraine and the pains of gouty and rheumatic origin, but is of no value in pain due to a local inflammation; it may be used hypodermically. **Acetanilid** is highly efficient in doses of 4 to 7 grains for the pains of locomotor ataxia and those of rheumatic origin, also locally as a dry dressing for painful wounds, ulcers, etc.; it is the active ingredient in a host of recent proprietary remedies against pain. **Acetphenetidin,** efficient in 10-grain doses, for neuralgia, hemicrania; is largely used for the relief of pains of the character for which antipyrin is employed. **Phenocoll hydrochlorid,** in doses of 12 to 15 grains, is a good analgesic in the neuralgic pains of influenza, and in gouty and rheumatic pain. **Lactophenin** is analgesic and nontoxic; a feeling of comfort follows its use. **Chloroform** by inhalation as a general anesthetic; internally for the pain of colic, even that of lead colic, and externally as liniment with other substances for chronic neuralgic or rheumatic pains; the vapor to the raw surface of cancers, to the photophobic eye, etc. **Ether** as spray for local anesthesia, by inhalation for general anesthesia; anesthetics should be

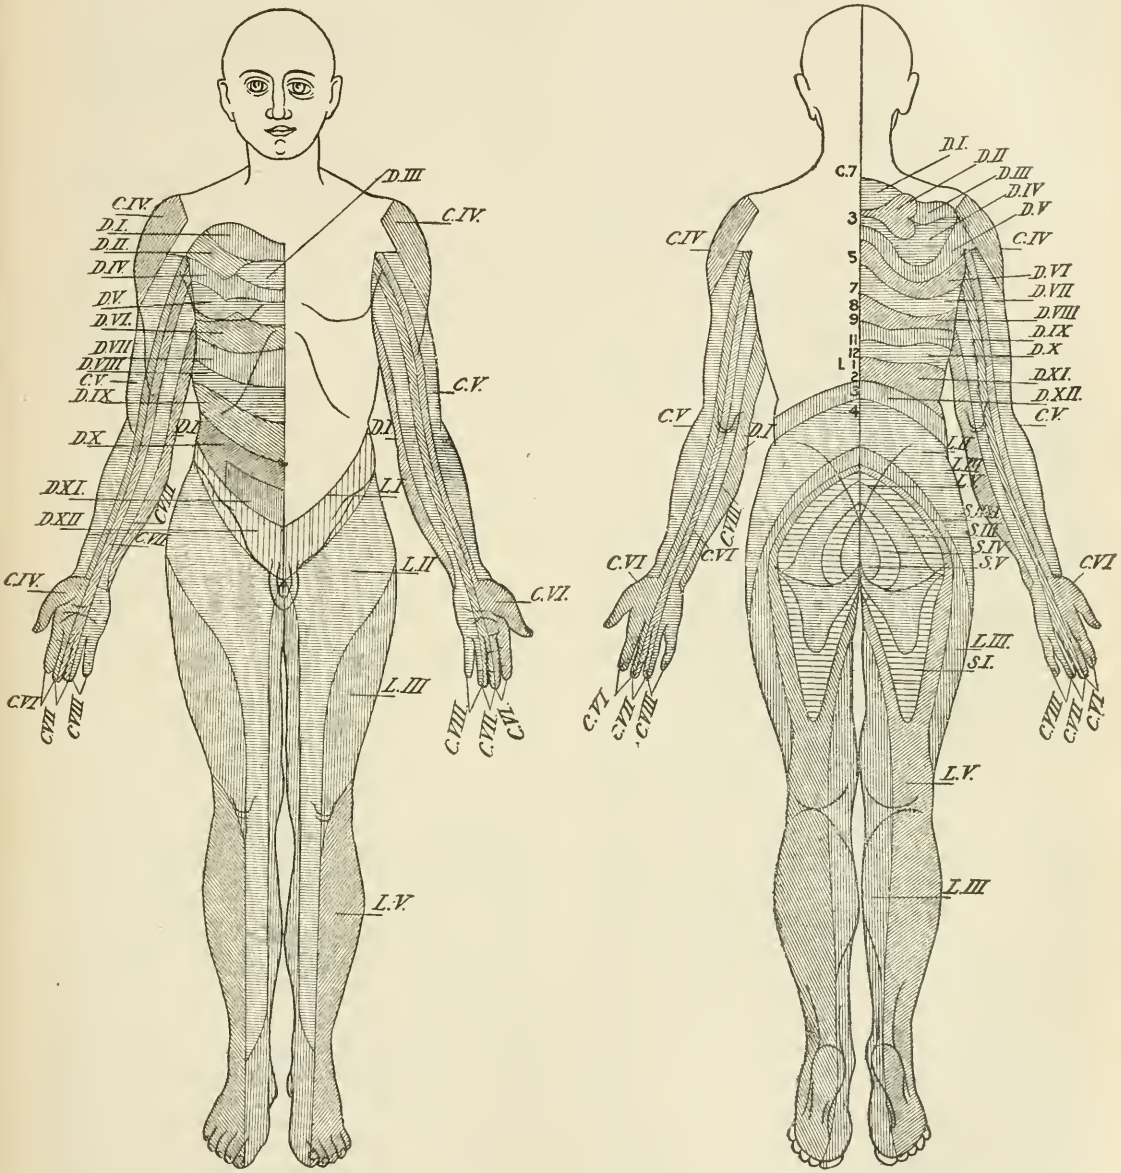


Diagram of Skin Areas Corresponding to Different Spinal Segments.—(*From Tyson, Starr and Head.*)

employed only when pain is exceedingly severe and transient. **Hydrated chloral** is analgesic only in large and dangerous doses; sometimes relieves neuralgia, chronic rheumatic pains, colic, gastralgia, etc. **Aconite** was formerly much used for neuralgic pain; aconitin locally is one of the most certain and powerful palliatives in neuralgic, rheumatic and gouty pains; especially in trigeminal neuralgia. **Veratrin** as ointment locally for neuralgia, is readily absorbed through the skin and is more dangerous than useful. **Guaiacol,** locally or by hypodermic injection, 1 part in 10 of olive oil, or mixed with equal part of glycerin for painting on the surface, is an efficient local anesthetic, and is used successfully in orchitis, in neuralgic pains of tuberculous subjects, also in sciatica and rheumatism; a few drops rubbed in gently give immediate relief in many superficial pains, also in labor-pains. **Phenol** pure, is a local anesthetic, but has been supplanted by cocain. **Creosote** locally is efficient for the pain of an exposed dental nerve. **Ichthyol** locally is analgesic against inflammatory pain; hypodermically is analgesic, less so than morphin and less dangerous. **Amyl nitrite,** also nitroglycerin and other nitrites, are effective usually against cardiac pain; especially when arterial spasm exists as in angina pectoris. **Cannabis indica** is inferior to opium, but may be tried when the latter is contraindicated for any reason. **Salicylates** are efficient in rheumatic and gouty pain, also in rheumatic neuritis. **Mesotan** locally for superficial rheumatic pain. **Iodoform** in suppository for painful disease of the rectum or bladder; as a local analgesic in painful ulcers, hemorrhoids, anal fissures, etc. **Iodids** are magical for syphilitic nocturnal pains of the head; ammonium iodid (3 grains in 1 ounce of olive oil), with friction causes the disappearance of nocturnal syphilitic pains. **Cimicifuga** relieves many kinds of pain, as neuralgia of fifth cranial nerve, rheumatic headaches, ovarian neuralgia, dysmenorrhea; inferior to ergot in labor-pains or after-pains; ʒj doses of the tincture. **Conium,** in cancer, rheumatism, neuralgia, ovarian pain, also for the fulgurant pains of locomotor ataxia, chronic alcoholism, sciatica, phthisis, doses of ♏ x of a fluidextract of the unripe fruit every 1/2 hour, well watched. **Iron,** with belladonna, for the wandering pains of anemia, in which morphin is dangerous and bromids are useless. **Oil of peppermint** locally is sometimes very effective in relieving pain; has been long used in China for neuralgia and subacute rheumatism. **Menthol** freely rubbed on for superficial neuralgic pain of peripheral origin. **Rhatany** relieves the pain of ulcers, burns, and blisters. **Methylene-blue** relieves neuralgic and rheumatic pains; has some analgesic action, but is uncertain, and has no advantage over the newer anilin derivatives. **Electricity,** the galvanic current for neuralgia; it is powerless against pain of phlegmonous inflammations; galvanism of the affected nerve gives certain relief; the positive pole on point of emergence, negative over superior ganglion of cervical sympathetic. **Heat,** if pain is without fever or inflammation, warm injections soothe the pain of cystitis, prostatitis and abdominal pains generally. **Hot water,** as bath, relieves pain most wonderfully; **cold,** when pain is inflammatory in origin. **Phototherapy,** the ultra-violet rays are very effective in relieving acute muscular pain, especially if obtained with iron-carbon electrodes.

Organ Diseased.	Spinal Segments whose Sensory Areas are Painful.	Cranial Areas in which Pain may also be Felt.
Heart	1, 2, 3 dorsal (angina pectoris).	Orbital.
Lungs	3, 4 cervical, 1, 2, 3, 4, 5 dorsal.	Frontonasal, orbital, frontotemporal, temporal.
Ascending aorta	1, 2, 3, 4 dorsal	Orbital, frontotemporal.
Arch of aorta	5, 6 dorsal	Frontotemporal.
Stomach, cardiac	6, 7 dorsal	Frontotemp., temporal.
Stomach, pyloric	8, 9 dorsal	Vertical, parietal.
Liver and appendages.	7, 8, 9, 10 dorsal	Temporal, vertical, parietal, occipital.
Intestine	9, 10, 11, 12 dorsal.	Parietal occipital.
Kidney and ureter.	10, 11, 12 dorsal	Occipital.
Prostate	10, 11, 12 dorsal, 5 lumbar, 1, 2, 3 sacral.	Occipital.
Ovary or testicle	10 dorsal	Occipital.
Rectum	2, 3, 4 sacral	
Epididymis	11, 12 dorsal	
Oviduct	11, 12 dorsal, 1 lumbar.	
Bladder, mucous membrane and neck.	1, 2, 3, 4 sacral.	
Bladder, over-distention and ineffectual contraction.	11, 12 dorsal, 1 lumbar.	
Uterus, in contraction.	10, 11, 12 dorsal, 1 lumbar.	
Uterus, os	1, 2, 3, 4 sacral (5 lumbar very rarely).	

PALATE, DISEASES.—The affections of the palate are mostly surgical. The diseases of the palate are: (1) Congenital malformations; (2) inflammation; (3) ulcers; (4) necrosis; and (5) tumors.

Congenital malformations (see Cleft Palate) may be simple or phlegmonous, of the soft parts, or involve the hard palate, affecting the periosteum and bone.

Ulcers.—The principal forms of ulceration are those of syphilitic, tuberculous, or epitheliomatous origin. Injury gives rise to simple ulcers, which present no special feature of interest. Syphilitic ulcers are common, in the early secondary stages of the disease being superficial, while deep ulcers occur in the tertiary stage and appear late—5 to 8 years after the primary lesion. They are generally single, have the usual characters, and may spread to the base of the cranium. Tubercular ulcers, most usual in childhood, are associated with tubercular disease elsewhere. Small tubercles, projecting slightly above the surface, first appear, break down the erosions, coalesce into irregular ulcers of little depth, with festooned borders and a yellowish base covered with pale granu-

lations. They may become serpiginous. Epitheliomatous ulcers are rare.

Tumors.—The glandular tumor is the most common. It is often found on the hard palate, is usually soft and elastic to the touch, painless, and causes no symptoms beyond the encroachment upon the buccal cavity. Erectile tumors are confined to the hard palate. Papilloma is infrequent and sarcoma is rare. Epithelioma rarely develops primarily in the soft palate. Cysts—mucous and dermoid—fibroma, enchondroma and osteoma, myxoma, lipoma and adenoma, and tumor growths of the palate, while inflammatory, and tubercular and gummatous swellings occur.

Treatment of diseases of the palate must, as a rule, be directed to the particular disease affecting the palate in common with other adjacent structures. Local antiseptic, astringent, and caustic treatment is of value. Surgical operations are often of the greatest service.

PALMAR ABSCESS.—See HAND.

PALPITATION.—Any spasmodic fluttering or tremor, especially the abnormally rapid beating, of the heart, of which the person is conscious. It is often associated with a choking sensation in the throat. It may be due to organic disease or to functional disturbance of the heart; very often it is caused by disorders of the stomach. See HEART-DISEASE (Functional).

PALSY.—See PARALYSIS.

PANARITIUM.—See MORVAN'S DISEASE.

PANCREAS, DISEASES. Relations of Pancreas.—The pancreas is a compound racemose gland, consisting of a broad, slightly curved portion called the head, while the left extremity terminates in a pointed end denominated the tail, and the middle portion forms the body. The pancreas is from 6 to 8 inches in length, extending transversely across the posterior wall of the abdomen, occupying the epigastric and left hypochondriac regions. The head of the pancreas is in close relation with the duodenum and common bile-duct, the body being covered by the posterior wall of the stomach and the transverse colon, while the tail is placed over the left kidney and impinges upon the concave border of the spleen.

Pancreatic Apoplexy.—Hemorrhage into the pancreas is generally the result of venous engorgement, traumatism, or atheromatous condition of the blood-vessels. The hemorrhage may be excessive, producing a rapid enlargement of the organ, with sudden pain, great tenderness, and a sense of fulness in the affected region, and accompanied by vomiting, paleness of the face, cold extremities, rapid and feeble pulse, and evident symptoms of sudden collapse. Death usually occurs within from 3 to 7 days.

Acute Pancreatitis.—Acute inflammation of the pancreas.

Etiology.—Septic infection through the medium of the pancreatic ducts, caused by such organisms as the colon bacillus, pyogenic cocci, typhoid bacillus, etc. See COLON BACILLUS INFECTION.

Pathology.—The pancreas is enlarged from excessive amount of blood in the part, and the infiltration of the tissues with red blood-cells and leukocytes. In some cases the process is a rapid one, leading to fatty degeneration, giving rise to abscess (suppurative pancreatitis) or gangrene (gangrenous pancreatitis).

Symptoms and Clinical Course.—In acute inflammation of the pancreas the onset is marked by tenderness in the region of the pancreas, enlargement of the organ, slight fever, vomiting, and gastric distress.

If the process is a suppurative one, or if gangrene supervenes, all the symptoms become more pronounced, with sweat and chills, paleness of face, cold extremities, rise of temperature at first, then sudden decline, with evident symptoms of collapse. In the latter forms death usually occurs within 4 to 6 days.

Prognosis is unfavorable.

Treatment is the same as that for PERITONITIS (*q. v.*).

Chronic interstitial pancreatitis may be the result of cholelithiasis or biliary obstruction, or of the simple form of hemorrhagic pancreatitis. The resulting sclerosis then causes constriction of the common bile-duct and so gives rise to jaundice and a variable distention of the gall-bladder, accompanied by wasting and paroxysmal attacks of pain and ague-like seizures. The pulse may then be rapid, and so differs from the pulse in ordinary jaundice. If such symptoms arise in patients under forty, chronic interstitial pancreatitis may be suspected, since cancer of the head of the pancreas is rare until after that age. A hard lump may be felt in the region of the head of the pancreas, and if there is also fat in the feces, sugar in the urine, and bronzing of the skin, a diagnosis may be arrived at. A special test for glycerin products of fat decomposition by Dr. Cammidge should give a positive reaction. The treatment is cholecystenterostomy together with the removal of any gall-stones met with. The result may be a good and lasting recovery. Some cases of pancreatic diabetes appear to have been secondary to this form of chronic pancreatitis, and the possibility of warding off diabetes is a further recommendation for cholecystenterostomy.

The Cammidge reaction in the diagnosis of pancreatic disease, while it is not pathognomonic, is still believed by some physicians to be highly suggestive.

Technic of the Improved Method.—A 24 hour specimen of urine must be freed from albumin and sugar. To 40 c.c. of filtered acid urine are added 2 c.c. of concentrated hydrochloric acid and the mixture is boiled 10 minutes, cooled and to it added water up to 40 c.c., then also 8 grams of lead carbonate and it is then cooled again. After filtering the filtrate is treated with 8 grams of tribasic lead acetate to remove the glycosuric acid. The precipitate is removed by filtering and to the filtrate is added 4 grams of powdered sodium sulphate, the mixture heated to the boiling-point, then cooled and carefully filtered. To 10 c.c. of the filtrate made up in a flask to 17 c.c. with distilled water, are added 0.8 gram of phenyl hydrazin hydrochlorid, 2 grams of sodium acetate and 1 c.c. of 50 percent acetic acid and the mixture boiled 10 minutes. While hot it is filtered and the fil-

trate made up to 15 c.c. with hot water and allowed to stand. In several hours a yellow precipitate forms which is observed under the microscope to consist of yellow crystals arranged in sheaves and rosettes.

Carcinoma of the Pancreas.—The disease is usually primary and of the scirrhous variety. The seat is usually at the head of the organ. It may be secondary to carcinoma elsewhere, as in the stomach or intestines.

Pathology.—The carcinomatous infiltration invades the tissues of the organ; there is great multiplication of cells, which become packed together and form dense nodules. If the process continues, the common bile-duct becomes occluded from the pressure, and jaundice follows. Metastasis may occur, and the process extend to the duodenum, liver, stomach, or peritoneum.

Symptoms and Clinical Course.—Jaundice, tenderness in the epigastric region, and the presence of a nodular immovable tumor are the three most common symptoms. Together with these symptoms there are fever, emaciation, fatty or greasy stools, and often glucose in the urine.

Diagnosis.—From cancer of the stomach it may be distinguished by the fact that if the stomach is involved, the tumor is more superficial, is movable, and there is hematemesis and absence of free hydrochloric acid in the gastric contents one hour after a test-breakfast. In aneurysm of the aorta the tumor is not lifted up and down with each pulsation, as in cancer of pancreas, and in the former there is a thrill on palpation, a bruit sound on auscultation, and jaundice is absent.

Prognosis.—The disease is always fatal.

Treatment is merely palliative. The diet may be the same as that used in cancer and ulcer of the stomach.

Cysts of the Pancreas.—These are usually retention cysts, the result of impaction of calculi in the pancreatic ducts. These cysts may attain considerable size.

Symptoms and Clinical Course.—There is a slightly movable tumor in the left side of the epigastric region, containing a brownish or chocolate-colored fluid. Occasional attacks of colic and fatty stools may help distinguish the disease, although a diagnosis is often impossible.

Treatment is purely surgical.

PANCREATIC EXTRACT.—The pancreas, both in substance and extract, has been administered as a remedy for diabetes, but the results have been negative. A few instances are recorded in which its use was followed by some temporary amelioration of the symptoms of the disease. See ORGANOTHERAPY.

PANCREATIN.—A mixture of the enzymes naturally existing in the pancreas of warm-blooded animals, usually obtained from the fresh pancreas of the hog, or the ox, and consisting principally of amylopsin, trypsin, and steapsin; and proved to be capable of converting not less than 25 times its own weight of starch into substances soluble in water. Dose, 3 to 15 grains.

Pancreatin digests albuminoids and converts starch into sugar and proteids into peptones, also emulsifies fats in the presence of an alkaline solution. Prolonged contact with mineral acids renders it inert. It is digested by pepsin, and hence probably never passes into the duodenum in its own character. Pancreatin is used to partially digest (peptonize) milk, gruel, soups, and other foods, before their administration in cases of great digestive debility. These peptonized foods may be administered by the stomach or the rectum, and are valuable in intestinal dyspepsia, wasting diseases, and convalescence from acute affections. See also ORGANOTHERAPY.

PANNUS.—Vascularization of the cornea, usually due to the irritation of trachoma granulations. See CORNEA (Diseases), TRACHOMA.

PANOPHTHALMITIS.—Inflammation of all the tissues of the eyeball. It is a purulent iridochoroiditis resulting in abscess formation. There is protrusion of the eyeball and perforation of the coats.

PANTOPON.—A preparation said to contain all the alkaloids of opium in the form of chlorids; dose one quarter of a grain.

PAPAIN.—A proteolytic ferment obtained from papaw-milk, the juice of *Carica papaya*, a tree native to South America. It has the digestive properties of pepsin, but is far more active, dissolving fibrin in neutral, acid, or alkaline liquids. It is an excellent solvent of false membranes. *Papayotin* and *caricin* are other names for the ferment. Dose, 1 to 3 grains.

PAPAVER.—The poppy, the juice and extracts of which possess narcotic properties. Opium is obtained from *P. somniferum*. See OPIUM.

PAPAVERIN.—An alkaloid found in opium. It is narcotic, and produces primarily muscular relaxation; later, convulsions. It stands midway between morphin and codein in its action on the central nervous system, but it is a comparatively weak poison.

PAPAW.—See PAPAIN.

PAPAYOTIN.—See PAPAIN.

PAPER.—Paper has been introduced into surgery as a substitute for lint on account of its cheapness. Porous varieties resembling blotting paper, and capable of absorbing a large amount of fluids, have been manufactured; hence, it is suitable for applying wet dressings, as lead-water and laudanum, etc. When once saturated, owing to its friable character, it cannot be reapplied. Waxed paper, made by immersing sheets of tissue paper in hot wax or paraffin, which, when cooled, forms a thin coating that makes it impervious to water is universally employed in hospital practice as a substitute for oiled silk; owing to its cheapness it can be destroyed after each application. Because of its extreme thinness it is advisable to use several layers, otherwise the moisture soon makes its way through. Parchment paper has been introduced as a substitute for mackintosh in the Lister antiseptic gauze dressing. When first removed from the package, it is soft and pliable, but on drying becomes crisp. The paper, when applied over wet dressings to prevent the escape of moisture, appears to fulfil all purposes for which oiled silk has served.

Paraffin paper is employed as a dressing in some

forms of skin-disease accompanied by crusting and exfoliation, with the object in view of macerating the skin and thus loosening the products of disease. In other cases it is employed as a protector. Paper is valuable in applying ointments and moist dressings. It is superior to rags and cloths. The paper is to be cut into pieces of the appropriate size, spread with the selected ointment, and closely applied to the surface, being kept in place by a bandage. In affections of the fingers and toes, as well as the limbs generally, paraffin paper is easily adapted to the inequalities of the skin surfaces. The fact that it soon becomes friable and torn is an advantage, as it insures more frequent change of dressings, and consequent cleanliness.

Blotting paper rolled between the fingers and introduced into the nostrils is recommended by Sajous for removal of secretion from nasal passages in young children. It has been suggested also as a material for making tampons for arresting nasal hemorrhage.

Before soaking in a solution of nitrate of potash, paper should be cut in strips 3 inches long by 1/2 inch broad. It is next dipped in the solution in a cylindric vessel 4 inches high and 2 inches in diameter. The paper should thed be ignited and the smoke inhaled by repeated deep inhalations. Nitrated papers, according to Lefferts, should be kept in tin-foil or prepared in small quantities, as required. See Potassium Nitrate, Chartæ.

PAPILLITIS.—Inflammation of the optic disc or papilla of the eye. The old terms, choked disc, descending neuritis, etc., implied unproved theories of causation, and have been replaced by the adoption of the better term, papillitis. Intracranial diseases, as tumors, meningitis, abscess, etc., are the most frequent causes. See Optic Neuritis.

PAPILLOMA.—A term loosely employed to include corns, warts, horns, and certain nævi. Papillomata stand midway between true tumors and inflammatory growths; a papilloma is any growth on the skin or mucous membrane based upon, or resembling, a normal papilla. A hard papilloma is a form in which the connective-tissue framework is denser and the cells fewer than usual. It grows chiefly from the skin. A soft papilloma is one growing from mucous membranes, especially in the uterus, rectum, and bladder. See Corn, Tumors, Warts.

PAQUELIN CAUTERY.—See Cautery.

PARACENTESIS.—Piercing or tapping a cavity of the body, such as the chambers of the eye, the membrana tympani, the abdomen, or the thorax, for the evacuation of fluid. See Ascites, Cornea (Operation), Ear, Pericarditis.

PARADOXIC CONTRACTION.—See Nervous Diseases (Examination).

PARALDEHYD. $C_6H_{12}O_3$.—A polymeric form of acetaldehyd. It is a colorless liquid of repulsive odor and unpleasant taste. It is a reliable hypnotic, and is diuretic. It is valuable in delirium tremens, mania, tetanus, and other nervous affections. Dose, 20 minims to 2 drams. It will dissolve trional, and this solution forms a powerful hypnotic.

Paraldehyd Habit.—The morbid addiction to the use of the drug gives rise to symptoms similar to delirium tremens. Emaciation, anemia, weakness and irregularity of the action of the heart, gastric derangement, costiveness, general tremulousness, especially in the tongue, facial muscles, and hands, feebleness and unsteadiness of gait, general restlessness, paresthesia, insomnia, mental anxiety and agitation, mental confusion, mental excitement, temporary loss of memory, incoherence of speech, hallucinations, delusions. The odor of paraldehyd may be appreciable in the breath. Treatment requires about 3 months in an inebriate asylum.

PARALYSIS.—Loss of the power of voluntary motion. **Paresis** is simple weakening of such motor power.

By **monoplegia** is meant isolated paralysis of one part of the body, as an arm or leg. By **hemiplegia** is meant paralysis of the entire half of the body, including half of the face, one arm, and one leg, also known as unilateral paralysis. By **paraplegia** is meant simultaneous paralysis of corresponding halves of the body. Paralysis of the two arms is spoken of as **superior paraplegia,** of the two legs as **inferior paraplegia,** while the word paraplegia alone is often used for the latter condition. **Diplegia** is paralysis with spasm of all the extremities.

Impairment of voluntary muscular power must be the result of structural change in the motor area of the cortex, in the great motor tract of the brain or cord, or impairment in the integrity of the efferent nerves, or it may be more rarely, in the muscle itself, "myopathic palsy;" or the power of the will may be abrogated. In diseases of the peripheral nerves, when the paralysis is called peripheral, it is limited to the region of distribution of the affected nerves, whether one or many. It may be said in general that hemiplegia is the usual form of cerebral paralysis, while paraplegia is the expression of spinal paralysis. Monoplegias are usually due to lesions of the cortex or are peripheral palsies.

In all hemiplegias caused by lesions above the pons, the palsy, including face and extremities, is on the side opposite the lesion, but in most lesions in the pons there is **crossed paralysis**—that is, there is paralysis of the extremities on one side and of the face on the other side, because the fibers of the facial nerve cross much higher than the fibers to the extremities. The result is a paralysis of the face on the same side with the lesion, and of the extremities on the other. If the lesion is higher up, above the decussation of both the facial and pyramidal tracts, the paralysis is on the side opposite the lesion, in both face and extremities. Other nerves may substitute the facial in this crossed paralysis, as the hypoglossal or abducens. In rarer instances there may be lesion at the very decussation of the pyramid, cutting the motor fibers of one extremity before they cross, and those of another after crossing, producing the very rare condition of paralysis of an arm on one side and leg on the other (Tyson). See Brain, Muscles, Nerves, Spinal Cord.

PARALYSIS, ACUTE ASCENDING (Landry's **Paralysis**).—A rare disease characterized by paraly-

sis appearing suddenly in the feet and ascending rapidly to the other muscles of the body, and finally involving the medulla. The paralysis is ordinarily preceded by a prodrome including anorexia, malaise, fever, pain in the head and back and tingling in the extremities. There are no pain and no trophic changes; the knee-jerk is usually diminished; sensation is generally preserved, but there may be hyperesthesia and muscular tenderness; the special senses are unaffected; the sphincters are uninvolved. The spleen may be enlarged. The paralysis is a flaccid one, the muscles are relaxed but do not atrophy or yield reactions of degeneration because of the rapidly fatal termination. The pathology is obscure, and the malady is a very fatal one, usually terminating in death within a week, although it may continue for 3 or 4 weeks. Recovery, however, has occurred in some cases. Males are more frequently attacked than females, and the affection occurs chiefly between the ages of 20 and 40 years.

Diagnosis.—Acute myelitis is distinguished from Landry's paralysis by the wasting, anesthesia, electrical changes, early involvement of the sphincters. In multiple neuritis there are marked sensory disturbances.

Treatment.—Rest in bed is essential. Dry or wet cups should be applied to the spine and counterirritation kept up by a mustard plaster. Paquelin's cautery may be tried. Ergotin (10 to 20 grains a day), salicylates, perchlorid of iron, iodid of mercury, are all recommended.

PARALYSIS AGITANS (Shaking Palsy; Parkinson's Disease).—An affection marked by tremor or alternate contraction and relaxation of the muscles of the part involved.

Symptoms.—The movements are regular and rhythmic (in distinction from insular sclerosis), and begin usually in one hand. They almost never affect the head. They persist during rest, and are little influenced by voluntary movement. Later in the disease there is a typical gait, known as *festination* or *propulsion*. It consists in a progressive increase in the rapidity of the gait until the patient breaks into a run, which grows faster and faster until he either falls or seizes some support. This peculiar gait is ascribed to the bent position of the trunk, which throws the head so far forward as to bring the center of gravity beyond the line of the feet. Rarely the movement is backward; this is called *retropulsion*. It may be to one or the other side—*lateropulsion*. The speech is slow, monotonous, and high-pitched. The face is fixed and expressionless. In advanced stages there is an almost statue-like rigidity of the body. The hand assumes a peculiar position, as if rolling a small body between the thumb and the fingers, but later the position becomes constant, similar to that in which the pen is held—hence, the term of *writing hand*. The knee-jerk may be exaggerated. Flushing and heat are sometimes complained of. Paralysis agitans is most common in males over 40 years of age.

Diagnosis.—*Disseminated sclerosis* exhibits a tremor, but only of voluntary movements—intention tremor. There are also scanning speech and ataxic gait, with mental enfeeblement, as shown by an unnatural contentment with the physical condition and surroundings.

Chorea displays a tremor, but the movements are general, and particularly involving the muscles of the face. Again, chorea is a disease of children and young adults. See CHOREA.

The course is of long duration, the disease at times lasting 20 or 30 years.

The lesion is probably a diffuse sclerosis of the brain and spinal cord.

Treatment.—The patient should receive rest, bodily and mental. Nutritious food, cod-liver oil, hypophosphites, or arsenic should be administered. Hyoscyamin sulphate, 1/30 to 1/10 grain, 3 times daily, is a valuable remedy. Good results have followed the use of hyoscin hydrobromid, 1/200 to 1/100 grain, 3 times daily. Mild galvanism, 2 or 3 times a week, acts as a nerve-stimulant.

PARALYSIS, BELL'S.—See FACIAL PARALYSIS.

PARALYSIS, BULBAR, ACUTE.—This paralysis is the result of hemorrhage into the medulla or pons, or of thrombosis or embolism of the vessels supplying these centers. The symptoms are sudden; in addition to those of the progressive or chronic type there may be loss of consciousness, deranged cardiac and respiratory action, high fever. If the motor tract is involved there is the peculiar crossed paralysis that usually accompanies hemorrhage into the pons—paralysis of the face on one side and of the extremities on the other.

PARALYSIS, BULBAR, ASTHENIC (Erb's Disease, Myasthenia Gravis, Hoppe-Goldflam Symptom Complex).—A chronic disease characterized by progressive loss of muscular power affecting first the muscles of the eye, face, neck, tongue, larynx. The muscles involved become rapidly fatigued on effort, but regain power temporarily after rest. A similar effect obtains on faradization of the muscles (Jolly's myasthenic reaction).

Treatment consists in prolonged rest, massage, galvanization of muscles, liquid food, tonics.

PARALYSIS, BULBAR, PROGRESSIVE (Glossolabiolaryngeal Paralysis, Atrophic Bulbar Paralysis).—A form of paralysis due to a degeneration of the nuclei of origin of the nerves (facial, glossopharyngeal, vagus, spinal accessory, and hypoglossal) arising in the oblongata. Bulbar symptoms may precede or follow spinal symptoms. A similar condition affecting the eye muscles is called progressive ophthalmoplegia.

Etiology.—The condition is sometimes a sequel to exposure to severe cold; it may be caused by morbid growths or by syphilis. Rheumatism, gout, and neck traumatisms are also causes.

It is usually confined to the latter half of life, and its prognosis is bad.

Symptoms.—At first only the muscles of the lips, tongue, and pharynx are affected. The disease is marked by difficulty in mastication, deglutition, respiration, phonation, and articulation, and by wasting of the muscles concerned in the performance of these functions.

Treatment is entirely symptomatic. Galvanism is the most promising remedy. Stabile applications, the electrodes on the mastoid processes and

in the opposite direction, galvanization of the sympathetic, and applications to the lips, tongue, and fauces should be persistently used. Anti-syphilitic remedies should be administered in all suspicious cases. General tonic and hygienic treatment is indicated.

PARALYSIS, CEREBRAL.—See BRAIN (Hemorrhage, Tumors, etc.).

PARALYSIS, DUCHENNE'S.—A chronic disease characterized by progressive muscular weakness, associated with an apparent hypertrophy of the affected muscles. There is an interstitial fibrous overgrowth of the muscles, frequently accompanied by an accumulation of fat and atrophy of the true muscle-fibers. The disease usually begins in the muscles of the calf, and spreads over the body, the muscles of the hand almost always escaping. There are marked lordosis and a characteristic gait, with wide separation of the legs and swaying of the body from side to side. The characteristic symptom is the manner in which the patient rises from the floor—he "climbs" up on his legs, on account of the weakened state of the extensor muscles of the back. The disease is essentially a chronic one, but the patient becomes absolutely helpless long before death. It is most common in young male children, usually under 10 years of age. The disease is entirely myopathic, no adequate nerve-lesion having as yet been discovered.

PARALYSIS, GENERAL, OF INSANE (Paretic Dementia).—An organic disease of the brain, characterized by progressive loss of power and by a deterioration of the mental faculties, ending eventually in dementia and death. The duration varies from a few weeks or months to three or more years, being, on the average, longer in females than in males, and in the well-to-do than in the poor.

Etiology.—The affection is most common in males between the ages of 30 and 60. It is induced by overwork and mental and physical strains, intemperance, syphilis, and lead-poisoning.

The lesion is essentially a meningoencephalitis, with thickening of the cerebral meninges and wasting of the cortical substance.

Symptoms.—In most cases mental symptoms precede distinct motor ones. General paralysis does not supervene in ordinary insanity. The mental symptoms occur in the most varied possible time and mode of sequence. The moral feeling, perturbed at first, rapidly undergoes disintegration and decay. After a preliminary despondency, the emotional state tends to be gay; later, to be depressed, morose, or peevish, and finally to die out. More or less dementia is present in all cases from the early stages, is irregularly progressive, and often very extreme toward the close.

Three stages are marked: (1) A period of mental alienation, associated with fibrillar tremblings, noticeable in the tongue and facial muscles; (2) a period of chronic mental failure and bodily decay; (3) a stage of complete mental ruin, in which there is failure of motor, sensory, and nutritive functions.

In the first stage there is much difficulty in deciding as to the nature of the disease, there being some alteration in the moral nature before friends notice any bodily defect, so that a gradual alteration in character may take place. The principal mental symptoms are alterations in demeanor, conduct, temper, and disposition, enfeeblement of memory and loss of power in the highest acquirements, especially if the latter demand much skill and originality.

The principal body signs and symptoms in the early period are some defect of sight, hearing, or smell. The onset may take any clinical form, as maniacal, melancholic, stuporous, or of the nature of dementia. Delirium of exaltation is a very frequent symptom. Whatever the form of onset, dementia is the natural tendency of the disease, and, therefore, loss of memory and filthy habits are likely to occur with much greater frequency than in ordinary melancholia.

The characteristic motor signs may be masked, and usually consist of increased difficulty of speech, stoppage or stuttering, or great effort to enunciate, associated with marked twitching of the lips or face. Great loquacity exists in the expansive forms, but amnesia is most often seen. A loss of expression in the lower part of the face, the lines being smoothed out, is found; the tongue is protruded with difficulty, or is jerked out and sucking; swallowing or masticatory movements are common.

In the second stage physical signs become more marked and speech more incomprehensible, the appetite is voracious, face expressionless, gait feebler, and the general condition worse.

In the third stage the extreme of mental and physical deterioration is reached, and the patient is bedridden.

Severe cases may end in death in a week, but the average duration is over 2 or 3 years, some cases lasting 10 to 15 years; is longer in females than in males, and in quite demented cases and in those of hereditary tendency.

Diagnosis.—General paralysis is frequently overlooked. Moral perversions are common, but distinct change in character in a man in middle life, especially if he has been active in business, should excite suspicion. From ordinary acute mania or other forms of insanity the diagnosis is difficult in the early stages, but made certain by the occurrence of motor symptoms. Acute mania from alcoholic excess may resemble general paralysis at the onset, especially if associated with exaltation and tremors. Syphilitic disease of the brain or meninges may simulate the demented forms of general paralysis. From the monomania of grandeur, the speech, and other motor symptoms, the more changeable nature of the exaltation and the course of the disease, differential diagnosis is made. Intracranial tumors sometimes cause simulation of the demented form of this disease. Disseminated sclerosis, dementia associated with hemiplegia or other paralyses, and paralysis agitans may possibly be confused with general paralysis. Epileptiform seizure frequently marks the onset of general paralysis, but true epilepsy is said never to be followed by the latter. Plumbism and excessive

use of bromids may give rise to conditions simulating general paralysis.

Prognosis.—The disease is practically incurable when the characteristic symptoms have developed.

Treatment.—In the earliest stage complete cessation of all causes of emotional or mental strain may act beneficially, but instead of rest, attempts to stimulate to cheerfulness are usually made. No drugs appear to have any effect in cutting short the disease. Antisyphilitic remedies may be tried in appropriate cases. General paralytics are very susceptible to powerful drugs, and such should be used with caution. A return to home-life accelerates the final break-down, especially if followed by attempts at sexual intercourse or indulgence in any form of excess.

PARALYSIS, INFANTILE CEREBRAL. Synonyms.—Spastic hemiplegia, diplegia, or paraplegia.

Infantile Spastic Hemiplegia.—In most instances this paralysis is of the acute, acquired type, developing at any time after birth but usually before the fifth year.

Etiology.—It may be due to abnormal conditions or accidents or disease (especially syphilis) of the mother during pregnancy; it may be the result of lesions during delivery. After birth it may be caused by traumatism, embolism, scarlet-fever, pneumonia, measles, diphtheria, variola, mumps, typhoid fever, meningitis. It is very often brought on by pertussis. Convulsions may be the cause or the result of the lesion.

Pathology.—There may be hemorrhage, embolism or thrombosis. The main lesions found at autopsy are sclerosis and atrophy.

Symptoms.—The onset is sudden with convulsions, which are usually repeated, and coma. In exceptional cases the hemiplegia may come on suddenly in apparently well children. Fever is usually present, with delirium and vomiting. As the child recovers consciousness the paralysis is discovered usually complete though sometimes it is at first only paresis. If the face is involved, it soon recovers. Power is gradually restored in several weeks to the leg though in most cases a persistent halt remains, but the arm recovers so slowly that contractures are apt to develop in several years and moderate atrophy ensues. There is more or less rigidity as a rule, lessened during sleep and increased by excitement and attempts to overcome the spasm. Aphasia is common in right hemiplegias and is found too in left. Electrical reactions are usually normal. Disturbances in sensation are slight and transient. Posthemiplegic chorea or athetosis is often found. The mental condition is often defective though it may be normal. Epilepsy is a frequent sequel.

Infantile Spastic Diplegia. Synonyms.—Bilateral infantile spastic hemiplegia; Little's disease; spastic rigidity of the new-born; birth palsies.

Etiology.—The causes are the same as of infantile hemiplegia. Most cases date from birth and are due to lesions during delivery. The lesions are bilateral and involve practically only the motor areas of the cortex. Usually the primary cause of cerebral birth paralysis is meningeal hemorrhage. From the resulting blood-clot or from meningo-encephalitis, sclerosis or porencephalous defect follows.

There may be convulsions, often a series, after birth. In mild cases, however, the first symptom, limpness of the muscles, may be noticed only after 6 or 8 months. This flaccidity is often mistaken for rickets. Some rigidity of the legs and exaggerated knee-jerks will be found later. Athetoid or choreic movements are seen frequently. Mental defect is usually present.

Infantile Spastic Paraplegia.—Etiology is the same as in the preceding types, with the additional factor premature birth.

Symptoms.—The spastic paralysis of the lower extremities dates from birth or the first years of life. There is talipes equinus or equinovarus, adductor spasm, rigid gait and no muscular atrophy. There may be slight or no mental defect.

Diagnosis.—Infantile cerebral paralysis must be differentiated from infantile spinal paralysis (see below). Spastic diplegia and paraplegia are distinguished from pseudoparalytic rigidity and tetany by the history—existing from birth; the parts involved: the legs almost to exclusion of arms; by the painless character of the spasm; and by the continuous duration.

Prognosis.—This is grave in diplegia and paraplegia. The majority of these due to intrauterine or birth lesions die in infancy, the rest usually are feeble-minded and helpless. The outlook is brighter in hemiplegia; the onset being later the brain is less apt to be injured seriously. The residual paralysis may be so slight that there may be no suspicion of a previous paralysis until the occurrence of epilepsy.

Treatment.—The stage of convulsion should be treated by chloral, absolute rest, ice to the head. The established paralysis is for the most part intractable, but baths, hygiene, gymnastics, good food, manipulations, surgical appliances, electricity, may be used. If mentally deficient, the child should be placed in an institution for the feeble-minded.

PARALYSIS, INFANTILE SPINAL. Acute Anterior Poliomyelitis; Acute Atrophic Paralysis.—An acute infectious disease characterized by a rapidly developed inflammation of the anterior horns of the gray matter of the cord, occurring suddenly in children, occasionally in adults—acute spinal paralysis of adults—characterized by mild fever, muscular tremors and twitchings, and paralysis of groups of muscles, followed by more or less atrophy.

Etiology.—The disease is due to a filterable virus. It is essentially a disease of early life, from the second month to the third or fourth year, but it may rarely be observed in adults. The affection is more common during the summer months, and males are most often attacked. It occasionally appears in epidemic form. Exposure to cold and damp, dentition, injuries, and the infectious fevers may act as predisposing causes. The nasopharynx is supposed to be the portal of entry as well as the place of exit; and the disease is conveyed by the secretions of the nose and bronchi as well as by

food, dust and flies. Coughing, sneezing and kissing are possible means of dissemination; and the existence of "carriers" must be remembered.

The disease may occur in adults, under thirty, though rarely. When it does, the symptoms are the same as in children; care, however, should be taken not to confound it with multiple neuritis.

Pathology.—Infantile spinal paralysis is due to an inflammation of the gray matter of the anterior portion of the spinal cord. The early changes are: Medullary hyperemia, vascular exudation, and inflammatory softening, although the naked eye may not recognize any changes. Microscopic examination reveals inflammatory softening of the anterior horns of the gray matter. Among other constant lesions are atrophic degeneration of the multipolar ganglion-cells and of the anterior nerve-roots. The changes noted as occurring in the cord are usually limited to the dorso-lumbar and cervical enlargements. The virus has been found in the central nervous system and in the cerebrospinal fluid. The tonsils and lymph glands are enlarged.

As a direct result of the changes in the trophic centers and the nerve degeneration of the muscular fibers supplied, there ensue changes in the bones and joints, leading to great deformities.

Symptoms.—The onset of the affection varies; it may be acute, subacute, or chronic; it is usually sudden, with an attack of mild fever of a remittent type, of a few days' duration, on recovery from which it is noticed that the child is paralyzed. There is often pain or soreness at the beginning of the disease. Rarely, the paralysis may be preceded by convulsions.

The paralysis may affect both arms and both legs, the legs alone, or only one of the four extremities; it may, very rarely, be a hemiplegia. As a rule, however, the leg suffers more frequently than the arm; in paralysis of the leg the muscles below the knee suffer more severely than those above. The bladder and rectum are not affected, or, if so, only temporarily, and anesthesia or numbness cannot be detected. The temperature of the paralyzed limb is low and the part is cyanosed in appearance. After a few days there is a slight improvement in the paralyzed parts, although the muscles show a rapid wasting, which is progressive until all muscular tissue is gone. The reflex movements are impaired or abolished.

The electro-contractility by the faradic current is abolished in the paralyzed parts.

The *nerves* affected show: (1) Nuclei swollen and granular; (2) the white substance of Schwann is broken up; (3) the axis cylinders are broken, and (4) the nerve substance becomes a fibrous cord. The *muscles* show: (1) Great increase in fibrous tissue; (2) presence of granules; (3) atrophy of muscular fibers; and (4) disappearance of the transverse striæ.

Sequels.—Among the deformities resulting from the paralysis are the different forms of talipes.

Talipes equinus, the result of paralysis of the antero-external muscular group of the leg.

Equino-varus, the result of paralysis of the antero-external muscular group of the leg, together with the adductors of the foot.

Talipes calcaneus, the result of paralysis of the muscles of the calf of the leg.

Talipes cavus—"pes cavus"—characterized by the hollowing of the sole of the foot, with prominence of the instep, the result of paralysis of the calf muscles with contraction of the long flexor of the toe or the long peroneus—the foot flexors.

Diagnosis.—The recognition of acute poliomyelitis is not always possible at the onset or during the early days of its course, as localized paralyses are difficult of detection in children, but *immobility of one leg or arm* in children with febrile symptoms, or following convulsions is always an indication of poliomyelitis. After the initial stage has passed, the presence of paralysis, wasting, presence of R.D. (reactions of degeneration), loss of reflexes, and the absence of anesthesia, render the diagnosis very easy.

Hemiplegia from acute cerebral affections in children can be distinguished from infantile paralysis by the disorders of intelligence and the special senses, and the perseverance of the normal electro-contractility.

Paralysis of myelitis occurs in older persons, and is associated with disturbances of the genito-urinary organs and bed-sores.

Pseudo-muscular hypertrophy, with paralysis, begins gradually, becoming progressively worse with increase in the size of the limbs.

Prognosis.—Except in cases in which the onset is very severe, the outlook as regards life is generally regarded as good; but in some epidemics the death rate is high. More or less paralysis with muscular wasting and deformities always results, but by its early recognition and prompt treatment the extent may be greatly lessened.

Treatment.—During the febrile stage the patient should be placed at rest in bed and all the secretions rendered free. If the affection is suspected at this period, the limbs should be wrapped in cotton-wool and ergot administered to lessen the spinal congestion. The nose and throat must be kept as clean as possible; gargling with 2 per cent solution of hydrogen peroxid is useful. Counterirritation is unnecessary. As soon as the febrile reaction has subsided and the paralysis becomes manifest the child should be well fed and taken out-doors once daily. Urotropin, in doses of 5 grains every 3 or 4 hours, has been recommended. Gentle friction should be applied to the affected muscles at first, followed later by the hot spinal douche and mild galvanism. Internally, quinin, belladonna, ergot, and potassium iodid may be of value. Later, as improvement takes place tincture of nux vomica, ♏j to iij, three times daily, or hypodermic injections of strychnin sulphate, gr. 1/16 to 1/100, according to the age, twice a week, and faradism to the paralyzed muscles are to be used. Means should be taken to prevent deformities. It must be borne in mind that the recovery of paralyzed parts and the restoration of lost muscular power and function is a process which extends over a very long period of time—months, and even years.

PARALYSIS, PSEUDOHYPERTROPHIC MUSCULAR.—See Muscles (Progressive Dystrophies).

PARALYSIS, SPASTIC SPINAL.—See Lateral Sclerosis.

PARAMYOCLONUS.—The convulsive tremor of Friedreich, a functional neurosis marked by the sudden shock-like character of the muscular contractions, their bilateral symmetry, and the freedom of the extremities. There is no ataxia, paralysis, or anesthesia; electric irritability is normal; consciousness is unimpaired; the convulsive movements are usually in abeyance during sleep. The disease generally occurs in males, and manifests itself both in children and in adults. It is supposed to be caused by fright or physical overstrain.

Paramyoclonus multiplex is an affection characterized by clonic contractions, chiefly of the muscles of the extremities, occurring either constantly or in paroxysms. It occurs usually in males, and follows emotional disturbance, fright, or straining. The contractions are usually bilateral, and may vary from 50 to 150 a minute.

PARANOIA (Monomania).—A chronic mental disease, characterized by fixed logical or systematized delusions of persecution, unseen or impossible agencies, or of self-exaltation, the emotions and memory being only paroxysmally defective, while, however, the life of the individual is dominated by the delusions. The term paranoia, as it is now commonly used—to cover a group of insanities which are degenerative in origin, chronic in course, and characterized by systematized delusions, with little impairment of the emotional faculties—is not generally accepted as a synonym for monomania. There is generally a hereditary predisposition to insanity in monomania or paranoia. The exciting cause may be the result of an acute mania or melancholia, or the result of alcoholism or of malnutrition in those who have had a struggle to keep their position in the world; extreme worry in individuals with mental instability; following primary or acute delusional insanity.

Symptoms.—The course of monomania is essentially chronic, the delusions becoming perfectly fixed and unchanging upon one particular subject or set of subjects, which in turn dominate the life of the individual. Most commonly these systematized delusions are delusions of persecution or suspicion, delusions of exaltation or of pride, and delusions of unseen agencies.

Diagnosis.—In the diagnosis of monomania there are three points to keep in mind: (1) The duration: the fixed, systematized delusions must have existed over one year. (2) The absence of symptoms of mania or melancholia. (3) The presence of systematized delusions affecting the personnel of the individual.

Monomania is an incurable disease. Unless tuberculosis develops within a few years, dementia results.

Treatment is symptomatic. The best hygienic conditions are demanded. See Mania.

PARAPHIMOSIS.—Retraction and constriction of the prepuce behind the glans penis. See Penis.

PARAPLEGIA, ATAXIC (Posterolateral Sclerosis, Gowers' Disease).—Degeneration of the posterior and lateral columns of the cord. The etiology is unknown. Syphilis, heredity, neurotic tendency seem to be factors. It is always associated with general paralysis of the insane. The symptoms resemble spastic paraplegia in the loss of power and muscular rigidity and tabes dorsalis in the marked incoordination. The reflexes, however, are exaggerated, incuding ankle clonus and knee-jerk. The sphincters are sometimes involved. Treatment is chiefly symptomatic. See Paralysis.

PARASITES.—Parasitism is essentially a condition of infestment of some form of life by another living organism, usually of lower type. The parasite is the invading form, whether animal or vegetable, and is spoken of as either an *ectoparasite*, if living upon the surface, or as an *endoparasite*, if inhabiting some part of the internal structures of the invaded organism. The latter is spoken of as the *autosite*, or *host;* and when in the life of the parasite there are special stages in its cycle, the host of the fully developed organism is spoken of as the *primary* or *definitive host*, the one or more hosts accommodating the intermediate stages of the parasite being denominated the *secondary* or *intermediate hosts*. Parasites of man are *animal* and *vegetable*.

There are three kinds of parasitism: (1) *True Parasitism*. In this condition the parasite does harm to the host, and derives all the benefit of the association; example, the hook-worm infecting man or animals. (2) *Mutualism*. In this there is mutual benefit to each party of the association; example, the presence of colon bacilli in the intestines, where the bacillus is furnished a suitable habitat and in return protects its host against strictly pathogenic bacteria. (3) *Commensalism*. Here there is benefit to the parasite, but no injury to the host; example, the trichomonas vaginalis which lives in the vaginal mucus, but, so far as is known, does no injury to the host.

Animal Parasites

The *effects of animal parasitism* may be practically *nil* according as the numbers of parasites present are small or the influences of the parasites are slight, or according to the part of the host affording accommodation to the parasites in question. On the other hand, pathogenic influences are exerted and anatomical changes and symptoms of variable intensity are produced by animal parasites just as in case of infection by pathogenic bacteria. The irritation caused by the presence and by the movements of the parasites, with consequent inflammatory effects, as well as the possibility of tissue destruction, pressure atrophy, and secondary degenerations, must be taken into consideration. The possibility of obstruction of more or less important channels, as the occlusion of blood or lymph vessels by the ova of blood flukes or the embryo filarial worms, as well as a large number of similar possible disturbances in other parts of the body by one or other form of parasites, must from time to time be reckoned with. The abstraction of food-stuff from the economy of the

host by the parasite cannot be looked upon as of serious import in itself, but the possibility of loss of valuable matter, as in blood destruction by the malarial hematozoon or the loss of blood by hemorrhage from the wounds in the intestinal mucosa through lesions caused by hook-worms and other sucking parasites, may constitute serious factors of disease for the host. Moreover, there unquestionably are toxic influences generated in one or other manner in animal parasitism which may exert marked and deleterious influences upon the infested organism, as doubtless in malaria, in uncinariasis, bothriocephalus disease and a number of other similar affections.—(*Tyson.*)

The important classes of animal parasites in man are the PROTOZOA (*q. v.*), the WORMS (*q. v.*), and the arthropods. Of the arthropods the important ones are (1) the *acarina* (mites, ticks), to which species belong the acarus scabiei (the itch mite), the leptus autumnalis (the harvest bug), and the demodex folliculorum (the comedo mite); (2) the *pediculidæ* (lice); and (3) the *diptera*, to which belong the fleas and flies. *Myiasis* is a condition due to the deposition of the larvæ of flies in open sores, or in the nose, ears, eyes, pharynx, or vagina.

Insects and Communicable Disease.—Recent studies in communicable diseases have shown that certain insects are essential to the propagation of some maladies, and incidentally are of importance in others. In malaria the mosquito is certainly the most important if not the only means by which the disease is spread; in this affection the sexual cycle of the plasmodium is completed in infected mosquitos. It is generally conceded that the mosquito is necessary to the propagation of yellow fever, the immediate cause of which is not known. In malaria and filariasis the animal parasites undergo definite cycles of evolution in the interior of the insect. In trypanosomiasis the tsetse-fly inoculates the disease from animal to animal, but, so far as at present known, the flagellate parasite has no definite cycle within the insect. There are reasons for believing that relapsing fevers can be transmitted by bedbugs, and that the bites of fleas coming from plague-stricken man or animals may induce the disease. In another group of diseases, including cholera, typhoid, tuberculosis, plague, and infections of the types indicated, the germ causing the disease may be deposited upon the food, and in that and similar ways be conveyed from sources of infection to the healthy.—(*Coplin.*)

Vegetable Parasites

The chief forms are the schizomycetes (fission fungi) or BACTERIA (*q. v.*); the blastomycetes or YEASTS (*q. v.*); and the hyphomycetes or *molds*. The mold fungi are made of filaments, hyphæ, so interlaced that they form a network, the mycelium. They reproduce by sporulation. Pathogenic molds are the direct agents in the production of the following diseases: favus (achorion Schönleinii); thrush (oïdium albicans); actinomycosis (actinomyces, ray fungus); mycetoma (streptothrix madura, one of the actinomyces group). The large-spore fungus or small-spore fungus to which ringworm is due has been shown to be not a common mold, but a specific fungus. Tinea versicolor is due to the microsporon furfur; erythrasma is caused by the microsporon minutissimum; pinta is due to several fungi of the class aspergillus; to this class *otomycosis* and *myringomycosis* are believed to be due. Sticker has found 16 cases of pulmonary disease to be caused by the aspergillus fumigatus—*aspergillomycosis*. The leptothrix—a long segmented fungus—is abundant in the lungs in pulmonary gangrene and may cause the formation of patches on the tonsil simulating diphtheritic membrane—*pharyngomycosis leptothrica*. The *leptothrix buccalis* is thought to play a significant rôle in the production of caries.

PARATYPHOID FEVER.—An infectious fever exactly simulating typhoid clinically, but due to a bacillus intermediate between the bacillus typhosus and the bacillus coli, called the paratyphoid or paracolon bacillus. The Widal reaction is negative, but the serum reacts upon fresh cultures of the paratyphoid bacillus.

Diagnosis is based solely on the paratyphoid agglutination test.

Treatment is the same as that of enteric fever except that obviously the paratyphoid bacillus or its product is used in specific treatment.

PAREGORIC.—The camphorated tincture of opium. It is of especial service in the treatment of diarrhea, because it contains a volatile oil and camphor, and it is a most common ingredient of cough mixtures.

In bronchitis:

℞.	Paregoric,	℥ ss
	Tartar emetic,	gr. j
	Potassium nitrate,	ʒ ij
	Bitter-orange water,	℥ xij.

Give 1 teaspoonful every hour when needed for the cough.

In diarrhea:

℞.	Paregoric,	ʒ iij to iv
	Dermatol (bismuth subgallate),	ʒ ij
	Chalk-mixture, add enough to make	℥ iij.

Give 1 teaspoonful every hour until relief is obtained.

PAREIRA (Pareira brava).—The dried root of *Chondrodendron tomentosum*, a plant of South America. It is diuretic and laxative, and tonic to the mucous membrane of the genitourinary organs. It is valuable in cystitis, gonorrhea, and leukorrhea, and is used internally and locally for the bites of poisonous serpents, etc. **P., Flext.** Dose, 10 to 45 minims. **P., Infus., unof.** Dose, 1 to 2 ounces.

PARESIS.—See PARALYSIS (General).

PARIS GREEN.—A preparation of copper, chemically known as cupric acetoarsenite, and used as a pigment for wall-paper coloring and as an insecticide. It is highly poisonous; and for treatment of the poisoning by Paris green see ARSENIC.

PARONYCHIA (Whitlow).—An abscess of the thumb or fingers.

The superficial whitlow consists of inflammation of the surface of the skin of the last phalanx, with burning pain or effusion of a serous or bloody fluid; it is generally seated immediately around and beneath the nail; it is attended by great pain and throbbing, and suppuration at the root of the nail, which may come off. The deep-seated variety, or *tendinous whitlow*, as it is called, is attended by severe, throbbing pain, exquisite tenderness, light but tense and resisting swelling, and very great constitutional disturbance. It may lead to suppuration, the pus extending along muscles and tendons from the fingers to the palm, and even to the forearm, causing sloughing of the tendons, with severe irritative fever, sometimes placing life in danger, and frequently leaving the limb stiff and useless.

If purgatives and fomentations do not speedily bring relief, the finger must be freely laid open. The knife, used early, should be carried deep enough to feel the resistance of the bone or tendon; the sheath of the latter should be thoroughly laid bare. If the matter has extended to the hand, an opening should be made until complete drainage is established. See NAILS (Diseases).

PAROÖPHORITIC CYSTS.—See OVARY (Diseases).

PAROTID DUCT, DIVISION.—See FACE (Injuries).

PAROTITIS.—Inflammation of the parotid gland, commonly called MUMPS (*q. v.*).

PAROVARIAN CYSTS. See OVARY (Diseases).

PARRESINE.—See PETROLATUM.

PARSLEY.—A biennial plant, from the fruit of which is extracted apiol, a nonvolatile, oily liquid, of green color, acid reaction, and pungent taste; it is often found in commerce as an impure oleoresin. See APIOL.

PARTURITION.—See LABOR.

PARULIS.—See ALVEOLAR ABSCESS.

PASTEURIZATION.—See MILK (Pasteurized).

PASTILLES.—See TROCHES.

PATELLA.—See KNEE-JOINT (Injuries).

PATHOLOGIC TECHNIC.—In this epitome, much of which is founded on the admirable work of Mallory and Wright on "Pathologic Technic," there are given very briefly the fundamental practical points. The subject is elaborated more fully under such special headings as BACTERIOLOGY, BLOOD (Examination), FECES (Examination), MICROSCOPE, POSTMORTEM EXAMINATION, SPUTUM, URINE (Examination), etc. In addition special pathologic technic is discussed under the headings of certain diseases, as GONORRHEA, TUBERCULOSIS, TYPHOID FEVER, etc.

Examination of Fresh Material

This may be examined after being teased apart or in sections.

Teased Preparations.—Place a small section on a glass slide, and cover with a normal salt solution, and tease apart by means of two sharp needles.

Sections of Fresh Specimens.—Freeze the specimen by the evaporation of ether, and shave off a small section by means of the blade of a carpenter's plane, allowing the specimen to fall into a normal saline solution. It should be spread out on a slide while remaining in the solution, then dried by blotting paper, and immediately examined. If it is desired to stain the specimen, add a few drops of Loeffler's alkaline methylene-blue solution, wash in water, and examine. Oil or fat in the fresh specimen may be demonstrated by means of a 1 percent solution of osmic acid.

Cover-glass Preparations.—Such preparations are usually made in examining blood, sputum, or other fluid or semifluid substance. In the case of sputum a tiny mass is placed on a cover-glass, another is pressed gently down upon this, and the two glasses are separated by sliding one over the other, the object being to secure a thin, even film on each glass. The film may also be spread with the edge of a cover-glass or with a platinum spatula. The preparations are then left to dry in air, or they may be dried by exposing them to a temperature of 120° F. for 20 minutes, or by passing them quickly 3 times through the flame of a spirit-lamp or Bunsen burner. When dry, they are ready to stain. To obtain a cover-glass preparation of blood, cleanse the finger, prick the tip, wipe off the first drop of blood that exudes, touch the apex of the second drop with a cover-glass, spread in the manner described, and dry in air.

Injection Masses.—On account of improvements which have been made in general pathologic technic within recent years, injections are not so essential as they were formerly, and are not generally used. If the specimen is well stained, the vessel and vessel walls are sufficiently prominent to be studied without being injected.

There are two kinds of injection masses—(1) cold and (2) hot. If the hot method is used, the fluid is injected into the tissue heated to the same temperature as the injection mass. The instruments are a syringe with various sized cannulas. Blood-vessels should first be washed out with normal salt solution.

Cold Injection Mass:

Soluble Berlin blue,	1
Water,	20.

Warm Injection Mass (Carmin Gelatin).—The warm injection mass is better to use. Place 2 to 2.5 grams of best carmin in about 15 c.c. of water containing enough ammonium hydroxid to dissolve it. Filter and place over a water-bath, and add a concentrated solution of gelatin, stirring constantly. Gradually add acetic acid until a bright red shade is produced. Care must be exercised in order to prevent too much acid from being used, otherwise the mass will become worthless, owing to the precipitation of carmin.

Fixing Reagents.—These reagents are used for the purpose of preserving intact the tissues, cells, and especially the nuclei. When the fresh specimen is obtained, it is immediately placed in the fixing reagent and afterward embedded and stained. A good fixative penetrates and kills tissues quickly, preserving the tissue elements. The choice of a

proper fixing reagent for a given tissue depends largely on the nature of the pathologic lesions present or suspected, and upon the object for which the tissue is preserved. For bacteriologic study of tissues, and for many valuable and chemic reactions, alcohol is best as a fixative reagent. For finer histologic work Zenker's or Orth's fluid is to be preferred. Flemming's solution is recommended for renal tissue when there is fatty degeneration. Tissues fixed in alcohol or in a solution of formaldehyd may remain as long as desired. Tissues hardened in most of the other fixatives must be transferred, after thorough washing in water, to alcohol for preservation. It is best to pass the specimen successively through alcohol of different strengths, as 30, 60, 90, and 96 percent, allowing it to remain from a few hours to a day in each strength. For general purposes the specimen may be transferred from water to alcohol of 70 to 80 percent, in which it may remain until it is desired to embed it.

Alcohol is used in the laboratory in 95 to 96 percent strength. The exposed surface of the tissues become shrunken and extremely hard when placed in alcohol. Tissue to be placed in either absolute or 95 percent alcohol should be cut into thin sections, 1/2 cm. thick. The volume of alcohol to be used should be 15 to 20 times as great as the specimen, and it should be changed after 3 or 4 hours. The tissue should be kept in the upper part of the alcohol by means of absorbent cotton, or the jar may frequently be inverted and the alcohol thus kept of even strength.

For general purposes it is best to place tissues at first into 80 percent alcohol, which should be replaced in 2 to 4 hours by 95 percent alcohol. In this way less shrinkage is caused and the surface of the tissues is not made so hard.

Zenker's Fluid:

℞.	Potassium bichromate,	2.5 gm.
	Sodium sulphate,	1 gm.
	Mercuric chlorid,	5 gm.
	Glacial acetic acid,	5 c.c.
	Water, enough to make	100 c.c.

This solution is practically Müller's fluid, saturated with mercuric chlorid and 5 percent of glacial acetic acid.

On account of the evaporation of the acid, it is probably best not to add all the acetic acid to the stock solution, but only in the proper proportion to the part selected for hardening.

Directions for Use.—(1) Fix the tissues in the solution for from 1 to 24 or 48 hours, according to thickness; (2) wash in running water 12 to 24 hours; (3) preserve in 80 percent alcohol until used.

Zenker's fluid penetrates quickly so that tissues do not require to be so thin as in the case of other fixatives. They should not, however, exceed 1/2 cm. in thickness. Occasionally there is a precipitation of mercury, which may be removed by adding a small quantity of tincture of iodin (up to 1/2 of 1 percent) to the alcohol in which the specimens are preserved. As soon as the color of the iodin disappears on account of its forming a colorless soluble compound with mercury, more iodin must be added, until the alcohol remains stained faintly yellow. Tissues hardened in Zenker's fluid stain best with alum hematoxylin. Good results are also obtained with eosin, followed by Unna's alkaline methylene-blue solution. Fuchsin and safranin stains are also useful. Nuclear figures, red blood-corpuscles, and protoplasm are all preserved by this fixative method.

Orth's Fluid:

℞.	Potassium bichromate,	2 to 2.5 gm.
	Sodium sulphate,	1 gm.
	Water,	100 c.c.
	Formaldehyd (40 per-cent solution),	10 c.c.

The formaldehyd should be added only at the time of using, otherwise the solution will become darker in 2 days, and a crystalline deposit will occur. The tissue should not be over 1 cm. in thickness. The specimens should be washed thoroughly in running water for from 6 to 24 hours, and then placed in 80 percent alcohol.

Mercuric Chlorid.—Use a saturated solution (made by heat) in normal salt solution. The addition of 5 percent of glacial acetic acid is sometimes advisable. (1) Harden thin pieces of tissue (2 to 5 mm. in size) for 1 to 6 hours; (2) wash in running water for 24 hours; (3) preserve in 80 percent alcohol. Tissues fixed by this method may be stained by nearly all solutions. With the Heidenhain-Biondi triple stain it yields good results.

Müller's Fluid:

℞.	Potassium bichromate,	2 to 2.5 gm.
	Sodium sulphate,	1 gm.
	Water,	100 c.c.

Harden the tissues for from 6 to 8 weeks. Change the fluid daily during the first week; once a week thereafter. Ordinary tissues are then washed in running water overnight before being placed in alcohol. Nervous tissue is transferred directly from the fluid to the alcohol. This fluid hardens tissues slowly without shrinkage, but is a poor nuclear fixative, and is gradually being displaced by more rapid methods.

Formalin.—The gas, formaldehyd (H.COH), is soluble in water to the extent of 40 percent formalin). The best strength of formaldehyd to use for fixing tissues is a 4 percent solution—that is, 10 parts of the aqueous 40 percent solution (formalin) to 90 parts of water—or, better, normal salt solution.

Sections of ordinary tissues not over 1 cm. thick are hardened in 24 hours. They may then be transferred to alcohol or may remain indefinitely in the formal in solution. Thin pieces are sufficiently hardened in 3 hours, when they may be frozen and cut, washed in water, then in alcohol, and stained.

Chromic Acid.—Used in aqueous or alcoholic solution in strengths varying from 0.1 to 2 percent. Weaker solutions are used for nerve tissue. Wash out several hours in running water. If the object is preserved in alcohol, it must be protected

from the light, or a precipitate will be thrown down on its surface. The brownish-green color of objects fixed in chromic acid may be removed by treating them with hydrogen dioxid. A 0.02 percent solution is recommended for macerating nerve tissue and nonstriated muscle tissue, a cube of 5 mm. requiring about 24 hours' immersion in 10 c.c. of the medium.

Flemming's Fluid (first formula):

Chromic acid,	0.2 gm.
Glacial acetic acid,	0.1 c.c.
Water,	100 c.c.

This is especially recommended for fixing the achromatic spindle-fibers in nuclei.

Second formula:

One percent chromic acid,	45 c.c.
Two percent osmic acid,	12 c.c.
Glacial acetic acid,	3 c.c.

This fixes small pieces (2 to 3 mm. thick) in from a few to 24 hours, and is useful for fixing the figures in cell-division and for many other purposes.

A weaker solution is also used:

One percent osmic acid, Glacial acetic acid,	each, 10 c.c.
One percent chromic acid,	25 c.c.
Water,	100 c.c.

The second formula is the one generally known as Flemming's fluid.

Decalcification

Tissues to be decalcified should be cut into thin slices of proper sizes (from 2 to 3 mm. thick), for embedding in celloidin. Softer tissues need not be thinner than 4 to 6 mm.

Steps in Decalcifying.—(1) The tissues must be thoroughly hardened, the three most useful reagents being alcohol and Zenker's and Orth's fluids. After using either of the two last reagents, the tissues must be washed thoroughly in water and placed in alcohol for at least 24 hours. They will then be ready for decalcification. (2) The decalcifying fluid should be used in large amounts, and, if necessary, be frequently changed. (3) After decalcification the tissues are to be thoroughly washed in running water for 24 hours, to eliminate every trace of the acid. (4) The tissues finally must be hardened again in alcohol.

The principal **decalcifying agents** are nitric acid, hydrochloric acid, chromic acid, and picric acid.

Directions for Using Nitric Acid.—(1) Decalcify in large quantities of a 5 percent aqueous solution of nitric acid, changing the solution every day for 1 to 4 days. (2) Wash for 24 hours in running water, to remove every trace of the acid. (3) Harden in 80 percent and then 95 percent alcohol. Embed in celloidin.

Phloroglucin and Nitric Acid.—Phloroglucin is not a decalcifying agent, but is added to nitric acid to protect the tissues, while allowing a stronger solution of the acid to be used than would otherwise be possible. The solution is prepared by dissolving 1 gram of phloroglucin in 10 c.c. of nitric acid. Solution takes place quickly, with the generation of considerable heat. The fluid is reddish-brown at first, but becomes yellow in the course of 24 hours. Dilute with 100 c.c. of a 10 percent solution of nitric acid. This gives nearly a 20 percent solution of nitric acid. The process of decalcification in this fluid is extremely rapid—a few hours only, as a rule, are required.

Picric Acid.—A saturated aqueous solution containing an excess of crystals is sometimes used for decalcifying. It has no injurious action on tissues, but is extremely slow, frequently requiring months. Fresh tissues may be placed directly in the solution, which hardens and decalcifies at the same time. Instead of being washed out in water, in which they would macerate, the pieces of tissue are placed directly in 70 percent alcohol to remove the acid.

Embedding Processes

Sections may be cut by means of the razor or Microtome (*q. v.*). Two substances are now principally used for embedding: they are celloidin and paraffin. Celloidin methods are preferred for general pathologic work and for histologic work, while paraffin sections should be reserved for the finest details or for the study of special tissues.

If large sections are desired, celloidin is preferable; if small sections are desired, paraffin is used.

Embedding in Celloidin.—Allow the section to macerate from 24 hours to several days in 2 different solutions of celloidin. The two solutions are spoken of as thin and thick solutions. To make a *thick* celloidin, 30 grams of the dry celloidin are dissolved in 500 c.c. of a mixture of equal parts of ether and absolute or 95 percent alcohol. This gives a 6 percent solution.

Diluted with an equal amount of ether and alcohol solution, it forms *thin* celloidin.

The steps of the embedding process are as follows (Mallory and Wright): Pieces of tissue which have been properly fixed and finally preserved in 80 percent alcohol are first to be cut with great care. They should rarely be over 4 to 8 mm. thick; for most purposes 2 mm. will be sufficient. Pieces of this thickness will furnish several hundred sections, will embed more quickly than larger masses, and will be more rigid when mounted on a block. They should never be broader or longer than is necessary to show the whole of the process under study. Very thin celloidin sections cannot usually be obtained with tissues over 1 1/2 or 2 cm. square, and smaller dimensions are preferable. Beginners usually embed larger pieces than are necessary.

The trimmed pieces of tissue are first hardened and dehydrated for 24 hours in 95 percent alcohol; then macerated in equal parts of alcohol and ether for the same length of time, to prepare them for the thin celloidin. In the latter they remain at least 24 hours, preferably for a number of days if at all thick, for in this solution occurs most of the in-

filtration with celloidin. Finally, the pieces are macerated 24 hours or more in thick celloidin. They are then mounted on blocks of vulcanized fiber, exposed to the air for 2 or 3 minutes until the surface hardens a little, and placed in 80 percent alcohol for 6 to 24 hours to allow the celloidin to harden.

Summary of the Different Steps in Celloidin Method.—(1) Place in 95 percent or absolute alcohol for 24 hours; (2) then in ether and 95 percent or absolute alcohol (equal parts) for 24 hours; (3) in thin celloidin for from 24 hours to 1 or more weeks; (4) in thick celloidin for from 24 hours to 1 or more weeks; (5) mount on blocks of vulcanized fiber; dry for 1 or 2 minutes in the air; (6) harden the celloidin in 80 percent alcohol for from 6 to 24 hours.

In cutting, the microtome knife should be held very obliquely, and covered with 80 percent alcohol. Celloidin sections may be stained by nearly all methods without removing the celloidin. It can be removed, however, by placing the sections in absolute alcohol, in oil of cloves, or in equal parts of alcohol and ether for 5 to 10 minutes, then passing the sections back through absolute into ordinary alcohol.

To Transfer Sections to the Slide.—Transfer the section from water to a slide and dry with cloth and press down firmly with filter-paper or blotting paper before it becomes dry. It may also be transferred in the following manner: Place in 95 percent alcohol and transfer to the slide; at the same time allow the vapor of ether to soften the section, when it may be smoothly fixed to the slide; wash with 80 percent alcohol to harden the celloidin.

Embedding in Paraffin.—This method is very useful, especially when thin sections are desired. The pieces of tissue should be small, soft, and of uniform consistency. In pathologic work it is better to cut the sections and to stain them after they are fastened to the slide than to stain in the mass beforehand, because a variety of stains may be used, which is a distinct advantage. The first step in the preparation of hardened tissues for the paraffin bath is to cut them into small, thin, square or rectangular pieces not over 1 cm. square, preferably not over 2 to 3 mm. thick. The pieces of tissue are then thoroughly dehydrated by macerating first in 95 percent and then in absolute alcohol. From alcohol they are put in some substance, such as chloroform or oil of cedar, which has the property of mixing with alcohol and of dissolving paraffin. From chloroform they are transferred to a saturated solution of paraffin in chloroform, and then passed through 2 or 3 separate baths of the melted paraffin to get rid of every trace of chloroform. If oil of cedar is used, the specimens are transferred directly from it into the melted paraffin.

Summary of Different Steps in Paraffin Method.

Method No. 1.

1. Ninety-five percent alcohol,	6 to 24 hours.
2. Absolute alcohol,	6 to 24 hours.
3. Chloroform,	6 to 24 hours.
4. Chloroform saturated with paraffin,	6 to 24 hours.
5. Paraffin bath, 3 changes,	1 to 6 hours.
6. Embed and cool quickly in cold water.	

Method No. 2.

1. Ninety-five percent alcohol,	6 to 24 hours.
2. Absolute alcohol,	6 to 24 hours.
3. Oil of cedar, 2 changes,	6 to 24 hours.
4. Paraffin, 3 changes, until no odor of oil of cedar,	2 to 8 hours.
5. Embed and cool quickly in cold water.	

In the second method instead of oil of cedar, xylol, equal parts of oil of cloves and turpentine, or oil of cloves and xylol may be used.

For embedding the specimens, metallic boxes, or paper boxes made of stiff writing-paper, may be used. Melted paraffin is poured into the paper box to the depth of about 1 cm. The pieces of tissue are placed in the box with that side down from which sections are preferred. Several pieces of tissue are thus placed in the melted paraffin when the box is placed upon cold water. After the paraffin has hardened, the paper is removed, and the paraffin is divided up according to the pieces in it.

One of the blocks is fastened to the object-holder by heating the latter in a flame until it will just melt the paraffin when the block is held in proper position against it. The holder is then quickly cooled in cold water. Trim off the overlying paraffin until the specimen is reached, and adjust in the paraffin microtome. To get the best specimens the temperature of the room must be so regulated that the sections are ribbon-shaped.

The sections are laid on the surface of a large dish of warm water, about 44° C., and, if necessary, gently stretched so as to remove wrinkles. Paint the surface of a slide with a thin layer of Mayer's glycerin albumin mixture (equal parts of white of egg and glycerin); wipe off excess with a towel so that a faint layer is left; dip the slide under the sections; arrange them in order; life the slide, and drain off the water. The slide is then placed in a slanting position until dry, when it is put in the thermostat for from 2 to 12 hours at a temperature of 54° to 60° C. To get rid of the paraffin in the sections they are treated with 2 or 3 changes of xylol, and then with absolute alcohol, followed by 95 percent alcohol.

If the celloidin and oil of cloves mixture is used, the paraffin is removed by means of xylol, followed by oil of origanum or oil of bergamot, and finally by 95 percent alcohol, because absolute alcohol will dissolve the celloidin (Mallory and Wright).

Serial Sections by the Celloidin Method.—The specimen is embedded, mounted on vulcanized

fiber, and hardened in 80 percent alcohol. Moisten the knife of the microtome with 95 percent alcohol. As the sections are cut they are drawn upon the surface of the knife and arranged in the proper order by means of a camel's-hair brush. Place the slide against the back of the knife and transfer the section by means of the camel's-hair brush. The section is then fastened to the slide by allowing a few drops of ether to be poured upon it, after which all the edges are smoothed down very carefully. The slides are then numbered, and may be kept in a jar of 80 percent alcohol.

Serial Sections by the Paraffin Method.—Cut ribbons a yard long, if necessary, and place them on sheets of paper in proper order. They may then be divided into short series with a needle, and fastened to the slide by means of Mayer's albumin mixture.

Staining Solutions

Aqueous Alum-hematoxylin Solution:

Hematoxylin in crystals,	1
Saturated aqueous solution of ammonium-alum,	100
Water,	300
Thymol,	a crystal.

Dissolve the hematoxylin in a small quantity of hot water. The combined solution is then exposed to light in a bottle tightly stoppered with a plug of cotton. The solution will be ready for use in about 10 days, after which time it should be kept in a tightly stoppered bottle. It is very easily prepared and gives excellent results.

Delafield's Hematoxylin:

Hematoxylin in crystals,	4 gm.
Alcohol, 95 percent,	25 c.c.
Saturated aqueous solution of ammonium-alum,	400 c.c.

Add the hematoxylin dissolved in the alcohol to the alum solution, and expose the mixture in an unstoppered bottle to the light and air for 3 or 4 days. Filter, and add—

Glycerin,	100 c.c.
Alcohol, 95 percent,	100 c.c.

Allow the solution to stand in the light until the color is sufficiently dark, then filter and keep in a tightly stoppered bottle. The solution keeps well and is very powerful. So long as it is good, the solution has a purplish tinge.

Alum-carmin:

Carmin,	2 gm.
Alum,	5 gm.
Water,	100 c.c.

Boil 20 minutes, adding enough water to make up for that lost in evaporation. When cool, filter and add a crystal of thymol to prevent the growth of mold.

Methylene-blue.—A saturated solution in 95 percent alcohol or absolute alcohol should be kept in stock to be used in making other solutions. This can be used as a stain by adding 1 part to 9 parts of water.

Loeffler's Alkaline Methylene-blue Solution:

Saturated alcoholic solution of methylene-blue,	30 c.c.
Solution of caustic potash in water (1 : 10,000),	100 c.c.

This solution keeps well for long periods of time.

Gabbett's Methylene-blue Solution:

Methylene-blue,	2
Sulphuricacid,	25
Water,	75.

Used as a decolorizer and contrast stain for tubercle bacilli.

Fuchsin.—A saturated alcoholic solution to be kept in stock. See FUCHSIN.

Ziehl-Neelsen's Carbol-fuchsin:

Saturated alcoholic solution of fuchsin,	10 c.c.
Five percent carbolic acid water,	90 c.c.

This solution stains quickly and keeps well.

Gentian-violet.—A saturated alcoholic solution; should be kept in stock.

Ehrlich's Anilin Gentian-violet Solution:

Saturated alcoholic solution of gentian-violet,	16 c.c.
Anilin water,	84 c.c.

Mix and let stand for 24 hours. Does not keep longer than 1 week or 10 days.

Safranin.—Any of the three following solutions may be used:

1. A saturated aqueous solution of safranin O, soluble in water (to be made with aid of heat).
2. A mixture of equal parts of a saturated aqueous solution of safranin O, soluble in water, and a saturated alcoholic solution of safranin, soluble in alcohol.
3. Two percent anilin water, 100
   Safranin O, soluble in water, in excess.

Saturate the solution with heat (60° to 80° C.), and filter.

Methyl-violet.—Aqueous solutions of several strengths, as 0.5 to 2 percent. Stains nuclei of cells, bacteria, etc.

Eosin.—Stains rapidly and gives a beautiful, diffuse, rosy hue. It is one of the best contrast stains with hematoxylin. Make a 5 percent aqueous solution, and dilute as required. It is also a specific stain for red blood-corpuscles (to which it gives a copper color), for certain leukocytes, and for the giant-cells of leprosy and tubercle.

Eosin-hematoxylin stain and the "polychrome" *methylene-blue, eosin solution (Romanowsky stain)*

are excellent for routine work. The former combined with Wright's stain is in conjunction especially valuable in the study of nuclear structures. The Romanowsky stain is particularly serviceable in examining the malarial organism and other parasites.

Ehrlich-Biondi-Heidenhain Triple Stain.—To 100 c.c. of a saturated aqueous solution of orange add, with continual agitation, 20 c.c. of a saturated aqueous solution of acid fuchsin and 50 c.c. of a like solution of methyl-green; dilute with from 60 to 100 volumes of water. A drop on blotting paper should form a spot bluish-green in the center, orange at the periphery; a red zone outside the orange indicates that the mixture contains too much fuchsin. From 6 to 24 hours are required to stain. Wash out in alcohol and clear in xylol. Chromatic elements are colored blue; cytoplasm, violet or orange-red; karyoplasm the same, but in lighter tones, and all the denser protoplasmic elements the same, but darker (Gilson). This is the best stain for photomicrography, except for connective tissue (Lindsay Johnson). A slightly acid reaction of the alcohol used for washing out will produce a relatively strong coloration by the methyl-green; while that by the fuchsin will be relatively pale; the opposite result will be obtained if the alcohol contains a trace of alkali. The addition of very dilute acetic acid, until the red tint is markedly intensified, will restore the energy of the fuchsin, which is likely to decline after a time (Heidenhain).

Wright's Stain.—A modification of Jenner's stain, an alkaline eosinate of methylene-blue. To a 1/2 percent aqueous solution of sodium bicarbonate in an Erlenmeyer flask is added 1 percent of Grübler's medicinal methylene-blue. The mixture is placed in steam sterilizer for an hour. When cooled to it is added with constant stirring a 1 to 1000 aqueous solution of Grübler's water-soluble yellow eosin till the original color changes from blue to purple and forms a yellowish scum on the surface. The resulting precipitate upon filtration is dried and added to methyl alcohol (3/10 gram will require 100 c.c. for solution). The solution is filtered and to the filtrate is added 25 percent of methyl alcohol.

Giemsa Stain.—The formula is as follows: Azure II, 3 grams; eosin B. A., 0.8 gram; glycerin (C. P.), 250 c.c.; methyl alcohol (C. P.), 250 c.c. The films are fixed in methyl alcohol and then stained 5 minutes in a mixture of 14 drops of the stain to 10 c.c. of distilled water. A trace of sodium carbonate added to the water accentuates the basic stains. Then wash, dry and mount.

Pianese Double Stain.—Prepare a saturated solution of nigrosin in a saturated alcoholic solution of picric acid; mix 2 volumes of this with 1 volume of anilin water, and evaporate in open air. The crystals deposited are dissolved in absolute alcohol, and from this solution green crystals are obtained, soluble in alcohol, ether, and water. For tissues, make a 2 percent solution in alcohol; for microorganisms, in water. Stain sections first in lithium carmin, treat with acid alcohol, wash, and immerse in an alcoholic solution of picronigrosin until they assume a brown hue. Decolorize in oxalic acid. Nuclei are stained red; plasma dark yellow; cartilage yellow; connective tissue pale green; elastic fibers violet.

Silver Nitrate.—Particularly adapted to the study of epithelial and connective tissues. Make a 1 percent solution in distilled water, and dilute from 2 to 4 times for use. Very thin sections of fresh tissue are washed in distilled water to remove the chlorids, immersed for 1/2 hour in the solution in the dark, washed in distilled water, and then placed in water and exposed to sunlight until brown. Fix in a solution of sodium hyposulphite in the dark, and mount in glycerin jelly.

Gold Chlorid.—Recommended for tracing nerve-endings in fresh tissues, and for staining connective tissue and cartilage cells. Place small pieces of tissue, 1/4 inch square, in from a 0.5 to a 1 percent solution of commercial gold chlorid in distilled water. Keep in the dark, and when the tissue has become yellow, wash in distilled water. Then expose to the light in 50 c.c. of water containing 2 drops of acetic acid for 48 hours, or until the tissue acquires a purple tint.

Osmic Acid.—Tissues fixed in osmic acid and subsequently treated with weak pyrogallic acid are stained greenish-black (Lee). It is a fixing reagent as well as a stain for fat or myelin. A 1 or 2 percent solution is used. A developing mixture of water, alcohol, tannin, and pyrogallic acid, or a 5 percent solution of tannin is used by Kolosson. Treatment with oxalic acid 1 part, in water 15 parts, gives a Burgundy-red stain to osmium objects, which should be washed in water before they are put into the acid.

Clearing Reagents.—These reagents are used for the purpose of rendering certain tissue elements more distinct. For this purpose acetic acid may be recommended in the strength of 2 to 5 parts of acid to 100 parts of water.

This reagent causes swelling of the ground substance, and facilitates the study of the nuclei, elastic fibers, fat, myelin, and microorganisms.

Other reagents are also used for the purpose of clearing tissues, but care must be exercised to select one which will not dissolve the anilin dye in the section already stained, and one which will clear it when celloidin is used. When either the celloidin or paraffin method is used, one of the following clearing reagents is recommended: oil of bergamot, or a mixture of oil of cloves 1 part, and oil of thyme 4 parts. When anilin dyes have been used, the best clearing reagent is xylol. It is to be preferred also in unembedded sections, and for paraffin sections that have been dehydrated in absolute alcohol. Other reagents are oil of lavender, oil of cedar, and anilin oil.

Mounting Reagents.—The best mounting reagent is Canada balsam, although dammar and colophonium are sometimes used.

Staining Methods.—Tissues are stained for the purpose of differentiating the tissue elements; to show bacteria; to present evidences of pathologic change in the arrangement of the tissues, and to show the affinity of tissue for special anilin dyes. The three principal tissue elements are (1) the

cell, (2) intercellular substance, and (3) pathologic products.

The cell contains the nucleus, protoplasm, and cuticle. Within the *nucleus* may be seen the nucleolus, resting nucleus, and frequently bacteria. The *protoplasm* may show the centrosome and polar bodies, the different varieties of granules, dendritic processes of ganglion cells, axis-cylinder and terminal processes, contractile elements of striated muscle-fiber, red blood-globules, cilia of bacteria. Within the *cuticle* there may be seen certain dots in ependymal cells, cilia in certain renal cells, and bile capillaries.

In the intercellular substance may be studied the cement substance of endothelial cells; the ground substance of connective tissue; connective-tissue fibrillæ; myxomatous tissue; mucin; elastic fibers; intercellular substances of cartilage; ground substance of bone; myelin; neuroglia fibers; clubs of actinomyces, and capsules of bacteria.

Pathologic products may be shown after the staining process: as, for instance, the hyalin substance may be changed into substances such as fibrin, mucin, amyloid glycogen, hyalin colloid, keratohyalin, and eleidin. There may also be present fat, hemosiderin, hematoidin, or hemoglobin.

The tissue elements may be stained differentially in a number of ways, frequently one stain answering the purpose, while in others a series of stains may be required, depending upon the affinity of certain chemic constituents of the cell for certain dyes.

Nuclear Stains.—Probably the most serviceable stain for nuclei in general work is alum-hematoxylon, using eosin as a contrast stain. Such carmin stains as lithium carmin, followed by picric acid, have also been used.

Safranin is also highly recommended as a nuclear stain. Other nuclear stains are eosin, followed by methylene-blue, and Unna's alkaline solution of methylene-blue (methylene-blue, 1 part; potassium carbonate, 1 part; water, 100 parts).

Method.—(1) Stain for from 2 to 30 minutes; (2) wash in several changes of water; then leave the sections, if possible, for several hours or overnight in a large dish of water; (3) contrast stain usually an aqueous solution of eosin, 1/10 to 1/2 of 1 percent, for 1 to 5 minutes; (4) alcohol, 95 percent, 2 or 3 changes to dehydrate and remove excess of contrast stain; (5) clear in oleum origani cretici, or in the mixture of oil of cloves and thyme; (6) mount in Canada balsam.

To Study Changes of Karyomitosis.—In studying these changes it is essential that the tissue be selected and fixed in one of the reagents at the earliest possible moment after its removal. For this reason the figures produced by mitosis cannot be so well studied when removed postmortem. A fixing reagent should be selected which penetrates quickly, such as safranin.

To Stain Karyokinetic Figures.—Fix the section in Zenker's or Orth's fluid, embed in paraffin, and stain with Babe's anilin safranin solution, prepared as follows: Two percent anilin water, 100; safranin O, soluble in water in excess. Saturate the solution by heating in a flask placed in hot water at a temperature of 60° to 80° C., and filter.

Method.—(1) Stain the paraffin section from a few minutes to an hour; (2) wash in water; (3) wash in 95 percent alcohol, to which are added a few drops of acid alcohol (hydrochloric acid, 1 c.c.; 70 percent alcohol, 99 c.c.); (4) wash in pure 95 percent alcohol, followed by absolute alcohol; (5) clear with xylol; (6) mount in xylol balsam (Canada balsam, 4 grams; xylol, a sufficient quantity to make a fluid having a syrupy consistency).

If the specimen is embedded in celloidin, clear the section in oil of bergamot or oleum origani cretici after the 95 percent alcohol, wash in xylol, and mount in xylol balsam.

Carbol-fuchsin and anilin gentian-violet may also be used in the place of safranin.

Staining of Bacteria in Tissues.—After embedding the section in the usual manner—by the paraffin method preferably—it is cut in a very thin section and attached to a slide by means of Mayer's glycerin-albumin mixture (equal parts of white of egg and glycerin). The best staining fluids are dilute aqueous or alcoholic solution of the anilin dyes, such as methylene-blue, gentian-violet, and fuchsin.

The sections should be heated moderately while being stained, either in a thermostat or over an alcohol lamp.

The decolorizing agent will vary with the stain employed. Those generally used are dilute acetic acid, 1 : 100 up to 1 : 1000, alcohol, iodin in potassium iodid solution, dilute mineral acids, chlorid of anilin, anilin, and ethereal oils.

Many pathogenic microorganisms require special staining fluids for their detection in the tissues, for further discussion of which see under their special heads, as GONOCOCCUS, PNEUMONIA, TYPHOID FEVER, etc.

Gram's Method.—Heat 2 to 5 minutes, or stain cold 20 to 30 minutes (tubercle bacilli, 12 to 24 hours), in saturated solution of gentian-violet anilin-water; rinse quickly in absolute alcohol; transfer to Gram's solution (1 to 1 1/2 minutes), in which the specimen turns black; wash in alcohol until the black color vanishes and a pale gray color appears; dry and mount in Canada balsam. The decolorization may be hastened by adding 3 percent nitric acid to the alcohol and then washing in pure alcohol. All the tissue cells are decolorized by this method, while the bacteria are stained a deep blue. The cells may subsequently be stained with a watery or alcoholic solution of Bismarck brown 2 to 5 minutes, then washed in absolute alcohol until the section is yellowish-brown. This method is of diagnostic value, as certain bacteria are stained, others decolorized, by it.

Bacteria that are Stained by Gram's Method.—Staphylococcus pyogenes aureus; streptococcus pyogenes; micrococcus lanceolatus (of pneumonia); micrococcus tetragenus; bacillus of diphtheria; bacillus of tuberculosis; bacillus of leprosy; bacillus of anthrax; bacillus of tetanus; bacillus aërogenes capsulatus; ray fungus of actinomycosis.

Of these the tubercle bacillus and the bacillus

of leprosy require a much longer exposure to the stain than other bacteria in the list.

Bacteria that are not Stained by Gram's Method.—Gonococcus; diplococcus intracellularis meningitidis; micrococcus melitensis; bacillus of chancroids (Ducrey); bacillus of dysentery (Shiga); bacillus of typhoid fever; bacillus coli communis; bacillus pyocyaneus; bacillus of influenza; bacillus of bubonic plague; bacillus of glanders (bacillus mallei); bacillus of Friedländer; bacillus proteus; spirillum of Asiatic cholera; spirillum of relapsing fever.

Staining of Nervous Tissue.—The tissue element to be studied in this structure are: (1) The ganglion cells, including the dendritic and axis-cylinder processes; (2) the myelin sheaths, and (3) the neuroglia fibers. Each requires special fixing reagents to be studied in detail. Formaldehyd (4 percent) has, however, been recommended as a fixing reagent for the preservation of all of these elements of nerve tissue.

Special stains are also required for each element: thus for the *ganglion cells*, Nissl's and Lenhossek's methods have been used.

For staining the *dendritic* and axis-cylinder processes, Golgi's slow or quick method is recommended.

For staining the *myelin sheath*, use Weigert's quick method or Pal's modification of Weigert's process.

For staining *neuroglia fibers*, use Weigert's or Mallory's method.

All of these processes are quite complicated and require very accurate manipulation in order to get the best results.

Transmission of Materials Containing Bacteria, in the Mails.—The ruling of the Post-Office Department of the U. S. is as follows:

"That the order of the Postmaster General of December 27, 1897 (Order No. 677), amending Order No. 88 of February 5, 1896, prescribing the conditions under which specimens of diseased tissues may be admitted to the mails is hereby further modified in the following manner:

"Specimens of diseased tissues may be admitted to the mail for transmission to the United States, State or municipal laboratories, only when enclosed in mailing packages constructed in accordance with the specifications hereinafter enumerated: Liquid cultures, or cultures of microorganisms in media that are fluid at the ordinary temperature (below 45° C. or 113° F.) are unmailable. Such specimens may be sent in media that remain solid at ordinary temperatures.

"Upon the outside of every package shall be written or printed the words 'Specimen for Bacteriological Examination. This package to be treated as letter mail.' No package containing diseased tissue shall be delivered to any representative of any of said laboratories until a permit shall have first been issued by the Postmaster General certifying that said institution has been found to be entitled, in accordance with the requirements of this regulation, to receive such specimens."

The regulation includes not only cultures, but "specimens of diseased tissues." The specifications prescribing the manner of packing, which are minute and complicated, may be obtained from local postmasters.

PEDICULOSIS (Lousiness; Phthiriasis).—A contagious animal parasitic disease, characterized by the presence of pediculi, hemorrhagic points, and scratch-marks.

Varieties.—There are three varieties: (1) Pediculosis capitis; (2) pediculosis corporis; (3) pediculosis pubis.

Pediculosis Capitis.—Pediculosis capitis is due to the invasion of the scalp by the pediculus capitis, or head-louse. It is characterized by severe itching, which excites scratching and leads to the formation of excoriations with serous, purulent, or sanguineous exudation. This dries in the form of crusts and mats the hair together. A foul odor is usually present. Owing to the irritation, the postcervical glands may become enlarged, and in some cases suppurate. The occipital region is the most frequent seat of this particular dermatitis. Scattered papules, pustules, and excoriations are frequently seen about the face and neck. Pediculi are present in varying numbers, and ova or "nits" in abundance. Ova are grayish, translucent, pyriform bodies, attached to the hair by a membranous sheath, they hatch out in from 3 to 8 days. Pediculosis capitis is far more common in children than in adults.

Diagnosis.—Owing to the presence of the pediculi and the "nits," the diagnosis, is as a rule, easy. Every pustular eczema in the occipital region should be regarded with suspicion, and warrants a search for pediculi and ova.

Treatment.—The object of treatment is to kill the pediculi, devitalize the ova, and subdue the accompanying inflammation. Among the most popular and efficacious remedies are petroleum, either pure or with equal parts of olive oil, and balsam of Peru. They should be thoroughly applied to the scalp for 1 or 2 nights, followed in the morning by a shampoo of the scalp with soap and water or tincture of green soap. Other remedies, such as cocculus indicus, staphisagria (2 fluidrams to 4 fluidounces dilute acetic acid), or corrosive sublimate (1 to 4 grains to 1 fluidounce), may be employed.

When there are much pustulation and crusting, the following ointment may be applied:

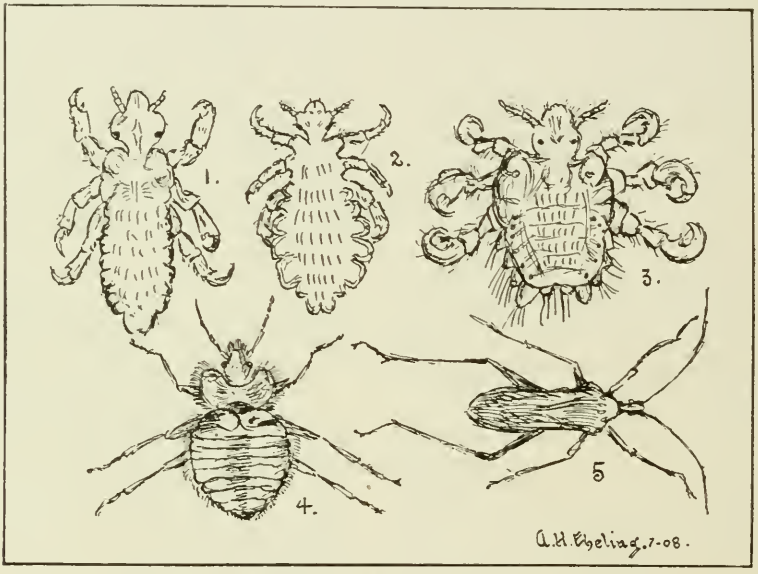
℞.	Ammoniated mercury,	gr. xxx
	Petrolatum,	℥ j.

For the removal of "nits," alkaline solutions (such as carbonate of sodium, borax, etc.) or acid solutions (dilute acetic acid) should be applied frequently. There is rarely need of sacrificing the hair in women, although this may be done in children.

Pediculosis Corporis.—This is produced by the pediculus corporis or vestimenti, a parasite larger than the scalp louse. It resides in the seams of the underclothing, where the ova are deposited. They hatch out in about 6 days. The louse is

merely present upon the skin when foraging. The perambulation of the parasite produces intense itching, which gives rise to violent scratching. As a result linear scratch-marks, blood crusts, and, in chronic cases, pigmentation and thickening may be seen. The parts affected are those coming in contact with the seams of the undergarments—namely, the scapular region, the chest, waist, and thighs. Hemorrhagic points mark the sites from which pediculi have extracted blood. The disease is common among the poorer classes in adults of middle or advanced age. It is rare in children.

Diagnosis.—The characteristic features are the presence of excoriations, nail-marks, blood crusts, and hemorrhagic points upon the scapular region and around the waist. Careful search in the seams of the undergarments will usually reveal the existence of pediculi.



1. Head Louse. 2. Body Louse. 3. Crab Louse. 4. Bed Bug. 5. Mexican Bed Bug.—(*Stitt.*)

Treatment.—The most important part of the treatment is the sterilization of the clothes and bed-linen. These should be thoroughly boiled or baked. A lotion of carbolic acid or thymol will relieve the itching quite effectually. When sterilization of the clothing cannot be carried out, it is best to prescribe an ointment of sulphur (1 dram to 1 ounce) or staphisagria (2 drams to 1 ounce).

Pediculosis Pubis.—The pediculus pubis, or crab louse, is responsible for this form. It is the smallest of the pediculi, and is found clinging tenaciously to the hair with the head buried in the follicular orifice. The "nits" are seen attached to the hair-shaft. Itching about the genitalia, variable in degree, is the most prominent symptom. Hemorrhagic points, papules, and excoriations may also be present. The pubis and perineum are the usual regions involved. Occasionally the axillæ and sternal regions are attacked, and in rare cases the beard, eyebrows, or eyelashes. The disease is almost exclusively observed in adults, and is usually contracted during sexual intercourse.

Diagnosis.—The diagnostic features are itching about the genitalia and the presence of pediculi and ova.

Treatment.—The parts should be washed with soap and water twice daily. Lotions, being more cleanly than ointments, are preferable. Corrosive sublimate, the tincture of cocculus indicus, or the fluidextract of staphisagria are all excellent applications.

℞. Fluidextract of staphisagria, ʒ ij
Dilute acetic acid, ʒ iij
Distilled water, ʒ iij.

White precipitate ointment (1 dram to 1 ounce), or mercurial ointment, is effective. Vinegar, dilute acetic acid, and soda and borax solutions are of value in effecting the removal of the nits.

PELIOSIS.—See Purpura.

PELLAGRA. Synonyms.—*Malatie della miseria, Mal del sole, Pellarella,* Asturian leprosy, Alpine scurvy, *Mal rosso, Mal del padrone.*

Definition.—Pellagra is a chronic specific disease, probably infectious, characterized locally by erythema involving usually the exposed portions of the body surface and recurring from year to year during the summer months; characterized constitutionally by symptoms involving the gastro-intestinal tract and the mental and nervous systems.

History and Distribution.—The first authentic description of the disease as a distinct entity was written by Gaspar Casal, a Spanish physician, his monograph on the subject appearing in 1762, after his death. The disease was observed by him as early as 1735 and was described as "*Mal de la rosa.*"

His description of the disease was based on clinical observations among the peasants of the Asturias (Oviedo, Spain). In Italy, the first recorded reports appeared in 1700 (Ramazini) and 1740 (Pujati), but it was not until 1771 that serious attention was directed to the disease through the efforts of Frapolli. Though these are the first recorded reports of the disease, Sambon adduces abundant evidence in support of the supposition that the disease existed in Italy for several centuries prior to this time.

In Italy, the disease has always been most prevalent in the North—Piedmonte, Lombardia, Veneto—sweeping from the Julian Alps to the Piedmont Alps and from Lago Maggiore downward to the Arno. Within recent years, however, with betterment in general conditions, with the tremendous growth in industrial concerns, and with the extensive temporary emigration during the summer months, the disease has practically disappeared in Piedmont, and is rapidly decreasing in Lombardy and certain sections of the region of Venice.

The disease is extending to the south of Italy, and is to be found in Umbria, Tuscany, the Marche and the Abruzzi. In 1881, the number of pellagrins reported from Lombardy was 36,630. In the 1905 census this number had decreased to 15,746. In Umbria, Tuscany and the Marche, the official figures show an increase:

	1881	1905
Tuscany,	924	1137
Marche,	406	1436
Umbria,	872	4250

The disease is quite common in Spain, Portugal, the Tyrol, Austria-Hungary, Roumania, Servia, Bulgaria, and Asia-Minor; it has also been observed in India. Sandwith has reported its extensive prevalence in Egypt, and its occurrence in Southern Africa. On the Western Hemisphere it is to be found in North, Central and South America, Barbados, Jamaica and Porto Rico.

Though isolated cases were reported in the United States by Gray and Tyler in 1864, Sherwell 1883, Harris 1902 and Sherwell 1902, no widespread interest was manifested in the disease until 1907, at which time Searcy, of Alabama, and Babcock, of South Carolina, reported independently extensive outbreaks in institutions for the insane in Alabama and South Carolina. Since 1907 a rapidly increasing interest in the subject has been evinced and to-day—1911—the disease is reported from more than twenty states. Unfortunately, in many of the states in which the disease is most prevalent, there are no facilities for the determination of accurate statistics as to incidence and no accurate estimate can be made as to the prevalence of the disease. Could accurate statistics be obtained, there can be no doubt that the figures would show not less than 10,000 cases n the United States in 1910. The disease is most prevalent in the Southern United States—North and South Carolina, Tennessee, Georgia, Florida, Alabama, Mississippi, Louisiana. Siler saw in the State of Illinois approximately 200 cases in 1909 and 150 cases in 1910, and the disease is reported from other middle western states and California.

Etiology.—The specific agent producing pellagra is unknown. During the past century many theories have been advanced, among them the following: Insufficient nutriment (including vitamin deficiency), insolation, syphilis, poverty, insanitary surroundings, leprosy, alcohol, molds, bacteria, metazoa, maize, protozoa, etc.

All theories concerning etiology except the bacterial, maize, metazoal, protozoal and vitamin deficiency may be dismissed as unworthy of comment.

Bacterial Theory.—Tizzoni has recently announced the isolation of a specific bacterium as the causative agent—namely, the *streptobacillus pellagræ*. Nichols and Siler failed to confirm this observation, notwithstanding the fact that they repeatedly attempted to cultivate microorganisms from the blood, spinal fluid and body organs, on various kinds of culture media. Many other observers in different sections of the United States have reported like results.

It has been suggested that the specific bacterium is present in the intestinal canal. This theory should be regarded with skepticism, as it is extremely difficult to harmonize with it the clinical picture of the disease, some peculiarities in its topographic distribution and more particularly some striking facts as to transmissibility. Should the specific agent prove to be an intestinal bacterium, the method of transmission is probably by water or by contact. During the summers of 1909 and 1910, Siler studied pellagra in an institution averaging more than 2000 patients, 350 of whom were pellagrins. Notwithstanding the facts that all patients and the large force of employees used the same water and that the nurses were thrown in intimate contact with the patients, not one case of pellagra developed in any of the attendants.

This has been the experience of Italian investigators and, with one exception, also of investigators in the United States.

Maize Theory.—This theory which has been advanced so positively by continental authorities, particularly Italian and Roumanian, assigns to Indian corn, of one sort or another, the rôle of principal etiologic factor. Adherents of this theory disagree as to just how and why corn products produce the disease.

1. *Sound Corn.*—It is asserted by one group of investigators that sound corn produces the disease, but opinions differ as to the actual exciting factor. Briefly, the following views are held: (a) Deficient nourishment with particular reference to nitrogen starvation in those subsisting, mainly, on a corn diet. (b) Toxic substances of various kinds, for example, toxins normally present in corn, toxins generated by the action of intestinal bacteria after the ingestion of corn.

2. *Damaged Corn.*—Another group asserts that damaged corn is the factor of principal import. Here, again, opinions differ, the following views being held: (a) Specific toxins are generated during the decomposition of corn. (b) Poisons are generated during the period of germination. (c) A specific poison is produced through the action

of *Penicillium glaucum* on corn. (d) Toxins are generated by the action on corn of certain fungi—namely, *aspergillus fumigatus* and *aspergillus flavescens*.

Italian investigators hold corn products responsible in great part on the following hypotheses: Pellagra followed the introduction of maize into Italy, and the extension of the disease was coincident with increase in area of corn cultivation. The disease occurs exclusively among people who subsist mainly on corn products and in districts in which corn is either cultivated or into which it is imported.

The Italians claim to have greatly reduced incidence and mortality rates in the endemic areas, by inspection of corn with condemnation and exchange of damaged lots; by the installation of drying apparatus; by the provision of proper baking ovens; by the compulsory notification of pellagrins to the health authorities; by supplying to all pellagrins corn-free meals twice each year for periods of not less than 40 days; by the issue of free salt to pellagrins and by the establishment of special hospitals—"Pellagrosarii"—for the treatment of this disease.

In 1905, Sambon suggested that corn was not the agent producing the disease; and in 1910 he further elaborated his hypothesis after an investigation of conditions in Italy. His investigations tend to refute all theories alleging a relationship between corn *per se* and pellagra.

In this connection it should be stated that Italians seem to have lost sight of pellagra in their investigations and have confined their researches almost exclusively to corn.

Sambon has presented quite conclusive evidence, that though pellagra was first described in Italy about the middle of the eighteenth century, it must have existed centuries prior to that time and has no coincident relationship with the introduction of corn from America; nor is there any definite proof to substantiate the supposition that corn was introduced into Europe from America.

The topographic distribution of pellagra does not coincide with that of corn cultivation and corn consumption. In Italy the disease is confined largely to endemic foci, and though corn is cultivated throughout certain provinces and the diet of the peasants throughout such districts consists almost exclusively of corn—"polenta"—it by no means follows that pellagra will be observed throughout such districts; on the contrary, the disease is frequently sharply limited to restricted areas.

The disease in Italy is almost, without exception, confined to the field laborer and is never found in cities, notwithstanding the fact that the peasant in cities subsists, in large measure, on "polenta." The disease has practically disappeared in certain provinces and shows marked decrease in others.

The claims put forward by Italian authorities in explanation of the decrease in the disease are subject to criticism. The laws providing for inspection, condemnation, and exchange of corn are in numerous instances a "dead letter." The use of a drying apparatus for extracting moisture is an unpopular measure, and is but seldom applied to home grown corn. The lists of cases notified to the health authorities as pellagrins are inaccurate and contain the names of many patients who are not pellagrins, while many actual cases of pellagra are not included. It is difficult and beyond reason to attribute any permanent or even temporary prophylactic benefit to the soup kitchen. These kitchens are open only for a fortnight in the spring and autumn, supply only a midday meal, are frequented largely by non-pellagrins, and many actual cases of pellagra (for various reasons), do not attend. The special hospitals for the treatment of pellagrins are few in number and admissions are confined largely to children.

It would seem more reasonable to attribute the decrease in the disease in Italy to other factors. The disease is intimately associated with field labor. In many sections there has been a marked increase in industrial pursuits and as the peasant changes his occupation from that of a field laborer to that of an operative in silk factories, cotton factories or other industrial concerns, the exposure to the probable transmitting agent necessarily becomes more remote.

It is also a fact that in many communes numbers of the inhabitants emigrate temporarily during the summer months to Switzerland, France, Austria, and other countries, for the purpose of engaging in tunnel and railway construction.

There can be no doubt that corn is not the etiologic factor in the production of pellagra, and this opinion is substantiated by experience with the disease in this country. Any one familiar with the extensive use of corn products in the Southern States, can well understand that the maize theory, pending thorough investigation, would be accepted as explaining the etiology of pellagra. Corn-meal, however, comparatively speaking, plays but an insignificant part as an article of diet throughout the remainder of the United States. During the summer of 1909 Nichols and Siler followed an outbreak of pellagra in an Illinois institution. The disease was apparently endemic, affecting about 200 of 2000 patients. It was possible to collect reliable statistics, covering a period of 4 years, as to the amount of corn products consumed. It was found that the average amount consumed per patient was less than 2 ounces daily and the corn products used were always fresh and of excellent quality.

To more thoroughly test the relationship of corn products to the disease a feeding experiment was instituted at the suggestion of Nichols to be continued for a period of 1 year. Two cottages, each with a capacity of 60 patients, were filled with selected nonpellagrins. In one cottage the diet included approximately 16 *ounces* of *corn-foodstuffs per day*, while in the control cottage a *corn-free* diet was instituted. The patients were carefully observed for a period of 1 year. The results reported by Watkins are as follows:

	Patients	Cases of pellagra	Suspects
Corn diet,	59	4	1
Corn-free diet,	58	5	3

The proportion of new cases developing in these cottages agrees practically with the percentage of new cases developing throughout the institution (2000 patients). Corn products were eliminated from the general diet of the institution in the summer of 1909.

Nichols has carried out extensive experimental inoculations on animals—rabbits and guinea-pigs —using extracts of cultures of various molds and bacteria grown on corn. His results were negative.

An attempt has been made to transmit the disease to animals—monkeys. No definite results have been obtained.

Metazoal Theory.—Quite recently—May, 1910 —Prof. Alessandrini, of Italy, has recorded the finding of a nematode (Filaria?) as yet unclassified, in the skin of pellagrins and in the drinking water of endemic areas, to which he assigns etiologic significance. But other observers have failed to confirm this observation.

Long has recently (1910) suggested, as a working "hypothesis," that the entamebæ together with the inflammatory changes brought about by their action are the etiologic factors of importance. Nichols and Siler in 1909 directed attention to the strikingly large percentage of pellagrins presenting evidence of entamebic infection and were impressed with the fact that this infection was not an etiologic, but an important complicating and possibly predisposing factor.

Protozoal Theory.—In 1905 Sambon suggested that the disease is parasitic (protozoal) and in 1910 reiterated this opinion and further elaborated it by assuming that the disease is not only parasitic, but insect-borne and conveyed by some species of *simulium* (sand-fly). He bases his theory on the following facts: (1) The disease is parasitic for the reasons that: (a) the cutaneous and other symptoms usually recur periodically each spring for many years even though the patients remove from an endemic area and subsist on a corn-free diet; (b) its peculiarities in distribution, symptoms, chronicity and pathology correspond to those of other protozoal diseases (trypanosomiasis, kala-azar, syphilis). (2) The disease is insect-borne because: (a) it is not directly contagious; (b) infection through food or water does not explain its epidemiology; (c) it is limited to rural districts, being practically restricted to the field laborer. (3) The disease is conveyed by *simulium*, because: (a) the topographic distribution of the *simulium* and pellagra appear to be coincident; (b) the adult stage of the *simulium* apparently presents a seasonal incidence similar to pellagra; (c) the insect is found in rural districts only, but seldom entering houses or towns; (d) the only class of people constantly exposed to the bite of the *simulium* are field laborers; (e) the disease is practically confined to the field laborer, and (f) other similarly small blood-sucking flies are strongly suspected of being conveyors of disease—*phlebotomus, papatassi, dilophus febrilis.*

It seems quite likely that eventually the disease will be placed among those of parasitic origin, probably protozoal.

Vitamin Deficiency.—Many now believe that pellagra, along with beriberi and scurvy, belongs to the group of "food deficiency" diseases. Just as beriberi is caused by the absence of a neuritis-preventing substance or vitamin in the dietary, so is the symptom-complex of pellagra brought about by the absence from the dietary of some vitamin or vitamins essential to proper metabolism. There are various ideas as to the factor which eliminates the pellagra-preventing vitamins. Some think that in the process of milling maize the vitamin containing outer portion (bran) has been taken off just as with beriberi producing white rice, from which the pericarp with its neuritis-preventing vitamin has been more or less completely removed. From analyses of milled maize and millings Funk has recently suggested that pellagra in different countries is in relation to the degree of milling. Just as with rice so does excessive milling of wheat get rid of vitamins, therefore, bread made from highly milled flour is dietetically deficient.

Again, as brought out by Voegtlin, alkalis tend to destroy any remaining vitamins in such bread. The practice of using sodium bicarbonate in preparation of bread is a further factor in the food deficiency problem. With the use of baking powder or buttermilk the alkaline carbonate of soda is neutralized so that there is no destructive effect on vitamin content.

The vitamin deficiency of highly milled flour and highly milled cornmeal runs parallel with the phosphorus pentoxid content of such products. Whole wheat shows about 1.1 percent P_2O_5, while highly milled flour contains only about 0.1 percent. Whole corn has about 0.76 percent P_2O_5, while highly milled cornmeal has only about 0.3 percent.

Others think that as the result of bacterial or mold diseases of the corn grain these important vitamins are destroyed. Then too, as with rice and beriberi, the prevailing idea is that while there is a striking association between a maize dietary deficient in the pellagra preventing vitamin and the occurrence of pellagra, yet this deficiency may be supplied by other foods. Then too this vitamin is thought to be present normally in other cereals than corn so that grain foods deficient in this vitamin, other than corn, may be factors in producing pellagra, just as a preponderating diet of a single cereal, other than polished rice, which has a vitamin deficiency as the result of milling or disease, may produce beriberi.

Goldberger and his colleagues, after a careful investigation of pellagra epidemiology, decided that such facts as the complete absence of the disease among the nurses and attendants of the pellagrous insane, or among the prison guards of institutions where pellagra prevailed extensively, as well as among those caring for pellagrous orphans, indicated that a dietary factor rather than an infectious one was operative in the disease. Even where it was stated that attendants and inmates of institutions had the same dietary investigation indicated that as a matter of fact the insane and the prisoners were not as well fed as the other group. Then too the insane frequently fail to avail themselves of the food provided.

A study of the records of the Army and Navy of the United States failed to show that a single case of pellagra had ever developed among the personnel, although large numbers of the men came from pellagrous districts of the South. This exemption they thought due to the generous service ration.

Goldberger's Experiment.—In February, 1915, Goldberger started a "pellagra squad," consisting of 11 prisoners on a diet of wheat flour (patent), cornmeal, corn grits, corn starch, polished rice, granulated sugar, cane syrup, sweet potatoes, fat fried out of salt pork, cabbage, collards, turnip greens and coffee. Baking powder was used for making biscuits and corn bread. The food value of each man's diet averaged 2952 calories. A control was carried out with prisoners on a normal diet. The experiment was continued until Oct. 31, 1915. Of the 11 volunteers on the excessive carbohydrate diet 6 developed symptoms. Loss of weight and strength and mild neurasthenia were early symptoms. Definite cutaneous manifestations appeared only after 5 months. The skin lesions were first noted on the scrotum, later appearing on backs of hands in two cases and back of neck in one case.

There are those who believe that the methods of preserving foods, cereal or protein, by sterilizing at high temperatures, destroy these vitamins so essential to proper metabolism so that people who subsist extensively on canned vegetables and preserved meats, instead of fresh meats and vegetables, may develop pellagra. Evidence of this sort is obtainable in the mill-villages of the Southern States of the United States where pellagra is so very prevalent.

We are now beginning to recognize that slight and vague digestive trouble may be pellagrous in nature although never going on to the development of the cutaneous, neurological and alimentary tract diagnostic triad of symptoms.

Again there would appear to be efficient resistance to pellagra in those who are in good physical condition, but when reduced by illness, or the effects of poor diet and defective hygienic surroundings, they may develop it. There are those who think that hookworm disease is an important factor in predisposing to pellagra.

Not only does alcoholism, when coexistent with pellagra, make for a bad prognosis but there are many who think that any abuse of alcohol predisposes to pellagra. Against this, however, is the fact that pellagra in the United States is about 5 times as common among women as among men. It is generally recognized that pregnancy and lactation predispose to pellagra (Stitt).

Clinical Description.—In attempting to outline the clinical picture of this disease, one is confronted by a multitudinous variety of symptoms enumerated by various authorities as making up the symptom-complex. Many of these symptoms, when analyzed, can definitely be ascribed to complicating factors and are of no diagnostic value in pellagra *per se*. The disease, under ordinary circumstances, is chronic, extending over a period of many years—about 4 to 25 or more. The incubation period is unknown. The disease is not hereditary.

An *acute typhoidal* type of the disease, of sudden onset and rapid course, usually ending in death, is referred to by many authorities. As such cases, however, are of rare occurrence and likely to be confounded with an exacerbation of a chronic condition, they do not merit classification as a distinct type.

The symptoms are cutaneous—involving more particularly the extensor surfaces; and constitutional—involving the gastrointestinal tract and nervous system. Prodromal symptoms—general malaise, vertigo, digestive disturbance, obscure epigastric pain and various other symptoms—are referred to by many authorities, but these symptoms are so indefinite in character and so inconstant in occurrence as to preclude reliable deductions for diagnostic purposes.

Cutaneous Symptoms.—The skin symptoms are by far the most striking, most constant, most characteristic and most important from a diagnostic standpoint. In their absence, a diagnosis of pellagra is unwarranted.

The eruption usually appears suddenly as an erythema, irregular in outline, involving most frequently the dorsal aspect of the hands. Its most characteristic feature is the symmetry of

Showing Edema of Hands. Bleb Formation Occurred, and Illustration Shows Condition after Blebs have Ruptured.—(*Reproduced by courtesy of Dr. George A. Zeller.*)

the lesions on both hands. The erythema may be confined to the dorsum of the hands, or extend downward to the finger-nails or upward on the forearm. Quite frequently it encircles the wrist as a more or less broad cuff and the exact similarity of the bands on both wrists constitutes a striking picture. The erythema, while most commonly observed on the dorsum of the hands, is by no means confined to this area. It is of frequent occurrence on the face, usually as symmetrical patches on the cheeks or forehead. Occasionally the entire face is involved—"pellagra mask"; this has been observed in Italy but not (by Nichols and Siler) in the United States. The neck is frequently involved, the erythema appearing in symmetrical patches or occasionally encircling the neck as a broad or narrow band—"Casal's collar." Triangular tongues of erythema, base above, are occasionally observed extending from the neck downward, in front or behind, depending greatly on the type of clothing worn. It not infrequently

appears on the dorsum of the feet and as bands encircling the legs, particularly so if no shoes are worn. Occasionally reddish-brown patches, resembling hemorrhagic areas, appear on the upper and lower lids. The erythema in the early stages may easily be mistaken for a sunburn of moderate severity in mild cases. It may be differentiated by the fact that the sunburn clears up within 3 or 4 days, while the pellagrous erythema pursues a different course.

Showing Erythematous Cuff around Both Wrists and Slight Extension to Palm over Thenar Eminence. —(*Reproduced by courtesy of Dr. George A. Zeller.*)

The color, at onset, depends largely on the type of patient affected. In blondes the color is first a bright pink, in brunettes usually a dull red. As the erythema progresses, the affected areas gradually take on a darker shade and within a few days show a characteristic purplish, dusky red color. In brunettes, the lesions are occasionally of a dark, greenish-bronze cast. At the onset of the erythema the color disappears on pressure, but later the contrary is the case. The line of demarcation between healthy skin and affected areas is usually distinct and clear cut. Ordinarily, the color begins to fade after about 10 days, and desquamation occurs. The exfoliation of epidermis may occur in fine scales or in large bran-like flakes. After desquamation is practically complete the skin is soft, smooth and pinkish in color, a distinct line of partially desquamated epithelium being noteworthy around the edges, showing distinctly the extent of the lesion. The entire course of the erythema and subsequent desquamation may occur within a period of a few days, but it usually lasts for a period of 3 or 4 weeks, or even longer. In some cases, edema of the affected area may be observed and occasionally vesicles appear. These vesicles frequently become confluent and may become infected. Nichols and Siler found the bleb formation to be a symptom of serious omen, and to bear an important relationship to prognosis.

Eventually the skin becomes pigmented and thickened, and as the erythema recurs from year to year this pigmentation is accentuated. After repeated recurrence of the erythema, atrophy of the skin occurs. The elbows and knees occasionally show evidence of erythema—pigmented, roughened, thickened skin. The genitalia are occasionally involved. Palmar involvement has been recorded by many observers. In observations covering several hundred cases in the United States and Italy, Siler saw this in only one case in which a complicating factor could not be excluded.

Pain is but seldom complained of in the sites of erythema, though a burning sensation may be present.

The erythema appears during the spring, summer, or autumn, more commonly spring and autumn. The exact time of its appearance depends largely on climatic conditions; being hastened by warmth, sunlight and settled weather conditions; and retarded by cold, rainy unsettled weather. Though the erythema may occur without exposure to sunlight, it is an undoubted fact that direct exposure to the sun's rays markedly accentuates the condition. During the winter it disappears.

Pellagrous Erythema, Involving the Face and Neck. Desquamation Taking Place.—(*Reproduced by courtesy of Dr. George A. Zeller.*)

Constitutional Symptoms.—Gastrointestinal symptoms may or may not be present. Some writers go so far as to attribute important diagnostic significance to the appearance of the tongue and to a special odor noted in the diarrheic stools. Siler concludes that in some instances there are no gastrointestinal symptoms; while in many others these disturbances may be attributed to complicating factors, most frequently amebic dysentery. This complication has been

referred to also by many observers in the southern sections of the United States, notably Allen and Long.

Among other complicating factors may be mentioned bacillary dysentery and various protozoal and zoo-parasitic intestinal parasites (flagellates and ciliates, uncinaria, ascaris, trichuris, schistosomidæ, etc.). In the absence of clear and definite cutaneous symptoms, it is inadvisable to attribute any great diagnostic importance to gastrointestinal disturbances.

Bearing in mind the fact that the digestive disorders may be due in large part to a complicating factor, they may be briefly summarized in the following manner: The patient may suffer from dyspeptic symptoms, as evidenced by coated tongue, poor appetite and flatulency. Frequently there is redness of the tongue with exfoliation of epithelium, giving rise to so-called "bald" tongue. The digestive disturbances may be accompanied by a mild transient diarrhea, by diarrhea of a more stubborn type or by severe dysenteric symptoms—frequent small stools containing blood and mucus and of a highly offensive odor. None of these symptoms is distinctive of pellagra and may be accounted for by complicating factors (amebic and bacillary dysentery, etc.).

In the more severe manifestations of the disease the picture is characteristic, and it is evident that some specific agent is at work in addition to a complicating dysentery or other factor. The tongue is edematous and red; the buccal mucosa is intensely inflamed and dotted with ulcerating patches, and the gums are soft and spongy. There is swelling of the salivary glands accompanied by excessive salivation. The mouth symptoms may be so severe in character as to cause very intense pain, prevent protrusion of the tongue and interfere greatly with eating and drinking. The dysenteric symptoms in such cases are most pronounced and intractable. The gastrointestinal symptoms may precede, accompany or follow the cutaneous manifestations. Vomiting is seldom noted and vertigo is uncommon.

Nervous and Mental Symptoms.—Symptoms referable to the nervous system may or may not exist, depending partly on the stage of the disease. Ordinarily during the first 3 or 4 years, nervous symptoms are indefinite in character and frequently absent. During the periodical recurrences there may be in the early stages mental depression, insomnia, irritability, headache, vertigo, tremors, languor and exaggeration of reflexes.

Complications in pellagra—(uncinariasis, amebic and bacillary dysenteries, tuberculosis, syphilis, bilharziosis)—are so frequent and the mental symptoms observed differ so markedly in character as to make it impossible to define with any degree of accuracy the nervous symptoms referable to pellagra.

As the disease progresses a small percentage of cases manifest involvement of the nervous system and some develop the so-called "pellagrous insanity." It is said that 10 percent of pellagrins in Italy develop this type of mental derangement.

Note Symmetrical Erythematous Involvement of Hands, Forearms and Neck.—*(Reproduced by courtesy of Dr. George A. Zeller.)*

In the later stages the mental depression frequently develops into profound melancholia with eventual terminal dementia. There may be periods of excitability alternating with stupidity, hallucinations, delusions of persecution and suicidal tendencies. Suicide by drowning is reported as common; but of the thousands of cases of pellagra in the United States, Siler was able to find only one instance in which this tendency was exhibited. The reflexes are said to be diminished or absent in the later stages; but in a series of 100 cases Siler found the contrary to be true, both the patellar and plantar reflexes being increased in a majority of cases. The Babinski reflex is sometimes present.

The facies in pellagra—a fixed, despondent appearance—is said to be typical, but in many cases this has not been confirmed. The final picture resembles closely that of general paralysis of the insane. Sandwith attributes diagnostic value to tenderness on pressure along the sides of the dorsal vertebræ (4th to 9th).

Differential Diagnosis.—In the presence of cutaneous lesions, it is quite unlikely that pellagra will be mistaken for other diseases. *Sprue* gives rise to somewhat similar mouth conditions, but the characteristic copious, whitish diarrheic stools, with no history of cutaneous lesions, will serve to differentiate. It has been compared to *leprosy*, but it is inconceivable that the two diseases can be confounded. *Weeping eczema* on the dorsum of the hands differs from pellagra in many respects—irregular outline of affected areas, peculiar color, itching, persistent serous oozing on stimulation. Both in the United States and Italy, *vitiligo* is mistaken for a pellagrous eruption; but scaling is not present in vitiligo.

Pathology.—The disease presents no uniform definite pathologic findings. Abnormal conditions observed can, in many cases, be attributed to complicating factors.

The blood, in uncomplicated cases, shows slight decrease in red cells and hemoglobin, and a relative increase in the mononuclear elements with slight leukocytosis. The anemia in uncomplicated cases is of low grade. Blood platelets are found in excessive numbers. Though prolonged and careful search has been made of both unstained and stained blood preparations, with one or two exceptions all observers have failed to demonstrate any bacterial or protozoal organisms. The Wassermann and Noguchi modification complement fixation reactions are negative in uncomplicated cases. A specific complement fixation reaction has been obtained by the use of liver from pellagrins as antigen.

The cutano-reaction with extracts of all grades of corn has been worked out by Hirshfelder with negative results. Stained preparations from the spinal fluid, liver and spleen show no organisms. There is decrease or absence of hydrochloric acid secretion in the stomach.

Necropsies frequently show serious concurrent diseases. Atrophy of the muscles, heart, liver and small intestines is found. The spleen is frequently small in size and shows atrophic changes. The large intestine frequently shows numerous undermined ulcers of the amebic type or well marked folliculitis. Various intestinal parasites may be present. The nervous system may show no pathologic change.

In chronic cases there may be diffuse leptomeningitis with scattered thickened areas, degeneration of the nerve elements with round celled perivascular infiltration, and an excess of fluid in the ventricles. The spinal cord frequently shows sclerosis of the posteromedian and posterolateral columns.

Harris has observed in chronic cases atrophy of the pancreas, softening of the cord, and degenerative changes in the myelin sheaths of nerves and of nerve cells of the gray matter and ganglia.

Prognosis.—In determining mortality rates in this disease, complicating diseases must be considered. Experience shows that, on necropsy, sufficient cause for death is revealed in many cases, exclusive of pellagra.

The death rate shows wide variation from year to year. It may occasionally rise to 25 percent, but usually is from 5 to 10 percent.

The disease occasionally results in death during the first attack. Ordinarily its course is extremely chronic—persisting for from 5, 10, 20, 30 or even 40 years, frequently without apparent detriment to the patient.

Entire recovery is not infrequent, but at least 2 or 3 years should elapse, without symptoms, before cure is pronounced.

Prophylaxis.—"There does not seem to be any satisfactory evidence as to the contagiousness of pellagra, so that any method involving isolation is not indicated. It is possibly advisable that the stools be disposed of as would be indicated in typhoid fever, there being some evidence that where proper disposal of feces is operative there is an absence of pellagra.

"Even if not productive of pellagra it is certainly advisable to prevent the use of spoiled corn by state regulation.

"American authorities attach rather more importance to *Stomoxys* than to *Simulium* as a possible transmitting agent. *Stomoxys* breeds best in the hay mixed horse manure about stables and measures should be taken along this line.

"If the feces are of importance we should guard against the contaminating influences of the house fly.

"As a proper, well-balanced dietary is an important curative measure it is therefore prophylactic" (Stitt).

Treatment.—"In a disease which characteristically shows a marked amelioration in the winter or a disappearance of symptoms for one or more years we should be very conservative in attributing improvement to any drug. At the New York Post Graduate hospital, 17 cases were apparently cured on rest in bed and full nutritious diet. Hospital treatment, thereby removing the patients from the environment in which the disease developed, is generally conceded of the greatest benefit. It is always recommended by the advocates of some special drug treatment that the patient be kept on a nutritious diet. Roussel in 1866 stated: 'With-

out dietetic measures all remedies fail.' Many authorities speak highly of arsenic in various forms as Fowler's solution, atoxyl, salvarsan, etc. Others are equally pessimistic as to the value of arsenic in any form. Niles is a strong advocate of hydrotherapeutic measures. He recommends the drinking of two to six glasses of tepid water daily as well as colon irrigations, cold abdominal compresses, hot packs and saline baths. Deeks prefers to eliminate sugar and starchy food from the dietary of pellagrins for a few days at a time and to give fresh fruit juices, with broths and milk. He highly recommends dilute nitric acid, well diluted, before meals. As there is almost constantly anacidity and pepsin deficiency in the gastric juice it would seem that this condition should be treated. It is advisable to keep the patient out of the sun and require him to take his exercise after sunset. Dyer recommends 1/2 to 1 ounce gelatin daily together with the juice of two or more oranges or lemons. He prefers a diet of eggs, milk and well-cooked vegetables. He also gives quinin hydrobromate in 3 grain doses 3 times daily. Lavinder says that many people have pellagra because they have some other condition and when this is cured the pellagra is also cured. In truth, pellagra is very rarely a primary condition. We must then give careful attention to the predisposing causes which may not only be ankylostomiasis, alcoholism, or malaria, but, as well, various gynecological or alimentary tract disorders. Goldberger has cited the following as showing the influence of diet: In an orphan asylum with 211 orphans, 68, or 32 percent, had pellagra. These children were divided into 3 groups and given different rations, those under 6 years of age receiving milk and eggs, while those over 12 years were given meat, as they assisted in the work of the institution. The children between 6 and 12 lived practically on a vegetarian diet in which corn products and syrup preponderated with deficiency of legumes. Of 25 young children only 2 showed pellagra, and there was but 1 case in the 66 children over 12 years of age while the 120 between 6 and 12 gave 65 cases or 52 percent. As the result of increasing the milk supply, so that every child under 12 years got a pint daily, also at least one egg daily, together with an increase in the use of beans and peas, as well as fresh meat, the disease was entirely eradicated. The corn elements of the diet were reduced but not excluded. There was increase in proteins and a decrease of carbohydrates. Babcock recognizing the importance of the treatment of the pellagrous neurasthenia, recommends the Weir-Mitchell plan of prolonged rest in bed, nutrition, hydrotherapy and hygienic measures. 'Fat and blood' should be our aims and he notes the value of cacodylate of soda in increasing fat. He also refers to the susceptibility to suggestion of pellagrins and is an advocate of psychotherapy" (Stitt).

PELLETIERIN TANNATE.—A mixture of the tannates of 4 alkaloids obtained from pomegranate; it is an effective teniafuge. Dose, 3 to 8 grains, in powder, taken fasting, and followed after 20 minutes by a full dose of castor oil. Pelletierin is actively poisonous, causing weakness of the legs. It is best administered in the form of Tanret's pelletierin, each bottle of which contains an adult dose. But the practitioner had better not prescribe this for poor people, as each dose costs *three dollars!* See ANTHELMINTICS.

PELLITORY.—See PYRETHRUM.

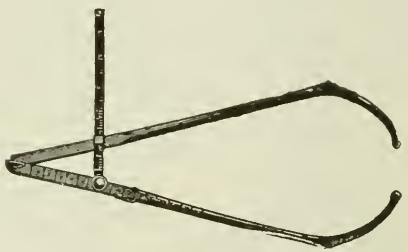
PELVIC INFLAMMATION.—See PUERPERAL FEVER.

PELVIMETRY.—The process of determining the size of the pelvis.

It is by no means desirable to subject every pregnant woman to the annoyance of a careful pelvic measurement. In private practice those patients should be measured who give a history of difficulty in former labors, or who are subjects of evident deformity, such as rachitis or kyphosis.

An accurate determination of the size of the pelvis necessitates both internal and external measurements. These measurements are made between certain well-defined bony prominences.

Pelvic Diameters.—The most important are the following: **Anteroposterior** (of pelvic inlet), that which joins the sacrovertebral angle and the pubic symphysis. **Anteroposterior** (of pelvic outlet), see



SCHULTZE'S PELVIMETER.

COCCYPUBIC. **Coccypubic,** that which joins the tip of the coccyx with the subpubic ligament; the anteroposterior diameter of the pelvic outlet. **Conjugate,** the anteroposterior diameter of the pelvic inlet. **Conjugate, diagonal,** that connecting the sacrovertebral angle and subpubic ligament. **Conjugate, external,** that connecting the spine of the first sacral vertebra and the middle of the upper border of the symphysis pubis. **Conjugate, true,** that connecting the sacrovertebral angle and the most prominent portion of the posterior aspect of the symphysis pubis. **Oblique** (of pelvic inlet), left and right, that connecting one sacroiliac symphysis with the opposite iliopectineal eminence. **Oblique** (of pelvic outlet), that extending from the middle of the under surface of the sciatic ligament upon one side to the junction of the ischiopubic rami on the opposite side. **Sacropubic,** see ANTEROPOSTERIOR. **Sacrosubpubic,** see CONJUGATE, DIAGONAL. **Sacrosuprapubic,** that connecting the sacrovertebral angle and the upper portion of the symphysis pubis. **Transverse** (of pelvic inlet), that connecting the two most widely separated points of the pelvic inlet. **Transverse** (of pelvic outlet), that connecting the ischial tuberosities.

Size of the Pelvic Inlet.—Its transverse diameters are obtained by measuring between the anterior

superior spinous processes of the ilia (26 cm.); between the widest divergence of the crests of the ilia (29 cm.), and between the two femoral trochanters (31 cm.).

The anteroposterior or conjugate diameter is obtained by measuring between the depression under the last lumbar vertebra and the upper edge of the symphysis (20 1/4 cm.). This is called the external conjugate diameter. A more reliable measurement is the internal conjugate diagonal. This is the measurement between the promontory of the sacrum and the middle of the subpubic ligament. It is obtained by passing the index and middle fingers of the left hand into the vagina in such a manner that the tip of the middle finger rests upon the top of the promontory of the sacrum. A mark is made on the upper surface of the hand, just where it presses against the under surface of the symphysis. The distance between this mark and the tip of the middle finger is the internal conjugate diagonal (12 3/4 cm.). The true conjugate is obtained from this diameter by simply subtracting 1 3/4 cm.

Size of the Pelvic Cavity.—This is determined approximately by a vaginal examination. Thus, a tumor obstructing the pelvic canal could easily be discovered in this way.

Size of the Pelvic Outlet.—This is rarely decreased except in kyphosis, when it is the transverse diameter that suffers. This diameter is measured between the two tuberosities of the ischia (11 cm.).

TABLE OF MEASUREMENT OF THE FEMALE PELVIS COVERED WITH THE SOFT PARTS

Between iliac spines,	26 cm.
Between iliac crests,	29 cm.
External conjugate diameter,	20¼ cm.
Internal conjugate diagonal,	12¾ cm.
True conjugate, estimated,	11 cm.
Right diagonal,	22 cm.
Left diagonal,	22 cm.
Between trochanters,	31 cm.
Circumference of pelvis,	90 cm.

PELVIS, DEFORMITIES.—The pelvis is divided into two parts by the iliopectineal line. The shallow, expanded portion situated above this line is known as the **false pelvis.** It has very little influence on the course of labor.

The narrow, more contracted portion situated below the iliopectineal line is called the **true pelvis.** Contraction or deformity of this part of the pelvis may cause serious difficulty during childbirth. The shape of the pelvic inlet or superior strait is usually cordiform, the pelvic cavity is irregularly circular, and the outlet or inferior strait is cordiform. The pelvic cavity is lined with muscles, the most important of which is the iliopsoas. These muscles serve as cushions or protectors to the bony wall during labor, and also guide the presenting part in the most favorable direction for its expulsion. The pelvic floor, which almost completely closes the pelvic outlet, is formed chiefly by the levator ani muscle. This muscle, by the direction of its resistance, directs the presenting part upward and outward under the symphysis pubis.

For the measurements of the normal pelvis, see PELVIMETRY.

The frequency of pelvic deformity is about 14 percent. It is probable, however, that in not more than 5 percent is the deformity severe enough to seriously complicate labor.

The following is the most satisfactory classification of deformities of the female pelvis:

CLASSIFICATION OF DEFORMITIES OF THE FEMALE PELVIS, ACCORDING TO SCHAUTA

A. ANOMALIES OF THE PELVIS THE RESULT OF FAULTY DEVELOPMENT.
1. Simple flat.
2. Generally equally contracted (*justominor*).
3. Generally contracted flat (*nonrachitic*).
4. Narrow funnel-shaped (*fetal* or *undeveloped*).
5. Imperfect development of one lateral mass of the sacrum (*obliquely contracted* or *Naegele's pelvis*).
6. Imperfect development of both lateral masses (*transversely contracted* or *Roberts' pelvis*).
7. Generally equally enlarged (*justomajor* or *giant pelvis*).
8. Split pelvis.

B. ANOMALIES DUE TO DISEASE OF THE PELVIC BONES.
1. Rachitis.
2. Osteomalacia.
3. New growths.
4. Fractures.
5. Atrophy, caries, and necrosis.

C. ANOMALIES IN THE CONJUNCTION OF THE PELVIC BONES.
1. *Too firm union* (*synostosis*).
   (1) Of symphysis.
   (2) Of one or both sacroiliac synchondroses.
   (3) Of sacrum with coccyx.
2. *Too loose a union or separation of the joints.*
   (1) Relaxation and rupture.
   (2) Luxation of the coccyx.

D. ANOMALIES DUE TO DISEASE OF THE SUPERIMPOSED SKELETON.
1. Spondylolisthesis.
2. Kyphosis.
3. Scoliosis.
4. Kyphoscoliosis.

E. ANOMALIES DUE TO DISEASE OF THE SUBJACENT SKELETON.
1. Coxalgia.
2. Luxation of one femur.
3. Luxation of both femurs.
4. Unilateral or bilateral club-foot.
5. Absence or bowing of one or both lower extremities.

Contracted Pelvis.—Only the commoner varieties of contracted pelves will be considered. These, as found in this country, are:
1. The generally equally contracted pelvis.
2. The simple flat pelvis.
3. The rachitic flat pelvis.
4. The kyphotic pelvis.
5. The obliquely contracted pelvis.

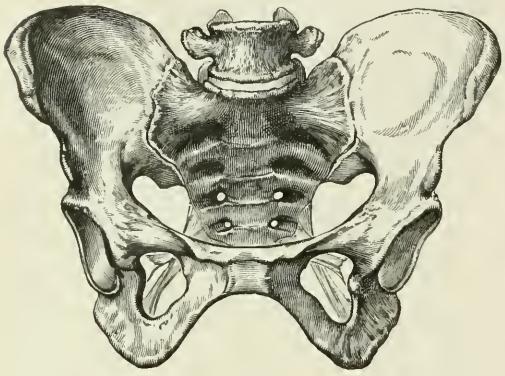
The generally equally contracted pelvis is, as its name implies, a pelvis in which there is proportionate contraction of all its diameters. This contraction very rarely exceeds 2 or 3 cm. This pelvis is the result of arrested development at an early period of life. It has been thought to be due to a mild degree of rickets which has passed away rapidly, leaving no characteristic deformity.

The diagnosis of this variety of contracted pelvis is easily made by noticing the proportionate degree of contraction of the different pelvic measurements.

The mechanism of labor in the generally equally contracted pelvis differs but slightly from the

normal. Vertical flexion at the inlet is somewhat exaggerated, while there is little or no lateral flexion.

The treatment of labor obstructed by this variety of pelvis will depend upon the degree of con-



Female Pelvis, Seen from the Front.

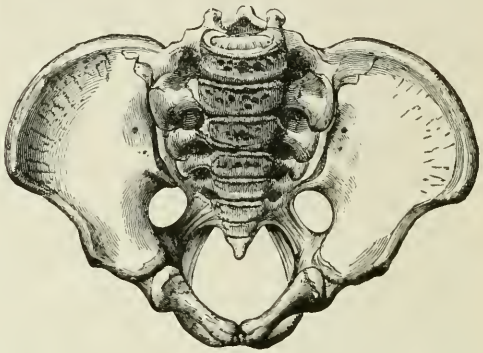
Outlet of Pelvis. Anteroposterior and Transverse Diameters of Outlet seen from Below.

traction. If the true conjugate diameter measures 9 1/2 cm. or over, delivery at term with forceps should be comparatively easy. With a contraction between 8 and 9 1/2 cm., the induction of premature labor is advisable. This, supplemented by the use of forceps, if necessary, will be found almost uniformly successful. When the contraction is below 8 cm., choice will have to be made between symphysiotomy, cesarean section, and craniotomy.

The simple flat pelvis is one in which there is shortening of the anteroposterior diameter, the other diameters being normal. The amount of



Infantile Pelvis, Viewed in the Axis of the Brim.

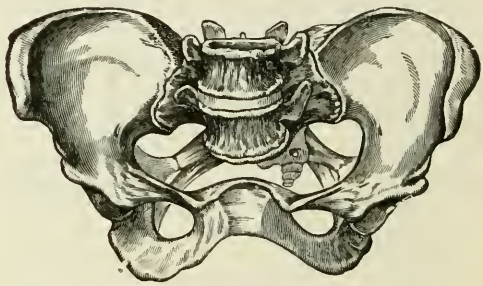


Figure-of-eight Rachitic Pelvis.

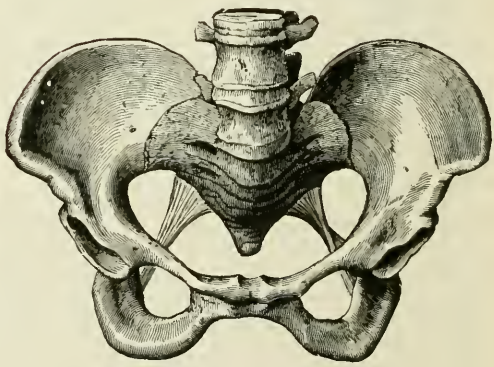
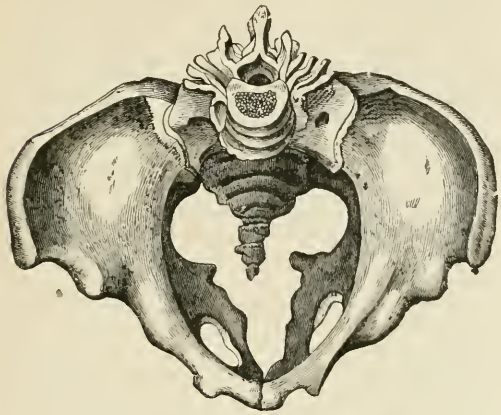


Reniform Rachitic Pelvis.

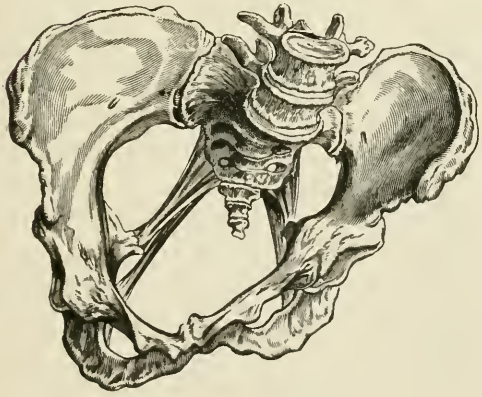
contraction very rarely exceeds 3 cm. It may be congenital in origin, or it may be caused by carrying heavy weights during early childhood. In this variety of pelvis the external conjugate diameter will be less than 20 1/4 cm., probably 18, or even 17; the true conjugate will be less than 11 cm., probably as low as 8. The other pelvic measurements will practically be normal.

The rachitic flat pelvis is one of the results of infantile rickets. In this disease there is a diminution of the mineral constituents of the bones, which



Kyphotic Pelvis.

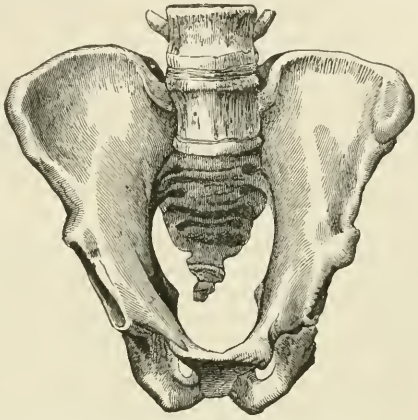
Oblique Pelvis, from Ankylosis of the Hip-joint and Disuse of the Right Leg.



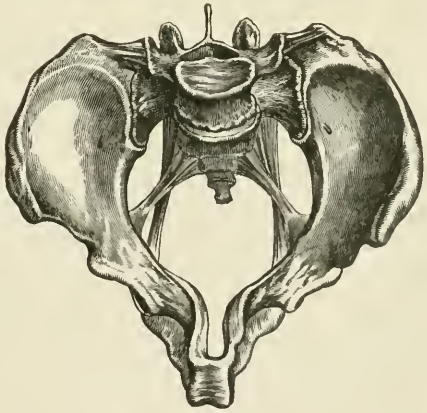
Oblique Pelvis of Naegele.

results in a preternatural pliability. There is a tendency, therefore, to an exaggeration of the changes which occur in the development of an adult from an infantile pelvis—*i. e.*, there is excessive rotation of the sacrum on its transverse axis. This results in an abnormal projection of the promontory, which causes a decrease in the conjugate diameter, an increase in the curve of the sacrum, a decrease in the depth of the pelvis, and a widening of the iliac spines and crests. The true conjugate diameter may be as low as 4 cm.

Diagnosis.—This pelvis is recognized by the marked decrease in both internal and external conjugate diameters; by the disturbance of the relation between the iliac spines and crests, the



Transversely Contracted Pelvis of Robert.



Rostrated Malacosteon Pelvis in Early Stage of Deformity.

distance between the crests being almost or fully as great as between the spines; by the marked sinking of the depression under the last lumbar vertebra, it being now almost on a level with the posterior superior iliac spines; and by the accompanying constitutional signs of rickets.

The mechanism of labor in the simple flat and in the rachitic flat pelvis is the same. The long diameter of the head engages in the longest diameter of the pelvis, which is now the transverse; there is exaggerated lateral flexion of the head, so that it may adapt itself to the increased sacral curve; and there is imperfect vertical flexion, so

that the bitemporal diameter (8 cm.) may first be brought in relation with the contracted conjugate instead of the biparietal (9 1/4 cm.).

The treatment of labor complicated by a flat pelvis depends upon the degree of contraction. Four grades are usually recognized:

1. When the true conjugate measures 9.5 to 11 cm. Here it is advisable to allow the patient to proceed to term. A rather prolonged and difficult labor should be expected, with perhaps malposition of the child or prolapse of the cord. If, after waiting a reasonable length of time, the head will not engage, version should be performed; if the head engages, but further delivery ceases, forceps should be employed.

2. When the true conjugate measures 8 to 9.5 cm. If the patient is seen in time, labor should be induced at the thirty-sixth or thirty-eighth week of gestation. If, now, there is difficulty in delivery, or if the patient is not seen until term, version or forceps, as previously described, will usually prove successful.

3. When the true conjugate measures 6.5 to 8 cm. Here one of the graver obstetric operations is indicated. Choice must usually be made between symphyseotomy, cesarean section, and craniotomy. It should be remembered, however, that spontaneous birth may occur even with a contraction as low as this, and also that version or forceps may prove successful. The size and compressibility of the child's head and the strength of the uterine contractions are factors which must not be overlooked in the treatment of a contracted pelvis.

4. When the true conjugate measures less than 6.5 cm. This is an absolute indication for cesarean section, since it would be dangerous to pull even a mutilated child through such a degree of contraction.

The kyphotic pelvis is that variety of pelvic deformity resulting from Pott's disease of the lower spinal column. In this deformity the promontory of the sacrum is pushed backward and the conjugate diameter at the pelvic inlet is slightly increased. The deformity is most marked at the pelvic outlet; the transverse diameter is markedly decreased by approximation of the ischial spines, and the conjugate diameter is somewhat lessened by forward displacement of the coccyx.

The diagnosis is easily made by the marked decrease in the transverse diameter at the outlet and by the associated kyphosis with its characteristic signs.

The mechanism of labor in this variety of pelvic deformity may differ but little from the ordinary. Posterior rotation is frequent; also, the first stage of labor may be precipitate, while the second stage is abnormally slow.

Treatment.—Here, again, the treatment depends upon the degree of contraction. If the contraction of the transverse diameter is slight—not below 8 cm.—spontaneous delivery may be expected. With a greater degree of contraction than this, choice will be made between the induction of premature labor, forceps, symphysiotomy, cesarean section, and craniotomy.

The obliquely contracted pelvis is due to a variety of causes, such as scoliosis, coxalgia, club-foot, the absence of one extremity, and dislocation or fracture of one limb. The pelvis becomes obliquely contracted from the overuse of one limb, or, in the case of the scoliotic pelvis, from unequal pressure from above. The diagnosis is easily made by the presence of the marked asymmetry of the pelvis, associated with one of its various causes. Unless the deformity is marked, no treatment is necessary. Marked degrees of contraction will require forceps, version, the induction of premature labor, symphysiotomy, cesarean section, or craniotomy.

PELVIS, INJURIES.—**Fracture of the pelvis** is usually the result of direct violence—a heavy fall, a cart-wheel passing over the pelvis, a squeeze between the buffers of two railway cars, and similar accidents. It may, of course, result from gunshot wounds or from indirect violence, as when a person falls from a height and alights on his feet.

The symptoms are inability to walk, though the patient may be able to move his limbs in bed; mobility and crepitus, obtained by pressing on both crests of the ilium; pain on moving or coughing; displacement, which may be recognized by external examination, by the rectum, or by the vagina. Inability to empty the bladder or voiding of bloody urine denotes some injury of this organ.

Fracture of the acetabulum is indicated by the crepitus elicited on rotating the femur with one hand placed over the trochanter.

Separation of the symphyses, or of the **sacro-iliac articulation,** is recognized by the free mobility of the part, and at the same time an interval may be felt in the situation of the separation. The pelvic viscera are frequently injured in this fracture; rupture of the bladder or urethra, giving rise to extravasation of urine, laceration of the rectum or of the larger blood-vessels, may occur.

Usually the rami of the pubes and ischium are the seats of fracture. The line of fracture may pass above the acetabulum in various directions, or it may involve the acetabulum, fissuring its floor or fracturing its margin. The acetabulum may be comminuted, and the head of the femur driven into the pelvic cavity. Any portion of these bones may be broken, including the crest of the ilium or the tuberosity of the ischium, and not infrequently both innominate bones.

Treatment.—Absolute rest of from 6 weeks to 2 months is essential. The pelvis must be bound around with a broad roller-bandage, and the patient laid to rest on a flat bed or mattress. The thighs must be flexed upon the abdomen and supplied with pillows under the knees.

Fracture of the acetabulum must be treated by means of a long splint, or hip splint of gutta-percha, molded to the side of the pelvis and thigh so as to fix the joint. A catheter should be introduced to ascertain the state of the bladder. If bloody urine or other symptom of injury to this organ or to the urethra is present, the catheter must be kept in the bladder to prevent extravasation. See BLADDER (Injuries).

PEMPHIGUS.—Pemphigus is an acute or chronic inflammatory disease of the skin, char-

acterized by the formation of successive crops of variously sized, rounded or oval bullæ, affecting seriously the general health and often terminating fatally.

Symptoms.—There are two principal types—pemphigus vulgaris and pemphigus foliaceus.

Pemphigus Vulgaris.—With or without febrile disturbance, there appear upon the limbs, face, or trunk, pea-sized to egg-sized, rounded or oval, tense blebs. These rise abruptly from the normal skin, and, while having at times a slightly reddened base, have no areola. The contained fluid is at first serous, later becoming turbid and purulent. The eruption occurs in crops, a half of a dozen or more blebs appearing at a time. These persist for a few days (the fluid disappearing by absorption or rupture), and are then followed by another crop. The parts most frequently affected are, in their order of frequency, the limbs, the face, and the trunk. The mouth, vagina, conjunctiva, and other mucous membranes may become involved. The disease in some cases runs a more or less acute course, getting well in a few months. Far more frequently, however, it persists for years, greatly impairing the general health.

Pemphigus Foliaceus.—In this form the blebs, which are flaccid and purulent, rupture before distention and dry to crusts, which are thrown off with the surrounding epidermis, exposing to view the reddened corium. A new crop of blebs succeeds the old, often developing upon the same site, and giving to the skin the appearance of a severe scald. The entire cutaneous surface may thus become involved, and the general health seriously compromised. The process lasts for months or years, and almost always leads to a fatal termination.

Neumann has described a rare form of pemphigus, characterized by the development of wart-like or papillary vegetations upon the sites of ruptured bullæ. This form he has called **Pemphigus Vegetans.** The mouth, vagina, or other mucous membranes are often first affected. The favorite situations upon the skin are the genital and anal regions, the neck, axillæ, and flexures of the extremities. The affection lasts months or years, and tends to a fatal termination. The subjective phenomena in pemphigus are itching and burning (usually moderate in degree), and often tenderness, pain, and a feeling of tension. The disease is distinctly rare, particularly in this country.

Etiology is obscure. The disease has been observed in many cases in which marked changes in the central and peripheral nervous systems were noted. In addition, mental strain, nervous exhaustion, and a lowered or vitiated state of the general health are considered to be causative.

Pathology.—The blebs are usually situated between the horny layer and the rete mucosum, but may occur at any depth in the epidermis. The contents of the bullæ consist of a slightly alkaline serum containing a few leukocytes. There is dilatation of the papillary vessels, and a leukocytic infiltration of the papillæ, corium, and subcutaneous tissue. The affection is looked upon as a trophoneurosis.

Diagnosis.—It should be remembered that all bullous eruptions are not pemphigus. Care should be exercised to differentiate the bullous forms of erythema multiforme, dermatitis herpetiformis, impetigo contagiosa, and syphilis (pemphigus syphiliticus of the older writers). The blebs of pemphigus are large, tense, abruptly elevated, noninflammatory, and come out in crops. These characteristics, with the history and course of the disease, should enable one to make the diagnosis.

Prognosis.—The course of the disease is uncertain. Mild cases may recover after a duration of months. Severe cases (particularly pemphigus foliaceus) are likely to end fatally. The occurrence of flaccid or hemorrhagic blebs, extensive cutaneous involvement, frequent outbreaks, or constitutional depression are all unfavorable signs.

Treatment.—Both internal and local treatment are to be employed, the former alone, however, being curative. Arsenic is by far the most valuable remedy. It is to be perseveringly tried, beginning with small doses and increasing until the physiologic limit is reached. Quinin in full doses is also of value, as are, at times, iron, strychnin, and cod-liver oil. Nutritious food, good hygiene, and bodily and mental rest are important therapeutic factors.

Local treatment is designed to heal the abraded surfaces and relieve the subjective symptoms. The blebs should be evacuated, and simple dusting-powders, ointments, or lotions applied. The calamin lotion is a most grateful application. Bran and starch baths are useful in extensive cases. In pemphigus foliaceus the continuous bath is perhaps the best treatment, the patient living day and night, for weeks and months, immersed in water.

PENIS, DISEASES.—**Inflammation** is usually the result of injury or associated with venereal disease. Cuts, twists, "breaking" a chordee, ligation of the penis, or forcing rings over it, passage of instruments, and impactions from calculi are the ordinary injuries. Injuries to the perineum may result in inflammation of the penis from extension. Excessive sexual intercourse or persistent masturbation are causative agents in inflammation. It may be a sequel to the exanthems and diphtheria. It is also found in gouty and diabetic subjects.

The treatment follows the general treatment of inflammation, with especial regard to the cause or condition in connection with which the inflammation has arisen.

Herpes of the penis is a vesicular eruption, occurring on the cutaneous or mucous surface of the prepuce, and running its course in about a week, but being liable to recur at stated intervals. Its recognition is important, because its appearance after doubtful intercourse may lead to improper treatment. A sedative lotion and the avoidance or prevention of all irritation are all that are needed in treatment. See CHANCROID.

Priapism.—The condition of temporary and functional fulness and firmness of the penis, clitoris, etc., due to sexual excitement, friction, spinal irritation, etc. The mechanism consists in an overfilling of the blood-vessels with an inhibition of the return circulation.

Treatment.—Hyoscin hydrobromid, 1/120 to 1/60 grain at bedtime, will prevent erections and check emissions. Belladonna in gradually increasing doses brings good results. Camphor often succeeds, while potassium and sodium bromids are especialy sedative in irritable states of the genitourinary organs in which erections occur. Chloral, given at bedtime, may be repeated every night. A few drops of a 4 percent solution of cocain upon the glans penis often promptly controls an erection. Cold applications are of value. The anaphrodisiacs lower the sexual appetite and depress the genital centers in the brain and cord. See ANAPHRODISIACS, CHORDEE, GONORRHEA.

Deformities.—The roof may be defective (epispadias); or the floor (hypospadias); or the invagination that forms the fossa navicularis may fail to meet the part behind. If the urethra is imperforate, the kidneys become cystic, and the child dies at or before birth. Usually, however, there is hypospadias, and occasionally the two channels run one above the other for a considerable distance.

Hypospadias.—The orifice is usually at the base of the glans, or a little further back; the frenum is absent; the prepuce forms a great fold on the dorsum like a caul, and the corpus spongiosum possesses scarcely any erectile tissue. In other cases it lies at the end of the membranous urethra, the bulb and the scrotum failing to unite in the middle line, and forming labia, as in the female. When the defect is slight, the fossa navicularis may run back and end blindly; in other cases the penis is small, and the corpus spongiosum, if it is developed, incapable of erection.

Epispadias.—The complete form is always associated with ectopia vesicæ; occasionally the urethra opens behind the corona, the rest of the penis being well developed.

The treatment is not very promising. If the defect is slight, and micturition not impeded, it is better not to interfere. The orifice should be dilated to prevent any strain upon the structures behind; and if the urethra fails in front, so that it is impossible to direct the stream, an attempt should be made to carry it forward by means of a plastic operation. The flap must be double, so that a cutaneous surface may face the new channel; the deeper layer is taken from the side of the penis near, and twisted round upon itself; the superficial one borrowed from the redundant prepuce the center of the caul being dissected up, and the glans thrust through the opening, so that the dorsal surface becomes inferior, or *vice versa*, as the case may be.

Phimosis may be congenital or acquired, following balanitis, soft sores, chancre, or injury. In the former case the glans is often adherent, and the orifice may be reduced to the size of a pinhole, so that the prepuce swells out with each act of micturition. Circumcision should always be performed, unless the corona can be thoroughly and easily exposed; the secretion collects inside; there is a constant risk of balanitis and paraphimosis; preputial calculi may form; and the liability to syphilis and phagedena is much greater. If gonorrhea occurs, it is more severe, and the constant irritation undoubtedly favors carcinoma.

Circumcision.—In the operation of circumcision the prepuce is drawn well forward, and clipped with a pair of polypus forceps in front of the glans; the projecting end cut off; the cutaneous sheath allowed to retract, and the mucous membrane slit up along the dorsum as far as its attachment. Each half is then cut away, following the line of the corona, and leaving the frenum and just enough to hold a few sutures. If catgut is used, and the wound dried and covered with iodoform, the dressing may remain on until the skin has united.

Paraphimosis is the condition produced by forcing the glans through the orifice of the prepuce when it is too narrow to admit it. The immediate result is congestion and inflammation, ending, if left, in ulceration and sloughing. The glans becomes swollen; the prepuce overhangs it like an edematous collar, and concealed behind this is a tight, unyielding ring formed by the orifice. In early cases reduction can usually be effected by oiling the parts well, and drawing the foreskin forward with the index- and middle fingers of the two hands, while the thumbs compress the glans; or the penis may be wrapped round with lint soaked in equal parts of adrenalin solution 1:1000 and cocain solution 1:100; this is left on for 15 minutes, when the edema disappears, and reduction is often easy. In cases that have already lasted some days, it is often necessary to slip the end of a director under the constricting band on the dorsum, and divide it with a bistoury.

Epithelioma.—Squamous epithelioma is not uncommon after middle life, commencing on the glans or the inner surface of the prepuce, especially in cases of phimosis. It usually begins as a warty nodule, which soon breaks down into an ulcer, with intensely hard base and edges. If allowed to remain, the growth spreads rapidly, owing to the constant irritation of the urine; the corpora cavernosa and the glans are quickly infiltrated; the lymphatics in the groin become involved, and secondary deposits follow. The diagnosis from syphilis rests chiefly on the character of the base, which is covered with decaying epithelium, and the intense induration beneath and around.

Treatment.—Amputation is the only treatment. Until recently this was accomplished either with a single sweep of the knife, or more deliberately, forming a flap of skin to cover the surface of the wound, leaving the corpus spongiosum and the urethra longer than the rest, and stitching the edge of the mucous membrane to that of the skin. Recurrence, however, is exceedingly common after this operation; cicatricial stricture at the orifice invariable; and all power of directing the stream of urine lost. To avoid this, Thiersch recommends an oval incision round the root of the penis, prolonged a little backward in the median raphe of the scrotum, and then dissecting off the whole of the corpora cavernosa from the rami of the pubes and the triangular ligament. The corpus spongiosum and the urethra are dealt with separately, through an incision in the median line of the perineum behind, as

much being removed as appears desirable, and the rest sutured to the skin in front of the anus. Micturition must, of course, be effected in the sitting posture, but there is not the same tendency to the formation of stricture, and there is much further freedom from return of the growth.

Benign Tumors.—Of these there are cystic, vascular, fibrous, horny, fatty, sebaceous, and other new growths. The most common are the papillomata or warty growths, which are associated chiefly with venereal disease. They may arise from uncleanliness, especially if the prepuce is long. They constitute a "cauliflower" mass, and sometimes completely cover the mucous surface of the glans and prepuce. Removal by scissors, or by torsion with forceps, is a most speedily effectual treatment. Repeated applications of zinc, calomel, tannic acid, burnt alum, or the pressure of dry lint between the foreskin and glans may suffice. Cleanliness is essential.

PENNYROYAL.—See HEDEOMA.

PEPO.—Pumpkin seed. The ripe seed of *Cucurbita pepo*, with properties due to a resin contained in the inner covering of the embryo. Dose of the resin, 15 grains; of the seeds 1/2 to 1 1/2 ounces, made into a suitable emulsion.

It is efficient and harmless used as a vermifuge against the tape-worm. The husks should be removed and the remainder rubbed into an emulsion with water, or into an electuary with sugar, should be taken on an empty stomach, and followed in 1 or 2 hours by an active purge. See ANTHELMINTICS, WORMS (Tape-).

PEPPER.—See PIPER.

PEPPERMINT.—See MENTHA PIPERITA.

PEPSIN.—A name for the hypothetic digestive principle in the gastric juice, unknown as a definite body. All preparations vary much. Pepsin forms either a fine, white or yellowish-white, amorphous powder, or thin, translucent scales or grains, free from any offensive odor, soluble in about 100 parts of water, more soluble in water acidulated with hydrochloric acid, but insoluble in alcohol, ether, or chloroform. It should never be alkaline. Commercial pepsin is obtained from the rennet bags of sheep or the stomachs of pigs. It is precipitated by sodium chlorid, lead acetate, or by drying the peptones on glass plates. Alcohol also precipitates it. **Saccharated pepsin** consists of 1 part pepsin, triturated with 9 parts of sugar of milk. One part should digest at least 300 parts of egg-albumen. The dose is 5 grains to 1 dram, given shortly after meals. **Liquid pepsin** contains 40 parts of saccharated pepsin, 12 of hydrochloric acid, 400 of glycerin, and enough water to make 1000 parts. The dose is 2 to 4 drams, after meals.

Every manufacturer of pepsin has his own preparation, with his peculiar name, but all preparations have in some degree the power of digesting albumin or fibrin.

Pepsin is a ferment, not a solvent; it converts casein, albumin, fibrin, and other albuminoids into peptones for assimilation, being aided by lactic and hydrochloric acids. It should be given within 2 or 3 hours after taking food. Its activity is destroyed by alcohol, and alkalies and many mineral acids precipitate it. It is chiefly employed in dyspepsia, and in apepsia of infants, gastralgia, anemia, chlorosis, gastric ulcer and cancer, infantile diarrhea, and in the vomiting of pregnancy.

It is added to rectal enemata of nutritive character, and when injected into fatty tumors or morbid growths homologous to the tissues, may arrest their growth and promote absorption. Among the laity it is a much overrated remedy for indigestion. Pancreatin is usually of more service.

In indigestion with atony:

℞.	Strychnin,	gr. 1/24
	Powdered pepsin,	gr. x
	Powdered starch,	gr. vij.

Give at 1 dose.

PEPTONIZED FOOD.—This is indicated when the natural digestive powers are enfeebled or suspended. In gastric catarrh, with pain and intolerance of food, in gastric ulcer, in anorexia and dyspepsia associated with valvular heart-disease, and in pyloric and intestinal obstruction, in defective nutrition and intestinal irritation, it is serviceable. Peptonized food does not keep well, especially in warm weather. It should be prepared twice daily, and never be given when more than 12 hours old, or after having been reboiled. Peptonized food may be prepared by the gastric method, using pepsin and hydrochloric acid, or by the intestinal method, making use of the extract of pancreas. The latter is the preferable method. Probably the best solvent for an extract of pancreas is dilute spirit. The pancreas of the pig yields the best or most active preparation, but that of the ox or sheep may be employed. Calf pancreas yields an active extract, not, however, affecting starchy materials.

To make an extract of pancreas, first free the pancreas from fat, and cut into small pieces. Mix with 4 times its weight of dilute spirit, cork in a wide-mouthed bottle, and set aside for a week, agitating once daily, at the end of which time it is strained through muslin and then filtered through paper until clear.

Peptonized Milk.—Heat a pint of milk mixed with half a pint of water to about 140° F., or heat one-half of the milk and water to the boiling-point, and add to the other (cold) half 2 teaspoonfuls of the extract of pancreas and 10 grains of sodium bicarbonate. Pour into a covered jug and place in a warm situation. In an hour or hour and a half it is to be boiled for 2 or 3 minutes and may then be used like ordinary milk.

Peptonized Gruel.—It may be prepared from wheaten flour, oatmeal, arrow-root, sago, pearl-barley, pea or lentil flour. The gruel should be well boiled, thick, and strong, and poured into a jug and allowed to become lukewarm. Pancreatic extract, a dessertspoonful to a pint of gruel, may then be added, and the jug kept warm for 2 hours or so, and then the gruel brought to a boil and strained. This gruel is not generally an acceptable food for invalids, but it serves as a basis for peptonized soups, jellies, and blanc-manges.

Peptonized Milk-gruel.—This may be regarded as a predigested bread and milk, and is especially useful for weak digestions. Thick gruel from farinaceous articles, while boiling hot is added to an equal quantity of cold milk. To each pint of this mixture 2 or 3 teaspoonfuls of extract of pancreas and 10 grains of sodium bicarbonate are added. It is then treated as peptonized milk or gruel. If too bitter, less pancreatic extract may be used.

Peptonized Soups, Jellies, and Blanc-manges.—One way of making soups is to add to peptonized milk or gruel what is known as "stock." A better way is to use thin and watery peptonized gruel instead of simple water for extracting the soluble matters of shins of beef and other materials used in preparing soups. Jellies may be made by simply adding the due quantity of gelatin or isinglass to hot peptonized gruel and flavoring to suit. Blanc-manges are made in the same way, using peptonized milk instead of gruel, and adding cream. If the final boiling in the preparation of the peptonized gruel or milk is not complete, the extract will act on the gelatin, and the power of setting on cooling will be lost.

Peptonized Beef-tea.—To a pint of water are added a pound of finely minced lean beef and 10 grains of sodium bicarbonate. Allow this combination to simmer for an hour and a half in a covered sauce-pan. Decant the ensuing beef-tea into a covered jug. Beat up with a spoon the undissolved beef residue into a paste, and add to the tea in the jug. When it is cool enough to be tolerated in the mouth, a tablespoonful of the extract of pancreas is to be added, and the whole stirred together and kept warm for 2 hours, being occasionally agitated, at the end of which time the contents of the jug are boiled for 2 or 3 minutes, and finally strained. Beef-tea prepared in this way contains about 4 percent organic residue, of which more than three-fourths consists of peptone. When seasoned with salt, its taste resembles ordinary beef-tea.

Peptonized Enema.—To the enema prepared in the usual way—with a mixture of milk and gruel, or of milk alone, or of gruel and beef-tea—is added, just before administration, a dessertspoonful of liquor pancreaticus, or extract of pancreas. The ferment, in the warm temperature of the bowel, acts favorably, and no acid secretion interferes with the completion of the digestive process. It is a valuable resource when the stomach is intolerant of food, or obstruction exists in higher portions of the digestive tract.

PEPTONURIA.—The presence of peptone in the urine. The proteid body found in the urine in peptonuria is really not a peptone but an albumose, and a better term would be albumosuria. Albumose is characterized by yielding the biuret reaction; it is not precipitated by heat, but is precipitated by ammonium sulphate. Peptonuria—*i. e.*, albumosuria—occurs in all conditions attended by the destruction of tissue, especially in suppurative processes, purulent pleurisy, purulent peritonitis, abscesses, cerebrospinal meningitis, pyelonephritis, bronchoblennorrhea, in some cases of pulmonary tuberculosis with cavity formation, and during the puerperal state. The blood in leukemia may also contain albumose. Propeptonuria is probably only an albumosuria of high degree. See URINE.

PERCENTAGE SOLUTIONS, TABLE OF

Based on 456 Grains as the Weight of One Fluid Ounce of Water

Dissolve the quantity of ingredient (in grains) in less water than the required volume of solution, and then add sufficient water to bring the solution up to the required volume.

(POTTER.)

PERCUSSION.—A method of physical examination applied by striking upon any part of the body, with a view of ascertaining the conditions of the underlying organs by the character of the sounds elicited. In percussing attention is paid to the resonance, the pitch, and the duration of the sound, and to the resistance of the parts. Percussion is sometimes performed by striking with the entire hand. The method, in the case of the chest, serves to distinguish marked degrees of dulness from resonance.

Auscultatory percussion is percussion combined with auscultation. The method by which fine shades of difference in the quality of sounds may be detected. It is employed for outlining organs, both those containing and those not containing air. It is best applied by placing a double stethoscope at a fixed point and percussing gently all around. The stethoscope may be held with one hand, while with a finger of the other immediate percussion is made; or an assistant may percuss. See CHEST (Examination).

PERICARDITIS.—See HEART-DISEASE (Organic.)

PERICARDIUM, INJURIES.—See HEART (Injuries).

PERIHEPATITIS.—See LIVER.

PERIMETER.—See FIELD OF VISION.

PERINEUM, INJURIES.—Injuries to the perineum are almost invariably the result of childbirth. They are classified, according to the extent and position of the injury, into: (1) Slight median tear not involving the anal sphincter; (2) median tear in which the sphincter is divided; (3) laceration in one or both vaginal sulci; and (4) subcutaneous laceration of the muscles and fascia.

These injuries should be repaired by **perineorrhaphy.** Primary perineorrhaphy, or repair of the injury within the first few hours after labor, is preferable. When this cannot be done, or when it has been neglected, secondary perineorrhaphy should be performed. This may be done any time after cicatrization has occurred.

Slight Median Tear not Involving the Sphincter.—This tear passes through the fourchet, and may extend down the median line of the perineum as far as the sphincter. It usually extends for 1/2 of an inch or more up the posterior vaginal wall. In this injury there is no involvement of the supporting structures of the pelvic floor, and, therefore, there is no tendency toward prolapse of the vaginal walls and pelvic organs. This tear should be closed immediately after labor by the introduction of sutures, as shown in the accompanying illustration. The first stitch should be introduced at the apex of the tear in the posterior vaginal wall. It should be carried well out, so as to include sufficient tissue, and should emerge at the bottom of the tear; it should be reintroduced here, to be brought out on the opposite side of the tear at a point corresponding with its first point of introduction. Sufficient stitches should be introduced, about 1/4 inch apart, to completely close the wound. The external tear should be closed in a similar manner. The sutures may be tied or shotted. If this tear is neglected at the time of its occurrence, the secondary operation of perineorrhaphy is not indicated.

Median Tear in Which the Anal Sphincter is Divided.—This tear, although an extensive one, does not injure the supporting structures of the pelvic floor. There is, therefore, no tendency toward prolapse of the pelvic organs or the vaginal walls. The laceration takes place in the median line of the perineum, extends through the sphincter muscle, and may involve the rectovaginal septum to a greater or less extent. Permanent incontinence of feces is the result of this injury.

It is of the utmost importance that an injury of this character be repaired immediately after labor. The stitches are introduced as follows: The tear in the rectovaginal septum should first be closed by interrupted sutures, placed about 1/4 inch apart. They should be introduced from the vaginal aspect, beginning at the apex of the tear, and should extend to, but not through, the rectal mucous membrane. These sutures should now be shotted. The sutures which bring together the divided ends of the sphincter ani muscle are next introduced. This is obviously the most important step of the operation, since failure to bring together the ends of this muscle will result in continued incontinence of feces. The ends of the divided muscle are usually clearly marked by a dimple well back of and to each side of the anal opening. The first suture is introduced from the skin surface, back of and to the inner side of this dimple, close to the rectal mucous membrane. It is passed upward and outward through the dimple, and finally inward, to emerge at the apex of the tear in the rectovaginal septum, or if the septum has been extensively torn and repaired, just below the last stitch in the septum. It is reintroduced here, and is passed outward, downward, and inward through the septum, to emerge on the skin of the perineum just below the dimple of the opposite side. For greater security, a second similar stitch is introduced a little to the outer side of the first one. The subsequent steps of the operation consist in closure of the external perineal tear by a row of interrupted stitches. These stitches are now shotted, the two sutures holding the sphincter ani being secured first. If this injury is neglected at the time of its occurrence secondary perineorrhaphy must be performed. The technic of this operation is similar to that just described, except that the torn surface will have to be denuded. This is done with sharp scissors, particular care being taken to expose the ends of the divided sphincter muscle.

Laceration in One or Both Vaginal Sulci.—This tear extends in the direction of the ischiorectal fossa, and divides the vaginal sphincter, the transverse perineal muscle, and the inner fibers of the levator ani. The anal sphincter usually escapes, since it is out of the line of injury, which is usually bilateral, the left sulcus being, as a rule, the more extensively torn.

The result of this injury is prolapse of the vaginal walls and pelvic organs, since the supporting structures of the pelvic floor are lacerated. Repair should be immediately undertaken by first closing the torn sulci, and finally the tear of the external perineum in the manner that is described under the secondary operation.

The best secondary operation for the repair of a tear involving the sulci is *Emmet's*, which is performed as follows: The crest of the rectocele is seized with a tenaculum; the labia majora are seized with tenacula at about the height of the orifice of the ducts of the vulvovaginal glands. If the rectocele is drawn to one side, a triangular area is exposed which represents the site of the old laceration. This area is next denuded. The rectocele is now drawn to the opposite side, when a similar area is exposed and denuded. The base of the rectocele and a small portion of the skin of the perineum are next denuded. In denuding these areas care should be taken to remove every particle of scar tissue and mucous membrane.

The stitches are next introduced, the sulci being closed first. The first stitch passes directly across the apex of the tear in the left sulcus. The second stitch is introduced about 1/4 inch lower down, and about 1/8 inch from the edge of the mucous membrane on the left vaginal wall; it passes outward, downward, and inward, emerging at the bottom of the sulcus. It is reintroduced here, and emerges on the edge of the mucous membrane of the rectocele at a point corresponding to its point

of insertion. A third, and sometimes a fourth, suture is introduced in a like manner. Similar stitches are introduced in the right sulcus.

The skin of the perineum is now closed by a suture which is known as the crown stitch. It is introduced on the skin, passes outside of the denuded area, and emerges at the edge of the mucous membrane of the left lateral vaginal wall just below the last suture in the sulcus. It is then passed through the rectocele below the mucous membrane, and finally through the lateral denudation of the opposite side. A second suture, somewhat like the crown stitch, is usually necessary. The sutures in the sulci are first shotted, and finally those which close the skin of the perineum.

Subcutaneous Laceration of the Muscles and Fascia.—In this tear the muscles and fascia are injured, while the mucous membrane and skin remain intact. This is due to the great elasticity of the latter, which enables them to stretch, while the deeper structures, which are less elastic, tear. This injury invariably occurs in the sulci, and its results and treatment are the same as the preceding tear. It is sometimes called relaxation of the perineum. The best suture material for the foregoing operation is silkworm-gut. After the operation is completed, a douche of sterile water is given and a light vaginal tampon of iodoform gauze is introduced. This tampon is removed at the end of 24 hours. The bowels are moved on the third day. The stitches are removed at the end of 2 weeks, after which the patient may get out of bed. She should avoid heavy lifting, long standing, or any other form of active or tiresome exercise for at least 2 months after the operation.

PERIOSTITIS.—See Bone (Diseases).

PERISPLENITIS.—See Spleen (Diseases).

PERITOMY.—See Pannus, Trachoma.

PERITONITIS.—Inflammation of the peritoneum. According to cause it may be primary or secondary; according to extent, local or general; according to time, acute or chronic; and according to the exudate, serofibrinous, fibrinous, or purulent.

Etiology.—(1) Traumatic; (2) secondary to a suppurative process elsewhere, as abscess, pyosalpinx, endometritis, appendicitis; (3) secondary to obstruction of the bowels with infection; (4) secondary to certain diseases, as typhoid fever, hepatic abscess, empyema of the gall-bladder, tuberculosis, nephritis, or rheumatism. (See Colon Bacillus Infection.) Idiopathic peritonitis is no longer recognized. Traumatic peritonitis, following chemical irritation as well as injury, gives rise to distinctly localized trouble and is very different from true acute peritonitis, which is always caused by bacterial infection. In the former condition the elevation of temperature is probably caused by the absorption of fibrin ferment or other chemical substance generated in the injured tissues.

Acute Peritonitis

Pathology.—The membrane is red, swollen, and covered with an exudate—serofibrinous, fibrinous, or purulent. Frequently the coils of intestines are glued together through the medium of the inflammatory creamy exudation, which in many cases undergoes organization with the formation of fibrous bands. The endothelium undergoes desquamation or is infiltrated with liquid, and if infection takes place, fatty degeneration ensues, with the formation of pus. The usual infective microorganisms are the bacillus coli communis and the streptococcus.

Symptoms and Clinical Course.—Diffuse pain over the entire abdominal region and abdominal distention are the two most characteristic symptoms. On pressure over this area the patient complains of excessive tenderness, and, as in appendicitis, the dorsal decubitus is assumed to relieve as much as possible the tension of the abdominal muscles. Vomiting is an early symptom: first the contents of the stomach are ejected, and later the vomitus has a greenish tint, showing the presence of bile. The bowels are obstinately constipated; the temperature is considerably elevated (103° to 104° F.); the pulse is rapid (120 to 140), small, hard, and of a wiry character; the respirations are increased in number (30 to 40), and deep breathing is painful on account of distention of abdomen; the skin is moist and cold, devoid of color; the eyes are sunken; the cheek bones are prominent; the nose is pinched, giving rise to the Hippocratic facies. When the case terminates favorably, the fluid may be collected in sacs formed by the adhesion of the peritoneum to that of the intestine, and small areas of dulness may be found. The duration of an acute attack of peritonitis is from 6 to 9 days.

Diagnosis.—See table under Intestinal Obstruction.

Prognosis is always grave, but modern methods of treatment have lowered the mortality rate. The pulse is the best index of the gravity of the infection.

Treatment.—Medical treatment offers little hope in this affection. The cases which terminate favorably under its employment would probably do equally as well if no drugs were used. The key-note of success is early determination and removal by surgical means of the causative lesion. Opium should never be given until a diagnosis has been made, as it obscures the symptoms and also confers a false sense of security upon the patient, who naturally thinks that the relief of pain which follows its administration is a sign that his condition is improving. In cases in which operation is refused and in those in which the surgeon is called when it is too late to operate, then of course its use is permissible. Saline cathartics, at one time highly esteemed by some practitioners in the early stage of the disease, are not only devoid of curative effect but undoubtedly are harmful in that they may cause dissemination of an infection which nature is endeavoring to localize. A movement of the bowels may be obtained by a simple or medicated enema. Neither food nor drink should be given by the mouth, but enough fluid given by rectum to relieve thirst. As diagnosis is usually not difficult in the early cases an exploration can be made with no little degree of

assurance that the causative lesion will be found and removed. The later cases constitute one of the most difficult problems of surgery. As a general rule it may be stated that the decision to operate or not to operate will depend upon the degree of collapse from which the patient is suffering. Each case of this kind must be decided upon its own merits as there is no invariable rule which will apply to all. In operations in these cases all delaying minutiæ of technic should be disregarded. The abdomen is opened, the cause of the peritonitis removed, if possible, and drainage made through the original wound and also through a suprapubic incision. The postoperative treatment is very important. John B. Murphy has taught the profession the value of introducing large quantities of water or salt solution into the rectum by means of a constant though gentle flow. The patient is placed in the high-head (Fowler's) position and a nozzle, perforated in three or four places and attached to a container by a rubber tubing, is inserted into the anus. The container is placed but a few inches above the level of the rectum, so that the fluid shall flow in very slowly, no faster than it is absorbed. The flow may be regulated by compressing the tube, so that no fluid shall accumulate in the bowel. From a pint to a quart will ordinarily be absorbed in an hour. (See Proctoclysis.) In addition to the institution of this measure, food by the mouth is withheld, in order to prevent peristalsis. Concentrated liquids may be given by rectum either separately or mixed with the fluid used for proctoclysis. Strychnin and morphin given hypodermatically may be used according to the indications of the individual case.

Chronic Peritonitis

A form of peritonitis of slow development, and generally secondary to some constitutional disease. It occurs in two forms, circumscribed adhesive or diffuse proliferative.

Etiology.—(1) Most frequently tuberculosis; (2) cancer; (3) nephritis; (4) chronic alcoholism, are the most common etiologic factors.

Pathology.—The coils of intestines are often firmly matted together, and bands of adhesions connect the intestine to the peritoneum, often forming pouches in which fluid may be present. Its color in tuberculosis and in malignant diseases is usually reddened from the presence of blood.

Symptoms and Clinical Course.—The symptoms at first are very indefinite, though a sense of tenderness may be complained of on pressure over the affected area. The abdomen becomes retracted and hardened, a stiff, rigid abdomen being quite characteristic of tubercular peritonitis. Later tympany is present especially in the upper part of the abdomen. Ascites may be present. Localized swellings may occur, giving rise to pain and edema on pressure. The temperature is usually normal, or only slightly elevated. Constipation and albuminuria are common.

Prognosis is unfavorable.

Treatment is palliative by opium and other appropriate remedies. Treatment for tuberculosis (*q. v.*) should be instituted in the tubercular form. When ascites is present, or there is a purulent condition, the surgeon should perform a celiotomy. An incision is made in the median line evacuating the serum or pus, and, by a lifting motion of the abdominal wall, causes a free access of air within the peritoneal cavity. Abscesses found may be iodoformized after evacuation and drying. The abdomen should be closed without drainage. Secondary infection and fecal fistula are apt to result from the use of a drain. Results have been most encouraging, although surgeons do not agree as to the way in which the cure is produced. Dense adhesion of the intestines to the abdominal wall takes place in the course of a cure.

PERITYPHLITIS.—Inflammation of the peritoneum surrounding the cecum. This is a disease most frequently encountered in the young and in males. It is usually due to some inflammatory disease of the vermiform appendix, and is marked by pain in the right iliac fossa, and a tumor—elongated, sausage-shaped, dull on percussion, and very tender—in the same region. The disease may give rise to general peritonitis from escape of pus into the general peritoneal cavity. The abscess may burst through the abdominal wall into the bowels, bladder, or pleural cavity. See Appendicitis.

PERMANGANATE, POTASSIUM.—See Manganese.

PERNICIOUS ANEMIA.—See Anemia (Pernicious).

PERNIO.—See Frost-bite.

PERSPIRATION.—See Diaphoretics, Sweat-glands.

PERTUSSIS.—See Whooping-cough.

PESSARY.—See Uterus (Retrodisplacements).

PETECHIA.—A small, round, oval, or irregular spot of ecchymosis beneath the epidermis, varying in size from a flea-bite to an area having a diameter of 1/2 inch or more. It is not raised above the level of the skin, but is of a reddish or purple shade, and does not alter by pressure of the finger. Flea-bites have in them a puncture which is always perceptible, and which contrasts strongly with the lighter color of the rest of the disc. The tint varies according to age and the amount of effused blood. They occur on mucous membranes as well as on the skin, in purpura, scorbutus, malignant fevers, and in constitutional diseases. The term *petechial* is applied to certain varieties of diseases, such as typhus, when petechiæ occur in their course, or the eruption becomes hemorrhagic.

PETROLATUM.—A mixture of hydrocarbons, chiefly of the methane series, obtained from petroleum. It is colorless or yellowish, and in the latter case is more or less fluorescent; amorphous, odorless and tasteless, of neutral reaction, insoluble in water, slightly soluble in absolute alcohol, readily soluble in ether, chloroform, petroleum benzin, benzene, carbon disulphid, oil of turpentine, and fixed or volatile oils. The soft variety is known commercially as *terralin*, *cosmolin*, *vaselin*, *petroleum ointment*, etc. Besides petrolatum itself it is official in the following-named forms—P. **Album,** a white, unctuops

mass, without odor or taste, of about the consistence of an ointment. **P. Liquidum,** a colorless, oily, transparent liquid, without odor or taste, but giving off, when heated, a faint odor of petroleum. **Paraffinum,** a mixture of solid hydrocarbons, a colorless, translucent mass, odorless and tasteless, and slightly greasy to the touch.

Petrolatum is a valuable protective dressing, and an excellent basis for ointments, having no acridity and no liability to become rancid. It is readily miscible with many active agents, as the alkaloids and phenol compounds, but it does not penetrate the skin so readily as animal fats and fixed oils. Uncombined, it forms an excellent bland application in all irritated conditions and injuries of the skin, and it has been used with benefit alone, or mixed with castor or olive oil, in chronic eczema accompanied by desquamation. Paraffin is employed by subcutaneous injection for cosmetic effects on saddle-shaped noses and other superficial deformities.

Liquid Petrolatum is used as a laxative in doses of a teaspoonful to 1 ounce at bedtime or 3 times a day. Lane advises the heavy Russian mineral oil, but Bastedo's investigations indicate that there is no important difference between the actions of heavy Russian and the heavy and light American oils. (Lightest specimen, sp. gr. 0.0857 at 22° C.) It is readily taken as it is almost tasteless, is unabsorbed and acts by softening and increasing the bulk of the feces. It is warmly recommended by Lane for chronic constipation and the autointoxication which manifests itself in so many forms as a result of intestinal stasis.

Ambrine, Mulene, and Parresine are names applied to proprietary paraffin mixtures of secret composition which have recently come into prominence in the treatment of burns. The greatest notoriety surrounds the sensational reports concerning Ambrine which is the French preparation; the other two are of American origin. The principle of the paraffin film method is supposed to be mainly mechanical, the film forming a protective covering to the exposed tissues and perhaps forming a sort of scaffold for the feeble granulations. It is easily removable.

PHAGEDENA.—See Ulcer.

PHARYNGITIS (Simple Angina).—An inflammation of the mucous membrane of the pharynx, and also very frequently involving the soft palate, uvula, tonsils, and larynx.

Varieties.—(1) Acute pharyngitis; (2) chronic pharyngitis.

Acute Pharyngitis

Definition.—An acute catarrhal inflammation of the mucous membrane of the pharynx.

Etiology.—(1) Exposure to the cold and wet; (2) overheated sitting or sleeping room, with a sudden chilling; (3) sedentary habit, with indigestion and constipation; (4) certain diseases, such as tuberculosis, gout, rheumatism, and lithemia; (5) inhalation of steam, dust, or noxious vapors.

Symptoms.—There is pain on swallowing, accompanied by a sensation of dryness or of a foreign body, and a desire to clear the throat.

Tenderness may exist in muscles in region of neck and pain may arise from pressure over the region of the tonsils; for this reason in many cases the mouth cannot well be opened. Should the catarrhal process extend upward, the orifices of the eustachian tubes may become occluded, giving rise to temporary deafness or ringing in the ears; and if it extends downward into the larynx, hoarseness will be added to the other symptoms. Often the senses of taste and smell are temporarily impaired.

Physical Signs.—On inspecting the pharynx it will be seen to be greatly reddened in color and the blood-vessels in a condition of hyperemia, especially on the posterior wall, and the uvula and fauces may be edematous. See Pharynx (Examination).

Prognosis is favorable.

Treatment.—Rest in bed is essential; free purgation at the onset is desirable. Calomel (1/6 grain) should be given every hour until 6 or 8 doses have been taken, followed by a saline purge. A hot mustard foot-bath at bedtime is recommended. A commendable prescription is:

℞. Tincture of aconite, ♏ xlv
Solution of potassium citrate, ℥ ij
Aromatic elixir, ℥ iv
Camphor water, add enough to make, ℥ iv.

One tablespoonful every 3 hours.

If there is much edema:

℞. Tincture of opium, ℥ j
Tincture of belladonna, ♏ xv
Camphor water, add enough to make ℥ iv.

One tablespoonful every 3 or 4 hours.

Also apply locally boroglycerid (50 percent) or glycerol of tannin to the affected parts if they are edematous. Quinin (4 grains) every 3 or 4 hours may be administered. If the disease is due to a rheumatic tendency, sodium salicylate (7 grains) or aspirin is indicated.

Local Treatment.—Give small pieces of ice on the tongue every hour or two; apply at onset of symptoms a few drops of a solution of cocain (4 percent), and also:

℞. Menthol, gr. vj
Almond oil, ℥ ij.

Apply every 3 hours.

In some cases it is advisable to apply a strong solution of silver nitrate (20 grains to 1 ounce) during the initial symptoms. If the fever is high, phenacetin (5 grains) may be given every 3 or 4 hours and the aconite discontinued. A nutritious fluid diet should be given.

Chronic Pharyngitis

Synonyms.—Clergyman's sore throat; chronic follicular tonsillitis.

Varieties.—(1) Hypertrophic; (2) atrophic; (3) ulcerative; (4) suppurative (hospital sore throat).

Etiology.—(1) Sequel of acute pharyngitis; (2) excessive straining of the voice or continuous clearing of the throat; (3) constant inhalation of dust or tobacco.

Symptoms and Clinical Course.—The voice is hoarse, often quickly fatigued, and may be entirely lost; cough is frequent and hacking in character; slight pain is complained of on deglutition. There is often a sensation of a foreign body lodged in throat, with a constant desire to expel it by forced effort, and, in some cases, the viscid, tenacious mucus may be tinged with blood.

Hypertrophic Pharyngitis.—The mucous membrane is swollen, hypertrophic, and covered with small reddish or pink granulations composed of glandular tissue. The capillaries are highly injected, and the surface of the mucous membrane seems rough and often mottled. The mucous secretion is thick, viscid, and very tenacious. Digestion is bad, and dyspepsia is a frequent accompaniment.

Atrophic Pharyngitis.—The mucous membrane is lighter in color and atrophied.

Ulcerative pharyngitis is characterized by the formation of ulcers, generally of a specific nature, such as from syphilis, tuberculosis, or cancer.

Syphilitic ulcers of the pharynx and tubercular ulcers of the pharynx are differentiated by Bosworth as follows:

Syphilitic Ulcers.	Tuberculous Ulcers.
Deeply excavated.	No apparent excavation.
Few granulations, and those highly inflammatory.	Much indolent granulation.
Deep-red areola.	Faint areola.
Sharply-cut edges.	Irregular and ill-defined edges.
Distinct demarcation.	Demarcation indistinct.
Yellow purulent secretion.	Grayish, ropy mucous secretion.
Discharge profuse.	Discharge scanty.
Penetrating to deeper tissues.	Superficial, with lateral in place of deep extension.
No fever as a rule.	Hectic fever as a rule.

Suppurative Pharyngitis.—There is a suppurative inflammatory process, first confined to the pharynx, but later extending downward to the larynx and trachea, or upward into the nasal chamber. The predominant feature is its tendency to involve the deeper structures, leading to suppuration and sloughing.

Prognosis depends upon the cause. In the atrophic form the disease may be very obstinate. In the suppurative variety grave complications may ensue.

Treatment. Hypertrophic Pharyngitis.—Correct any constipation by the use of Rochelle or Epsom salts (2 to 3 drams), taken before breakfast, or fluidextract of cascara (1/2 dram) at bedtime. A pill composed of aloin, strychnin, and belladonna may be taken 3 times daily. For the indigestion, avoid overloading the stomach, especially with rich desserts. Alcohol should not be used. Tobacco, tea, and coffee should be restricted. Give elixir of lactopeptin and gentian (2 drams) after each meal. As a general tonic, the elixir of the phosphates of iron, quinin, and strychnin, after meals, is valuable. In bathing it is necessary to guard against taking cold, and the time should be so arranged as to exercise the precaution. Frequent bathing is essential. To render the throat less susceptible, cold water may be sponged over parts once or twice daily. The habit of constantly clearing the throat should be absolutely repressed.

Local Treatment.—Alkaline sprays should be used every 2 or 3 days to keep the parts clean. For this purpose, an alkaline antiseptic tablet (Seiler), dissolved in 3 ounces of water, acts admirably.

Subsequent to the spraying of the throat by the alkaline solution, the following local application may be made by means of a spray:

℞.	Menthol,	gr. ij
	Eucalyptol,	gr. j
	Liquid vaselin,	ʒ j.

The anterior and posterior nares may also be cleansed in the same manner, and the local application made.

Spray for anterior nares to be used cautiously:

℞.	Menthol,	gr. j
	Compound tincture of benzoin	ʒ j.

Apply the smallest amount possible to parts by means of an atomizer, once a week.

Should the granulations not begin to disappear within the first 2 or 3 weeks of treatment, they may be touched with the galvanocautery and the other local applications be discontinued for a few days. Before applying the cautery to parts, the latter should first be cleansed with the alkaline spray and subsequently swabbed with a solution of cocain (4 percent), being careful that none of the solution is swallowed, as alarming symptoms have sometimes occurred from this accident. In case the galvanocautery is not used, an application of silver nitrate (20 grains to 1 ounce) may be made once a week, or boroglycerid (50 percent) or glycerol of tannin used every 3 days. Carbolic acid should be used cautiously about the nares, as it has been known to produce anosmia.

Atrophic pharyngitis may result from the hypertrophic form, and should be treated in much the same way. The crusts should be cleansed and an oily solution used to keep the nares moist.

Ulcerative pharyngitis should be treated specifically. Locally, iodoform in powder may be blown over the parts, equal parts of iodoform and boric acid may also be used. At certain intervals the granulations may be cauterized with molded silver nitrate or the same salt in strong solution.

Suppurative pharyngitis calls for surgical interference if abscesses develop. When this complication does not ensue, prescribe, as a gargle, the alkaline solution recommended for the hypertrophic form. Apply cold cloths to throat ex-

ternally, and give large doses of the tincture of ferric chlorid containing quinin.

PHARYNX, EXAMINATION. **Anatomy.**—The pharynx is that portion of the alimentary canal posterior to the nose, mouth, and larynx. It is a membranous sac about 4 1/2 inches in length, of cone shape, with the apex directed downward. The pharynx has 7 openings: Two posterior nares, 2 eustachian tubes, mouth, larynx, and esophagus. On each side of the pharynx and between the anterior and posterior palatine folds may be seen the tonsils.

Normal Appearance.—In color it is somewhat redder than the mucous membrane of the mouth. On the posterior surface may be seen minute elevations or follicles. The minute arterial and venous blood-vessels are very tortuous and distinct, but are occasionally obscured by an excess of saliva and mucus.

Examination of the pharynx may be made with either direct or reflected light. In the former instance the patient should sit facing the strongest light possible, and the examination conducted either by holding the tongue down with a tongue-depressor, or else have the organ grasped between the folds of a napkin and drawn forward. If the light is insufficient, the room may be darkened, and the light from a lamp reflected by means of the head-mirror. The posterior nares may also be examined at the same time by the use of the laryngoscopic mirror. In those cases in which there is a hypersensitiveness of the pharynx, and in which it is necessary to examine the posterior nares, a very small amount of a 4 percent solution of cocain may be swabbed over the vault of the pharynx. The laryngoscopic mirror should be gently heated before being introduced, otherwise the moisture from breathing will obscure the image.

PHARYNX, INJURIES.—See NECK (Injuries).

PHENACETIN.—A phenol derivative (acet-paraphenetidin), the product of the acetylization of paraamidophenetol. It occurs in white, glistening, crystalline scales, or fine, crystalline powder, odorless and tasteless, soluble in 70 parts of boiling water, in 12 of alcohol, nearly insoluble in water. Dose, 5 to 10 grains in powder, tablets or cachets, hourly or every two hours, but larger doses have been administered.

The action of phenacetin is similar to that of acetanilid. It is one of the safest of the new synthetic antipyretics, yet in sufficiently large doses it is as poisonous as any of its analogues. In one case 22 1/2 grains, taken by a woman within six hours, produced collapse with marked lividity, great dyspnea and restlessness, cold perspiration, and slightly dilated pupils; in another case 120 grains were taken in twelve hours without the production of any symptoms (Wood). A toxic dose causes vomiting, cyanosis, chocolate-colored urine, yellow discoloration of the body, leukocytosis, and death by respiratory paralysis. In medicinal doses it depresses the heart slightly, and does not affect the blood or the respiration. It acts more gradually than other antipyretics, its maximum effect being reached in three or four hours. It reduces fever by lessening heat production and causes perspiration without producing collapse. It is also analgesic and hypnotic, relieving pain and inducing sleep. It has been administered with benefit, in 2-grain doses with 1/2 grain of citrated caffeine at short intervals, for migraine; also in epidemic influenza, both as a prophylactic and as a remedy. As an antipyretic it is extensively employed in phthisis, peritonitis, polyarthritis, endocarditis, typhus and typhoid fevers; and as an analgesic in vasomotor neuroses, for the lancinating pains of locomotor ataxia, also in neuralgia and hemicrania. It is highly praised in whooping-cough, rheumatic and other fevers, and though slower in action than antipyrin or acetanilid, it is deemed fully as efficient in reducing pyrexia, while usually free from the depressant after-effects of the latter agents. It is strongly commended as a local antiseptic dressing.

For neuralgia:

℞.	Phenacetin,	gr. x
	Citrated caffein	gr. v
	Sugar of milk,	gr. xx.

Divide into 10 powders. Give 1 powder every 2 hours while the pain exists.

Incompatibles are: Acids (strong), alkalies (strong), chloral hydrate, oxidizers, piperazin, phenol, pyrocatechin, salicylic acid.

PHENOCOLL.—Produced by the interactions of phenetidin and glycocoll. **P. Hydrochlorid** is a soluble phenacetin, chemically and medicinally, and is distinguished by its comparatively free solubility. It is a white, fine powder, incompatible with alkalies, and is given in doses of 5 to 20 grains 4 times a day. It is best administered in capsule. It has decided antipyretic, antirheumatic, and analgesic powers, is promptly absorbed and readily excreted, and reduces fever without the marked sweating or other unpleasant after-effects of other coal-tar antipyretics. In hectic, malarial, typhoid, and other fevers, in acute rheumatism, neuralgia, epidemic influenza and its neuralgic pains, in gouty and rheumatic affections when accompanied by fever and pain, and in combination with piperazin (15 grains), it has been employed with success. **P. Salicylate,** the salicylate of the synthetic base phenocoll, combines the actions and uses of its constituents. Dose, 15 to 30 grains.

PHENOL. C_6H_5OH.—Formerly called carbolic acid—is procured from coal-tar by fractional distillation and subsequent purification, or made synthetically. It has a very peculiar and characteristic odor, a burning taste, is poisonous and has preservative properties. It crystallizes in colorless rhombic needles; and at ordinary temperatures it dissolves in water with difficulty (1:15), but is soluble in alcohol, ether, glacial acetic acid, and glycerin in all proportions. Upon exposure to light and air it deliquesces, and acquires a pinkish color. It is used in the manufacture of many of the artificial coloring-matters: *e. g.*, picric acid, used as a yellow dye. Large quantities of various qualities of carbolic acid are consumed for antiseptic purposes. Dose, 1/4 to 1 grain, well diluted.

Therapeutics.—Phenol is employed as an antiseptic, caustic, and local anesthetic. For antiseptic dressings and for purifying sponges, and for instruments, it is most useful. In diphtheria, infectious stomatitis, or ulcerative sore throat, combined with glycerin, it is a valuable application. Internally it is used in acute diarrhea and flatulent dyspepsia (1/4 to 1 grain), and as a deodorant inhalant in bronchiectasis, pulmonary gangrene, and phthisis. Injections of 3 to 5 minims of a 2 percent solution will often abort carbuncles and boils. It is in common use in dentistry as an antiseptic and local anesthetic. It will allay the itching in eczema, pruritus, and piles, and will check obstinate vomiting from gastric irritability. Mixed with vaselin, 5 drops to the ounce, it makes a soothing application for burns. As a caustic it may be used against condylomata and chancroids.

A wash in acne or impetigo:

℞.	Phenol,	gr. x
	Glycerin, Rose-water, each,	ʒ j.

In tympanites:

℞.	Phenol,	gr. j
	Extract of opium,	gr. j
	Bismuth subnitrate,	gr. xviij.

Make into 6 powders. One powder 3 times a day.

For mosquito-bites:

℞.	Phenol,	gr. xxx
	Glycerin,	ʒ iij
	Rose-water, enough for	ʒ viij.

Make into a lotion.

Poisoning.—A toxic dose of carbolic acid, taken internally, is one of the most rapidly acting poisons known, sometimes equaling prussic acid in this respect. The symptoms develop almost immediately, and death may occur in a very few minutes; but usually the patient lives from 1 to 10 hours; rarely over 2 days. In some cases a great amendment has occurred, with restoration of consciousness, but after some hours sudden and fatal collapse has supervened. The minimum fatal dose is not determined, but 1/2 of an ounce has frequently caused death; and doses as small as 6 minims have given rise to dangerous symptoms. Cases of suicidal and accidental poisoning by this drug are very frequent, by reason of the facility with which it may be obtained for use as a disinfectant.

If the patient is seen shortly after ingestion, apomorphin may be administered hypodermically, as a rapidly acting emetic; but in any case the stomach should be washed out freely with alcohol and water, equal parts of each, and 8 or 10 ounces of the same should be left in the stomach for a short time, and this is to be followed by a washing out with warm water. Next in value is any soluble sulphate to form the harmless phenolsulphonates: as, magnesium sulphate 1 ounce or sodium sulphate 1/2 of an ounce, dissolved in 1/2 of a pint of water. Even if several hours have elapsed since the ingestion of the poison, the sulphates should be used, as their antidotal action proceeds in the blood. In one case where 1/2 of an ounce of the 95 percent acid had been taken, nearly 3 ounces of magnesium sulphate (Epsom salts) were used, resulting in complete recovery from an apparently hopeless condition. Stimulants, as ether or brandy hypodermically, should be used freely; also hot-water bottles and hot blankets if signs of collapse appear. Vegetable demulcents may be given (but no oils or glycerin), to protect the mucous surfaces. Liquor calcis saccharatus or syrupus calcis is also antidotal to the poison in the stomach, but is much less efficient than the sulphates. Atropin hypodermically is a very complete physiologic antagonist to the systemic symptoms, maintaining the heart and respiration until elimination occurs (Post). Oils should not be used, as they increase the absorption of the poison (Potter).

Incompatibles are: acetanilid, acetphenetidin (phenacetin), antipyrin, albumin, antisepsin, borneol, bromal hydrate, bromin water, butylchloral hydrate, camphor, chloralformamid, chloral hydrate, collodion, diuretin, ethyl carbamate (urethan), euphorin, exalgin, ferric salts, gelatin in dilute solution, hydrogen dioxid, lead acetate, menthol, methacetin, naphthol, nitric acid, phenyl salicylate (salol), piperazin, potassium permanganate, pyrocatechin, pyrogallol, resorcinol, sodium phosphate, thymol, terpin hydrate.

Preparations.—**P. Liquefactum,** a liquid composed of not less than 86.4 percent by weight of absolute phenol, and about 13.6 percent of water. Dose, 1/2 to 2 minims. **Glyceritum P.,** has of liquefied phenol 20, glycerin 80. Dose, 3 to 10 minims. **Unguentum P.,** has of phenol 3, white petrolatum 97. For external use. **Sodii Phenolsulphonas** (*Sodium sulphocarbolate*), occurs in transparent, rhombic prisms, soluble in 5 of water. Dose, 2 to 10 grains. **Zinci Phenolsulphonas** occurs in transparent, rhombic prisms, soluble in 2 of water. Dose, 1 to 5 grains.

PHENOLSULPHONATE.—A salt of phenolsulphonic acid.

Zinc phenolsulphonate is antiseptic and disinfectant. It is used as an intestinal antiseptic and sometimes in small doses for fetor of the breath.

The phenolsulphonates of sodium and potassium are employed internally with advantage in septic diseases, the exanthems, diphtheria, puerperal fever, etc., with the object of obtaining the antiseptic action of phenol without the dangers attending its use in efficient doses. They may be used locally with good results in aphthæ, tonsillitis, otorrhea, gonorrhea, and for inflamed mucous membranes generally.

PHENOLSULPHONEPHTHALEIN TEST.—Rowntree and Geraghty have introduced a test of renal functional activity which has maintained its place for several years and represents the highest degree of accuracy so far obtained by simple and practical methods.

It should be thoroughly understood that normal excretion does not prove that the kidneys are free from disease. It does show that, at the time, the renal function is not seriously affected. We do not know what degree of change is required to produce recognizable impermeability.

Drug.—The drug is a non-toxic, bright red powder moderately soluble in alcohol and water and readily soluble in the presence of alkalies.

Normal Excretion.—It is excreted with almost incredible rapidity, appearing in the urine a few moments (five to eleven) after hypodermic injection, and being eliminated in normal cases almost wholly within 2 hours. From 50 to 60 percent of the drug should be excreted during the first hour, and from 70–90 percent by the end of the second.

Test Solution.—0.6 gram of the phenolsulphonephthalein and 0.84 c.c. of a 2/N NaOH solution (8 percent) are added to normal salt solution sufficient to make 100 c.c. The addition of a few drops more of the 2/N NaOH solution to the injection fluid at the time it is used changes the color of the test fluid to a wine red and renders it non-irritating to the tissues.

Technic.—(*a*) The patient is given 300 to 400 c.c. of water to insure free secretion. (*b*) A catheter is passed into and retained in the bladder after this viscus is completely emptied. (*c*) At a carefully noted time, 20 to 30 minutes after the ingestion of the water, 1 c.c. of the test solution (6 mg. of the drug) to which 2 or 3 additional drops of the 2/N NaOH solution have been added to prevent irritation, is injected into the upper arm. (*d*) From this time all of the urine is led into a test-tube containing a drop of 25 percent sodium hydrate solution and the first appearance of a pink color carefully noted.

This represents the initial excretion period which normally varies between 5 and 11 minutes.

Obstructive vs. Unobstructive Cases.—If no obstruction to micturition exists the catheter now may be removed, the patient voiding at the end of both the first and second hours.

In obstructive cases the catheter is clamped and maintained *in situ* until 2 hours have elapsed, the bladder being drained at the end of each hourly period.

Colorimeter.—The amount excreted is measured by a colorimeter. Each hour's voiding, being measured and its specific gravity determined, is placed in a 1-liter volumetric flask and treated with sufficient 25 percent NaOH solution to alkalinize it and thus develop the maximum color, a brilliant purple red.

Sufficient distilled water to bring the solution to the 1-liter mark is then added, the mixture thoroughly shaken up and a filtered portion taken for comparison with a standard solution consisting of 1 c.c. of the test solution in 1 liter of water, plus 1 or 2 drops of a 25 percent NaOH solution.

The standard solution is accurately adjusted to the 10-mm. mark of the scale and compared with the unknown solution, the percentage of drug excreted being calculated by the differences in scale required to secure uniformity of color in the two solutions.

Clinical Application.—In renal disease, both parenchymatous and interstitial, but especially the latter, the excretion is retarded and greatly diminished if the kidneys are insufficient.

Advantages Claimed for the Test.—Its originators claim for it the following advantages:

(*a*) It represents a non-toxic agent promptly secreted by normal kidneys, or by diseased kidneys, while functionally efficient, but retained for suggestively longer periods in actual renal insufficiency.

(*b*) The brilliant red of the solution lends itself readily to colorimetric determinations.

(*c*) In cardiorenal cases the drug may show clearly the extent of actual renal insufficiency inasmuch as simple chronic congestion, save in the most extreme degrees of incompensation, affects excretion but slightly as compared with actual nephritis.

(*d*) It permits better prognosis, forecasts or determines the presence of uremia and is of great importance with relation to proposed surgical procedure, and in warning the obstetrician of impending eclampsia.

(*e*) Within reasonable limits and in conjunction with ureteral catheterization it permits an estimate of the relative functionating values of the two kidneys.

Uremic Seizures.—During an actual uremic attack the elimination during 2 hours is almost nil.

Impending Attacks of Uremia.—In any nephritic patient a showing of 10 percent or less indicates an impending uremic seizure (Greene's *Medical Diagnosis*).

PHENOSALYL.—A clear, syrupy liquid, prepared by fusing together phenol 9 parts, salicylic acid 1, lactic acid 2, and menthol 0.1. It has a pleasant odor, is very soluble in water, and is used in a 1 percent solution as an antiseptic application, and in 10 to 30 percent solutions as a curative lotion for varicose ulcers and ulcerated gummata. It is said to be superior as a germicide to any one of its ingredients, and to prove much less toxic than the agents usually so employed.

PHIMOSIS. See Penis (Diseases).

PHLEBITIS.—See Veins (Inflammation).

PHLEBOTOMY.—See Venesection.

PHLEGMASIA ALBA DOLENS (Milk Leg).—An acute swelling of the leg due to venous obstruction from thromboses, and occurring most frequently in women after labor.

Etiology.—It is usually due to some form of septic infection of the genital region. Perineal or cervical tears may be the point of entrance of the poison. Infection of the blood-vessels at the placental site is probably the most frequent cause. Occasionally it may be due to simple pressure; these cases arise usually during the latter part of pregnancy.

Symptoms.—The symptoms usually develop from 1 to 3 weeks after labor. The leg becomes swollen, firm, and tender on pressure. The skin is strongly stretched and white in color; movement of the leg is extremely painful. There may be tenderness and redness over the course of the femoral vein. One or both legs may be affected. Fever, rapid pulse, and prostration, more or less

marked, are common accompaniments. In the severer cases suppuration and abscess of the cellular tissue of the leg may develop.

Prognosis.—The prognosis depends very largely upon the cause of the condition. If it is an accompaniment of a general septic process, it is very grave. It is always doubtful, on account of the liability to embolism.

Treatment.—This consists in elevation of the leg with absolute rest. It should be well protected with cotton, and, if the pain is very severe, hot applications or ichthyol ointment may be tried. Should abscess occur, free incision and drainage are required. The constitutional treatment should consist in plenty of good, nutritious food and free stimulation.

PHLYCTENULAR CONJUNCTIVITIS.—See Conjunctivitis.

PHONENDOSCOPE.—An instrument designed to be used in place of the stethoscope in auscultation. It consists of a shallow metal cup covered by a disc of ebonite, with a perforation in the cup to which are attached rubber tubes for the ears. From the center of the disc of ebonite arises a little rod with a button at the end. The tubes are placed in the ears, and the button is placed over the organ to be examined, while the finger is drawn over the skin, beginning at the point where the button is applied and running outward. The rasping bruit heard before the application of the phonendoscope ceases as soon as the finger passes beyond the organ. The instrument is useful to differentiate murmurs and distinguish between endocardial and pericardial sounds. It is a distinct improvement over the binaural stethoscope. See Chest (Examination).

PHOSPHORIC ACID. H_3PO_4.—Orthophosphoric acid. It is said to be of value in strumous affections, but is of little real benefit except as a feeble digestive stimulant. **Dilute phosphoric acid** contains 10 percent of the absolute acid. Dose, 5 to 45 minims.

PHOSPHORUS.—A nonmetallic element, having a quantivalence of III or V, and an atomic weight of 31. Symbol, P. Phosphorus does not occur in the free state, but is widely distributed in rocks, in fertile soils, in animal and vegetable tissues, in urine, and in guano. The human body contains a large quantity of calcium phosphate in the form of complex organic compounds. Phosphorus is an important constituent of nervous tissue. In commerce it is prepared from bone-ash, or from sombrerite, an impure calcium phosphate found in West Indian guano. Phosphorus may be obtained in several allotropic forms. **Ordinary phosphorus** is a yellowish-white, waxy solid, of a specific gravity of 1.837. It melts at 44.2° C., and boils at 290° C. It is insoluble in water, soluble to a slight extent in olive oil and in ether, freely in carbon disulphid. **Red or amorphous phosphorus** is formed when ordinary phosphorus is heated to 240° C., in an atmosphere free from oxygen; also by the addition of a trace of iodin at 200° C. It is a dark red powder, having a specific gravity of 2.11, insoluble in carbon disulphid, noninflammable, nonluminous, and nonpoisonous. **Metallic rhombohedral phosphorus** is an allotropic form produced by heating phosphorus in a sealed tube with melted lead. Its specific gravity is 2.34. Other modifications have been described. Phosphorus combines with other elements to form phosphids; with hydrogen and oxygen to form a series of acids, known chiefly through their salts.

Therapeutics.—Medicinally, phosphorus is used as an alterative in osteomalacia, rickets, and ununited fractures. It is also employed in sexual impotence, in threatened cerebral degeneration, in neuralgia, and in convalescence from exhausting diseases. Dose, 1/150 to 1/50 grain.

Poisoning.—Ordinary phosphorus is exceedingly poisonous; it causes a widespread fatty degeneration, most marked in the liver. Vomiting is one of the earliest symptoms, the material ejected being generally luminous in the dark. Jaundice appears usually within 36 hours; sometimes, however, much later. The liver is at first enlarged, but subsequently diminishes in size. Cerebral symptoms of an intense type occur—wild delirium, convulsions, coma. Death is generally due to failure of respiration and circulation. The urine in phosphorus-poisoning is albuminous, contains bile acids and pigments, and leucin and tyrosin. Chronic phosphorus-poisoning is common among workers in match factories. A prominent symptom is necrosis of the jaws. See Jaws (Diseases).

The treatment of phosphorus-poisoning consists in the administration of emetics and purgatives and of the antidote—copper sulphate or old French oil of turpentine.

Preparations.—**Acidum Hypophosphorosum,** a liquid composed of 30 percent by weight of absolute hypophosphorous acid, H_3PO_2, and 70 percent of water. **Acidum Hypophosphorosum Dilutum,** a liquid composed of 10 percent of the absolute acid and 90 percent of water. Used in the preparation Syrupus hypophosphitum. Dose, 5 to 10 minims. **P. Pilulæ,** each contain phosphorus 1/100 grain dissolved in chloroform, mixed with althæa and acacia in glycerin and water, and coated by shaking with a solution of balsam of tolu in ether. Dose, 1 to 2. **Calcii Hypophosphis,** colorless prisms, or thin, pearly scales, of nauseous taste, soluble in 6.8 of water, insoluble in alcohol. Is an ingredient of the syrupus hypophosphitum. Dose, 5 to 15 grains. **Ferri Hypophosphis,** a white or grayish-white powder, odorless and tasteless, slightly soluble in water. A ferruginous tonic. Dose, 1 to 5 grains. **Mangani Hypophosphis,** a pink, crystalline powder, soluble in water, almost insoluble in alcohol. Dose, 1 to 5 grains. **Potassii Hypophosphis,** white masses, or a white granular powder, deliquescent, odorless, of saline taste and neutral reaction. Soluble in 0.6 of water and in 7.3 of alcohol at 59° F. Dose, 5 to 10 grains. **Sodii Hypophosphis,** small plates, or a white, granular powder, deliquescent, odorless, of sweetish, saline taste, and neutral reaction. Soluble in 1 of water and in 30 of alcohol at 59° F. Dose, 5 to 30 grains. **Syrupus Hypophosphitum** has of calcium hypophosphite 4 1/2, of potassium and sodium hypophosphites 1 1/2 each, percent. Dose, 1 to 4 drams. **Calcii Phosphas Præcipitatus,** a

light, white amorphous powder, insoluble in water or in alcohol. Dose, 2 to 30 grains. **Syrupus Calcii Lactophosphatis** has of calcium carbonate 2 1/2, lactic acid 6, phosphoric acid 3.6, percent. Dose, 1 to 4 drams. **Sodii Phosphas,** large, colorless, monoclinic prisms, efflorescent, of saline taste and alkaline reaction; soluble in 6 of water, in 1 1/2 of boiling water; insoluble in alcohol. Its solubility in water is much increased by the addition of citric acid. Dose, 20 grains to 2 drams. **Sodii Phosphas Exsiccatus** is the crystallized phosphate allowed to effloresce, and then gradually heated to 212° F. until the salt ceases to lose weight. Dose, 10 to 20 grains. **Sodii Phosphas Effervescens** has of the exsiccated salt 20, sodium bicarbonate 47 3/4, tartaric acid 25 1/4, citric acid 16 1/4. Dose, 1 to 3 drams. **Liquor Sodii Phosphatis Compositus** has of the phosphate 100, sodium nitrate 4, citric acid 13, water to 100. Dose, 1 to 3 drams. **Sodii Pyrophosphas,** colorless, monoclinic prisms, of saline taste and alkaline reaction; soluble in 12 of water, insoluble in alcohol. Dose, 10 to 45 grains. **Elixir Ferri, Quininæ et Strychninæ Phosphatum** has 1/64 grain of strychnin in each dose of 1 dram. Dose, 1/2 to 2 drams. **Glyceritum Ferri, Quininæ et Strychninæ Phosphatum** has in each dose of 15 minims 1/80 grain strychnin. Dose, 10 to 20 minims. **Syrupus Ferri, Quininæ et Strychninæ Phosphatum** has in each dose of 1 dram 1/80 grain strychnin, and is prepared by mixing the glycerite 25 with syrup to 100. Dose, 1/2 to 2 drams. **Ferri Phosphas Solubilis,** and **Ferri Pyrophosphas Solubilis** are described under Iron. For glycerophosphates, see Glycerophosphoric Acid.

PHOTOMICROGRAPHY.—A photograph of a small or microscopic object, usually made with the aid of a microscope, and of sufficient size for observation with the naked eye. A microphotograph is a microscopic (in size) photograph.

Apparatus.—Different varieties have been devised; possibly the simplest consists of a camera with extra long bellows length and stable base or support upon which the microscope can be clamped. Of the different varieties, the horizontal, the reversible, and the reversible in a vertical position have been described. While sunlight is preferred, light derived from a paraffin lamp, incandescent gas, magnesium oxyhydrogen, acetylene or electric light will do. An apparatus which may be used in either the vertical or horizontal position is offered by the leading microscope makers in America and abroad. A compound microscope with larger diameter body tube is preferable.

The camera is so made that bellows is adjustable at both ends along its supporting bed bar attached to the heavy base which supports also the microscope in relation to the bellows so that the sensitive plate may at all times be kept parallel to the specimens under the microscope whether bellows stands vertically, inclined or in a horizontal position. The double plate carrier is the usual 4 by 5 inches size with kits for 3 1/4 by 4 1/4 plates. Any of the hand camera shutters may be used on the front board; a light-tight connection is provided between shutter and microscope tube. Where artificial light is used simply the lamp with bull's-eye lens separately or in combination will do. A more elaborate illuminating system of lamp and condensers as supplied on projection lanterns is used quite often. A dark room is necessary only for loading plate holders and developing plates after exposure. Depending upon the size of the objective and character of specimen, also light intensity, exposures from 1/25 second to 10 minutes are made.

Practical Manipulation (Crookshank).—For working with the paraffin lamp, the mode of procedure is, as regards the illumination, briefly as follows: The substage condenser, as well as the mirror, is dispensed with when a low power is employed, and the lamp is so placed that the image of the flat of the flame appears accurately in the center of the field of the microscope. A bull's-eye condenser is then interposed, so that the image of the flame disappears and the whole field is equally illuminated. With high powers the substage achromatic condenser is necessary, and a more intense illumination is obtained by using the flame edgewise. In using a low power with the oxyhydrogen light, the lantern is withdrawn some little distance from the microscope. By opening and closing the shutter of the camera, the plate is exposed usually about 3 seconds.

Determination of amplification varies with the object employed, and also with the distance of the focusing screen from the object. To determine the amplification afforded by a certain objective at a certain distance, a photograph should be taken, under the same conditions, of the lines of the micrometer slide. From this calculate the amplification obtained by the photomicrograph.

PHOTOPHOBIA.—A dread or intolerance of light, usually due to some inflammation of the eye. It is particularly common in strumous children with phlyctenular disease of the cornea. It may be present in any inflammatory condition of the eye, whether of the conjunctiva, cornea, iris, ciliary body, choroid, or retina. In many cases it is directly due to uncorrected ametropia. In such instances the constant use of tinted glasses is most pernicious. Photophobia is often associated with diseases of the nervous system, cerebral irritation, meningitis, etc. It is also seen in many pyrexial conditions. See Eye.

PHOTOTHERAPY (Light Therapy).—The treatment of disease by light rays. The beneficent effects of light upon the debilitated body have long been recognized. Besides the ordinary **sun-bath,** various means of using artificial light have been proposed. To the chemic properties of the ultraviolet rays are attributed the good effects of the **electric-light bath.** The functions of the organism are stimulated without elevation of temperature and consequent disturbance of circulation.

At the present time, the term phototherapy is more strictly used to designate the treatment of skin-diseases and other affections in the manner devised by Finsen, of Copenhagen. This investigator treated the exanthems of small-pox and other

eruptive diseases by means of red light. As the "chemic" (blue, violet, and ultraviolet) rays of light are capable of causing an inflammation (erythema solare) of the healthy skin, it may be assumed that they are equally capable of aggravating preexisting inflammations. In other words, if the diseased skin was protected against the injurious action of the chemic rays of light, it would be possible to diminish the intensity of the inflammation, and thus prevent suppuration. The object was therefore to exclude the chemic rays of light which are injurious to the skin. In a new treatment of lupus and other bacterial skin-diseases devised by Finsen, these rays are now used as curative agents. The method consists in treating local superficial bacterial skin-diseases by the concentrated chemic rays of light. Bie, an assistant of Finsen, published a description of the method and technic, and it is from his paper that the material for the present article has been obtained.

The experimentally proved data on which the method is founded are the following.

1. The bactericidal property of the chemic rays of light.
2. The power of the chemic rays of light to produce an inflammation of the skin (erythema solare).
3. The power of the chemic rays of light to penetrate the skin.

The Bactericidal Property of the Chemic Rays of Light

The bactericidal property of light, originally demonstrated by Downes and Blunt, has more recently been studied in detail by a great many investigators. The particular question which is of the greatest interest in this connection is the following: Whether the bactericidal property is essentially attached to a single part of the spectrum, or whether it resides only in the whole uncolored light. The most trustworthy examinations have given the result that it is especially due to the blue and violet rays. If it is desired to employ the bactericidal property of the light therapeutically, the greatest possible number of violet and ultraviolet rays must be procured. On the other hand, the red, yellow, and green are useless.

Another condition for the advantageous use of the bactericidal property of the light therapeutically is that the bacteria are quickly killed. Finsen has found that on days of bright sunshine at noon in July and August in Copenhagen, the sunlight killed the bacillus prodigiosus in plate-cultures within 1 1/2 hours of insolation. An electric arc-lamp of 25 amperes killed a plate-culture of the bacillus prodigiosus at a distance of 75 cm. from the carbon points after 8 or 9 hours' exposure.

Even the strongest sunlight in summer—which takes more than 1 hour to kill the bacteria in plate-cultures, and probably still longer when they are growing in the skin—has then too slight a bactericidial property ever to be of any use for therapeutic purposes, otherwise all bacterial skin-diseases would be cured spontaneously in the summer. In order to obtain a more energetic effect, Finsen concentrates the light by means of apparatus, which is described later. It is only when the light is concentrated in such a way that it contains as many blue, violet, and ultraviolet rays as possible that its bactericidal property becomes so powerful that it can be used therapeutically with advantage. Concentrated electric light, which Finsen now uses for the treatment of patients, kills the bacteria until now examined in a few seconds when they are spread in a stratum of agar about 1/5 mm. thick.

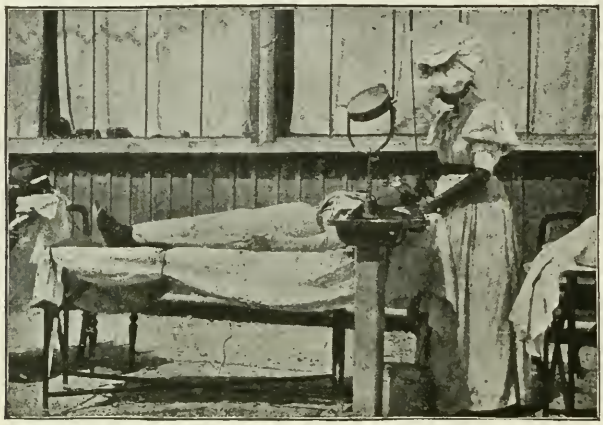
The Power of the Chemic Rays of Light to Produce an Inflammation of the Skin

The old name of erythema solare (erythema calorícum) proves that this disease was supposed to be due to a too intense heating of the skin consequent on the heat that always is inseparable from the light. Widmark (Stockholm) first experimentally showed the error of this view. He concentrated the electric light into parallel rays by means of a lens of quartz, and applied them to the skin, after they had passed either through a layer of distilled water, which absorbs the ultrared rays (dark rays of heat) or through a glass plate, which absorbs a large part of the ultraviolet rays. It turned out to be immaterial whether the light contained the ultrared rays or not; on the other hand, the absorption of the ultraviolet rays by the glass plate prevented completely the appearance of the inflammation. The experiments of Widmark prove, then, that the ultraviolet rays are of predominant importance in regard to producing light erythema. Later researches made by Finsen have confirmed this, and further he has proved that the blue and violet rays have also the power to produce the specific photochemic inflammation, but in a slighter degree than the ultraviolet rays. It is still impossible to decide finally of what importance this photochemic erythema is in regard to treating bacterial skin-diseases with concentrated chemic rays of light; but that, at any rate, it is not quite insignificant for the treatment of lupus vulgaris may well be considered probable, in view of the trials made of other methods of treatment which tend to cause an inflammation of the skin.

The Power of the Chemic Rays of Light to Penetrate the Skin

This point has been investigated by Godneff and Finsen. With a trocar Godneff placed small sealed glass tubes with silver chlorid under the skin of dogs and cats. Then he allowed some of these animals to remain in the dark, while he exposed the rest of them to the direct sunlight. After an hour he took out the tubes; and it was invariably found that the silver chlorid was blackened in those animals exposed to the sun, but not in those kept in the dark. The chemic rays of light can then penetrate the skin. Finsen thus proved that they penetrate far more easily in bloodless tissues than those filled with blood. He placed a piece of sensitized paper on one side of a man's ear, letting

the blue and violet rays of one of his apparatus for concentration of sunlight fall on the other side of the ear. After 5 minutes this paper was not affected; on the other hand, the paper was distinctly blackened in 20 seconds, if all the blood was pressed out of the ear between 2 glass plates. In agreement with this is the fact that by looking into a spectroscope through an ear filled with blood the observer will only discover a red stripe; if the ear is made anemic, the spectrum will consist of all the colors. Accordingly, the area of the skin that is going to be treated is made as anemic as possible.



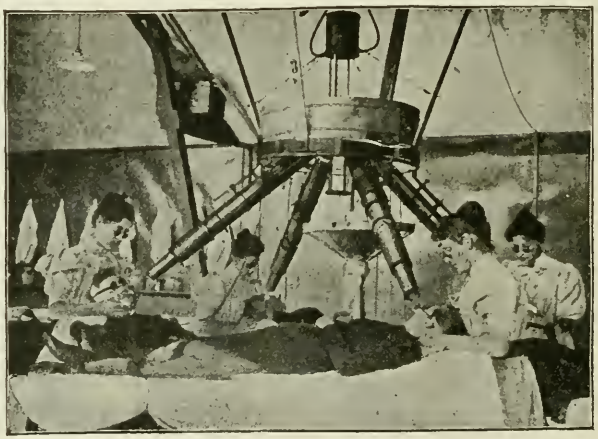
Treatment by Sunlight.

Description of the Apparatus

Based as it is on these three experimentally proved facts, this method of treatment is so rational that objections can scarcely be raised against it from a theoretic point of view. In the treatment of patients sunlight is used in the summer, when the sky is bright, otherwise the light of electric arc-lamps of 50 to 80 amperes. As already explained, it is only by concentration that the light becomes so powerful that its bactericidal property can be used in treatment. In order to avoid burning the skin it is also necessary to cool the light. This double object—to make the light stronger and cooler—is attained, in regard to the sunlight, by an apparatus consisting of a lens of about 20 to 40 cm. in diameter. The lens is composed of a plane glass and a curved one, which are framed in a brass ring, and between them there is a bright blue, weak, ammoniacal solution of copper sulphate. As one surface of the liquid is a plane, the other one being curved, its optic function is that of an ordinary planoconvex glass lens. By making the lens of a blue liquid instead of solid glass, a considerable cooling of the light will be obtained, because water absorbs the ultrared rays, and because the blue color excludes a considerable amount of the red and yellow rays. These three kinds of rays have particularly strong heating effect, while their bactericidal power is insignificant. On the other hand, the blue, violet, and ultraviolet rays, which it is important to procure in as great a number as possible, are but very slightly impaired by passing through the blue liquid. The lens hangs on a foot, made in such a way that the lens can be raised and lowered as well as turned on a vertical and horizontal axis; therefore it is easy to place the lens perpendicularly on the sun-rays, and at such a distance as to make the light strike the area of skin which it is intended to treat.

The apparatus for concentrating the electric arc-light consists of lenses of quartz framed in two brass tubes, which can be moved, the one into the other, like the two pieces of a telescope. Lenses of quartz are used because this material, in a far higher degree than glass, allows the ultraviolet rays to pass through. The apparatus for concentrating the sunlight may, on the other hand, be made of glass, because all the ultraviolet rays of the sunlight have so long a wave-length that they can pass through glass; those of a shorter wave-length are already absorbed by the atmosphere.

In the part of the apparatus which faces the lamp, two lenses are placed that have together a focal distance of 12 cm.; when the apparatus is placed in such a way that the first lens is exactly at this distance from the points of the carbons of the lamp, they consequently will concentrate the divergent rays coming from the lamp and make them parallel; these rays pass through the brass tubes, at the distal end of which they meet again with two lenses of quartz, which concentrate the



Treatment by Electric Light.

parallel rays, making them convergent. Between these two quartz lenses there is distilled water, which cools the light by absorbing the intensely heating ultrared rays, but does not impair the blue, violet, and ultraviolet ones. It is not possible, as in the apparatus for the sun, to make the water blue in order to cool the light further, because the extreme ultraviolet rays, which abound in the electric light, may well pass the quartz, but get absorbed by the blue coloring matters; the advantages of using the lenses of quartz would consequently be lost if the light got cold through a blue solution. Of course, the distilled water between the quartz lenses is heated by the absorption of the ultra-red rays. In order to avoid too much heating (boiling), cold ordinary water may be run through the mantle surrounding this end of the apparatus.

Four such apparatus for concentrating are fixed to an iron ring around each lamp, this ring again being fixed to the ceiling by 4 iron supporters. The lamp is movable up and down by the mechanism, and can be put exactly into the center of the ring by the aid of four strings, which are connected with screws in the iron support. The apparatus for concentrating hangs on iron arms, fastened to the ring, and depends from this at an angle of about 45 degrees, because the lamp sends out the strongest light in this direction; the apparatus for concentrating can be put nearer to or further from the lamp by sliding on the iron arm. By this disposition the lamp and the apparatus for concentrating can be fixed so that the points of the carbons are exactly in the focus of the front lenses of all the four apparatus. The apparatus for concentrating can be revolved on a perpendicular axis and a horizontal one by 3 screws; by this they can be so placed that the axis of the apparatus gets fused with the axis of the parallel rays, so that no light is striking the brass cylinders. The distant focus can be placed at the height which suits the patient by pushing the lowest cylinder into the uppermost one of the concentration apparatus.

Through the two forms of apparatus for concentrating described, the concentrating and cooling of the light are thus affected. But the light is still too warm to be applied to the skin without hurting it; the skin must therefore be cooled in order to avoid burning. This is effected by a little apparatus consisting of a plate of quartz and a plain convex lens of quartz, both framed in a conic brass ring which carries 2 small tubes and 4 arms; to each arm is fastened an elastic band, by means of which the apparatus is pressed against the skin. By making cold water run into one of the tubes and out of the other one, the skin would be cooled to such a degree that it can stand even the strongest light. By the pressure which the planoconvex quartz lens excites on the skin this is made anemic, so that the chemic rays penetrate it much better. In this manner an area of skin 1 1/2 cm. in diameter is treated for 1 hour each day. The treated skin reddens and swells, a bulla may appear, but necrosis has never been observed. The illustrations on the previous page show the arrangement of the apparatus for treatment.

Results of Treatment

Finsen has tried to treat different skin-diseases, known or supposed to be of microbic origin, but it is only of lupus vulgaris, lupus erythematosus, and alopecia areata that he has treated a number of cases sufficiently great to estimate the value of the method

Lupus Vulgaris.—Up to the time of publication of the first edition of this work about 350 cases of this disease altogether had been treated. The first patients were treated entirely by light; the same thing is done with all the slighter cases; on the other hand, in the more serious cases the treatment by light is assisted by treatment with pyrogallic acid ointment in order to make the skin smooth and as easily penetrable by the light as possible. While one part is being treated by light, the pyrogallic acid ointment is put on another part; when the cauterization is healed by a zinc ointment, this area of skin is treated by light; this treatment with ointment is not necessary for obtaining a good result, but it saves much time for the patient. All ulcerations are kept free from crusts by a cataplasm of a boric acid solution. The mucous membranes are touched with a solution of iodin and potassium iodid (1 : 2 : 2), or are treated with the galvanocautery. Only the skin, the hard palate, the front part of the septum nasi, tongue, and the mucous membrane of the cheek have been healed by this method.

In none of the cases was the treatment without effect, but in about 5 cases the improvement was very slow, either because the disease was progressing so rapidly that it was extending in one place while the treatment went on in another, or because the lupus was so deep that the light could only with difficulty penetrate to it. In all the 350 other cases the result of the treatment has been satisfactory. Of course, it takes some time—until all the diseased tissue is thoroughly treated and the formation of scar tissue has begun—before any improvement is visible; but from the moment it begins it is continued without interruption until the last nodule of the lupus patch has disappeared. In all these 350 cases this result was so certain and so constant that there is even reason to doubt the accuracy of the diagnosis of lupus vulgaris when this method of treatment appears to be ineffective.

The principal advantages of the method are, besides its reliability, its excellent cosmetic results, the infrequency of relapses and their slight extent, and that the treatment is painless. The good cosmetic result is due to the fact that there is no destruction of tissue, healthy or diseased. It is for the same reason that the results in respect to relapse are so favorable. One may, without harm, treat both the diseased tissue and the apparently healthy surrounding skin until one is fairly sure of having destroyed all the disease-germs. When the patient has been treated until there are no distinct nodules of lupus to be seen at the moment, the treatment is discontinued until the swelling and

redness of the skin have disappeared, so that it is easier to determine whether anything is left of the disease or not. If there is nothing visible, the patient is still kept under observation. Many must, however, be submitted to a second course of treatment. Whether the nodules which develop are the result of recurrence, or whether they could not earlier be recognized as lupus nodules, is a matter of little consequence in itself. The principal thing is that there have always until now been a few scattered nodules, which disappear after a short further course of treatment. If the treatment is carried on for some time after the last nodule of lupus seems to have disappeared, recurrence would be more surely guarded against. The fact that the treatment is discontinued as soon as it is thought justifiable to do so, is due solely to the wish to save the time and the money of the patients as far as possible. Inasmuch as the efficacy of the treatment is absolutely certain, and the patients, on account of its painlessness, are very willing to submit themselves to a second course, a recurrence is not nearly so serious a matter as it is after the older methods of treatment.

Lupus Erythematosus.—The treatment of this disease has in many cases given excellent results—permanent recovery and firm scars. Nevertheless, the effect of the treatment is not nearly so sure as it is in the case of lupus vulgaris. A few cases have improved very slowly and with a constant tendency to recurrence. What the cause of this great individual difference may be it is still impossible to determine, if for no other reason, because we have not a sufficiently great material (altogether only 28 patients).

Alopecia Areata.—As the indication for the treatment by concentrated chemic rays of light is that the disease must be superficial, local, and bacterial, and as it is at least possible that alopecia areata is due to an infection, Finsen has tried to treat this disease. In January, 1899, when the first experiments were published in Danish, 7 cases in all had been cured.

On the whole, the trials made until now look promising. Whether all the fresh cases will give results as satisfactory as in those described can be solved only by further experiments. To judge from the later experiments, even the old decalvans form seems to be curable, though only after a long treatment (Bie).

Roentgen rays have been used in same manner and for conditions similar to those treated by Finsen, as well as for epithelioma.

Light Cabinets

These are closed wooden compartments, in which the patient sits or stands, allowing only the head to protrude. Upon the inside of this cabinet is distributed a number of incandescent lamps (25 to 100).

All observers probably agree that the light cabinet is one of the best forms of sweat-bath, in that the perspiration breaks out more quickly and at a lower temperature than in other baths. Following the artificial sweating process there is a reduction in blood-pressure. The indication for treatment may be judged by these two physiological processes.

High power incandescent lamps consist of incandescent lamps of 300 to 600 candle power surrounded by reflectors which cause the rays to cross at certain points, or areas of intensification. They are used with a fair degree of success in the treatment of eczema, pruritis, impetigo, nevus, ichthyosis, herpes simplex, herpes zoster, tinea, psoriasis, carbuncle, acne, furunculosis, etc.

For the treatment of the above conditions the light from these lamps is brought close enough to produce a destructive effect, or far enough away to obtain only a stimulant effect. In the former, the surrounding tissues are protected by asbestos. The applications vary from a few seconds to 15 or 20 minutes.

These lamps are also used for the relief of painful conditions about the joints and muscles. The effect is due chiefly to the heat.

Conclusions

A more recent critical review by Bie leads him to the following conclusions:

Biologic Effects.—(1) The chemic rays, except the red, yellow and green can cause a burn of the skin (Bouchard, Widmark and Finsen). (2) The ultraviolet rays cause an enlargement of the cutaneous vessels which may last at least five or six months. (3) There is nothing to show that light has any influence upon the quantity of hemoglobin in the blood. (4) The assertion of Moleschott and of others that light increases the excretion of carbon dioxid cannot be counted as proved. (5) Chemic rays of light have an exciting influence on lower animals, light has probably a similar exciting influence on men; according to some investigators red light has an exciting effect and the violet rays have a quieting influence on psychic processes, a property which has been made use of with success for quieting maniacal patients. (6) The red light-rays can penetrate the organism deeply; the blue and violet rays can only penetrate the tissues when they are bloodless; the ultraviolet rays cannot penetrate farther than the superficial layers of the skin. (7) The same is true of the power of light to kill bacteria in the organism, a power which pertains almost exclusively to the chemical rays, having, therefore, curative effect only on superficial affections; there can therefore be no use trying to kill tubercle bacilli in the larynx or in the lungs by transmitted light, as some American physicians have proposed doing.

Therapeutic Effects.—(1) Finsen's treatment of small-pox with red light is based on this, that by the exclusion of the inflammatory influence of the chemic rays on the skin the formation of pus in the vesicles and also secondary fever and pocks are prevented. (2) The treatment of other exanthematous diseases by red light has not yet been thoroughly investigated. Bachmann and Chatiriere have obtained favorable results in the treatment of measles, and Krukenberg in the treatment of erysipelas. (3) The incandescent sweat-baths constructed by Kellogg must be considered as nothing more than sweat-baths which have no

specific effects. In this connection, however, there seems to be unity of opinion that they are the most complete of all sweat-baths. (4) The local illumination by incandescent or arc-lamps, made by various Russian physicians, especially Minin, have no claim on our attention. (5) The general light therapy of the future will undoubtedly be sun-baths without subsequent packing, or electric arc light-baths 150 to 200 amperes with sweating. We know at present too little of the general effect of light for us to be able to fix definite indications. (6) The only local application whose efficiency has been proved is Finsen's treatment of skin-disease with concentrated chemic light-rays. The excellent cosmetic results obtained are to be ascribed to the fact that the method is the most complete imaginable; nothing is destroyed; there is no shrinking; the scars are white and smooth; also, as the result of this treatment, not only can the diseased tissues be treated, but the contiguous sound tissues as well; in this way danger of recurrence is lessened; the treatment is painless; the curative effect is remarkable. In 640 patients the treatment had to be stopped on account of bad results in only 1.7 percent while 85 percent show an absolutely favorable result. Only in the case of 15 percent was the improvement so slow that the result could be considered as less favorable. The recurrent conditions are favorable under the treatment. In lupus erythematous the results were somewhat uncertain. In alopecia areata, nævus vascularis, acne vulgaris, acne rosacea, and epithelioma cutaneum very favorable results were obtained, especially when it is considered that the cases were almost always severe, such as could be cured by no other treatment.

PHTHISIS.—See Tuberculosis.

PHYSOSTIGMA (Calabar Bean; Ordeal Nut).—The seed of *P. venenosum*, native of West Africa. The properties of the drug depend upon 2 alkaloids, **physostigmin** or **eserin**, $C_{15}H_{21}N_3O_2$, which paralyzes the motor functions of the spinal cord and stimulates muscle-fiber, and **calabarin**, which acts similarly to strychnin. Physostigma should contain not less than 0.15 percent of alkaloids soluble in ether. Dose, 1 to 3 grains. Applied locally to the eye, physostigmin causes contraction of the pupil and diminishes intraocular tension. On account of its action on muscles it causes increased peristaltic movements of the intestines. In toxic doses death is produced by failure of respiration.

Its therapeutic uses are: In diseases of the eye, as in glaucoma and in iritis, to contract the pupil, and, alternated with atropin, to break up adhesions after iritis; in convulsive diseases, as tetanus and strychnin poisoning; in constipation from atony of the intestines; in bronchitis and dyspnea, from weakness of the bronchial muscles. It is also used as an antidote to atropin and to strychnin.

For poisoning give an emetic and inject atropin. In tetanus:

℞. Extract of physostigma, gr. iij
Powdered ginger, gr. vj.
Make 6 pills. One pill every hour.

To procure sleep in delirium tremens:

℞. Tincture of physostigma, ♏ xx
Water, ʒ j.
To be taken at one dose.

Preparations.—**Extractum Physostigmatis**, an alcoholic extract, of which the usual dose is 1/16 to 1/4 grain, but 1 to 4 grains are used in tetanus. **Tinctura Physostigmatis**, 10 percent. Dose, 5 to 20 minims. **Physostigminæ Salicylas**, *eserine salicylate*, colorless, columnar crystals, of bitter taste and neutral reaction, soluble in 150 of water and in 12 of alcohol. Dose, 1/100 to 1/30 grain. **Physostigminæ Sulphas**, *eserine sulphate*, a white, microcrystalline powder, of bitter taste, very deliquescent in moist air, very soluble in water and in alcohol. Dose, 1/100 to 1/30 grain. See Eserin.

PHYTOLACCA.—The dried root of *P. decandra*. It contains a neutral principle, *phytolaccin*, and an acid, *phytolaccic acid*, also tannin, starch, fixed oil, etc. Dose, as an alterative, 1 to 5 grains; as an emetic, 10 to 30 grains. It is an emetic, cathartic, and motor depressant. Toxic doses cause death by paralysis of the organs of respiration. Its action is antagonized by alcohol, opium, and digitalis. It is serviceable in chronic rheumatism, mastitis, tonsillitis, malignant tumors, eczema, and similar skin affections. It has also been used as a remedy for obesity. Fluidextract of Phytolacca. Dose, as an alterative, 1 to 4 minims; as an emetic, 10 to 30 minims.

PICA.—The craving for unnatural and strange articles of food; a symptom present in certain forms of insanity, in hysteria and chlorosis, and during pregnancy. Pica is especially urgent during the first 2 or 3 months of pregnancy. It is popularly known as "longings" or "pinings." In exceptional cases it may amount to insanity, and injurious substances—sometimes very disgusting ones—are eagerly partaken of. Regulation of the digestive tract, combined with moral suasion and some mental diversion, are about all that can be tried in the way of treatment. With the end of pregnancy the condition ceases.

PICRIC ACID, *carbozotic acid*, *trinitro-phenol*, $C_6H_2OH(NO_2)_3$, occurs in yellow scales which are soluble in 75 of water. Externally it is antiseptic, analgesic, coagulant, and in solution is nonirritant to the tissues, but is too corrosive for internal use. A saturated aqueous solution is highly recommended as a local application in erysipelas and burns, and is an efficient test for albumin in the urine. *Ammonium picrate* has been credited with antiperiodic and anthelmintic powers, and is highly praised in pertussis and in exophthalmic goiter, in doses of 1/8 to 1/2 grain thrice daily.

PILES.—See Hemorrhoids.

PILLS (Pilulæ).—Spherical masses composed of medicinal agents and intended to be swallowed whole. The *mass* consists of the active ingredients and the *excipient*, the latter being the substance which gives the mass its adhesive and plastic qualities.

There are 14 official pills:

Title:	Constituents.	Dose.
Pilulæ		
Aloes.....	Purified aloes and soap, each 13 gm., in 100 pills.	As a laxative, 1, 2, or 3 pills at bedtime; as a purge, 5 pills.
Aloes et Ferri.....	Purified aloes, iron sulphate and aromatic powder, each 7 gm.; confect. rose, q. s., in 100 pills.	2 pills.
Aloes et mastiches (Lady Webster dinner pills).	Purified aloes, 13 gm.; mastic, 4 gm.; red rose, 3 gm.; in 100 pills.	2 pills.
Aloes et myrrhæ..	Purified aloes, 13 gm.; myrrh, 6 gm. aromatic powder, 4 gm.; syrup, q. s. 100 pills.	From 3 to 6 pills.
Asafœtidæ.....	Asafetida 20 gm.; soap, 6 gm.; 100 pills.	3 pills.
Catharticæ compositæ.	Compound extract of colocynth, 80 gm.; calomel, 60 gm.; jalap (resin), 20 gm.; gamboge, 15 gm.; 1000 pills.	2 pills.
Catharticæ vegetabiles.	Compound extract of colocynth, 60 gm.; extract hyoscyam., 30 gm.; resin of jalap, 20 gm.; extract leptandra, 15 gm.; resin podophyllum, 15 gm.; oil of peppermint, 8 c.c. in 1000 pills.	2 pills.
Ferri carbonatis (Ferruginous pills, chalybeate pills. Blaud's pills.)	Ferrous sulphate, 16 gm. potassium carbonate, 8 gm.; sugar, 4 gm.; tragacanth, 1 gm.; althæa, 1 gm.; glycerin and water, q. s. in 100 pills.	2 pills.
Ferri iodidi.....	Reduced iron, 4 gm.; iodin, 5 gm.; powdered glycyrrhiza, 4 gm.; sugar, 4 gm.; ext. glycyrrhiza, 1 gm.; acacia, 1 gm.; q. s. each water, balsam tolu, and ether. (See U. S. P.)	2 pills.
Laxativæ compositæ.	Aloin, 1.39 gm.; strychnin, 0.05 gm.; extract belladonna leaves, 0.80 gm.; ipecac, 0.40 gm.; glycyrrhiza, 4.60 gm.; syr., 100 pills.	2 pills.
Opii.....	Powdered opium, 6.5 gm.; soap, 2.0 gm.; 100 pills.	1 pill.
Phosphori.....	Phos., 0.06 gm.; althæa, 6.00 gm.; acaciæ, 3.00 gm.; phosphorus dissolved in chloroform, and made into a pill with about 4 c.c. of a mixture of 2 vol. glycerin, 1 vol. water. Coated with 10 gm. balsam of tolu dissolved in 15 c.c. ether.	1 pill.
Podophylli, belladonnæ et capsici.	Resin podophyllum, 1.6 gm.; extract of belladonna leaves, 0.8 gm.; capsicum, 3.2 gm.; sugar of milk, 6.5 gm.; acacia, 1.6 gm.; glycyrrhiza syr. q. s. 100 pills.	1 pill.
Rhei compositæ....	Rhubarb, 13 gm.; aloes, 10 gm.; myrrh, 6 gm.; oil of peppermint, 0.5 gm., in 100 pills.	2 pills.

PILOCARPUS (Jaborandi).--The leaflets of *Pilocarpus jaborandi* or of *P. microphyllus*, yielding not less than 1/2 percent of alkaloids. They contain the alkaloids *pilocarpin*, a syrupy fluid, slightly soluble in water, and forming salts; *jaborin*, isomeric with pilocarpin, but antagonistic thereto in action, and does not form crystallizable salts; *pilocarpidin*, which acts like pilocarpin; also a volatile oil, which consists chiefly of *pilocarpene* and a peculiar acid. Dose, 10 to 45 grains.

Therapeutics.—Pilocarpin stimulates the peripheral ends of the secreting nerves going to glands, perhaps also the centers. It thus causes an increased flow of the saliva, marked sweating, secretion of tears, of mucus from the nose and the bronchi; of the gastric and intestinal juices. It also stimulates involuntary muscle. On the vagus it acts as a stimulant, causing slowing of the pulse; in large doses it paralyzes the vagus. Vomiting is produced by jaborandi and sometimes by pilocarpin alone. Pilocarpin causes contraction of the pupil. Its action is antagonized very completely by atropin. Therapeutically, pilocarpin is used chiefly in renal dropsy to produce sweating; also in uremia, for the same purpose. It probably causes an elimination of urea and other waste products, both in the sweat and in the saliva. As a diaphoretic it is also employed in coryza and bronchitis. It has been used most successfully in erysipelas. It may abort the paroxysms of malarial fever, but it is not to be employed in asthenic fevers, as typhoid. In pleurisy with effusion, in catarrhal jaundice of persistent type, in some forms of profuse sweating, and in stimulating hair lotions, it is serviceable. In small doses pilocarpin has been used in tobacco and alcoholic amblyopia. Early in erysipelatous inflammation it may be injected around the border-line of the area of inflammation.

For baldness:

℞. Fluidextract of pilocarpin, ℥ j
Tincture of cantharides, ℥ ss
Soap liniment, ℥ jss.

Apply locally once daily.

Preparations.—**Fluidextractum Pilocarpi,** Dose, 10 to 45 minims. **Pilocarpinæ Hydrochloridum,** white, transparent crystals, deliquescent in the air, very soluble in water or alcohol. Dose, 1/8 to 1/2 grain. **Pilocarpinæ Nitras,** white, shining crystals, permanent in the air; soluble in 4 of water and in 60 of alcohol. Dose, 1/8 to 1/2 grain.

PIMENTA (Allspice).—The immature fruit of *P. officinalis*. It contains an aromatic, pungent, volatile oil that is much used as a flavor and condiment. It is useful in flatulence and to prevent the griping of purgatives. Dose, 10 to 40 grains. **P., Oleum.** Dose, 2 to 5 minims.

PIMPLES.—See Acne.

PINEAL EXTRACT.—The pineal gland is present during the entire life of the individual, and its removal in animals has been followed by structural changes in the central nervous system. It is thought that the substance of this gland may act remedially in organic and functional affections of

the brain attended with failure of cerebral nutrition, as chronic softening, chronic mania, and dementia. See Organotherapy.

PINEAL GLAND.—See Pineal Extract.

PINGUECULA.—A small yellowish growth on the bulbar conjunctiva, close to the cornea, and usually to the inner side. It has no vascular supply, and is pale when the rest of the conjunctiva is congested. Mechanical irritation is the probable cause. There is little discomfort; although it may lead to pterygium no interference is necessary.

PINK EYE.—See Conjunctivitis (Acute contagious).

PINKROOT.—See Spigelia.

PIPER (Pepper).—The dried, unripe fruit of *P. nigrum*. It contains a base, *piperin*, which is official, also a green, acrid, concrete oil, abalsamic, volatile oil, starch, lignin, gum, extractive, etc. Dose, 5 to 20 grains.

Oleoresina Piperis, *oleoresin of pepper*, contains almost all the volatile oil and acrid resin extracted by acetone, with but little of the piperin. Dose, 1/4 to 1 grain.

Piperina, *piperin*, a feeble base obtained from pepper, and other plants of the piperaceæ. Occurs in colorless or pale-yellowish prisms, of neutral reaction, almost insoluble in water, slightly so in ether, but soluble in 30 of alcohol. Dose, 1 to 10 grains.

Pepper when applied to the skin acts as an irritant, internally its effects are similar to those of other aromatics, being a warm carminative and stimulant, increasing slightly the action of the heart, stimulating the kidneys somewhat, and toning up the mucous membrane of the urinary and intestinal passages, by which channels it is eliminated. It has been thought to possess antiperiodic power, and was formerly much employed in intermittents. Its chief medicinal use is to correct flatulence, and to excite action of the stomach, being very commonly taken as a condiment with food. It is occasionally employed in gleet, but more extensively in hemorrhoids and other diseases of the rectum. Its active constituents are the concrete oil or resin and the volatile oil, piperin having very slight action on the system except as an antiperiodic and antipyretic, qualities which it certainly possesses.

PIPERAZIN.—A synthetical basic compound formed by the action of ammonia upon ethylene bromid or chlorid; it occurs as a white, crystalline powder, soluble in water and liquefying when exposed to the air, from which it absorbs water and carbon dioxid. Dose of the base or its hydrochlorid, 5 to 15 grains. It may be injected hypodermically in 3 to 5 percent solution.

Incompatibles are: acetanilid, acetphenetidin (phenacetin), alkaloidal salts, alum, butyl-chloral hydrate, chloral hydrate, copper sulphate, ferric chlorid, ferrous sulphate, mercuric chlorid, phenol, phenocoll, picric acid, potassium permanganate, quinin, silver nitrate, solution of arsenic and mercury iodid, sodium salicylate, spirit of nitrous ether, tannic acid.

It forms with uric acid a soluble compound, is nontoxic, devoid of physiologic effects, and well borne for prolonged periods. It is used in gout, for the prevention of renal and vesical calculi in the uric acid diathesis, to allay the pruritus from uric acid diathesis, and the irritation of the bladder from an excess of uric acid. The usual dose of 15 grains is best given by dissolving this quantity in 1 pint of water, and having the patient drink a wineglassful of this solution frequently through the day. It should not be given in pill nor in powder form. It is patented, and sold at a high price.

PIPERIN.—See Piper.

PIPSISSEWA.—See Chimaphila.

PIRQUET'S (von) TEST.—See Tuberculosis.

PITCH (Pix).—A resinous exudation from the stems of certain trees of the genera *Pinus* (pines) and *Abies* (firs and spruces), and may also be obtained as a residue of the distillation of tar. Its chief constituents are resin and a volatile oil which is a mixture of several isomeric terpenes in varying proportions. The only official form is **Pix Liquida,** *tar*, a product obtained by the destructive distillation of the wood of *Pinus palustris* and other species of Pinus. It is thick, viscid, semi-fluid, blackish-brown, of acid reaction, terebinthinate odor, and sharp, empyreumatic taste; slightly soluble in water, soluble in alcohol, in oils and in a solution of potassa or of soda. Its principal constituents are oil of turpentine, creosote, phenols, pyrocatechin, acetic acid, acetone, xylol, toluol, methylic alcohol, and resins. By distillation it yields an acid liquor, *pyroligneous acid*, and an empyreumatic oil, the residue being pitch. Dose, 5 to 20 grains, in pill, up to 2 drams daily. It is a stimulant to the skin, and is chiefly used locally in skin-diseases, especially those of a scaly nature, such as psoriasis; internally it is of service in chronic bronchitis.

Pix Burgundica, *Burgundy pitch*, the prepared resinous exudation of *Abies excelsa*, the Norway spruce, a native of Europe and Northern Asia. It occurs in hard, brittle, opaque or translucent masses, with a shining, conchoidal fracture, almost entirely soluble in glacial acetic acid; is very fusible, and at the body-heat it softens and becomes adhesive. It is mildly stimulant to the skin, and is used as a basis for plasters. **Oleum Picis Liquidæ,** *oil of tar*, a volatile oil distilled from tar. Dark, reddish-brown (almost colorless when fresh), of tarry odor and taste and acid reaction, readily soluble in alcohol. Contains a great variety of compounds, including cresols, guaiacol, phenol, xylol, toluol, pyrocatechin, methylic alcohol, and acetone. Dose, 1 to 5 minims. **Syrupus Picis Liquidæ,** *syrup of tar*, has of tar 1/2 percent; and is a sweetened tar-water. Dose, 1/2 to 2 drams. **Unguentum Picis Liquidæ,** *tar ointment*, contains of tar 50 parts, yellow wax 15, lard 35. Is irritating unless mixed with finely levigated chalk.

In eczema (dry, scaly):

℞. Solution of coal-tar, } each, ℥ j
Solution of lead subacetate, }
Water, enough to make ℥ vj.

Use as a lotion.

Or the following, in hemorrhoids:

℞. Pitch, ʒ j
Powdered acacia, ʒ ss.

Make into 20 pills. Give 2 pills every night.

PITUITARY EXTRACT.—The complete removal of the pituitary body (or gland) gives rise to symptoms which occur in a definite order, beginning with lowered temperature and loss of appetite, then twitchings, tremors and nervous phenomena, and finally dyspnea and death. Many of these symptoms have abated considerably after the administration of pituitary gland substance or an extract thereof. This organ has been found enlarged in cases of myxedema in which the thyroid was functionally absent, and other observations point to some connection between it and the disease known as acromegaly. Internally administered it causes increase of the cardiac force, and a rapid rise of blood-pressure due to direct contraction of the vessels and slowing of the pulse; also increased elimination of phosphates without corresponding increase of the nitrogenous elements. It has been administered with the view of reestablishing perverted brain nutrition and function, also with the object of supplying tone and structural growth to the entire nervous and muscular systems, on which its secretion seems to act as an alterative. Of 13 cases of acromegaly treated with pituitary preparations 7 showed varying degrees of improvement, 5 none, and 1 became worse. In 2 cases the violent headache and neuralgic pains in the limbs were diminished, and in one case decrease of the affected extremities occurred (Kinnicut). It has been tried in epilepsy, but with no benefit, and there is no condition known in which it is of therapeutic use (Wood).

PITUITARY GLAND.—See Pituitary Extract.

PITYRIASIS.—A term formerly applied to various pathologically dissociated skin affections, the most striking clinical feature of which is the presence of fine, branny desquamation. Also a synonym of Seborrhea (*q. v.*). See Dermatitis, Lichen Ruber, etc.

PITYRIASIS CAPITIS.—See Eczema Seborrhoicum.

PITYRIASIS RUBRA PILARIS.—A rare skin disease, a hyperkeratosis, closely resembling Lichen Ruber (*q. v.*) but differing from that disease in the absence of systemic disturbance, in the paler color of the lesions, in the absence, practically, of itching and atrophic changes, and in the fact that it is not amenable to arsenical treatment.

PLACENTA PRÆVIA.—The attachment of the placenta to any part of the lower uterine segment. It occurs once in about 1500 cases.

Varieties.—Four varieties of placenta prævia are described, dependent upon its relation in situation to the internal os. These are named *central*, *partial*, *marginal*, and *lateral*.

Causes.—These are obscure, the most probable being that it is caused by a low insertion of the ovum, this being due to a preexisting endometritis. It is three times as frequent in multiparæ as in primiparæ.

Symptoms.—The one symptom of placenta prævia is hemorrhage. The time of its appearance, the amount, and the frequency are largely dependent on the variety. In the central variety the bleeding may occur as early as the third month, and may recur so frequently and profusely as to cause speedy death. In the lateral variety hemorrhage may not appear at all. Usually there will be a slight, painless hemorrhage during the latter half of pregnancy, which is followed, as the woman approaches term, by others which appear at decreasing intervals and in increasing amounts.

Physical Signs.—Before the os is dilated, the cervix is found particularly soft and large, and the presenting part is felt through the vaginal vault as though separated from the examining finger by a thick cushion or pad. After the os is dilated, the rough, maternal surface of the placenta is felt in striking contrast to the smooth, elastic membranes.

Prognosis.—This is grave for both mother and child. In general practice the maternal mortality is about 30 percent. Repeated loss of blood during pregnancy and at labor, lessened vitality, and low situation of the placental site, favoring sepsis, are all unfavorable factors. The infant mortality is about 60 percent. Asphyxia, hemorrhage, and accidents during delivery are accountable for this high death-rate.

Treatment.—The treatment of placenta prævia will depend upon the severity of the hemorrhages, and upon the time at which they make their appearance.

If the bleeding occurs early in pregnancy; if it is slight in quantity; and if it is not repeated too frequently, rest in bed and the administration of opium suppositories, 1 grain of the aqueous extract 3 times daily will be sufficient. Should the bleeding continue or increase in quantity, a firm tampon of iodoform gauze must be introduced into the vagina. This usually leads to abortion or miscarriage, and its subsequent treatment is the same as that described under Abortion (*q. v.*).

Should the patient pass successfully the seventh month of gestation, and should serious hemorrhage now occur, the induction of premature labor by rapid dilatation of the cervix and combined version are indicated. The patient is anesthetized, and the vulva and vagina are thoroughly cleansed. The operator introduces his right hand, made aseptic, into the vagina; the cervix is rapidly dilated until 2 or 3 fingers may be introduced into the uterus, when a foot is grasped and the child extracted to the knee. This allows the soft breech of the child to lodge in the lower uterine segment, where it exerts sufficient pressure upon the placenta to prevent free bleeding, and at the same time does not interfere materially with the exchange of blood between mother and child. Labor pains now appear, and the subsequent treatment is the same as in an ordinary breech presentation.

Should the operator feel incapable of performing version, or should the patient be seen in the midst of a most alarming hemorrhage, when further loss of blood might seriously endanger her life, the most effective treatment is a large antiseptic vaginal tampon. This usually excites labor pains,

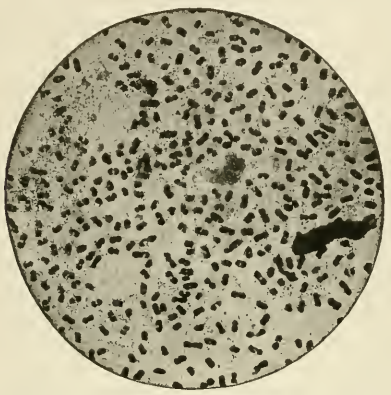
and the tampon is expelled before the advancing head. Should it fail to do this, the tampon will have to be renewed occasionally, until the os is dilated sufficiently to effect easy delivery.

The treatment at term is the same as that previously described—either combined version or a large vaginal tampon. The latter method usually sacrifices the life of the child.

PLAGUE. Synonym.—Pest. It is qualified as Oriental, Egyptian, Levantine, or Pâli plague. Mâhamâri (northwest India) is plague.

Definition.—An acute specific fever, common to man and some of the lower animals, usually attended with painful swelling of a group of superficial lymphatic ganglia, cardiac depression, hemorrhages, and a high mortality. In favorable cases it runs its course in 9 or 10 days and is followed by prolonged convalescence.

Cause.—Invasion and proliferation of *Bacillus pestis*. This bacillus belongs to that group which,



Bacillus of Bubonic Plague.—(*Yersin.*)

while causing several different diseases, is characterized by the production of *septicæmia hæmorrhagica* in all. It is pleomorphic; stains with all the simple dyes, but not by Gram's method; in smear-preparations some bacilli (only) show bi-polar staining. Direct inspection of smear-preparations is a valuable aid to diagnosis, but in doubt critical differentiation of the suspected microbe is essential, and can be made only by an experienced bacteriologist.

The germ gains entrance through the digestive and respiratory tracts, but especially through abrasions of the skin. Filth is a potent predisposing cause. The rat is a medium of transmission from house to house, while man in his travels is the agent of transmission through long distances. Flies, fleas, ants, and other insects may transmit the disease, while almost any of the lower animals are subject to it.

Clinical Varieties.—Three forms are distinguished by prominent clinical features: the *bubonic*, the *septicemic*, and the *pneumonic*. In milder bubonic cases the infection is confined to the lymphatic system; when fatal, however, this form always becomes septicemic, and the bacillus may be demonstrated in the blood-stream during the 24 hours preceding death. In the pneumonic form infection is, perhaps, by the lungs, to which the morbid process is usually limited. To these forms epithets have been applied. (a) "*Black*" has been used of those cases in which subcutaneous hemorrhages impart that coler to the general surface. (b) "*Fulminant*" (*pestis siderans*) denotes those in which death occurs in from 1 or 2 to 24 hours after manifestation of the first signs of illness. (c) "*Ambulant*" is applied when the symptoms, though well marked, are so moderate that the patient is able to attend more or less efficiently to his business, or spends but a single day in bed; this distinction has value only in relation to the widely held opinion that the infection is diffused mainly by human intercourse. (d) The term "*pestis minor*" has been applied to two forms of illness. One is abortive (or larval) plague, which stands on all-fours with abortive smallpox; a transient feverishness and headache are attended with prickling or actual pain in a superficial lymphatic gland, which sometimes becomes swollen, and may even suppurate; reference to presence of a declared epidemic at the same time and place is necessary to support the diagnosis. The other consists in very slight fever, and swelling of an inguinal gland which cannot be referred to any definite cause; it may be met with "before, during, after, or in the absence of, epidemic plague" (Cantlie). There is thus no evidence that it originates in plague-infection; and as it has been described chiefly within the tropics, it has come to be called "*climatic bubo.*"

Incubation.—There is no good evidence that the incubation period ever exceeds 5 days; it is very often limited to 3 days, or somewhat less.

Prodromes and Onset.—Prodromal symptoms are at most but rarely seen, and are but doubtfully distinguishable from the commencement of illness. In the great majority of cases the onset is sudden; often the patient can name to an hour the time at which he was attacked. Rarely it is gradual, and extends over 4 or 5 days of increasing illness, after which the patient suffers in one of the ways to be described below. Such symptoms cannot be described as prodromal; their lenity and gradual ingravescence are applicable by reference to the mode in which infection takes place.

Symptoms.—First, in every epidemic most cases are bubonic. Among colored races the proportion may be roughly estimated at 75 percent, the remainder being of the septicemic form, with a few only of the pneumonic; but among whites it is larger, cases of the septicemic form being fewer, and the pneumonic absent, or but 1 or 2 percent of the total. Second, the bubonic cases present every shade of severity, from the mildness of the ambulant variety upward. An average course is described:

1. The period of onset may be regarded as enduring about 12 hours; it resembles that of the acute infectious fevers in general. Feelings of chilliness or a rigor (in infants a convulsion), with frontal or vertical headache, are accompanied with nausea or vomiting, and sometimes by a slight diarrhea, and thirst. Discomfort or aching is felt in the limbs, and a severer pain in the loins or the lower abdo-

men. The face is flushed, the skin hot and dry; the temperature rises to 38.5° or 39° C. (101.3° to 102.5° F.); the pulse is full, of normal tension, and moderately quickened; respiration is quickened apart from lung-affections; the eyes are suffused; toward the end of the term there may be restlessness, and signs of mental confusion. Before, at, or shortly after an attack stiffness, pricking, or lancinating pain may be complained of in the groin, armpit, or neck; on palpation, tenderness is discovered; no tumefaction may be detected, or a single gland may be found very slightly enlarged, and in size from a pea to half a shelled almond.

2. A period of ingravescence ensues, during which the symptoms are developed in their totality; it may be regarded as lasting about 36 hours. The face is now pale; the expression apathetic, or dazed, or anxious, or terrified; hebetude is succeeded by restlessness, delirium with delusions, or mania; on being roused the patient collects himself with difficulty, and is sometimes angry at being disturbed; questions are intelligently though briefly and tardily answered; speech is frequently but not invariably blurred from incoordination of the muscles, and should the patient gain his legs, the latter is further manifested by staggering. There are sleeplessness, anorexia, and thirst; constipation is the rule; vomiting is continuous, the rejected matters being yellow, greenish, or bluish; except in the severest cases the urine is normal in amount, acid, sometimes offensive. The temperature rises to 41.5° or 42° C. (106.7° to 107.6° F.); the skin remains hot and dry; the pulse alters in character, and becomes rapid, small, easily compressible, and even in cases of moderate severity is often dicrotic. The tongue is swollen, moist, and characteristically furred; the dorsum carries a light creamy coating through which red papillæ show, while the tip and edges are clean and bright red; but during this stage it begins to become brown and dry. The gland which was first the seat of pain enlarges; other glands of the same group become slightly swollen; pain or tenderness becomes severer with the increasing tension, and the patient disposes his limbs so as to lessen pressure; swelling of other groups may begin, but is attended with much less pain.

3. From the third to the sixth or seventh day may be distinguished as the period of state. The temperature usually falls to from 38.5° to 39° C. (101.3° to 102.5° F.), and thereafter, although rising with the occurrence of suppuration in the bubo, never attains the height it had previously reached. The patient presents an aspect of extreme prostration; decubitus is dorsal; the face is pallid or shallow, and pinched, sometimes singularly expressionless from relaxation of the muscles; the eyes are closed, or half open; the conjunctiva injected, especially at the palpebral angles. The tongue is dry, brown, and retracted; sordes appear; constipation continues, but severe diarrhea with tympanites sometimes supervenes and is likely to be followed by death; the urine is not diminished in quantity, but in about 75 percent of cases contains albumin in small quantity, hyaline casts, and renal epithelial cells, and is often slightly tinged with blood. A peculiar odor exhales from the body. Delirium gives place to stupor or coma; but at beginning of this stage, or in milder cases, restlessness attended with desire for change of place continues; all patients require constant watching, and often mild restraint. Cardiac depression becomes marked; the pulse is small, feeble, dicrotic, or running and uncountable. External hemorrhages appear: epistaxis, hematemesis, melena, hematuria, purpura. The bubo often attains a considerable size; it becomes involved in a doughy swelling, which mats together and obscures the whole group of glands; the skin over the large tumor becomes reddened. At any time during this stage a slight bronchitis may develop, and in a considerable proportion of cases scattered patches of pneumonia also occur. Death commonly happens between the fourth and the seventh days; occasionally the intellect remains clear to the end; most often stupor precedes death.

4. But if the patient survive, the period of decline is ushered in by a fall of temperature to normal or a little below it, usually by crisis, sometimes by lysis; whereupon the skin becomes moist and sleep returns; the pulse continues extremely feeble, and the least effort is liable to cause death by syncope. The bubo which occasionally disappears by resolution may usually be opened; but sometimes partial resolution is followed by late suppuration about the twelfth day; the temperature, which has risen again during suppuration, then falls, and remains normal.

5. During convalescence cardiac failure, aphasia, peripheral neuritis, paraplegia, hemiplegia, or facial paralysis may occur; gangrene of the skin may set in; interstitial keratitis and panophthalmitis sometimes lead to loss of sight in one or both eyes.

Septicemic Form.—The attack is violent; the temperature soon attains to 41° or 42° C. (106.7° to 107.6° F.); prostration is extreme from the beginning; early delirium rapidly gives place to coma; there are no buboes; hemorrhages commonly occur; diarrhea and tympanites are frequent. Death often happens within 24 hours, and life seldom extends beyond the fourth day; two-thirds or more of such cases in whites are fatal.

Pneumonic Plague.—In the preceding forms bronchopneumonia frequently occurs; the respiration is then much quickened; the expectoration is abundant, but little aerated, and streaked with blood; later it becomes tenacious, devoid of air, and rusty or mucopurulent. But this, which is due to local arrest and subsequent development of the bacillus, is an incident. Primary plague-pneumonia consists in a bronchopneumonia which is attended by moderate fever, a quickened pulse, only slightly quickened respiration, a slight cough with watery, serosanguinolent expectoration, which is not rusty but blood-stained (prune-juice); the characteristic of this form of plague being prostration and illness out of all proportion to the physical signs. It is almost always fatal, and endures about 5 days.

Postmortem Appearances.—Externally, vibices, petechiæ, or larger ecchymotic patches are commonly present; less often the remains of pustular or

vesicular eruptions (contents sanious, scabs black), carbuncles, infiltrated areas of skin which may be sloughing, occasionally great edema of one limb from pressure on the great veins at the armpit or groin. In the commoner bubonic form a tumor of varying size exists at the angle of the jaw, lower in the neck, in the axilla, under the outer border of the pectoralis major, or in the groin. Internally, the blood is liquid, or ill coagulated, the serum hemoglobin-stained; normal shades of white and yellow are wanting, all the tissues presenting a dirty red tinge which strikes the eye. The primary external bubo is due to enlargement of one gland of the affected set to the size of a bean, or from that to a walnut, and of the rest of the group to a moderate extent. The former is in a state of intense, purple, inflammatory congestion, and is softened or broken down at several points; there is inflammatory congestion of the surrounding tissues; a blood-stained gelatinous effusion, which often penetrates even the subjacent muscles, mats the whole group into one edematous mass in which it is difficult to identify the glandular tissue by inspection; the other glands of the group are less swollen, and congested. All the lymphatic glands of the body are blood-full, rosy to purple on section, one member of some group other than that in which the primary bubo is seated (more rarely, of several groups) may be found rather more enlarged; and deeply congested; these latter are secondary buboes. In primary plague-pneumonia a bubo may be found in the lymphatic glands connected with the lungs. In all internal parts submucous and subserous hemorrhages are seen, from the size of a pin's head to several square inches in area.

The various visceral changes are: *Brain:* Inflammation of the meninges and meningo-encephalitis have been noted. *Lungs:* Hypostatic congestion, almost always; in addition, scattered foci of lobular pneumonia, distinguishable from other varieties only by the intense inflammatory reaction of the surrounding lung tissue; rarely a whole lobe is found solidified. Such patches result from localization of the bacillus; but occasionally the pneumonia is primary, and the manifestations of the disease are then confined to the respiratory system (primary plague-pneumonia). *Heart:* The pericardial fluid increased in quantity, sanguinolent; petechiæ of the visceral pericardium; myocardium pale and softened. *Kidneys:* There is always acute parenchymatous inflammation more or less advanced; hemorrhages in the adrenals. *Liver:* This organ is normal in volume; there is degeneration of the parenchyma and a nutmeg-section; on the upper surface whitish specks and small patches are seen, which indicate necrotic areas. *Spleen:* Enlarged, dark, soft, or diffluent; trabeculæ obscured; rarely it is normal in size and consistence. *Stomach and intestines:* These present petechiæ on both surfaces; internally, submucous edema, with a slight enlargement of the glands. The bacillus may be demonstrated at all centers of localization in all hemorrhages, and in the general circulation. It must be remembered that death not infrequently occurs early, as well as suddenly, from cardiac failure, when most of the above signs are wanting.

Diagnosis of the classic form is not difficult; during an epidemic a careful observer soon learns to recognize the sudden onset, peculiar aspect, early muscular prostration, state of tongue, and increasing depression of the circulation; which, if attended or followed by glandular pain and swelling, then often suffice to establish it. Nevertheless discrimination of plague from streptococcic septicemia is often difficult, especially when the point of entry is not apparent, or, if found, when lymphangitis is absent; and when absolute certainty is desirable (at beginning of epidemics, or in cases in which exposure to plague-infection is possible though not known, as at seaports), bacterioscopy can alone furnish the proof. A sterilized metal box, containing a tube of sloped nutrient agar, and an ordinary hypodermic syringe should be furnished from the hygienic laboratory. If the case be bubonic, the skin should be carefully cleansed with soap followed by alcohol; the swollen gland having been steadied and the skin over it rendered tense, the hypodermic needle should be carefully and steadily thrust into it; the piston is then to be slightly withdrawn half a dozen times, the needle also being partly withdrawn, and thrust into different parts of the gland. In this way sufficient liquid can usually be removed. The contents should then be carefully projected onto the agar surface, and both tube and needle (the latter not cleansed) carefully replaced in the box and transmitted to the laboratory, where the bacteriologist will make smears, cultures, and inoculations into animals. In primary pneumonia, diagnosis turns entirely on demonstration of the bacillus in the sputa, although the remarkable disproportion between the auscultation signs and the patient's evident danger may have aroused suspicion. In septicemic cases the blood may be examined; the bacillus is often discoverable in this form in the peripheral circulation about 24 hours after attack (a little earlier or later as the case may be).

Plague may be confused with malarial intermittent, relapsing, and typhus fevers, and with acute alcoholic poisoning. In *intermittent fever* the patient is likely to have dosed himself with quinin, when no hemamebæ will be found; however, the algid stage is much more intense and longer, while the hot stage is unattended by great prostration, and muscular strength and intelligence are preserved. In *relapsing fever* examination of the blood reveals *Spirillum Obermeieri;* the attack is sudden with vomiting, but there is less prostration; the face is injected, and expresses neither hebetude nor anxiety. During epidemics of plague attention is drawn to many cases in which glandular swellings are present, but unattended by important constitutional symptoms; and in a considerable proportion it will be found impossible to assign any definite cause to them. Some of them may, no doubt, be cases of *pestis minor* at a late stage; but there is a belief that this explanation should be very cautiously accepted; for attention is then arrested by cases which at other times would be

treated with simple remedies without need appearing to investigate their exact cause. However, the banal causes—venereal or scrofulous disease, sepsis, and injury—should in every case be excluded as a matter of routine.

Prognosis.—This should always be very carefully guarded until the eighth day of illness has passed; patients are then unlikely to die of the fever; but the degenerated heart-muscle exposes them to great risk from syncope, which even the effort of rising from the supine to the erect sitting posture in bed may cause. At the commencement of illness it should be borne in mind that the mortality of plague among colored races is always between 80 and 90 percent, in whites it is usually about 33 percent, while primary plague-pneumonia is almost always fatal, as are about two-thirds of all septicemic cases in whites. A sudden fall of temperature to below normal, attended with coldness and dampness of the surface occurring during the period of state, betokens death (the internal temperature continues to rise); sharp diarrhea with or without tympanites, and external hemorrhages, unless in very small amount, are both of grave import. The situation of the primary bubo is important, a fatal issue more frequently attending on buboes in the neck than in the armpit, least frequently on those in the groin. Convalescence is always lengthy. Occasionally recovery from the effects of the acute morbid process fails, and death by exhaustion occurs many weeks later.

Prophylaxis.—It is highly important to exterminate rats by trapping, by a careful disposal of the garbage and other particles of food for the rat, which if available will prevent the inducement of the rat to eat poisoned bait or bait in traps. Where rats are on shipboard fumigations of sulphur dioxid are usually employed. In pneumonic plague the infection is contained in the droplets of sputum projected into the air when the patient coughs. The attendant should be protected by a gauze mask and goggles for the eyes.

General treatment is symptomatic. Attempts may be made to encourage elimination by calomel and diuretics; fever may be reduced by cold or tepid sponging, although failing circulation may render application of heat to the feet necessary at the same time, but drugs, unless free from risk of depressing the heart, are hardly admissible for this purpose. To combat sleeplessness, ice to the head is valuable, but morphin, tetronal, trional, hyoscyamin, hyoscin, and the bromids may be employed, a combination of morphin and atropin, or of morphin and potassium bromid, being specially valuable. Against cardiac depression alcoholic stimulants, especially champagne, are most useful, but to them digitalis and strophanthus given by the mouth to strengthen contraction of the cardiac muscle, with digitalis and strychnin to counteract feebleness of the blood-vessels, must be added. It is said that the best results have followed subcutaneous injections of a combination of strophanthus and strychnin; of which latter, as well as of some other drugs, plague-patients are remarkably tolerant. As to buboes, early incision, leeches, and excision are harmful. Extract of belladonna may be applied to them, but ice gives most relief to pain. As soon as there is clear evidence of pus they should be opened by a free incision, such as will afford exit to sloughs; and antiseptics should be applied to the cavity. Phenol, in doses of 12 grains every 2 hours, diluted, has been used with marked success.

Specific treatment consists in the administration of subcutaneous and intravenous injections of Yersin serum; other serums are known, but this appears on the whole to have yielded so far the best (though still not satisfactory) results. Subcutaneous injection should be made in that area of skin the lymphatics of which converge to the primary bubo, and at a moderate distance below the latter. The quantity injected at one time may be from 40 c.c. to 80 c.c. or more. For intravenous injection a vein on the dorsum of the hand, or one at the bend of the elbow, should be selected; a ligature should be put on the limb so as to bring the vein into prominence; this should be further rendered tense by pressure of the thumb of the hand used to steady the limb, as in venesection; a hollow needle can then be plunged into it. Penetration of the vein is ascertained by beginning to inject before the ligature is removed; if it swells, the latter may be loosened and the injection completed. The quantity injected should not exceed 40 c.c. at any one time, but in severe cases this may (and should) be repeated after 5 or 6 hours. Intravenous administration is the more effectual. The serum causes a fall of temperature; the clinical guide to repetition is a rising temperature. Every case should receive a subcutaneous injection of 40 c.c. as soon as the clinical diagnosis has been made; but in severer cases 40 c.c. should at once be given intravenously, and at the same time another 40 c.c. subcutaneously. These massive doses, repeated at least twice in 24 hours, give the patient a chance of recovery, and seem, on the whole, to have sometimes succeeded; and as even smaller quantities are followed by reduction of temperature and improved arterial tension, the remedy, from which no ill effect need be apprehended, should be pushed. A sterilized diphtheria-antitoxin or other suitable syringe may be employed; the operation must be done with every aseptic precaution. All serums which have been stored present a slight deposit; this may be injected with the serum subcutaneously, but should be filtered out before introduction into a vein; and it need hardly be added that every care to avoid introducing air must be used in the latter case. Injections are liable to be followed by urticaria and joint-pains.

Specific preventive treatment consists in subcutaneous administration of 10 c.c. of Yersin serum, or of Haffkine's prophylactic in the dose for adults which is mentioned on each bottle, and which is usually 5 c.c. The former confers a passive immunity which is manifested immediately; the latter brings about active immunity which does not develop for about 8 days. Hence Yersin's serum should be used for protection of the members of a household among whom an indigenous

case has appeared; their danger will cease either on removal from the premises or as soon as ordinary thorough cleansing and disinfection has been done. But Haffkine's prophylactic should be used for protection of individuals who are subject to prolonged intermittent exposure, by being obliged to visit the infected quarters of a city or to attend on the sick. The inoculation should be done at the back of the upper arm with aseptic precautions; it is not painful. It is followed in a few hours by slight malaise and headache, with feverishness; the ensuing night is often sleepless; the temperature has risen to 38.5° or 39° C. (101.3° to 102.5° F.) the next morning; after about 24 hours the puncture is found to be the seat of a small hard swelling, and there is a good deal of redness and diffuse swelling of the superficial tissues below it; the slight feverishness and malaise disappear in the course of the second 24 hours, having been, as a rule, not such as to interfere with usual engagements, and the redness and superficial swelling a little later; the hard swelling persists for about 3 weeks. Inoculation with prophylactic during the incubation-period does not aggravate the illness when it commences. Its general effects are to lessen liability to attack and to improve chances of recovery if attack should occur.

General Preventive Treatment.—*Bacillus pestis* is the cause of plague; it is found in the bodies of the sick, from which it may escape with excretions and secretions, with the pus of bubonic abscesses, and with discharges from those eruptions and skin-lesions which have the same specific origin. In the vast majority of cases it enters the body by inoculation through the skin; but in primary pneumonic cases it probably gains access through the respiratory mucous membrane. It can survive in viable and even in virulent form outside the human body; but this knowledge has been drawn from laboratory experiments the results of which, as M. J. Rosenau has judiciously observed, must not be applied to the varying conditions of daily life without reserves and cautions. As a matter of fact, the bacillus has been observed outside the human body only in the bodies of animals, among which rats and mice have most importance from their close association with man, and in the bodies of suctorial parasites, among which, again, fleas are of most importance. Then, it is now generally conceded that, as a matter of fact, the infection is very rarely conveyed from the sick suffering from the bubonic and septicemic forms to the healthy; only the pneumonic form is highly infectious, probably (as in tuberculosis) when the healthy inhale specks of saliva and expectoration projected in coughing. These appear to be the important facts touching diffusion of plague as it appears among a civilized population of whites, and from them the general precautions necessary in individual cases can be deduced. Importation to an average poor household (and *multo majore* to better placed households) of a case which has received the infection elsewhere appears to involve no risk to others even in absence of such precautions during the earlier days of illness as are usually taken with the commoner infectious fevers. It being clearly understood, however, that these latter are necessary in prudence, no more need be said on the subject of personal prophylaxis; nevertheless the central health authority (whose operations do not fall within the scope of this article) will properly insist on removal of every case of plague to hospital at the earliest moment, or else, when that is impossible, upon retaining the control of the home nursing-staff in his own hands. Acid sublimate solution 1:500 for mixing with excreta, etc., and the same 1:1000, together with 5 percent carbolic solutions for other purposes are as useful disinfectants as any. Proper sanitation should be established; the dead should be cremated, and all infected articles burned if possible. Rigid quarantine of persons, animals, and goods, should be enforced. Infection has not infrequently been conveyed by rats and cargoes; consequently the cargo of every suspicious ship should be fumigated and all rats aboard as well as on shore should be destroyed. The direct agent in conveying the infection from rats to man being the rat-flea, disinfection of clothing and kit of travelers should be insisted upon.

PLASMODIUM.—See MALARIAL FEVERS.

PLASTER (Emplastrum).—An adhesive, solid or semisolid, medicinal substance spread upon cloth or other flexible material, for application to the external part of the body. **Plasters are usually spread** on muslin, leather, paper, etc., and have as a basis, lead plaster, a gum-resin, or Burgundy pitch. **P., Antiseptic,** a plaster consisting of the ordinary adhesive plaster dipped in a hot solution of carbolic acid (1:60). **P., Black,** lead plaster. **P., Casts,** a model of an object produced by pouring plaster-of-Paris mixed with water into a mold of that object. **P., Court-,** a plaster prepared by dissolving 30 grams of isinglass in enough water to make 360 grams, and spreading the mixture thinly upon silk in two portions, one the watery solution, the other mixed with 120 grams of alcohol and 3 of glycerin. The reserve side of the silk is painted with tincture of benzoin. It adheres firmly to the skin when moistened. **P., Diachylon.** Synonym of P., Lead. **P., English.** Synonym of P., Court-. **P., Isinglass,** a substitute for adhesive plaster, used in superficial wounds. **P., Jacket,** a bandage surrounding the trunk, and made of plaster-of-Paris. It is used in caries of the vertebræ. **P., Logan's,** a plaster containing litharge, lead carbonate, Castile soap, butter, olive oil, and mastic. **P.-machine,** an apparatus used by pharmacists for spreading plasters. **P., Mahy's,** one containing lead carbonate, olive oil, yellow wax, lead plaster, and Florentine orris. **P., Miraculous,** one containing red oxid of lead, olive oil, alum, and camphor. **P., Mull,** a plaster made by incorporating mull or thin muslin with a mixture of gutta-percha and some medicament dissolved in benzin. **P., Mustard,** one made by spreading powdered mustard, or a mixture of mustard with flour or other powder, reduced to the consistency of paste by the addition of water, upon muslin. **P., Pitch,** a plaster containing Burgundy pitch, frankincense, resin, yellow wax, oil of nutmeg, and olive oil. **P., Rademacher's,** a plaster composed of red lead,

olive oil, amber, camphor, and alum. **P., Resin,** a plaster composed of resin, lead plaster, and yellow wax or hard soap. See PLASTER (Adhesive). **P., Rubber,** a plaster in which the adhesive material is spread on thin muslin, and which sticks without being previously warmed. **P., Spice,** a plaster composed of yellow wax, suet, turpentine, oil of nutmeg, olibanum, benzoin, oil of peppermint, and oil of cloves. **P., Sticking-,** emplastrum resinæ. **P., Stomach.** See P., Spice. **P., Strengthening,** emplastrum ferri. **P., Surgeon's,** adhesive plaster. **P., Thapsia,** one containing yellow wax, Burgundy pitch, resin, terebinthina cocta, Venice turpentine, glycerin, and thapsia resin. **P., Vesicating,** cantharides plaster. **P., Vigo,** one containing lead plaster, yellow wax, resin, olibanum, ammoniac, bdellium, myrrh, saffron, mercury, turpentine, liquid storax, and oil of lavender. **P., Warm, P., Warming,** emplastrum picis cum cantharide.

There are seven official plasters:

TITLE.	CONSTITUENTS.
EMPLASTRUM;	
Adhæsivum..... Adhesive plaster.	Rubber, 20 gm.; petrolatum, 20 gm.; lead plaster, 960 gm
Belladonnæ. (Should not contain less than 0.38 percent. nor more than 0.42 percent of mydriatic alkaloids.) Belladonna plaster.	Extract of belladonna leaves, 300 gm.; adhesive plaster, 700 gm.
Capsici..... Capsicum plaster.	Oleoresin of capsicum, 0.25 gm.; adhesive plaster, q. s.
Hydrargyri..... Mercurial plaster.	Mercury, 30 gm.; oleate of mercury, 1 gm.; hydrous wool-fat, 10 gm.; lead plaster, 59 gm.
Opii..... Opium plaster.	Extract of opium, 6 gm.; water, 8 c.c.; adhesive plaster, 90 gm.
Plumbi (Diachylon plaster.) Lead plaster.	Soap, 100 gm.; lead acetate, 60 gm.; water, sufficient quantity.
Saponis..... Soap plaster.	Soap, 10 gm.; lead plaster, 90 gm.; water, sufficient quantity.

PLASTER, ADHESIVE.—The lead adhesive plaster was universally used before the introduction of the rubber adhesive plaster, and which, because it is less irritating to sensitive skins, is still preferred by some practitioners. It is made by adding to 80 parts of lead plaster 14 parts of resin and 6 parts of yellow wax. It is then spread on muslin prepared for the purpose. Adhesive plaster, while based upon the lead plaster, is rarely, if ever, used for the purposes of exhibiting the impression of oxid of lead.

To obtain the best results from adhesive plaster, the material must be freshly cut from a roll which has been kept in a tin box or other close-fitting receptacle. The plaster is best heated over an alcohol lamp or against the side of a vessel containing hot water (the smooth or nonadhesive side being placed in contact with the heated surface until the plaster is thoroughly softened), when it must be immediately applied to the skin. Placing a strip of adhesive plaster around a stove-pipe, with the adhesive side out, will often prove practicable in private practice. When strips are used, which, from their great length it is inconvenient to heat, the plaster surface may be softened by rubbing it over with a bit of raw cotton moistened with chloroform or ether.

Adhesive plaster may be worn for weeks at a time without producing cutaneous irritation. Hence it is to be preferred to rubber plaster for making extension for fracture of the thigh, or for affections of the hip-joint. Firmly applied over an ulcer and supported by a bandage, it forms a reliable method of dealing with leg ulcers due to varicose veins. Adhesive plaster is extensively employed in the treatment of fractured ribs and contusions of the chest. A number of strips about 2 inches wide are applied parallel to the ribs, beginning at the lowest and passing up to the axilla. Each strip is to be applied with firm traction, and extend from the vertebral column to a point a little beyond the median line in front. Marked relief is afforded by this procedure. In fracture of the clavicle in children a dressing of adhesive plaster will be found a satisfactory means of keeping the ends of the bone in position. Sayre's dressing for fractured clavicle is made of adhesive plaster. Sprains are often strapped with adhesive plaster.

PLASTER-OF-PARIS.—Gypsum or calcium sulphate is used for making stiff or immovable bandages and dressings, and for the preparation of casts. An ordinary creolin or loose-web bandage is well rubbed with fine plaster-of-Paris. The bandage is then applied to the part wet, additional plaster is rubbed in, and the cast thus formed is allowed to dry or "set."

The method of testing the quality of plaster-of-Paris by taking a small pinch of the powder between the thumb and finger and gently rubbing it; if small particles of grit are felt, it indicates that parts of the plaster have already absorbed water, and it is therefore unfit for use. The same test may be observed by taking a pinch of the powder again and placing the fingers under water, and then rubbing in the same way as before. If, however, in both of these tests no grit is felt, and, under water, a thin, creamy substance is formed which is easily rubbed off the fingers, the plaster is in a proper condition for use. When plaster has been kept for a long time, or when it is gritty, its condition can be very greatly improved. It may be redried by putting it in a metal dish, such as a pie-plate or iron pot, and placing it in an oven of a hot stove or over a gas-jet. As soon as it becomes heated, it will be observed that a process identical with boiling water is taking place. When this ebullition has entirely ceased, the powder is freshly kiln-dried. If the method of testing is again resorted to, it will be found that the gritty appearance and feeling will have disappeared in a very large measure, leaving only the now dry powder ready for use. If there are any lumps remaining, they may be removed by the use of a sieve. Plaster-of-Paris must always be kept in a hermetically sealed jar, or in a very dry place.

To Remove a Plaster Dressing.—In order to facilitate the removal of plaster-of-Paris dressing from limbs, the following plan should be followed:

After application of the usual thin layer of absorbent cotton around the limb, parchment paper, which has been previously moistened, is wet and applied. Over this, in the direction that the dressing is to be sawed open, a good sized string which has been well rubbed with vaselin is laid on and the dressing then applied. The ends of the string are then tied together over the bandage. When in the course of time the plaster dressing is to be laid off, the ends of the cord are untied, one, tied to the end of a sufficiently long steel wire, which has been closely nicked, is drawn through the channel filled by the oiled string, and after each end of the wire has been attached to the handles of a chain saw, it is drawn to and fro until the plaster has been sawed through. Then the dressing is easily removed.

PLASTIC SURGERY.—Plastic surgery is that branch of the operative art by which congenital or acquired defects and deformities are repaired. With the extension of surgery, plastic operations have been extended from the skin, to which they were long limited, to the various mucosæ, to bone, to tendon, and to nerve. The present article will be limited to its considerations as applied to the skin alone.

The rationale of all plastic surgery is based on the inherent vitality of tissues after they have been removed from their original site and implanted in a new position, whence they thereafter obtain nutrition. In dermatoplastic operations two chief methods are to be considered:

Gliding Pedicle, or Flap.—Those procedures in which the skin to be utilized for filling a gap retains, for a time at least, some connection with its original site.

Skin-grafting Proper.—In this method of plastic surgery the integument utilized may be taken from the body of the patient himself. For this the term autoplasty is used. Heteroplasty is reserved for the utilization of tissues from a person other than the patient, or from an animal.

For the relief of many defects—as, for example, of the lip, the eyelid, or a part of the nose—the first method is still the only one applicable. The area of the defect is first to be freshened by clean incisions extending through the entire thickness of the skin. All scar tissues must be removed. By doing this the defect will be seemingly greatly increased. The margins and floor of the wound should be made as smooth as possible, and all bleeding checked before proceeding to shape the skin structures which are to cover the gap. In fashioning the skin to be transferred, one of two plans may be followed: (1) That of gliding, and (2) that of making a flap to be nourished by a pedicle.

The gliding method of closing a defect by traction on the vivified edges of the skin surrounding it, is based on the extent to which skin can be stretched and yet retain its vitality. Oval or triangular defects, or such as can be converted into either shape, are best suited for a gliding operation. To facilitate the gliding of the skin destined to cover the gap it is undermined for a varying distance. This is a safe method; it leaves no new defect and the broad attachment of the skin assures its viability even under considerable tension from traction. When the form and size of a defect preclude its closure by traction alone, the skin in the immediate vicinity may be dissected up in a patch of requisite size and by a process of gliding be brought edgewise into the position of the part to be repaired, when, after proper adjustment, it is retained by sutures. Triangular or rectangular defects, such as follow partial removal of the lip or of the eyelid, can best be repaired in this way.

When the gliding method is impracticable, **flap formation** must be resorted to. The defect is vivified, as in the gliding operation. The flap is taken from the most available part. Usually it is taken from near the defect. It may, however, be taken from a distance, as in rhinoplastic operations, where the skin flap is taken from the arm. To cover large defects of the extremities, as after burns of the elbow or wrist, the integument may be taken from the abdomen or side of the chest. Mr. Croft's operation, in which this is done, is of greatest value in the conditions named. In this procedure a flap of skin 6 or 8 inches long, and 2 or 3 inches wide, is raised from the underlying tissues of the abdomen and retained by bridges of skin above and below. For a week or 10 days the under surface is allowed to granulate. Now only is the lower attachment of the flap severed and brought into the freshened gap—as, for example, of the elbow or wrist—and sutured there. Until firm union has resulted, the arm is firmly bandaged to the side of the body. After another 10 days, the upper bridge is severed, and the flap finally placed in its new position.

Viability of the flap is the first requisite of success. It should be fashioned to insure a sufficient blood supply. It should contain the entire thickness of the skin and a part of the underlying subcutaneous layer. Bleeding flaps are viable. From the natural contractility of the skin, flaps shrink considerably. They should, therefore, be cut one-third larger than the defect to be filled. In formal plastic operations the pedicle should measure not less than 1 inch in width. Excessive torsion of the pedicle must, for obvious reasons, be avoided. The fixation of the flap by sutures forms the final step of the plastic operation. Accuracy of apposition is essential. The absence of blood within the wound and strict aseptic and antiseptic precautions tend to assure success. In plastic operations about the face the buried subcuticular suture is particularly to be advocated. The after-treatment is simple. A dry gauze dressing, held in position by bandage or strips of adhesive plaster, will go far toward supporting the parts and assuring primary union.

Skin-grafting.—In 1869 **Reverdin** first published a method of rapidly causing the closure of superficial wounds and ulcerated surfaces by implanting in them small grafts of epidermis that had been entirely removed from the body. The grafts were the size of a pin's head, and deposited in little depressions made with a knife in the surface to be covered. From these grafts the epidermis developed in minute islands, which, as they grew,

coalesced, and eventually covered the entire surface. The method of Reverdin was often uncertain and slow in achieving a result. For this reason it failed of general adoption, and was entirely superseded by that of **Thiersch**, advanced in 1886. This is based on the viability of strips of the superficial layers of the skin when entirely removed from their original sources of nutrition, and their tendency to form permanent attachment to denuded surfaces. Wolfe, in 1868, and after him a number of ophthalmic surgeons, transplanted large portions of the skin from the arm in plastic operations on the eyelids.

Among the conditions in which skin-grafting by large films is indicated may be mentioned: (1) Indolent ulcers, as of the leg, or those following burns. (2) Fleshy denuded areas resulting from the removal of neoplasm, as after the excision of superficial epitheliomata or lupus patches from the face. Immediate closure of the wound can thereby be accomplished. (3) After excision of extensive growths, as for mammary cancer, when the wound cannot be closed by traction suture without dangerous tension. (4) Areas of the bone that have recently lost their covering of soft parts, and can be covered in no other way. Areas of bone exposed after necrotomy operations. Skin-grafts unite readily to aseptic bone surfaces.

Operation.—The locality where the skin is to be grafted must be a flesh wound, or, in the case of an ulcer, it must be so converted by removing all granulations by the use of the sharp spoon. All hemorrhage must be checked by hot salt solutions and compression. The presence of blood under the graft would, more than all else, endanger the success of the procedure. Unevenness in the floor of the defect does not militate against the adherence of the grafts.

The epidermal strips are usually taken from the anterior surface of the thigh or from the outer surface of the arm. This part should be sterilized as for ordinary operations, some time before the strips are cut. When everything is ready for cutting the strips, the skin is made tense by the left hand of the operator or by an assistant. A constant flow of salt solution likewise is directed against the field of operation. With a sharp, broad razor, preferably plane on one surface, the surgeon cuts strips of the epidermis and papillary layer of the skin. The cutting is done parallel to the surface, and by a to-and-fro or sawing movement. The strips are cut of requisite length and width, and may be made an inch or more wide, and 5 or 6 inches long. Each strip is at once transferred to its new habitat and placed in position with raw surfaces in opposition. The edges of the graft have a marked tendency to curl in a manner that would bring the epidermis underneath. This can easily be corrected by gently using a probe and mouse-tooth forceps. As many strips as may be needed are cut and placed in position. The edges should be made to slightly overlap. When there has been no bleeding under the grafts, adhesion takes place rapidly, probably as a result of atmospheric pressure.

Dressings after skin-grafting should be aseptic, not antiseptic. Solutions of corrosive sublimate are harmful. The dressing may be that of rubber protective or silver-foil or oiled silk moistened with salt solution. An excellent dressing is gutta-percha tissue in that it can be readily sterilized by formaldehyd fumes, is pliable and free from odor, and is not disintegrated by body temperature and moisture. The gutta-percha tissue cut in narrow strips is applied directly to the newly grafted surface. Over this the ordinary gauze and cotton dressing are retained by a bandage. The gauze dressing is removed daily and sterile normal saline solution is applied with a camel's-hair brush to clear away an exudate that appears between the strips.

In exceptional cases the entire thickness of the skin is utilized for the graft (**Wolfe's method**). A flap of the desired size and form is outlined by an incision to the fascia. The edge of the skin is raised with mouse-tooth forceps, and the flap removed from the subcutaneous layer by long and even strokes of the knife. Fat lobules are to be carefully removed from the flap before it is placed in its new position.

As a rule, the skin is very pale and continues so for a number of days after transplantation. Sutures are, as a rule, unnecessary, if not harmful. The after-treatment is the same as for the epidermal graft. With many operators, gold-beaters' skin or silver foil is made to take the place of the moist rubber protective dressing.

PLETHORA.—Abnormal fulness of blood or superabundance of blood. Serous plethora is an excess of serum in the blood. The best drug for affections of plethoric subjects is aconite, and it is decidedly the best remedy for apoplexy in the plethoric. When there is a determination of blood to the head, arsenic may be used to advantage, while sulphur is to be used as a mild purgative for plethora from cessation of the menses. For abdominal plethora, saline and hydragog cathartics are of service. The purgative saline waters, such as Vichy or Saratoga, are also valuable. Grape-juice has helped many cases. Dry diet is indicated in dyspepsia and hepatic enlargement from excessive beer-drinking. Avoid much bread, salted or twice-cooked meats, rich sauces, solid vegetables, especially soups, cucumbers and fruits. Biscuits, fresh meats, lemons, fish, fowl, and game may be used.

Venesection (*q. v.*) is sometimes employed.

℞. Resin of podophyllin, gr. vj
Compound extract of colocynth, gr. xij
Alcoholic extract of belladonna leaves, gr. iij.
Divide into 12 pills. Give 1 pill every night.

PLEURA, INJURIES.—Rupture of the costal pleura probably occurs spontaneously in every case of fractured rib or severe contusion of the thorax, but, owing to the skin being unbroken, the injury is repaired at once, with only a transient or local pleurisy at the most; and though such com-

plications as hematothorax from rupture of an intercostal or internal mammary artery and pneumatocele may occur, they are very rare. When there is an external wound, the pleura only may be injured, without the lung, if the weapon is blunt and enters the thorax slowly, so that it pushes the lung in front of it, or if the wound is in the tenth or eleventh interspace; for though the pleura usually extends as low as the last rib, the lung, unless it is emphysematous, only reaches the tenth. In this case, however, the diaphragm and the subjacent viscera are very likely to suffer. Other complications depend upon the size and extent of the wound. If it is merely a puncture or a small incision, the diagnosis is often never made; but if it is extensive, the lung may protrude without injury through the opening (*hernia*); it may collapse and fall back, leaving the pleura full of air (*pneumothorax*); the cavity, as already mentioned, may be partly filled with blood, and the air may either pass in and out freely through the wound (*traumatopnea*), or it may be forced into the cellular tissue under the skin, and spread over a considerable area (*emphysema*). This, however, is seldom extensive unless the lung is wounded. Finally, at a later period, pleurisy may set in, and even run on to empyema. See CHEST (Injuries), LUNG (Injuries), PLEURISY.

PLEURISY.—Inflammation of the pleura.

Varieties.—According to cause, it may be divided into primary or secondary; according to extent, into unilateral, bilateral, or local; according to time, into acute or chronic; and according to the exudation, into serofibrinous, fibrinous, or purulent.

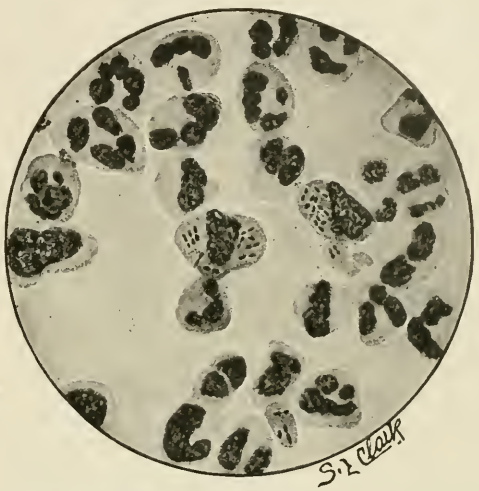
Etiology.—(1) It may be idiopathic from exposure to the cold and wet; (2) traumatism; (3) it is usually associated with lobar pneumonia and pericarditis; (4) it is secondary to certain infective and toxemic conditions, such as acute rheumatism, pyemia, typhoid fever, gout, nephritis, and tuberculosis (common); (5) cancerous (rare).

The exciting cause is said to be infection by pneumococci, staphylococci, or streptococci.

Pathology.—Pleurisy consists of three stages: (1) Stage of congestion; (2) stage of effusion; (3) stage of organization or absorption. In the early stage, to the naked eye the pleura is red, swollen, and covered with flakes or curds of yellowish or whitish lymph (dry pleurisy). The process may stop in this stage, or the effusion may accumulate in large quantities in the pleural sac (serofibrinous). It may be only covered with a film of deposit mostly fibrinous (fibrinous), or it may become infected, giving rise to purulent pleurisy (empyema).

Serofibrinous Pleurisy.—The amount of fluid varies greatly from half an ounce to several pints. As the liquid accumulates in the stage of effusion, it gravitates toward the lower portion of the pleura sac, compressing the lung upward and backward. The diaphragm is displaced downward and the heart toward the opposite side of the lung affected. The fluid may be absorbed, may be organized into new tissue, or may become purulent.

Fibrinous Pleurisy.—In this form the deposit is scanty, thick, whitish or yellowish in color, and generally circumscribed. A considerable amount of cellular infiltration may occur, giving rise to the formation of new tissue and causing the two surfaces of the pleura to be bound together (adhesive pleurisy). If the process is a progressive one, the lymphatics may become involved, spreading to the lung and causing bronchopneumonia.



CELLS FROM EXUDATE, CASE OF EMPYEMA.—(*Coplin*). The large hyaline cells (macrophagocytes) contain many pneumococci.

Purulent pleurisy (empyema) generally results by metastasis during the course of pneumonia or tuberculosis. An empyema, however, may be primary or may become purulent by infection during the course of a serofibrinous pleurisy. The septic process may cause erosion of the visceral layer, thus extending to the lung and finally the bronchi, when the purulent collection may be discharged during the act of coughing. If the rupture takes place in the parietal layer, the pus burrows its way externally, producing an abscess in one or more of the intercostal spaces, generally near the sternum. In young patients this process generally causes great deformity of the chest after the pus has been evacuated. See COLON BACILLUS INFECTION.

Hemorrhagic Pleurisy.—Effusion of blood in the pleural sac, resulting from cancer, tuberculosis, scurvy, and grave forms of anemia.

Symptoms and Clinical Course. Acute Pleurisy.—The onset is generally marked by chilly sensations, slight cough, the act of which gives rise to a sharp pain (stitch) in the affected side. The temperature is somewhat elevated (100° to 102° F.), pulse full and only moderately increased in rate, and frequently not corresponding to the height of fever. The respirations are increased, often being painful, especially on taking deep inspirations. The cough is distressing, generally being cut short by the sharp pain in the side. The sputum is occasionally tinged with blood; in certain cases the sputum may be profuse, while in others it may be

suppressed. As the disease progresses, dyspnea becomes apparent, and the patient lies on the affected side to relieve the intense pain set up during the course of the disease. As the fluid accumulates, this symptom gradually abates, the fever becomes lower, while the respirations still remain embarrassed.

Physical Signs. Stage of Congestion.—There are diminished expansion and, perhaps, decreased tactile fremitus over the affected area. On auscultation a to-and-fro grazing, creaking, or crackling friction sound is heard. The crackling sound is often mistaken for crepitant or subcrepitant râles. If due to râles, the sound is generally removed by coughing, while in the former instance the sound is not modified.

Stage of Effusion.—There is diminished expansion over affected area, often bulging of intercostal spaces and displacement of apex-beat to the right or left, according to pleura affected. Palpation confirms inspection; diminished vocal (tactile) fremitus. Percussion elicits movable dulness. If the upper level is at the third intercostal space when the patient is in sitting posture, it will be at fourth interspace of lower when lying down. The line of dulness is usually curved, being higher posteriorly. Above the line of dulness a zone is found which yields a hyperresonant (tympanitic) note, or Skoda's resonance. On auscultation the respiratory murmur is weak, the expiratory breath-sound frequently being inaudible in the stage of effusion. Earlier in the disease bronchial breathing is present, most marked along the spine and interscapular region. A friction sound may be detected above the level of the fluid anteriorly in some cases. Vocal resonance is diminished in the stage of effusion, but when bronchial breathing is present in cases of moderate effusion, bronchophony may be heard. The unaffected lung is doing vicarious work, and both inspiration and expiration are harsh in quality on that side which also yields a hyperresonant note. When there is a small amount of fluid present, egophony is elicited, most marked near the angle of scapula of the affected side. Mensuration shows increase in anteroposterior diameter on affected side. Aspiration detects the presence and character of fluid, whether serofibrinous or purulent. The white blood-corpuscles, red cells, and hemoglobin remain about normal.

The Stage of Absorption.—There is gradual return to the normal physical signs. Occasionally friction redux is detected.

Physical Signs of Chronic Fibrinous Pleurisy.—Chronic pleurisy may result from the acute form, the fluid not being absorbed, and therefore yields the same physical signs as in acute form. In dry or plastic pleurisy (chronic) on inspection the chest is greatly deformed on affected side. Palpation yields diminished vocal (tactile) fremitus. On percussion there is impaired resonance. Auscultation detects pleuritic grazing or creaking friction sounds, and diminished vocal resonance. The respiratory murmur is diminished in intensity.

Symptoms of Purulent Pleurisy (Empyema).—There are hectic symptoms, sweats, chills, high irregular fever, dyspnea, expectoration of very offensive material, edema and redness in the intercostal spaces, and on aspiration the purulent fluid is obtained.

Diagnosis depends upon the subjective and objective symptoms.

Acute Pleurisy.	Lobar Pneumonia.	Intercostal Neuralgia.
Subjective Symptoms.	*Subjective Symptoms.*	*Subjective Symptoms.*
1. Onset marked by chilly sensations, sharp cough.	1. Onset marked by shaking chill, cough, dyspnea.	1. Onset marked by stitch in side, pain along intercostal spaces.
2. Cough often checked by darting pain in side.	2. Cough gives rise to pain in throat and general chest pains.	2. Cough absent.
Objective Symptoms.	*Objective Symptoms.*	*Objective Symptoms.*
1. Fever slight (100°) and very irregular.	1. High fever (104°) with diurnal variation.	1. Fever absent.
2. Slight dyspnea (20 to 30 respirations a minute). Patient lies on affected side.	2. Dyspnea great (40 to 50 respirations a minute). Patient uncomfortable in all positions.	2. Respiration normal. Patient lies on affected side.
3. *Inspection.* — Diminished expansion of affected area and bulging of interspaces; heart displaced.	3. Physical signs observed in pleurisy are different.	3. Diminished expansion during inspiration.
4. *Palpation.* — Diminished tactile (vocal) fremitus.	4. Increased vocal fremitus.	4. Normal vocal fremitus.
5. *Percussion.*—Percussion-note dull over effusion, movable dulness, Skoda's resonance from effusion.	5. Percussion note dull.	5. Percussion-note normal.
6. *Auscultation.*—Respiratory murmur diminished, egophony at angle of scapula, grazing or crackling pleuritic friction sound.	6. Bronchial breathing, crepitant râle on inspiration, increased vocal resonance (bronchophony).	6. Respiratory murmur normal.
7. *Mensuration.*—Affected side increased in diameter.	7. Diameter both sides of chest equal.	7. Diameter of chest equal.
8. Sputum may contain streaks; of blood (uncommon).	8. Sputum contains blood ("rusty colored") and diplococci.	8. Sputum normal.
9. Aspiration detects fluid.	9. No fluid withdrawn on aspiration, as a rule.	9. No fluid on aspiration.

Prognosis.—For acute pleurisy in adults the prognosis is favorable. In children great deformity of chest may ensue. In purulent pleurisy the prognosis should be guardedly favorable if the fluid is removed early. In tubercular pleurisy the prognosis is unfavorable.

Treatment demands absolute rest in bed and a light diet, such as sweet milk, soup, beef-juice, soft-boiled eggs, rice, bread and butter. The chest may be enveloped in flannel or a light cotton jacket,

Pain is relieved by hypodermic injections of morphin (1/4 grain) with atropin (1/125 grain), and by strapping chest with adhesive plaster. If the pulse is strong and bounding, the tincture of veratrum viride (20 minims) or the tincture of aconite (10 minims) may be given every 3 hours until 5 or 6 doses have been taken. Late in the disease, when the effusion is great, these drugs are dangerous on account of the profound depression induced by their action. In the early stages blisters add to the distress of the patient; late in the disease a series of small blisters do good. As in ascites, catharsis may have some influence in diminishing the amount of fluid in the pleural cavity. Of the different remedies, possibly magnesium sulphate (4 drams) is the best. It should be given before breakfast. Compound jalap powder (20 to 40 grains) every 4 hours may be taken instead of the salts. Three bowel movements a day are sufficient. If the fluid shows no signs of absorption before the second or third week of the onset of disease, one of two methods remains to be chosen: First, to get rid of the effusion by means of blisters and cathartics; second, to aspirate. Each method has its advocates.

Removal of Effusion by Blisters and Cathartics.—As has been mentioned, possibly magnesium sulphate (4 drams), preferably taken before breakfast, is the most reliable drug. At the time of administration of the purgative it is best to restrict the amount of water and liquid food to the minimum. A series of small blisters (1/2 by 2 inches) may be induced by cantharidal plaster over the affected region; when signs of healing are noticed, a new site may be selected for the blisters. The daily application of the tincture of iodin may be substituted for the blisters. The administration of potassium iodid (6 grains 3 times a day) is also recommended.

Removal of the Fluid by Aspiration.—Aspiration is always indicated in the following conditions: (1) When the level of fluid extends above the third rib; (2) when the dyspnea is intense; (3) when it remains unabsorbed from 2 to 3 weeks of onset, or after subsidence of the fever; (4) when the disease is bilateral and the total amount of fluid present is equal to the volume of one pleural sac; (5) when the fluid is purulent (empyema). Resection offers the most hope to the patient in the last instance.

The patient should take the sitting posture. The point for introduction of aspirating needle is either at the outer angle of scapula in eighth interspace, or near the posterior axillary line in the seventh interspace. Either point may first be rendered as aseptic as possible, and after anesthetizing the part by means of a few drops of a solution of cocain (5 percent), the needle is introduced with a quick thrust into the pleural sac and the cannula withdrawn. If the fluid does not at once drain away, it may be due to the needle being plugged with fibrin—inserted too far or not far enough. It is not a good plan to rotate the needle in different directions for fear of lacerating the parts. If the quantity of fluid is excessive, about two-thirds should be drawn off, and the remainder allowed to remain for 2 or 3 days. During the latter part of the process the patient frequently feels faint, and a small quantity of whisky should be at hand to combat the exhaustion.

Thoracoplasty, or **Estlander's operation**, consists in removing a portion of several of the ribs, for the purpose of allowing the chest-walls to fall in, in cases of empyema where, after the pleura has been drained, the lung, in consequence of adhesions, does not expand. An incision 3 or 4 inches in length may be made obliquely downward and inward over the side of the chest, just in front of the latissimus dorsi, across the ribs the portions of which it is intended to excise. The edges of the wound being retracted to expose the ribs, an incision is next made through the periosteum along the course of each rib for the required distance, the periosteum separated with a raspatory from both the outer and inner surface, and the rib then cut through with the saw or bone-forceps at each end of the incision, the soft parts being protected by a spatula passed beneath the rib.

Autoserotherapy.—The withdrawal of a syringeful of the exudate and hypodermic injection of it immediately is apparently efficacious, especially in acute cases. Repeated injections may be necessary in severe cases.

Vaccine and open-air treatment has recently been used with success, the vaccine administered being autogenous.

PLUMBUM.—See LEAD.

PNEUMATIC CABINET.—See PNEUMOTHERAPY, under TUBERCULOSIS, Pulmonary; LUNGS (Surgery).

PNEUMOCOCCUS INFECTIONS. Specific Treatment by Means of Antipneumococcic Serum.—Recently as a result of the experimental and clinical studies made at the Rockefeller Institute, the specific treatment of acute lobar pneumonia with antipneumococcic serum has been recommended. An essential to the successful use of antipneumococcic serum is the recognition of the fact that pneumococci morphologically and culturally alike, differ vastly in their immunological reactions. According to their immunological reactions they have been divided into four groups. The antipneumococcic serum used is derived from animals immunized against the specific type. In this way a serum of high potency has been obtained against organisms of Type 1, serum of less potency against organisms of Type 2, a serum of very slight potency against organisms of Type 3, and a serum of no potency against organisms of Type 4. Clinically the application of the serum, therefore, is of practical value only in cases due to pneumococci of Types 1 and 2. Sixty percent of the cases of pneumonia belong to these types (Cole). Fortunately there are few cases of Type 3, although the mortality is high and of the remaining number belonging to Type 4, the mortality is relatively low. Cole reports that "cases of Type 1 infection so far treated with serum is not large, but the results have been very encouraging. Seventy-two cases have now been treated by this method. Before beginning serum about one-third of the patients died. Of the 72 since serum treatment was com-

menced, 6 have died, a mortality of only a little over 8 per cent. Moreover, of these 6 fatal cases, one patient died late in convalescence from a pulmonary embolism, one died on the fifty-fourth day of the disease from a complicating general streptococcus infection, and two received serum treatment only when they were "*in extremis.*" (*Penn. Med. J.*, Feb., 1917.) Cole states further that in regard to the administration of the serum "the amount required has differed in the different cases, depending on the severity. Our plan is to give 80 mils and repeat this dose every 12 hours until the temperature and pulse rate fall. Some cases have received 500 mils or even more; in other cases one to two doses have been sufficient. To guard against the administration of serum to patients who are sensitive to such injections, it is our custom to give to all pneumonia patients on admission to the hospital 0.5 mil of horse serum subcutaneously in order to desensitize them. By the time the type of organism is determined, in 6 to 8 hours, we have considered it safe to go ahead with the treatment. So far in over 100 cases receiving serum of the various types there have been no alarming or unfavorable results. A large number of the patients receiving the large doses of serum suffer from serum sickness after a week or 10 days. The symptoms, while sometimes distressing, are never serious, and if the serum is efficacious, this disturbance is of course negligible."

PNEUMOGASTRIC NERVE, DISEASES.—Anatomy.—The pneumogastric nerve arises from the oblongata, between the origins of the glossopharyngeal and spinal accessory nerves. It passes through the jugular foramen, and is joined by branches of the spinal accessory. Giving off small branches, it passes down the neck behind and in the same sheath with the carotid artery, enters the thorax on the right side over the subclavian artery, and on the left between the subclavian and the carotid arteries. It passes through the thorax, beside the esophagus, and ends in branches to the stomach, spleen, and intestines. The most impotant branches are the pharyngeal, the superior laryngeal, the recurrent laryngeal, which passes back—the left around the arch of the aorta, the right around the subclavian artery. Branches pass to the esophagus and pulmonary branches to the lung and to the cardiac plexus for the heart. The nerve may be affected at its nucleus of origin, in its trunk, or in the terminal branches.

Etiology.—The nucleus most frequently is affected with bulbar paralysis, while tumors or aneurysms compress it within the skull, or it may be involved in meningeal thickening, whether syphilitic or otherwise. In the neck it may be compressed by aneurysm or glandular tumors, and is most liable, especially in the recurrent branch, to be ligated or wounded. When wounded it is necessary to remember that its fibers are composed of accelerator and depressor motor fibers for respiration, depressor fibers for the heart, motor and sensory fibers for the esophagus, and some sensory and motor fibers for the stomach.

Symptoms.—When the pharyngeal branches are affected, there is difficulty in swallowing, as they supply the constrictors of the pharynx and the levator palati muscle. When the laryngeal branches are affected, the voice usually becomes hoarse; coughing is impossible, and the glottis cannot be closed. Paralysis of the muscles of one side of the larynx is a prominent symptom when the trunk of the vagus in the neck or the recurrent is affected. In locomotor ataxia bilateral paralysis occurs, when the spinal accessory nuclei are affected—as is also the case in diphtheria and in bulbar paralysis. Bilateral spasm is often produced reflexly. In epilepsy the cry is produced by a tonic contraction of the vocal cords, and is part of the cortical discharge occurring locally. The "laryngeal crises" of locomotor ataxia are due to local irritation of the spinal accessory nucleus.

Spasm of the pharynx is paroxysmal in character, and is almost always part of functional nervous diseases. It forms part of the spasm of hydrophobia, and occurs in hysteria. In emotional states, as in fear and intense grief, swallowing may be impossible from such spasm.

Spasm of the laryngeal muscles is manifested in the adductors. When the recurrent branch is affected, direct spasm usually affects only one vocal cord.

Treatment.—The general treatment of diseases of the pneumogastric nerve depends upon the different causal conditions. Central disease is, as a rule, beyond the range of treatment. Potassium iodid will often remove suspected causes of pressure. In laryngeal paralysis electricity, locally applied, is often of benefit. Strychnin injections are also sometimes useful. In spasmodic affections, sedative inhalations, especially of chloroform, are useful, and applications of cocain will diminish afferent impressions of the larynx. Bromids and morphin lessen the irritability of the nerve-centers.

PNEUMONIA, CATARRHAL.—See BRONCHOPNEUMONIA.

PNEUMONIA, CROUPOUS (Lobar Pneumonia; Fibrinous Pneumonia; Acute Pneumonia; Pneumonitis).

Definition.—Pneumonia is an acute specific disease, due to infection with the diplococcus pneumoniæ (pneumococcus of Fraenkel) and, rarely, with other microorganisms, characterized by a fibrinous exudation into the pulmonary air-cells and bronchioles, and following a course that is more or less typical, the chief symptoms being those of toxemia and of interference with the respiratory and circulatory functions. Streptococcus-pneumonia is regarded as a more or less distinct form of pneumonia.

Etiology.—The greatest predisposition to pneumonia is in early adult life; it is less common as a primary disease before 20 and after 50 years. Women are nearly four times more liable to it than men, and it is more prevalent among the negroes in America than among the whites. There are more cases in the winter and early spring, and fewest from June to December, and it is relatively more rife in the Southern than in the New England

States. Surgical operations, ether narcosis, and previous attacks are also predisposing causes.

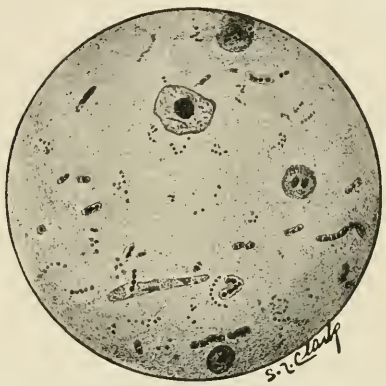
As a secondary disease it is associated with epidemic influenza, typhus and enteric fever, variola and other exanthems, diphtheria, erysipelas, puerperal septicemia, acute dysentery, whooping-cough, tuberculosis, acute and chronic nephritis, diabetes, malaria, gout, and chronic alcoholism. Emphysema, asthma, and chronic valvular heart-disease are said to confer a certain immunity.

Bacteriology.—It is now believed that the essential cause of pneumonia is a microorganism, and that the disease is a specific one. Although prolonged exposure to cold and sudden chilling are followed by attacks, yet if the accepted theory of pneumonia is true, such incidents prepare the tissue of the bronchioles and alveoli for infection, but do not in themselves cause the disease. The same may be said of contusions, fracture of the ribs, and other traumatic causes which are sometimes followed by pneumonia. The diplococcus of pneumonia is found in health in the mouth and upper air-passages, but infection does not take place unless some other influences, such as those mentioned, are brought into play. The microorganisms usually gain access to the alveoli through the bronchial tubes, but they may reach the lung through the circulation; this is shown by the presence of the pneumococcus in the exudate of meningitis, pericarditis, endocarditis, and in other lesions complicating fibrinous pneumonia, and by its occasional discovery in the blood.

Pneumococcus of Fraenkel in Sputum of Pneumonia Gram's Stain and Eosin.—(*Williams.*)

The specific microorganism most frequently found in typical fibrinous pneumonia is the diplococcus pneumoniæ (the pneumococcus of Fraenkel). There are cases presenting the characteristic symptoms and physical signs in which other bacteria have been found, as Pfeiffer's influenza bacillus, the streptococcus pyogenes, the staphylococcus aureus, and the typhoid bacillus. In view of these facts and of the failure of Fraenkel's parasite to produce pneumonia in animals by inoculation, it cannot be asserted that there is one specific cause of pneumonia. (See, too, Colon Bacillus Infection.)

Pathologic Anatomy.—The general distribution of lesions in pneumonia proves that it is a general disease. The lung presents the most serious changes, but the blood, serous membranes, kidneys, and spleen show decided alterations.



Sputum, Croupous Pneumonia.—(*Coplin.*)
In the extreme upper part of field is a leukocyte showing chromatolysis but containing englobulated cocci. Below and slightly to the left of this cell is a squamous cell from the mouth. To the right of the latter and slightly below is a polymorphonuclear leukocyte, and in the extreme lower part of the field is a small hyaline cell. The field also contains numerous encapsulated pneumococci a few streptococci and unarranged cocci that cannot be identified with accuracy.

Lungs.—It is usually stated that the lower lobe of the right lung is involved in three-fourths, and alone affected in one-half, of all the cases. Pye-Smith's figures give a different conclusion from this. Out of his 434 cases, the right base was the seat of disease in 140, the left base in 151, the right apex in 60, and the left apex in 20 cases. There were 8 cases of central and 55 of double pneumonia. Apical pneumonia is much less common than pneumonia of the base. Double pneumonia occurs in about one-sixth of the cases; it may involve both bases, or the apex of one and the base of the other lung. The inflammation spreads upward from the base and downward from the apex, and the tendency of the disease is to implicate the whole lobe or the entire lung.

The changes through which the lung passes are conveniently divided into three stages: (1) Congestion or engorgement; (2) consolidation or hepatization; (3) resolution.

1. Stage of Congestion and Serous Exudation.—The affected lung in this stage is congested, more resistant to touch, has somewhat increased weight and density, and is darker in color. On section a bloody liquid exudes, the tissue is brighter red than normal, and there is less crepitation on pressure. Toward the end of this stage the color is darker red, the density is greater, and there is even less crepitation, but pieces of the affected part

still float in water. From the resemblance of the lung to splenic tissue, this condition is called splenification. The increased density and changed color are found, microscopically, to be due to overdistention of the blood-vessels of the alveolar septa, and to the exudation of serum with the escape of leukocytes and a few red blood-cells into the alveoli and bronchioles.

2. **Stage of Fibrinous Exudation and Solidification (Hepatization).**—In this stage, beginning on the second or third day, the lung is increased in bulk and 3 or 4 times in weight; it is inelastic and liver-like in density and appearance (red hepatization). The cut surface is dark red or brownish-red, dry, and granular; crepitation is absent, and pieces sink in water. The tissue is friable and breaks down under rough handling.

The corresponding pleura, both parietal and costal, is covered with a layer of thick, soft lymph. At this period the alveoli and smallest bronchi are completely filled with a fibrinous exudate, seen with the microscope as a network of thread-like lines, with entangled leukocytes, red blood-cells, exfoliated alveolar epithelium, and diplococci or other microorganisms. It is this exudate which is the essential and characteristic feature of fibrinous pneumonia; by filling and then coagulating within the alveoli and minute bronchi, it renders the lung airless and solid. Later in this stage, the exudate compresses the alveolar capillaries and makes the tissue bloodless. Thus, "gray hepatization" is brought about, the lung remaining solid, but the color changing to grayish or yellowish-gray. Thrombi fill up the branches of the pulmonary artery as far back as the large vessels, but the nutritive vessels are pervious.

3. **Resolution.**—Between the fifth and eighth days, usually, the exudate begins to soften, and the entangled cells, among which are many leukocytes, undergo fatty degeneration. Liquefaction is followed by absorption, and, when the latter is completed, the alveoli are open and the lung is restored to a normal condition. In this process the lung becomes gradually softer, less resistant, and finally elastic. The whole of the affected lobe is not going through these stages at the same time: while the first part attacked is becoming consolidated, neighboring areas are in the state of congestion. The sudden crisis of the third stage, however, puts an immediate end to all processes. The nonpneumonic portions of the lung and the opposite lung may be congested and edematous; the bronchi are congested or in a catarrhal state, and the bronchial lymph-glands are congested, soft, and swollen.

In drunkards and cachectic individuals the exudate is hemorrhagic, and does not solidify, so that the stage of complete consolidation is not reached. In cases that have been prolonged, pressure on a cut surface leaves a pit that fills up with a purulent fluid; this condition, supposed to be a perverted and delayed resolution, has been called "purulent infiltration." In the terminal stage resolution sometimes does not occur, and by the breaking down of the septa an abscess cavity is formed; this empties into a bronchus, or is encapsulated. Gangrene of the lung is a very rare termination, as is also a fibrous alteration called fibrous pneumonia or carnification. An abundant serous effusion may take place into the pleura (pleuropneumonia), and not infrequently, especially after influenza pneumonia, empyema is a final stage.

Next in importance to pulmonary lesions are those of the **heart**, for it is upon the relative integrity of this organ that the fate of the patient most frequently depends. The right heart, as a rule, contains red or white clots that extend into the branches of the pulmonary artery; the left cavities may be empty. The heart-muscles may undergo parenchymatous degeneration. Pericarditis, especially in left-sided pneumonia, and endocarditis are not unusual. This last has the malignant form, and is rapidly fatal. In both lesions, as well as in all exudates, the pneumococcus has been found.

In the **kidney** the cells of the tubules show cloudy swelling or granular degeneration, and in a few cases there is acute nephritis.

The liver is congested, and the **spleen** large and soft.

The nervous system shows few changes, meningitis being the most common.

Symptoms.—Primary fibrinous pneumonia is always a serious disease; and has a necessary intensity, conforming more or less in uncomplicated cases to a definite type. Every variation from this type is unfavorable, whether in the direction of greater or less intensity, or in the loss of essential characteristics. A prodromal period of 2 or 3 days is noted sometimes, with nasal or pharyngeal catarrh, epistaxis, or loss of appetite and diarrhea.

First Stage.—The onset is sudden, with a chill, lasting a half-hour or longer; it is most common and most severe in young adults, but is absent in the aged and in children. After the chill the patient has flushed cheeks, a hot and dry skin, and a rapidly rising temperature; he complains of a sharp stitch in the region of the nipple, in the midaxillary line, or just anterior to the angle of the scapula; inspiration increases the pain, and an involuntary effort is made to relieve it by making the respirations shallow and irregular. A short and sharp cough is accompanied by a viscid sputum in small masses without air-bubbles, and of a peculiar, yellowish-red or "rusty" color. It consists of mucus, blood discs, leukocytes, and minute casts of the bronchioles. In stained preparations the diplococci or other microorganisms are seen.

Some importance as a symptom is to be given to a group of herpetic vesicles on the upper or lower lip, chin, or cheek. The tongue is coated; the urine is scanty, high colored and acid, depositing lithates on cooling, with more lessening of urea, chlorids, phosphates, and sulphates than in other febrile disorders. Headache, a sense of illness and prostration, insomnia, and slight delirium may be present from the beginning. Early in the attack the number of leukocytes in the blood is increased from the normal 8000 or 10,000 to 20,000 and 30,000 or even to 60,000.

They grow in number up to the crisis, and then quickly drop to the normal proportion. These are the symptoms of the stage of congestion and last about 2 days.

The physical signs during this period are diminished expansion, with normal vocal fremitus; the percussion-note is less clear, passing into dulness as consolidation begins; the respiratory murmur is feeble or suppressed; moist or dry râles may be found, and later there is bronchovesicular breathing. Crepitation, the only pathognomonic physical sign, may or may not be heard on inspiration. A pleural friction sound is rarely present.

Second Stage.—No well-defined line separates the symptoms of the second stage from those of the first, but by the second or third day an aggravation of all the symptoms has developed. The patient wears a more anxious expression, one or both cheeks have a dark, sometimes livid red color, the nostrils expand with inspiration, and the lips are often dark red, and in some cases purple. The temperature at the close of the first or second day reaches 104° F. to 105° F., and remains at about this maximum with diurnal variations. The pulse is 110 to 120, its tension and fulness lessening with the progress of the disease and growing feeble and intermittent.

The cough is less frequent than at first, and may, by the third or fourth day, cease altogether. The same is true of the sputum as well as of the local pain; both disappear when the lung is consolidated. The dyspnea, on the contrary, increases; the respirations are shallow, and are 30 to 40 or more to the minute, being relatively more frequent than the pulse. The tongue has a thick white fur, and there is constipation. In some cases jaundice occurs.

The nervous symptoms are very variable, but are often the most striking clinical features. Headache and general aching may disappear with the onset of delirium, which is maniacal or of the low muttering character; the active form occurs in drunkards and in cases of apical pneumonia; the typhoidal form may be present from the beginning or toward the end of the first week, and is accompanied by tremor of the limbs and tongue. In some instances there is mild delirium at night only, the mind being clear during the day, but at all times there is an absence of natural sleep.

The intense toxemia, in addition to the asphyxia and disturbance of the heart and circulation, bring about a very rapid change in the patient's appearance. The flushed cheeks, dilating nostrils, rapid breathing, and restless movements indicate the serious nature of the illness, and the changes for the worse, from day to day, are very decided.

The physical signs of the second stage are: The affected side expands less, and vocal fremitus, unless there is pleural effusion, is exaggerated. There is percussion dulness, with increased resistance over the solid lung, whether base or apex, and this extends upward or downward. Bronchial breathing and bronchophony are heard first over the locality of beginning consolidation, whence they spread over the whole of the pneumonic area.

Third Stage.—The beginning of resolution is a true crisis, and is shown in the sudden drop of the temperature and in the change in all the symptoms. It comes between the fifth and ninth day, being sometimes preceded by pseudocrisis; a normal or subnormal point is reached in from 5 to 15 hours, and is followed by a natural sleep, free sweating, and relief from suffering. The patient then enters upon convalescence.

On *physical examination* a subcrepitant râle (râle redux) is heard in the midst of the bronchial breathing, and the signs of consolidation gradually disappear with multiplying moist râles. Percussion dulness may last for some time, owing to the pleuritic exudate. By the twelfth or fourteenth day the lung has returned to its normal state.

Death may occur in 36 or 48 hours, or it may come in the last days of the first or beginning of the second week. Muscular and nervous exhaustion, with increasing feebleness of the pulse, delirium and coma, burning dry heat of the skin, cold extremities, and cyanosis are symptoms preceding death. It may be due to intense infection affecting the nerve-centers and the heart, to hyperpyrexia, or asphyxia due to loss of respiratory surface, or to some complication.

Variations.—Temporary hyperpyrexia during the first 4 days is not uncommon; in about one-fourth of the cases a temperature of 105° F. or over is maintained for 2 or 3 days, and in fatal cases this may be continued to the end. In children vomiting or a convulsion takes the place of a chill; nervous symptoms predominate, and the physical signs are slow in developing. As a rule, there is no localized pain, cough, or expectoration. In the aged the onset is insidious, the fever is less, cough and sputum may be absent, and the physical signs appear slowly. In alcoholics cerebral symptoms and fever may be the only indications to be relied on, the physical signs alone giving sure evidence of the disease. In the cachexias or in enfeebled constitutions consolidation of the lung is not complete; there is great prostration, with prune-juice expectoration.

Instead of resolution occurring on or about the ninth day, the progress may be delayed by the continuance of fever of irregular course and by persisting moist râles. It is under these circumstances that the lung is believed to be in the condition of "purulent infiltration." Delayed resolution and the continuance of the physical signs of consolidation with fever may end after some weeks in the sudden discharge from the lungs, through the bronchial tube, of a large quantity of pus—the so-called abscess of the lung. A much graver termination is gangrene of the lung, which is brought about by the closure of a nutrient vessel supplying the pneumonic area; this condition is shown by fetor of the breath, an offensive thin sputum, great prostration, and sometimes by the physical signs of a cavity.

The symptoms differ more or less from this description when pneumonia develops during the progress of, or at the end of, the various acute or chronic diseases enumerated under the head of etiology. It is then frequently the closing event,

and the picture is modified by the peculiar symptoms in each case. The anatomic condition of the lung and the physical signs are the same, however, as in the primary form. In secondary pneumonia the chill is usually absent and the temperature range is less constant, and, in many cases, not so high as in primary pneumonia. Cough, sputum, and localized pain may also be absent. The breathing is always much embarrassed and the serious nature of the illness is shown in the rapid decline of strength.

Complications.—In the respiratory organs the complications of pneumonia are laryngitis, general bronchitis, collateral hyperemia, and edema of the opposite lung. The fibrinous pleurisy that is a necessary part of pneumonia may be attended by the effusion of serum (pleuropneumonia) and empyema in from 1 to 5 percent of all cases, and may develop after the pneumonic symptoms have subsided. Pericarditis has been noted in 2 to 8 percent of cases, and endocarditis was present in 16 out of Osler's 100 cases, but in only 7 of Pye-Smith's 425 cases. The daily examination of heart would probably disclose a large proportion of cardiac lesions. Symptoms in pericarditis have not the same value as physical signs; endocarditis has, however, the characteristic and rapidly progressive asthenia of the malignant form. Meningitis occurs in intense general infection, and is associated not infrequently with malignant endocarditis; the symptoms are cerebral—active delirium passing into the low muttering form with coma. Other and rarer complications are acute nephritis, catarrhal, membranous, or ulcerative colitis, icterus, arthritis, otitis media, parotitis, thrombosis of the femoral vein, and peripheral neuritis.

Diagnosis.—Pneumonia developing in a previously healthy adult is recognized by the sudden chill, the high temperature, side pain, rusty or bloody sputum, and by physical signs that point to the lung as the seat of attack. Stained specimens of the sputum reveal the diplococcus in most cases. The subsequent course of fever, with the consolidation of the lung, the nervous and other symptoms, make a picture that is not easily mistaken. If any doubt exists, the critical change, at a more or less fixed date, clears up all uncertainty. Blood examination is of great value, as a leukocytosis of from 20,000 to 30,000, and ranging as high as 60,000, is invariably found; it varies with the seriousness of the attack, and continues up to the crisis. In secondary pneumonia the features are so modified by the primary disease that the diagnosis is often difficult. Physical signs have the most value, and the daily examination of the thorax will often explain the nature of symptoms that bear but little likeness to those of pneumonia. In drunkards, children, and old persons, fever alone, or associated with cerebral disturbance, may be the only symptom of a pneumonia that would escape detection if the lungs were not examined.

Pleurisy is distinguished from pneumonia by the lessened movement of the chest, the absence of fremitus, and by egophony. The symptoms, too, are less acute, and the characteristic sputum is wanting. If pleurisy with effusion complicates pneumonia, a judicious interpretation of the united symptoms and physical signs makes the diagnosis not a difficult one. In cases of great uncertainty an aspirator can be used without any danger.

Bronchopneumonia or catarrhal pneumonia is more common than fibrinous pneumonia in infancy and in advanced life, and as a sequence to pertussis and measles. It is preceded by the symptoms and physical signs of bronchial catarrh, the consolidation is in both lungs, although not always at the same time; the sputum is mucopurulent, and contains no pneumococci, but streptococci and staphylococci; the temperature is lower and more irregular than in lobar pneumonia, and the symptoms are without any definite duration, lasting longer, as a rule, than in fibrinous pneumonia and coming to an end gradually without crisis.

In hypostatic congestion with edema, cough, frothy, bloody expectoration, and dyspnea are present, but there is no chill and little or no fever. Slight dulness on percussion and subcrepitant râles are found on both sides.

Apical pneumonia and **tuberculosis** are sometimes confounded; both have local pain, cough, bloody expectoration, and fever; the physical signs of consolidation are the same, although advancing at a different rate and running a different course. But the fever in pneumonia is continued, and in tuberculosis is remittent or intermittent; bacilli in the sputum, and the absence of leukocytosis also favor the existence of tuberculosis. After 2 weeks have passed there can no longer be any question if the local signs and the symptoms continue unchanged. **Cancer** of the lung, a rare condition, resembles pneumonia up to a certain point, but the onset is gradual, without chill or much fever, and there are constant pain and rapid emaciation. In **appendicitis** pain and rigidity may be reflected through the lower intercostal nerves and simulate lobar pneumonia.

Croupous Pneumonia.	Pleurisy.	Typhoid Fever.	Acute Phthisis.
Subjective Symptoms.	*Subjective Symptoms.*	*Subjective Symptoms.*	*Subjective Symptoms.*
1. Onset sudden, with severe chill.	1. Onset sudden, with chill or chilly sensations.	1. Gradual onset, with vague pains, epistaxis, diarrhea, and eruption.	1. Onset sudden, with severe chill; history of phthisis in family.
2. Pain in affected side not so great as in pleurisy.	2. Sharp pain (stitch) in affected side.	2. Pain on pressure in right iliac region; tenderness about spleen.	2. Same as pneumonia.
3. Cough which increases pain in affected side.	3. Severe cough often cut short by "stitch" in side.	3. Slight cough.	3. Same as pneumonia.
4. Delirium after first two days.	4. Delirium uncommon.	4. Delirium frequent.	4. Same as pneumonia.

Croupous Pneumonia.	Pleurisy.	Typhoid Fever.	Acute Phthisis.
Objective Symptoms.	*Objective Symptoms.*	*Objective Symptoms.*	*Objective Symptoms.*
1. High fever 104°, and very regular.	1. Moderate irregular fever.	1. Moderate fever and regular.	1. High irregular fever, frequently varying several degrees.
2. Pulse full, bounding; rate moderately increased.	2. Pulse full; rate slightly increased.	2. Pulse dicrotic; rate gradually increased.	2. Pulse rapid and feeble.
3. *Inspection.*—Diminished expansion.	3. Same as pneumonia.	3. Expansion normal.	3. Same as pneumonia.
4. *Palpation.*—Increased vocal (tactile) fremitus.	4. Diminished vocal fremitus.	4. Fremitus normal.	4. Same as pneumonia.
5. *Percussion.*—Note in first stage hyperresonant; subsequent dulness at base of lung.	5. Percussion-note dull.	5. Percussion-note normal.	5. First stage same as pneumonia; later dulness at apex of lung.
6. *Auscultation.*—Bronchial breathing; crepitant râle; bronchophony, occasionally pectoriloquy.	6. Respiratory murmur almost inaudible; pectoriloquy.	6. Sonorous and sibilant râles are common.	6. Bronchial breathing; mucous small râles; later gurgling râles.
7. *Mensuration.*—Normal on each side.	7. Increase in anteroposterior diameter on affected side.	7. Normal.....	7. Normal or decreased diameter.
8. Sputum "rusty color," containing diplococci.	8. Sputum whitish, frequently streaked with blood.	8. Sputum normal.	8. Sputum often contains blood and tubercle bacilli.

Prognosis.—The fatality of primary fibrinous pneumonia varies from 15 to 25 percent. Among young, healthy men composing armies, it is much less; in 40,000 cases in the German army the death-rate was 3.6 percent. In children under 5 years it is not above 3.3 percent; after 50 years it reaches 50 percent and upward. This difference is due to the lessened resistance of the aged, and especially to senile degenerations in the heart, kidneys, and other organs. In hospitals the mortality is higher than in private practice, in the proportion of 26.1 (Osler to 12 percent. Previous conditions of ill health and the drinking habit are the chief causes of this difference; the latter has a most fatal influence in pneumonia. More deaths occur in the autumn and winter than in the spring and summer. In individual cases the danger lies in the toxemia and in the mechanic interference with respiration and circulation. Pneumonia of one lobe is much less serious than of the whole lung, and this is less so than double pneumonia, which has a death-rate of 50 percent and upward.

Unfavorable symptoms are a temperature above 105° F., increasing frequency and weakness of the pulse, feeble heart-sounds, prune-juice sputum, early delirium of the maniacal or the low muttering form, muscular tremor, profuse sweating (except at the crisis), excessive tympanites and hiccup, cold extremities, and cyanosis and abundant bronchial and tracheal râles.

A slight leukocytosis, below 14,000, or a very high leukocytosis with a low temperature, are discouraging indications. Complications of the heart, kidneys, and meninges of the brain add greatly to the danger.

Secondary pneumonia has no fixed death-rate, the result depending upon the nature of the previous or coexisting illness; but in all cases the mortality is higher than when pneumonia begins in previously healthy persons.

Treatment.—Experiments on animals and the inoculation of cases of pneumonia with the blood-serum of immunized rabbits and of convalescents from pneumonia have given much hope that ultimately an antipneumotoxin may be found. An abortive or distinctly curative treatment cannot be employed generally until a successful antitoxin is as readily obtainable as the antitoxin of diphtheria. See Pneumococcus Infections.

In the meantime pneumonia must be recognized and treated as an acute, infective disease, tending to self-limitation, the chief dangers of which are, first, toxemia, with the resulting high fever and exhaustion of the heart and nervous system; and, secondly, the lessened air-space and obstruction to circulation through the right heart and pulmonary vessels. Fresh air is of vast importance. The patient should be placed in a well-ventilated room, with an open fire and open window; the temperature of the room should be kept below 70° F.—65° F. being the minimum. In no disease is a trained nurse more needed, and strict sick-room discipline should be maintained from the beginning. The strength should be husbanded by the use of the bed-pan, and by not permitting the patient to sit up for food or for examinations of the chest. Milk is the best food—3 to 4 ounces every 3 hours, so as to amount to 2 or 3 pints in the 24 hours. Tympanites and undigested casein in the stools call for a less quantity and for dilution of the milk with barley or Vichy water. If there is a distaste for milk, koumiss, matzoon, or farinaceous gruels may be given as substitutes. The disease is of short duration, and but little food can be digested and assimilated; fever, prostration, and dyspnea will be increased by excessive feeding. The craving for liquids must be gratified by the free use of cold water, or by any of the effervescent waters.

The eliminative treatment is important. Perspiration should be promoted and a purgative may be prescribed at the start—calomel is the best, followed by a saline. No other drug, as a rule, is needed in the first stage, and in many cases none will be called for throughout the entire illness. A. H. Smith believes in the efficacy of "an attack upon the pneumococcus through the

medium of the blood, the object being that the exudate, when it escapes into the air-cell, shall be impregnated with a substance that will unfit it to serve as a culture medium." To effect this may be given calomel, 20 to 30 grains in one dose; chloroform or creosote (creosotal preferably) by the mouth or by inhalation; quinin, or a salicylate. Creosotal is given in 10 minim doses in capsule or emulsion every 4 hours. Sodium salicylate or aspirin is to be preferred, 60 to 120 grains in 24 hours, after the plan of Robert Liegel.

It is claimed for the external applications of cold water that, as in typhoid fever, they not only reduce temperature, but eliminate the toxins, and thus strengthen the heart and relieve the nervous symptoms. For adults this can best be done by applying to the front and back of the entire chest a compress made after the pattern of the oil-silk jacket, wrung out of water at 60° to 70° F., and covered with flannel. This is reapplied every half-hour or hour, according to the height of the temperature and the effect produced; it should be discontinued when 99.5° F. has been reached.

Mays uses large, flat, rubber ice-bags—2 to the head and 2 or more to the chest. He claims a mortality of 4.25 in 400 collected cases treated with ice applications. It must be taken into account, however, that a number of these cases were in children.

The cold tub-bath is objectionable, because it fatigues and excites the patient. Tepid or warm baths are preferable. In some cases the warm or cold wet-pack, with an ice-bag to the head, has a most happy effect, especially in the onset of pneumonia in children, with cerebral excitement and high temperature. The patient may be left in the pack from one-half an hour to an hour. Cold sponging my take the place of the compress or pack if a less decided effect is desired.

In serious cases hypodermoclysis is efficacious, 1/2 to 1 pint of normal hot salt solution (0.6 per cent) being injected daily or oftener.

Optochin (ethyl hydrocuprein) has been recommended. It is said to reduce the death rate, but it may produce disagreeable symptoms such as deafness, dimness of vision, and even blindness. See Optochin.

Insomnia is inevitable, and a too vigorous effort should not be made to relieve it. It is best treated by hydrotherapy, but if there is no sleep in 24 hours, alcohol, sodium bromid, chloralamid (10 to 20 grains), or hyoscin hydrobromid (1/100 grain) hypodermically, may be given at night. Morphin, however, is most to be relied on for this purpose, given hypodermically in doses of 1/32 to 1/16 grain, and repeated in 1 to 2 hours, the dose to be increased on subsequent nights if found to be too small. In cases of feeble heart it can be combined with strychnin or other cardiac stimulants. Dover's powder has no advantage over morphin.

The treatment of delirium is covered by the foregoing suggestions. In alcoholic cases it is necessary to give stimulants according to the degree of habitual use.

The heart and pulse must be sustained from the beginning. Alcohol and strychnin, 1/60 to 1/20 grain, repeated every 3 to 6 hours, are the best remedies for this purpose. Atropin, caffein, strong coffee, or strophanthus may be used as aids or substitutes. Nitroglycerin has a special influence and value in cases of weak heart, with venous congestion of the organs; the rule as to dosage should be to give enough of it to produce a desired effect and to sustain this effect as long as necessary.

Digitalis has been by turns condemned and praised. Theoretically, there are objections to its use; it increases arterial tension and does not relieve the pulmonary stasis, but it has the property of neutralizing the pneumococcus toxin, and has been given with good effect in large doses by Petresco, of Bucharest, and by Maragliano. The former gave 60 to 90 grains of the dried leaf daily. Maragliano gave 60 grains in infusion on the first day, repeated in lessening doses as the pulse becomes slower. But little support has, as yet, been given to this heroic procedure.

For the relief of dyspnea and cyanosis, oxygen inhalations are usually employed. Their effect, however, is rarely what theoretic considerations would lead one to look for. In the severe cases in which such effect is most needed, the improvement in the character of the pulse, in the breathing and color of the lips, is temporary and not definite and complete. Still, it should always be used in such cases in conjunction with cardiac stimulants.

Secondary pneumonia, as a rule, needs early alcoholic stimulants and a treatment modified by the preceding disease. In influenza pneumonia great irregularity and weakness of the heart are a greater danger than the condition of the lung, and call sometimes for strychnin and nitroglycerin in large doses until improvement is assured. In the pneumonia of typhus and typhoid fever and other secondary forms, hydrotherapy is much less efficient than in primary cases. Each complication must be met, when possible, by treatment. Paracentesis may be needed in pericarditis and in pleurisy; and in empyema, section of the rib and drainage should be done as early as the diagnosis is made.

A word should be said about bleeding in pneumonia. As a rule of treatment, it received its death-blow from J. Hughes Bennett, and has not been since advised except as a resort in exceptional cases. In young, vigorous, and plethoric adults, with hyperpyrexia and a pulse of high tension, it may be beneficial in the first 48 hours. A small bleeding of 6 or 8 ounces has been advised in later stages, when there is cyanosis from overdistention of the right heart. The advocacy of venesection is only half-hearted, and its use is hedged about with so many restrictions that the rule of never bleeding, under any circumstances, is a safer one to follow. To restore faith in bleeding, even as a resort in exceptional cases, severe therapeutic trials are needed to prove the value of the favorable, but limited, individual support of this lost art. Instead of bleeding veratrum viride is highly praised by some.

The "*open air treatment*" is beneficial. The patient must be well wrapped up and protected, and then allowed all the fresh air that is available. See Pneumococcus Infections.

PNEUMONOKONIOSIS.—A general term indicating chronic disease of the lungs due to the inhalation of dust. Various names have been devised denoting the kind of dust causing the inflammation; *anthracosis* or coal-miner's disease; *siderosis*, due to inhalation of iron dust; *chalicosis*, due to inhalation of mineral dust as of lead in lead miners' phthisis; *lithosis* or *silicosis*, stone-grinders' or potters' phthisis, due to inhalation of particles of silica. Steel-grinders' phthisis is probably due to the particles of grindstone that are inhaled. Ganister disease is due to the dust of a siliceous rock. The dust particles, when they can no longer be disposed of by the natural protective agencies of the lungs, find their way into the peribronchial and periarterial lymph-spaces, where they set up an inflammation. This is characterized by a marked tendency to fibroid change, manifesting itself in the formation of hard, indurated nodules of various size. The fibroid areas may soften and break down, forming the so-called ulcers of the lung. Tuberculosis is prone to develop for the pulmonary lesions form a favorable nidus for the tubercle bacillus.

PNEUMOTHERAPY.—See TUBERCULOSIS (Pulmonary).

PNEUMOTHORAX.—Air in the pleural sac.

Etiology.—(1) Perforation of the pleura adjacent to a phthisical cavity; (2) perforation of the diaphragm from malignant disease of the stomach or esophagus; (3) rupture of the lung by overstraining; (4) rupture of empyema into the lung; (5) traumatism.

Pathology.—There is effusion of air into the pleural sac. Coexisting with pneumothorax there is frequently an effusion of fluid into lung tissue—pneumohydrothorax, or pneumopyothorax, if purulent. The disease is usually unilateral, and may cause great displacement of the heart. The lungs are usually smaller than normal, due to the compression.

Symptoms and Clinical Course.—Sudden pain, dyspnea, cyanosis, or collapse (subnormal temperature, rapid pulse, and cold extremities) may mark the onset of the disease. When slight, no special symptoms are produced in many cases. If pleurisy is present, the characteristic stitch in the side is pronounced.

Physical Signs. Inspection.—There is bulging of the intercostal spaces, usually limited to one side, and displacement of apex-beat.

Palpation shows diminished vocal (tactile) fremitus.

Percussion-note is tympanitic over affected area, while immediately below this area dulness is elicited on account of presence of fluid. On turning patient to opposite side, the fluid gravitates and dulness may be replaced by tympany.

Auscultation shows an absence of the respiratory murmur and normal vocal resonance. If due to rupture of phthisical sac, amphoric breathing is heard. At times metallic tinkling is detected. This is due to the dropping of fluid from above downward in an inclosed sac.

Succussion detects splashing sound.

Bell tympany is frequently present. It is elicited by placing the flat surface of a coin on the bare chest over affected area, and on being struck by another similar coin while listening over opposite side of chest in same relative position, a clear metallic sound is heard.

Diagnosis.—Pneumothorax may be mistaken for a diaphragmatic hernia, but the stomach-tube would indicate the displacement. In dilated stomach the tympanitic note is continued downward to umbilicus, as well as upward.

A large phthisical cavity simulates pneumothorax closely, and in many cases is identical with it. Usually phthisical cavities do not produce bulging of the intercostal spaces, are circumscribed, and the dulness is not movable.

Prognosis is unfavorable.

Treatment is symptomatic. If collapse threatens, strap the chest by means of adhesive plaster, and give hypodermics of whisky, strychnin (1/4 grain), and atropin (1/125 grain). Keep up bodily temperature by application of hot-water bag or hot blankets to extremities.

PODAGRA.—See GOUT.

PODODYNIA.—Pain in the foot, and especially in the sole of the foot; the word is now usually limited to painful heel—a neuralgic condition about the heel, attended with little or no swelling, no discoloration, and no affection of the joints. The pains are very severe, though often limited to a very small area. It may be associated with rheumatism or gout, and with certain occupations requiring much standing.

PODOPHYLLUM (May-apple).—The root of mandrake, *P. peltatum*. Its active principle is a *resin* which is official and contains two isomeric glucosids, *podophyllotoxin* and *picropodophyllin;* also podophyllinic acid and protocatechuic acid. Podophyllum probably contains the alkaloid *berberin*, which is found also in berberis, hydrastis and other plants. It is a tonic astringent, cholagogue, and purgative, and is likely to produce nausea. It is recommended in remittent fever, bilious vomiting, and malarial jaundice. Dose of the root, 5 to 20 grains; of the resin, 1/8 to 1 grain. **P., Fluidextract.** Dose, 2 to 20 minims.

Pilulæ Podophylli, Belladonnæ et Capsici, have in each pill 1/4 grain of the resin, with 1/8 grain extract of belladonna and 1/2 grain capsicum. Dose, 1 to 2 pills.

For constipation:

℞. Resin of podophyllin, Powdered aloes, } each, gr. iij to vj
Extract of nux vomica, Extract of belladonna, } each, gr. iv.

Make 24 pills. One pill night and morning.

POIKILOCYTOSIS.—See BLOOD.

POISONING.—According to Reese, a poison is a substance capable of producing noxious and even fatal effects upon the system, no matter by what avenue it is introduced; and this, as an ordinary result in a healthy state of the body, and not by a mechanic action.

Witthaus defines a *poison*, as "a substance which being in solution in, or acting chemically upon, the blood may cause death or serious bodily harm;" and a *corrosive*, as "a substance capable of causing death or injury by its chemical action upon a tissue with which it comes in direct contact."

The most energetic poisons are hydrocyanic acid, potassium cyanid, nicotin, strychnin, phenol, and some reptile venoms. The poisons usually selected by poisoners for criminal purposes on others are those which produce effects resembling the symptoms of natural disease, as arsenic, colchicin, tartar emetic, strychnin, morphin and aconite. Those generally chosen for suicidal purposes are such as may be most readily obtained by the laity, namely—phenol, morphin, illuminating gas, charcoal gas and potassium cyanid, the first being easily purchased for disinfecting purposes, while the last is commonly used in the arts.

Diagnosis.—If diagnosis cannot be made from direct history, the process of exclusion should be instituted.

The following lists have been compiled by Murrell, but no attempt has been made to render them complete, and they must be taken as being merely suggestive:

The Patient is Dead.—Prussic acid (death in a few minutes at the outside); cyanid of potassium (usually kills very quickly); strong ammonia (may kill in a few minutes); carbonic acid gas (if pure, may kill almost at once); carbonic oxid; oxalic acid. Almost any active poison if given in a very large dose.

The Patient is Comatose.—Opium; morphin; alcohol; chloral; chloroform; camphor.

The Patient is in a Condition of Collapse.—Strong acids; alkalies; aconite; antimony; arsenic; tobacco; lobelia. Most poisons cause collapse toward the last.

The Patient is Delirious.—Belladonna (noisy, pleasing delirium, "the insane root that takes the reason prisoner"); hyoscyamus; stramonium; cannabis indica; alcohol; camphor.

The Patient is Tetanized.—Nux vomica; strychnin (think of vermin-killers); antimony; arsenic. There may be a condition approaching tetanus from excess of pain—in poisoning by strong ammonia, for example.

The Patient is Convulsed.—This may mean anything, the term being used vaguely. Antimony; arsenic; carbonic oxid; aconite. Strong acids, such as acetic or sulphuric, or strong alkalies, such as ammonia.

The Patient is Paralyzed.—Physostigmin; conium (from below upward); gelsemium; aconite; arsenic; lead.

The Pupils are Dilated.—Belladonna and atropin; hyoscyamus; stramonium; opium (in last stage); aconite; alcohol; chloroform (when taken in liquid form); conium.

The Pupils are Contracted.—Opium (very strongly if a large dose); physostigmin; chloral (during sleep).

The Skin Dry.—Belladonna and atropin; hyoscyamus; stramonium.

The Skin Moist.—Opium; aconite; antimony; alcohol; tobacco; lobelia. Almost any poison during the stage of collapse.

Rash on the Skin.—Belladonna (resembles rash of scarlet fever); stramonium (much like the belladonna rash); chloral (urticaria); arsenic (eczema, or may be like scarlet fever); antimony (pustular, like small-pox, but rare); opium (itching, followed by urticaria or papulous or roseolous patches, not common). Many other drugs excite cutaneous eruptions. For example, bromid of potassium and tar produce acne; copaiba, cubebs, and salicylic acid give rise to urticaria, and iodid of potassium may bring out a crop of petechiæ. Croton oil, tartar emetic, sulphur, hydrastis, and arnica are well-known rash-producers when applied locally. Murrell has known croton chloral hydrate, given for whooping-cough, to bring on urticaria. The discoloration of the skin resulting from the long-continued administration of silver requires no detailed mention.

Odor of the Drug on the Breath.—Prussic acid; laudanum; alcohol (brandy, whisky, etc.); carbolic acid; acetic acid; ammonia; chloroform; creosote; iodin; phosphorus; camphor; nitrobenzol. The odor is not always a reliable guide; for example, laudanum is not uncommonly taken in porter.

The Mouth and Tongue Dry.—Belladonna and atropin; hyoscyamus; stramonium; opium.

Salivation.—Arsenic; ammonia; cantharides. Most drugs which produce a corrosive action on the mucous membrane of the mouth or esophagus. Mercury, jaborandi, and muscarin may also be mentioned.

The Mouth Bleached.—Carbolic acid (mucous membrane white and hard); ammonia (epithelium coming off in flakes); potash; soda; nitric acid (white, soft, or yellow); corrosive sublimate. The numbness of the lips, mouth, and tongue, produced by aconite, will not be forgotten.

The Patient is Vomiting.—Arsenic (brown, mixed with blood); antimony (white, stringy mucus, may be tinged with blood); digitalis (vomited matter has a grass-green color); aconite; colchicum; colocynth; ammonia (stringy saliva mixed with blood, fumes with hydrochloric acid); phosphorus (vomited matter luminous in the dark).

The Patient is Purged.—Arsenic (continuous, with much pain, stools mixed with blood); antimony; corrosive sublimate (green in color, mixed with blood); cantharides (blood and slime); digitalis; colchicum; colocynth.

The Patient is Suffering from Colic.—Lead (about navel, eased by pressure); copper; arsenic; colocynth.

The Patient is Suffering from Cramp.—Arsenic; antimony; lead.

The Drug was Given Hypodermically.—Morphin; atropin; strychnin.

The Poison was Inhaled.—Ammonia; prussic acid; chloroform; ether; benzin; carbonic acid gas; carbonic oxid; coal-gas; sewer gas; cesspool gas and emanations.

Poisons Commonly Used for Murder.—Arsenic; antimony; aconite; digitalis; opium; strychnin; prussic acid.

Poisons Commonly Employed for Suicidal Pur-

poses.—Opium and its preparations commonest of all poisons); oxalic acid; rat paste; prussic acid; chloral; sugar of lead; strychnin. Patent medicines of all kinds unintentionally.

Drugs Used Popularly as Abortifacients.—Ergot; rue; gin and pennyroyal; savin; bitter apple (colocynth, very popular); hickery pickery (hiera picra, or holy bitters, a mixture of 4 parts of aloes and 1 of canella bark); Spanish fly (cantharides); yew-tree tea; green tea in large quantities; quinin is often supposed to exert a specific action on the pregnant uterus; actæa racemosa (cimicifuga racemosa) is sometimes said to be an abortifacient, but there is very little truth in the statement; at all events, 1/2 of a dram of the tincture 3 times a day is safe enough even in the later months of pregnancy. Pulsatilla is supposed to be capable of producing abortion, but this again rests on very imperfect evidence. "A handful of parsley chopped fine in a bottle of gin, allowed to stand a week, and a wineglassful 3 times a day" (Hospital Patient). Parsley contains apiol, which is a powerful oxytoxic. Jaborandi was at one time supposed to exert a powerful action on the uterus, but the idea is now exploded.

Indigenous Poisonous Plants.—Woody nightshade (*Solanum dulcamara*); garden nightshade (*Solanum nigrum*); deadly nightshade (*Atropa belladonna*); aconite, monk's-hood, wolf's-bane or blue-rocket (*Aconitum napellus*); foxglove (*Digitalis purpurea*); spotted hemlock (*Conium maculatum*); arum (*Arum maculatum*); colchicum (*Colchicum autumnale*); bryony (*Bryonia dioica*); henbane (*Hyoscyamus niger*); fly agaric (*Amanita muscaria*); mezereon, or spruge olive (*Daphne mezereum*); laburnum (*Cytisus laburnum*); and a host of others. These will be found figured in Stephenson and Churchill's "Medical Botany," and in Bentley and Trimen's "Medicinal Plants."

General Principles of Treatment (Potter)

(1) Lose no time. (2) Use the best remedy obtainable at once. (3) Get rid of the poison. (4) Stop its action. (5) Remedy the mischief already done. (6) Fight against the tendency to death (Tanner). In the treatment of poisoning, whether by mineral or vegetable substances, if the poison is known the first indication is to administer the proper chemical *antidote,* so as to render it harmless or comparatively so. Next, the stomach should be emptied and washed out, lest the newly-formed compound be absorbed after a time; also to remove any poison which may have escaped the action of the antidote. Next, the appropriate *antagonist* should be administered, to counteract the effects of such portion of the poison as may have been absorbed. Lastly, such *antagonistic measures* should be employed as may sustain the action of any organic function showing signs of failure. In most cases of alkaloidal poisoning absorption has proceeded so far before professional assistance is obtained that antidotes are of no value, hence reliance can be placed only upon the physiological antagonist and such supporting measures as will tend to maintain vitality until the poison can be eliminated by the natural channels.

Antagonists are agents which oppose each other in their physiological action, and may be employed against each other as counterpoisons, to neutralize their effects upon the organism. They do their work in the blood and tissues, after absorption, and are especially available against poisons administered hypodermically, in which cases antidotes are useless. *Substances* so employed are generally the active principles of plants, a few being chemicals, as oxygen and choral. *Antagonistic measures* include such proceedings as tend to neutralize the remote effects of poisons, as artificial respiration, faradism of the respiratory muscles, hot and cold applications, douching, constant motion or absolute repose, and the use of physiological (normal) salt solution to maintain circulation and increase elimination.

Antidotes affect a poison, either physically or chemically or both, so as to remove it from the body or alter its character before absorption, and thereby prevent its toxic action upon the organism. They do their work in the alimentary canal or in the respiratory passages, and are applicable to vegetable as well as mineral poisons, but they are not available against poisons administered hypodermically. Among them are emetics, cathartics, washes, injections, ligatures, poultices, the use of the stomach- pump, of tourniquets, etc., which are termed *mechanical antidotes;* and the *chemical* or *true antidotes,* which include albumin, milk, charcoal, soap, starch, oils, tannin, turpentine, acids, alkalies, potassium permanganate, carbonates, hydrates, sulphates, sodium chlorid, iodin, iron preparations, etc.

Acids.—Vegetable acids, as acetic (or vinegar), citric (or lemon-juice), and tartaric, are employed as antidotes against the poisonous alkalies and alkaline carbonates. Sulphuric acid, well diluted with water, is antidotal to the soluble salts of barium and lead, with which it forms insoluble sulphates; also as a prophylactic against lead poisoning.

Albumin is an ideal chemical antidote, being harmless, easily procured, and forming compounds (which are more or less insoluble) with most of the metallic salts, corrosive alkalies and mineral acids, as also with iodin, bromin, chlorin, creosote, anilin, and alcoholic solutions of most of the alkaloids. It is especially suitable against inorganic poisons, and was recommended by Orfila for invariable use, even on the mere suspicion of poisoning. It should be well diluted, the whites of four eggs to a quart of lukewarm water; and should be followed by emetics and cathartics, as many of its compounds are soluble in an excess of itself.

Ammonia, diluted, used by inhalation, is an efficient antidote against the vapors of corrosive acids and nitrobenzol, also against chlorin, bromin, and hydrocyanic acid.

Calcium hydroxid and carbonate, in the form of lime-water, chalk, eggshells or powdered oystershells are used against acids, both mineral and organic, and especially against oxalic acid and the acid oxalates, which they neutralize and convert into the insoluble calcium oxalate.

Carbonates and bicarbonates of sodium and potassium are employed against most of the

poisonous metallic salts, especially those of zinc, which they immediately decompose, forming insoluble basic compounds; also against iodin, bromin, and potassium dichromate, forming the neutral chromate with the latter and harmless salts with the former. They are useful in dilute solution against acids, but are less easily tolerated than magnesium sulphate. They are contraindicated in poisoning by oxalic acid, with which they form dangerous compounds. Ammonium carbonate, in dose of 5 grains, administered hypodermically in the vicinity of wounds caused by poisoned arrows, was repeatedly used by Dr. Parke, the surgeon of Stanley's last expedition in Africa, with entire success in saving life when it was employed immediately after the injury. Persons so wounded, if they were at too great a distance to receive this treatment, invariably died within a short time.

Cathartics are generally employed after the use of a chemical antidote, to remove the compounds formed thereby from the intestinal canal. The best are castor oil, croton oil, senna, and magnesium sulphate (Epsom salt). *Castor oil* protects the mucous membrane and obstructs absorption, but is contraindicated in poisoning by phosphorus, phenol, copper salts, or cantharis, the absorption of which is aided by oils and fats. *Croton oil* is rapid and powerful in the dose of from 1 to 5 minims, in a bread pill. *Magnesium sulphate*, in the dose of 1 to 4 ounces, well diluted, is of special service in chronic lead poisoning and to remove antidotal compounds from the intestines. Senna, gamboge, and other drastics are the best cathartics in narcotic poisoning.

Charcoal has some antidotal value against many alkaloids, the metallic salts, and phosphorus, slowing their toxic action and postponing their effects, probably by a protective action upon the gastric walls. It has the valuable property of absorbing gases, but enters into no fixed compound with any mineral or vegetable poison. Fresh animal charcoal is the best, though wood charcoal is efficient, but in less degree.

Chlorin in the form of chlorin water, Labarraque's solution, or Javelle water, is employed externally as an antidotal wash for snake-bites and other poisoned wounds; also, well diluted, internally against alkaloids and other vegetable and animal poisons; and as a spray for antidotal inhalation against coal gas (carbonic oxid), ammonia, phosphoreted and sulphureted hydrogen, also hydrocyanic acid.

Copper carbonate, in dose of 3 to 6 grains, with sugar and water, preceded and followed by an emetic, is recommended in phosphorus poisoning, being supposed to coat the particles of phosphorus first with a layer of copper phosphide and then with one of copper itself, thus preventing their solution in the fluids of the stomach.

Emetics, when employed, should be used without delay. They are often rendered needless by vomiting induced by the poison itself, or by the free use of diluent drinks; and are contraindicated when there is severe corrosion of the alimentary canal or when abdominal inflammation exists. The best emetics are: *Zinc sulphate*, for stomachal administration, being non-nauseating, 20 to 30 grains in water, 5 grains for children. *Apomorphin*, 1/16 to 1/8 grain, hypodermically, when narcosis prevents the use of emetics by the mouth. It should be administered hypodermically, as it is very uncertain in action when given otherwise. The following may be used: Copper sulphate, 1 to 5 grains in water; ipecac, in powder; emetin, 1/12 to 1/3 grain; tartar emetic, 1 1/2 grain, acts slowly and is depressant; turpeth mineral; cadmium sulphate; sodium chlorid (common salt), 2 teaspoonfuls in a pint of water; mustard, 2 teaspoonfuls in a cup of warm water; also olive oil, soap-suds, snuff, melted fats, and tickling the fauces with the finger or a feather. *Sodium chlorid* as an emetic is contraindicated in poisoning by tartar emetic or corrosive sublimate, and so also are oils and fats and substances containing them, in poisoning by phosphorus, cantharis, phenol or copper salts.

Gelatin is of especial value against iodin, bromin and the alums, but requires too much time for its preparation, as it should be broken up, soaked in water for half an hour and reduced to the consistency of honey.

Gluten is of value against corrosive sublimate, but is less so than albumin and is not easily obtained.

Gum arabic, in the form of mucilage, is chiefly used as a protective against corrosive poisons, and has been recommended in copious draughts against poisoning with the bismuth salts.

Iodin, in very dilute solution, is used as an antidote against alkaloids and their salts, other vegetable poisons, and snake-venom. All its compounds are more or less soluble and toxic, and must therefore be removed from the system as soon as possible. *Bouchardat's antidote for vegetable poisons* consists of 3 grains of iodin, 30 grains of potassium iodid and 11 ounces of distilled water. The dose, which is from 1 1/2 to 3 ounces, should be repeated frequently.

Iron.—The **hydroxid** $Fe(OH)_3$, is by far the best antidote to arsenic in solution or in a soluble form, as it combines with the latter to form a ferrous arsenate, and also protects the gastrointestinal mucous membrane against the local action of the poison. In the proportion of 10 parts to one of arsenic the union is very complete, but its union with the salts of arsenic is limited even when it is in great excess, though much more effectual if there is added to it a small amount of ammonia or other caustic alkali, or if the basic ferric acetate is mixed with it. For the preparation of the official arsenic antidote see Arsenic. Dialyzed iron, saccharated iron, and the basic ferric acetate have all been used with more or less success in arsenic poisoning.

Magnesia (MgO), is obtained by heating magnesium carbonate, which is a compound of the hydroxid and carbonate of magnesium with water. When the carbonate is heated at a low temperature it becomes calcined, losing CO_2 and H_2O; then mixed with 25 times its weight of warm water it becomes gelatinized, in which condition it is best for antidotal purposes, in doses of from 1 1/2

to 2 ounces, at short intervals for a few doses, then at longer intervals. An excess does no harm, but rather benefits the patient by its cathartic action. Magnesia is the most efficient antidote against acids and the acid salts, also against oxalic acid and the acid oxalates, in the absence of the calcium antidotes therefor. It is also valuable against arsenic, phosphorus, mercury, corrosive sublimate and other metallic salts in solution, precipitating the corresponding oxids or basic salts.

Milk is a good substitute for albumin, its antidotal action being nearly the same in range and due to its casein, albumin and free alkali. It is particularly valuable against metallic salts, corrosive acids and alkalies (especially ammonia) and the alkaline earths, but it is contraindicated when fatty antidotes are to be avoided, by reason of its richness in fat.

Oils and Fats are efficient against the corrosive acids and alkalies, the metallic oxids and salts; but are contraindicated in poisoning by phosphorus, cantharis, phenol, or copper salts, the absorption of which they promote. With the caustic alkalies they unite to form soaps, liberating glycerin; they are inferior to albumin against the metallic salts, and as their action is slow they are less efficient than acids against alkalies. Those used are olive, cotton-seed, linseed and almond oils, also melted butter and lard.

Potassium ferrocyanid, given in doses of 30 to 60 grains in water, is of special value against the copper salts, but albumin is equally efficient and more easily obtained.

Potassium permanganate is the best antidote against organic poisons, if used promptly, before absorption has taken place, as it rapidly destroys them by oxidation. It has been used successfully against morphin and strychnin salts and phosphorus in the stomach, and locally for snake-poison.

Soap, as Castile soap, dissolved in 4 times its bulk of hot water, to make "suds," and given by the cupful, is one of the most efficient antidotes against corrosive acids and metallic salts, especially corrosive sublimate, potassium dichromate, and salts of tin and zinc. It is inferior to albumin against these, but is preferred to caustic alkalies against acids, as of itself it has no corrosive action. It should not be used against alkalies.

Sodium borate (borax), in milk (5 percent), is recommended as a convenient and efficient general antidote; acting by the alkaline effect of the sodium, which precipitates metallic hydroxids from solutions of their salts, and also precipitates alkaloids from their salts. The milk acts by virtue of its albumin, forming albuminates and casein compounds with the poisons. The stomach should always be evacuated after the use of this agent, as the compounds formed are soluble in the digestive fluids.

Sodium chlorid (common salt), in dilute solution, is the best antidote against the silver salts, converting them into the insoluble chlorid of silver. It may be given with albumin, which is also a very efficient antidote in this form of poisoning.

Sodium thiosulphate in doses of 15 grains, in very dilute solution and frequently repeated, is a valuable antidote against bleaching powder (calcium hypochlorite), Labarraque's solution (sodium hypochlorite), and Javelle water (potassium hypochlorite), which it reduces to chlorids, itself undergoing oxidation to the sulphate.

Starch, in paste, 1 to 15 of water, is the antidote for iodin and bromin, with which it forms compounds which are almost harmless. It has some value against corrosive acids, corrosive sublimate, and zinc and copper sulphates, but it is not so efficient as albumin, which is preferred for these poisons as well as for iodin, since it has a greater affinity than starch has therefor.

Stomach pump and **stomach siphon** are efficient, and do not weaken the patient as emetics do, but they are not always available, and cannot be used when there is corrosion of the stomach or esophagus, for fear of perforation. Washing of the stomach at regular intervals is a measure of great importance in the case of soluble poisons, some of which are excreted into the stomach. These appliances are almost useless when the poison is in solid form and in large pieces (as meat, sausage, fish, cheese).

Sulphates of magnesium and sodium (Epsom and Glauber's salts), the soluble sulphates, are particularly efficient against phenol and the salts of barium and lead.

Tannin (tannic acid), precipitates the alkaloids and their salts, with which it forms compounds (tannates), which, though comparatively insoluble are not entirely inactive, and should be removed at once from the alimentary canal by emetics and drastic purgatives. It acts well against many metallic salts, though inferior to albumin for these, except against tartar emetic, which albumin does not affect, but tannin renders harmless. It is given in doses of 15 to 45 grains in a 2 percent solution, every quarter of an hour; and if combined with about 10 percent of its weight of iodin its antidotal effect on vegetable poisons is greatly increased. If not itself obtainable, decoctions or infusions of substances containing it may be used, as tea and coffee, nut-galls, kino, rhatany, catechu, and the barks of oak, willow and cinchona.

Turpentine, after long exposure to the air, therefore containing much oxygen, is one of the antidotes against phosphorus. It should be administered immediately after the ingestion of that poison, alone or in hot water, and in quantity 100 times that of the phosphorus supposed to be present.

Antidote bag, designed by Martindale, of London, contains the following-named articles, labeled, with directions for use, viz.: Dialyzed iron, syrup of chloral, chloroform, spirit of chloroform, calcined magnesia, aromatic spirit of ammonia, oil of turpentine, acetic acid, tincture of digitalis, tannic acid, amyl nitrite, zinc sulphate, ipecacuanha, potassium bromid, potassium permanganate. Solution of ferric sulphate, 40 c.c. in 125 c.c. of water. Magnesia, in solution, 10 grams in 750 c.c. of water, in a bottle of 1000 c.c. capacity. These two, mixed together, make the official antidote against arsenic. Also a hypodermic

syringe, and solutions or pellets therefor of morphin sulphate, atropin sulphate, apomorphin hydrochlorid, pilocarpin nitrate, strychnin nitrate.

General antidotes have been devised for use when the nature of a poison is unknown, with the object of a "shot-gun prescription," intended to hit something. One of the best is Jeaunel's, composed as follows: Liquor ferri sulphatis (specific gravity, 1.45), 2 1/2 ounces; magnesium oxid, 2 ounces; carbo animalis, 1 ounce; aqua, 20 ounces. These ingredients should be kept separate—the solution of the sulphate in one vessel, the others together. When needed, the former should be added to the latter and violently agitated. Dose, 1 1/2 to 3 ounces. This is a perfect antidote to arsenic, zinc, digitalin. It delays the action of salts of copper, morphin, and strychnin, and slightly influences compounds of mercury. It is valueless for cyanid of mercury, tartar emetic, hydrocyanic acid, phosphorus, or the caustic alkalies.

Bellini, of Florence, considers the iodid of starch a valuable antidote to alkaline sulphids, earthy sulphids, vegetable and caustic alkalies, and ammonia. In the first two cases he considers it superior to all other antidotes.

A fresh mixture of the sulphids of iron and sodium with magnesia is said to be a perfect antidote for copper salts, corrosive sublimate, and mercuric cyanid. If the nature of the poison is entirely unknown, a harmless yet effectual antidote in most cases is one composed of equal parts of magnesia, wood charcoal and the ferric hydroxid, given freely in plenty of water.

The following table of poisons includes the names of the various poisonous substances, the particularly prominent symptoms, the mode of producing death, and the antidotes and general treatment. Tables showing the anatomic distribution of lesions in death from poisoning and the lesions characteristic of the more important poisons are given under Poisoning (Medicolegal Duties in Fatal Cases).

POISONS, TABLE OF

Name.	Symptoms of Poisoning.	Mode of Producing Death.	Treatment and Antidotes.
Acetanilid	Cyanosis; peculiar discoloration of the blood due to formation of methemoglobin.	Sudden cardiac failure.	Strychnin, oxygen, and warmth; heart-stimulants.
Acetic Acid. See *Acid, Acetic.*			
Acetphenetidin. See *Phenacetin.*			
Acid, Acetic	Vomiting, purging; pain in the stomach, foul breath.	Asphyxia	Alkalies; soap; demulcent drinks; opium.
Acid, { Arsenous / Arsenic } See *Arsenic.*			
Acid, Boric	Nausea, vomiting, erythema, rapid, feeble pulse, collapse.	Cardiac paralysis.	
Acid, Carbolic (*Phenol*)	Immediate burning pain from mouth to stomach; giddiness, loss of consciousness, collapse; subnormal temperature; partial suppression of urine, which is dark in color; pupils very much contracted; characteristic odor.	Respiratory and cardiac paralysis.	Wash out stomach with alcohol and water; hypodermic of apomorphin; magnesium sulphate; atropin.
Acid, Chromic	Yellow stains; abdominal pain; vomiting and purging; collapse.	Cardiac paralysis.	Evacuate; chalk, milk, or albumin; demulcent drinks.
Acid, Hydrochloric (*Muriatic*).	Pain throughout digestive tract; vomiting, feeble pulse, clammy skin, collapse; eschars externally; yellow stains on clothing, but none on skin.		Alkalies; demulcent drinks; oil; stimulants (intravenous injection).
Acid, Hydrocyanic (*Prussic*).	Sudden unconsciousness, slow labored respirations, slow pulse, staring eyes, purple face, general convulsions, then relaxation and collapse, odor of peach kernels; death may be almost instantaneous.	Asphyxia	Stomach tube if possible. Dilute ammonia; opium, to relieve pain; alternate cold and warm affusions; atropin and heart-stimulants; artificial respiration.
Acid, Lactic	Violent irritation of alimentary canal		Alkalies and demulcents.
Acid, Nitric	Yellow stains on skin; otherwise similar to *Acid, Sulphuric.*		Alkalies; demulcents; soap; stimulants.
Acid, Nitrohydrochloric	Same as *Acid, Nitric.*		
Acid, Oxalic	Hot, acrid taste; burning, vomiting, collapse; sometimes general paralysis, numbness and stupor.	Paralysis of respiration and of heart.	Lime or chalk.

POISONS, TABLE OF

Name.	Symptoms of Poisoning.	Mode of Producing Death.	Treatment and Antidotes.
Acid, Prussic. See *Acid, Hydrocyanic.*			
Acid, Pyrogallic.....	Vomiting, diarrhea, rigors, fever, black urine, great dyspnea.	Formation of thrombi.	Mineral acids; alkalies; salts of iron.
Acid, Salicylic.....	Mydriasis; quick and deep respiration; delirium; dyspnea; lessened arterial pressure; deafness; olive green urine.	Respiratory paralysis.	
Acid, Sulphuric.....	Black stains; pain throughout digestive tract, vomiting often of tarry matter, feeble pulse, clammy skin, profuse and bloody salivation.	Asphyxia.....	Chalk; magnesia; soap; demulcent drinks.
Acid, Sulphurous.....	Cough, bloody expectoration, pulmonary inflammation.	.....	Air; cold to head; artificial respiration; bleeding.
Acid, Tartaric.....	Pain in abdomen; vomiting, etc.....	.....	Magnesia; lime; soap.
Aconitum napellus (*Monkshood*). Aconite.	Sudden collapse, slow, feeble and irregular pulse and respirations, tingling in the mouth and extremities, giddiness, great muscular weakness, sometimes pain in the abdomen, pupils generally dilated, but may be contracted, marked anesthesia of skin, mind clear, convulsions at times.	Asphyxia.....	Tannic acid solution for washing out stomach; digitalis, atropin, and stimulants; artificial respiration; warmth and friction.
Actæa spicata (*Baneberry*)...	Vomiting; diarrhea; cardiac depression; faintness; dizziness; foul breath; dryness of pharynx.	Cardiac paralysis...	Heart-stimulants.
Agaricus. See *Fungi.*			
Alcohol.....	Confusion of thought, giddiness, tottering gait, slight cyanosis, narcosis from which patient can be aroused; full pulse; deep stertorous breathing; injection of eyes, dilatation of pupils, low temperature, convulsions, coma, death often hours or even days after apparent recovery.	Paralysis of heart..	Evacuat stomach; coffee; battery; amyl nitrite; hot and cold douches.
Aloes.....	Tenesmus, weight in pelvis, profuse diarrhea.		
Amanita muscaria (*Truffles*). See *Fungi.*			
Ammonium and its compounds.	Intense gastroenteritis, often with bloody vomiting and purging; lips and tongue swollen and covered with detached epithelium; violent dyspnea; characteristic odor.	Asphyxia.....	Vegetable acids; demulcents.
Amygdalus communis (*Bitter Almond*).	Similar to *Acid, Hydrocyanic, q. v.*		
Amyl Nitrite.....	Throbbing headache, flushed face, sense of heat, tumultuous heart's action; diminished sensibility, mobility and reflexes.	Paralysis of respiratory centers.	Evacuate; air; recumbent position; artificial respiration; stimulants; strychnin; ergot; digitalis.
Amylene Hydrate.....	Sleep and coma.....	Paralysis of medulla.	Remove vapor; air; stimulants; artificial respiration.
Anilin.....	Giddiness, apparent intoxication, sweating, blue color of mucous membrane of mouth; odor of anilin; coma.	Asphyxia.....	Removal of cause; stimulation; oxygen; artificial respiration.
Antifebrin. See *Acetanilid.*			
Antimony and its compounds.	Metallic taste, violent vomiting becoming bloody; feeble pulse, pain and burning in the stomach, violent serous purging, becoming bloody; dysphagia; cramps in extremities; thirst; great debility; sometimes prostration, collapse, unconsciousness, and convulsions without vomiting or purging.	Paralysis of the heart.	Tannic acid; demulcent drinks; opium; alcohol; external heat.

POISONS, TABLE OF

Name.	Symptoms of Poisoning.	Mode of Producing Death.	Treatment and Antidotes.
Antipyrin (*Phenazon*).....	Headache, nausea, vomiting, a rash like that of measles, vertigo, drowsiness, deafness, confusion of ideas, cyanosis, collapse.	.....	Recumbent position: warmth; strychnin; stimulants; oxygen; artificial respiration.
Apocynum androsalmifolium (*Dogsbane*).	Vomiting, nausea, drowsiness.....	.....	Evacuate; stimulants.
Apomorphin.....	Violent vomiting, paralysis of motor and sensory nerves, delirium, depression of respiration, heart-depression.	Cardiac failure.....	Cardiac and respiratory stimulants.
Aristolochia clematis (*Birthwort*).	Nausea; griping pains in the bowels; vomiting; dysenteric tenesmus.	.....	Evacuate; demulcent drinks.
Arnica montana (*Leopardsbane*).	Transient excitement, headache, unconsciousness, pupils dilated, paralysis of the nervous system, collapse.	Paralysis of the nervous system.	Cardiac stimulants.
Arsenic and its compounds...	Violent burning pain in the stomach, retching, thirst, purging of blood and mucus with flakes of epithelium; tenesmus, burning in the urinary organs with suppression of urine; sense of constriction with dryness in throat; pulse small and frequent.	.....	Hydrated sesquioxid of iron; precipitated carbonate of iron; emetics; castor oil; demulcents.
Artemisia absinthium (*Absinthe*).	Tremor, stupor, epileptiform convulsions, involuntary evacuations, stertorous breathing.	.....	Emetics; stimulants; demulcents.
Aspidium (*Male Fern*).....	Vomiting, purging, great pain in the abdomen, collapse; giddiness; coma; amaurosis; cramp in extremities.	.....	Evacuate; stimulants.
Atropa belladonna (*Deadly Nightshade*). Atropin. Belladonna. Homatropin.	Heat and dryness of the mouth and throat; pupils widely dilated, scarlet rash; quick pulse, at first corded, later feeble; rapid respirations, early strong, late shallow and feeble; retention of urine; sometimes convulsions, collapse, and paralysis; suppression of saliva, difficulty in swallowing; great thirst, indistinct vision, noisy delirium; skin dry.	Paralysis of the heart.	Evacuation of stomach and bladder; stimulants; coffee; pilocarpin; artificial respiration; physostigmin may be of benefit.
Barium and its compounds...	Pain in the abdomen, purging, vomiting, feeble pulse, short and labored breathing, cramps, convulsions, collapse.	.....	Evacuate; Glauber's or Epsom salts; dilute sulphuric acid; warmth.
Bitter Almond (*Amygdalus*)..	Similar to *Acid, Hydrocyanic, q. v.*		
Bittersweet. See *Solanum.*			
Bloodroot. See *Sanguinaria.*			
Boric Acid. See *Acid, Boric.*			
Bromin and its compounds.	Respiration and heart's action lessened; reflexes sluggish; diminished sensibility; motility and sexual function impaired; acne; fetid breath; mental faculties impaired.	Cardiac and muscular paralysis.	Heat; stimulants; digitalis; ergot; atropin; strychnin; artificial respiration.
Brucin. See *Strychnin.*			
Bryonia dioica (*Bryony*).....	Giddiness, delirium, vomiting, diarrhea, with watery motions, dilated pupils, coma.	Heart-depression...	Emetics; mustard; salt; ipecacuanha; stimulants, freely.
Caffea arabica. See *Caffein.*			
Caffein.....	Burning pain in the throat, giddiness, faintness, nausea, numbness, abdominal pain, great thirst, dry tongue, tremor of extremities, diuresis, weak pulse, cold skin, collapse.	Paralysis of respiration.	Emetics; stimulants; warmth; morphin and atropin.
Calabar Bean. See *Physostig ma.*			

POISONS, TABLE OF.

Name.	Symptoms of Poisoning.	Mode of Producing Death.	Treatment and Antidotes.
Calcium. See *Lime.*			
Camphine. See *Turpentine.*			
Camphor.....	Characteristic odor; languor, giddiness, disturbance of vision, delirium, convulsions, clammy skin, smarting in the urinary organs, pulse quick and weak; no pain, no vomiting, no purging.	Asphyxia.....	Evacuate stimulants; warmth; hot and cold douches.
Cannabis indica (*Indian Hemp*).	Pleasurable intoxication; sense of prolongation of time; anesthesia with loss of strength especially in legs; rapid pulse; increased sexual desire; pupils dilated; heavy sleep.	.....	Strychnin; faradization; evacuate; stimulants.
Cantharis vesicatoria (*Spanish Fly*). Cantharides.	Burning in mouth and stomach, vomiting and purging, soon becoming bloody, and abdominal tenderness, tenesmus, the vomit containing shining particles of the powder; incessant desire to urinate, but only a little blood or albuminous urine passed at each attempt; priapism, abortion, convulsions, coma, and insensibility.	Paralysis of the respiratory centers.	Evacuate stomach; demulcent drinks; morphin; hot bath for the strangury; anesthetics may be necessary for the pain.
Carbolic Acid. See *Acid, Carbolic.*			
Carbon Disulphid.....	Headache, vertigo, nervous excitement, anesthesia with great muscular rigidity, characteristic odor of breath, urine, and feces.	Paralysis of the respiratory centers and of the heart.	Evacuate; stimulants; warmth; artificial respiration.
Castor-oil. See *Ricinus.*			
Chelidonium majus (*Celandine*).	Catharsis; vomiting; cardiac debility.....	Paralysis of the heart.	Evacuate; heart-stimulants.
Cherry Laurel. See *Prunus.*			
Chloral Hydrate.....	Deep sleep, loss of muscular power, lividity, reflexes diminished, pulse weak, respirations slowed, pupils contracted during sleep, but dilated on waking, temperature low.	Arrest of respiration or paralysis of the heart.	Evacuate; heat to the extremities; massage; coffee by the rectum; strychnin; amyl nitrite; artificial respiration.
Chlorin.....	Irritation of the throat, cough, tightness across chest, inability to swallow.	Asphyxia.....	Air; steam-inhalations; dilute ammonia-inhalations; ether or chloroform.
Chlorodyne. See *Opium.*			
Chloroform.....	Two methods of introduction, inhalation and swallowing; symptoms in latter case delayed. 1. Slight stimulation; 2. excitement and incoherence; 3. insensibility and relaxation.	Usually paralysis of the heart.	Draw tongue forward; air; artificial respiration; faradic current; hot and cold douches; amyl nitrite; atropin; evacuation of stomach if chloroform has been taken by mouth.
Chromium and its compounds. See *Acid, Chromic.*			
Cicuta maculata (*American Hemlock*).	Similar to those of *Conium, q. v.*		
Cicuta virosa (*Water Hemlock*).	Similar to those of *Conium, q. v.*		
Citric Acid. See *Acid, Citric.*			
Coal-gas.....	Headache, giddiness, loss of muscular power, unconsciousness, pupils dilated, breathing labored, coma, odor of gas.	Asphyxia.....	Fresh air; artificial respiration; ammonia; stimulants; oxygen; coffee; hot and cold douches.
Cocain.....	Faintness, giddiness, nausea; pulse small, rapid, and intermittent; severe prostration; respiration slow and feeble.	Spasm of heart and muscles of respiration.	Stimulants; amyl nitrite; artificial respiration.

POISONS, TABLE OF

Name.	Symptoms of Poisoning.	Mode of Producing Death.	Treatment and Antidotes.
Cocculus indicus (*Fish-berries*). Picrotoxin.	Nausea, vomiting, muscular debility, somnolence, sometimes convulsions, occasionally scarlatinal rash.	Paralysis of heart in diastole.	Evacuate; chloral hydrate; bromid of potassium.
Colchicum autumnale (*Meadow Saffron*).	Not unlike those of malignant cholera; griping pain in the stomach, vomiting and continuous purging of seromucous material; intense thirst, muscular cramps, great prostration; pinched face, profuse perspiration, collapse; dilated pupils; pain in the extremities.	Paralysis of the respiratory centers.	Evacuate; tannic or gallic acid; demulcent drinks; stimulants; morphin.
Colocynth.....	Persistent vomiting and purging, exhaustion, cold extremities, weak pulse, collapse.	.....	Evacuate; camphor, opium; stimulants; demulcent drinks; warmth.
Conium maculatum (*Hemlock*).	Weakness of the legs, gradual loss of all voluntary power, nausea, ptosis, pupils dilated, inability to speak or swallow.	Paralysis of the respiratory muscles.	Evacuate; tannic or gallic acid; stimulants; warmth; artificial respiration; atropin.
Convallaria majalis (*Lily of the Valley*).	Similar to *Digitalis*, *q. v.*.....	Cardiac paralyzant; arrests heart in systole.	
Convolvulus jalapæ. See *Jalap.*			
Convolvulus scammonii.			
Copper and its salts.....	Metallic taste in mouth, griping and colicky pains, nausea and vomiting, purging with straining, jaundice, hurried breathing, small, rapid pulse, weakness, thirst, giddiness, coma.	.....	Evacuate; barley-water; morphin; poultices to abdomen.
Coriaria myrtifolia (*Myrtle-leaved Sumach*). See *Sumach.*			
Creosote.....	Similar to *Acid, Carbolic*, *q. v.*		
Croton tiglium (*Croton-oil*)..	Intense pain in the abdomen, vomiting, purging, watery stools, pinched face, small and thready pulse, moist skin, collapse.	.....	Evacuate; demulcent drinks; camphor; stimulants; morphin; poultices to abdomen.
Cubebs.....	Nausea, vomiting, colicky pains; in some cases purging; in some an eruption resembling urticaria.		
Cucumis colocynthis. See *Colocynth.*			
Curare (*Indian War-poison*).	Complete paralysis of the voluntary muscles, slowing of the heart, gradually diminished respiration.	Arrest of the respiratory movements.	Artificial respiration; stimulants; ligate and wash wound; evacuate bladder frequently.
Cyanogen and its compounds.	Similar to *Acid, Hydrocyanic*, *q. v.*		
Cyclamen europæum (*Sow-bread*).	Inflammation of the alimentary canal; bloody stools; cold sweats; convulsive movements.	.....	Evacuate; opium; poultices to abdomen.
Cytisus laburnum (*Laburnum*).	Come on rapidly; purging, vomiting, great restlessness; drowsiness and insensibility, convulsive twitchings.	Asphyxia.....	Evacuate; stimulants; coffee per rectum; hot and cold douches.
Daphne gnidium (*Sponge Flax*).	Pain; vomiting; purging.....	.....	Evacuate; demulcent drinks; heart-stimulants.
Daphne mezereum (*Mezereon*). See *Mezereon.*			
Datura stramonium (*Thorn-apple, Jamestown Weed*).	Symptoms and treatment similar to those of *Atropin*, *q. v.*		
Delphinium staphisagria (*Stavesacre*). See *Staphisagria.*			

POISONS, TABLE OF

Name.	Symptoms of Poisoning.	Mode of Producing Death.	Treatment and Antidotes.
Digitalis purpura (*Fox-glove*).	Purging, with severe pain, violent vomiting; vertigo; feeble pulse, although heart's action is tumultuous; headache; lethargy followed by delirium and convulsions; eyes prominent, pupils dilated, sclera blue; skin cold, coma.	Heart-paralysis....	Evacuate; tannic and gallic acids; stimulants; aconite; recumbent position.
Dog-bite. See *Saliva*.			
Duboisia (probably identical with *Hyoscyamus*).			
Elaterium (*Elaterin*).....	Purging, vomiting, salivation, prostration, clonic spasms; dyspnea.	.....	Emetics; stomach-pump; demulcent drinks; opium.
Ergot.....	Tingling in the fingers and feet, cramps in the extremities, dizziness, weakness, pupils dilated, pulse small, vomiting, retching, and diarrhea.	.....	Evacuate, quick purgatives, castor-oil or Epsom salts; tannic or gallic acid; recumbent position; stimulants; amyl nitrite.
Erythroxylon coca. See *Cocain*.			
Eserin. See *Physostigma*.			
Ether.....	Sense of strangulation; cough, stage of excitement (*cerebral intoxication*). Tetanic convulsive stage, complete insensibility, muscles relaxed, reflexes abolished, cerebral functions suspended.	Paralysis of respiration.	Withdraw vapor; lower the head; draw tongue forward; atropin; artificial respiration; amyl nitrite; ammonia; warmth.
Ethidene Dichlorid.....	Stertorous breathing, dilated pupil, pleasant dreams, depression of pulse.	.....	Remove vapor; draw tongue forward; artificial respiration; lower the head.
Ethyl Bromid.....	Very similar of those of *Chloroform*, *q. v.*		
Euphorbia officinarum (*Euphorbia Spurge*).	Pain; nausea; vomiting; purging; weak pulse.	Paralysis of cardiac and respiratory centers.	Evacuate; heart-stimulants.
Eqalgin.....	Numbness and tingling, cyanosis, salivation, vomiting, intense dyspnea feeling of alternate expansion and contraction of the head.	Paralysis of respiration.	Emetics; strychnin; stimulants.
Filix mas (*Male Fern*). See *Aspidium*.			
Fish, Poisonous. (Several kinda of fish, particularly shell-fish, are constantly poisonous, while some are so only to particular constitutions.)	Nausea, vomiting, irritation of eyes, depression, severe urticaria, or nettle-rash.	.....	Evacuate; quick purgative; stimulants.
Fish-berries. See *Cocculus*.			
Fly, Spanish. See *Cantharis*.			
Foxglove. See *Digitalis*.			
Fungi. (Several forms of fungi, known as mushrooms, toadstools, truffles, etc., are directly poisonous.)	Gastrointestinal catarrh, nausea, heat and pain, vomiting and purging, fainting, convulsions, small and frequent pulse; pupils dilated; delirium, stupor, death.	.....	Evacuate; quick purgative; Glauber's or Epsom salts; stimulants.
Fusel-oil.....	Rigidity of muscles, respiration shallow and slow, pupils small, odor of breath resembling amyl nitrite.	.....	Evacuate; heart stimulants.
Gamboge.....	Violent irritation of alimentary canal; vomiting; griping.	.....	Evacuate; demulcent drinks; opium.
Gaultheria procumbens (*Wintergreen*).	Very similar in action to *Acid, Salicylic*, *q. v.*		
Gelsemium sempervirens (*Yellow Jessamin*).	Symptoms appear in about 20 minutes; great muscular weakness; dimness of vision, ptosis, diplopia, labored respiration, weak pulse.	Paralysis of the respiratory centers.	Evacuate; atropin; stimulants; artificial respiration; hot and cold douches.

POISONS, TABLE OF

Name.	Symptoms of Poisoning.	Mode of Producing Death.	Treatment and Antidotes.
Glass	Purely irritant; may have hematemesis		Bread in crumbs, then emetic.
Gold	Causes a pink stain upon the skin		Sulphate of iron; albumin; evacuate.
Gratiolus officinalis (*Hedge-hyssop*).	Violent purging; pain		Evacuate; demulcent drinks.
Hedeoma (*Pennyroyal*)	Unconsciousness, extremities cold, pulse small, pupils slightly dilated, vomiting, delirium, opisthotonos.		Evacuate.
Hellebore, Green and White. See *Veratrum.*			
Helleborus niger (*Black Hellebore*).	Resemble malignant cholera; abdominal pain, vomiting, purging, vertigo, cold sweats, and collapse.	Paralysis of heart	Stomach-pump; tannin; mucilaginous drinks, heart-stimulants.
Hemlock. See *Conium.*			
Henbane. See *Hyoscyamus.*			
Holly Berries (*Ilex aquifolium*).	Vomiting, pain in the head and abdomen, purging, contraction of pupils, loss of consciousness, collapse.		Evacuate; stimulants; warmth; coffee.
Homatropin. See *Atropa.*			
Hura crepitans (*Sand-box*)	Irritation of alimentary tract; vomiting; purging.		Evacuate; demulcent drinks; opium.
Hydrophobia. See *Saliva.*			
Hyoscyamus albus (*White Henbane*). Hyoscyamus niger (*Black Henbane*). Hyoscyamin, Hyoscin.	Giddiness, sense of weight in head, general loss of power, pupils dilated, diplopia, presbyopia, flashes of light, incoherence of speech, delirium, insensibility, coma.	Paralyzes respiration.	Evacuate; quick purgatives.
Insects, Poisonous. (The bite or sting of several varieties of insects is poisonous.)	In most cases slight; in cases of tarantula and scorpion may be more serious; pain, swelling, fever, erysipelas, suppuration, and gangrene, with death.		In *milder* cases ammonia, soap, or other alkali to the wound. In *graver* cases similar to that of snake-bite, *q. v.*
Iodin and its compounds	Pain in throat and stomach; vomiting, purging; vomit yellow from iodin, or blue if starch be present in the stomach; giddiness, faintness, convulsive movements.	Paralysis of the heart.	Evacuate; starch; amyl nitrite; morphin.
Iodoform	Slight delirium; drowsiness; high temperature, rapid pulse; resembles meningitis.		
Ipecacuanha (*Ipecacuanha*)	Vomiting, hematemesis, and hemoptysis		Evacuate.
Iron and its compounds	Metallic taste, pain, vomiting, and purging; vomited matter black.		Magnesia and diluents; ice and opium.
Jaborandi. Pilocarpin.	Copious sweating, dizziness, salivation, vomiting, diarrhea, tearing pain in eyeballs, myopia, pupils much contracted.		Evacuate; stimulants; atropin or belladonna.
Jalap	Copious watery stools, tormina, and tenesmus.		Evacuate; demulcent drinks.
Jamaica Dogwood. See *Piscidia.*			
Jatropha curcas (*Indian Nut*).	Purging; vomiting		Evacuate; demulcent drinks.
Jatropha manihot (*Cassava*)	Same as those of *Prussic Acid, q. v.*		
Juniperus sabina. See *Savin.*			
Juniperus virginiana (*Red Cedar*).	Gastritis; nephritis; strangury; nervous disturbances; violet-like odor in urine; copaiba-like erythema.		Evacuate; demulcent drinks; stimulants.

POISONS, TABLE OF

Name.	Symptoms of Poisoning.	Mode of Producing Death.	Treatment and Antidotes.
Lactic Acid. See *Acid, Lactic.*			
Lactuca virosa (*Strong-scented Lettuce*).	Somewhat similar to those of *Opium, q. v.*		
Laudanum. See *Opium.*			
Lead and its compounds.....	Dryness of the throat, metallic taste, great thirst, colic relieved by pressure, abdominal muscles usually rigid, constipation, cramps in the legs, paralysis of the extremities, convulsions; in the chronic forms, a blue line at margin of the gums.	.....	Evacuate; dilute sulphuric acid; Epsom and Glauber's salts; milk; morphin; iodid of potassium to eliminate the poison; poultices to the abdomen.
Lime.....	Burning pain in the abdomen, great thirst, obstinate constipation.	.....	Vegetable acids; demulcent drinks.
Lobelia inflata (*Indian Tobacco*).	Severe vomiting, with intense depression and prostration, giddiness, tremors, convulsions, collapse.	Paralysis of respiration.	Evacuate stomach; tannic or gallic acid; stimulants; strychnin; warmth; recumbent position.
Lolium temulentum (*Darnel*).	Vertigo; dizziness; headache; sleepiness.		
Lytta vittata (*Potato-fly*)....	Similar to those of *Cantharis, q. v.*		
Male fern. See *Aspidium.*			
Meat. (Putrefactive changes in meat and some other forms of food produce active poisonous agents known as ptomains.	Gastrointestinal irritation sometimes very marked; occasionally death.	.....	Evacuate; irrigate stomach; sedatives; supportive treatment when prostration.
Melia azedarach (*Pride of China*).	Giddiness, dimness of vision, stertorous breathing, dilated pupils, stupor.		
Mercury and its compounds..	Acrid metallic taste, burning heat in throat and stomach, vomiting, diarrhea, with bloody stools, lips and tongue white and shriveled, pulse small and frequent, death in coma or convulsions; pain may be absent. Secondary symptoms; hectic fever, coppery taste, fetid breath, gums swollen, salivation.	.....	Albumin in some form; raw white of egg or flour; evacuate; potassium iodid; opium; calcium sulfid.
Methylene Bichlorid.....	Symptoms and treatment similar to those of *Chloroform, q. v.*		
Mezereon.....	Violent purging, vomiting, nephritis, and gastroenteritis; an exceedingly powerful local irritant.	.....	Evacuate; aperient and demulcent drinks; opium.
Milk. See *Tyrotoxicon.*			
Momordica elaterium (*Squirting Cucumber*).			
Morphin. See *Opium.*			
Mushrooms. See *Fungi.*			
Mussel. See *Fish.*			
Mydalin. See *Meat.*			
Myristica fragans (*Nutmeg*)...	Thirst; tightness in the chest; vomiting....	.....	Coffee and stimulants.
Mytilotoxin (*Mussel-poison*). See *Fish.*			
Naphthalin.....	Cyanosis, twitching over body, urine dark-brown changing to inky black, strangury.	.....	Demulcent drinks; stimulants.
Narcein. See *Opium.*			
Narcissus pseudonarcissus (*Daffodil*).	.....	.....	Evacuate; demulcent drinks; stimulants.

POISONS, TABLE OF

Name.	Symptoms of Poisoning.	Mode of Producing Death.	Treatment and Antidotes.
Nerium oleander (*Oleander*).	Similar to those of *Strophanthus, q. v.*		
Neurin. See *Meat.*			
Nicotiana tabacum. See *Tobacco.*			
Nightshade. See *Atropa.*			
Niter (*Potassium Nitrate*). See also *Potassium and its compounds.*	Pain in the abdomen, vomiting, coldness in the limbs, partial paralysis, tremors, convulsions, collapse.	Paralysis of the heart.	Evacuate; mucilaginous drinks, stimulants; warmth; amyl nitrite; atropin.
Nitric Acid. See *Acid, Nitric.*			
Nitrobenzin..... Nitrobenzol.	May be delayed; weariness, numbness in the head, confusion, marked cyanosis, lips nearly black, convulsions, pupils dilated.	Asphyxia.....	Cold to head; dilute ammonia; hydrated oxid of iron; stimulants; artificial respiration.
Nitroglycerin.....	Throbbing headache; pulsation over entire body, dicrotic pulse, flushed face, mental confusion, anxiety, sudden collapse.	Respiratory paralysis.	Recumbent position; cold to head; ergot; atropin.
Nitrohydrochloric Acid.	See *Acid, Nitrohydrochloric.*		
Nitrous Oxid.....	.....	Respiratory paralysis.	Pull tongue forward; air; artificial respiration; douche; oxygen.
Nux vomica. See *St. Ignatius' Bean.*			
Opium..... Morphin. Narcein. Codein. Laudanum.	Preliminary mental excitement, acceleration of heart; soon headache, weariness, sensation of weight in the limbs, sleepiness, diminished sensibility, contracted pupils; pulse and respirations slow and strong; patient can be roused with difficulty; later this becomes impossible; reflexes abolished, jaw falls; respiration slow, irregular, and stertorous; pulse rapid and feeble.	Respiratory paralysis.	Evacuate stomach; apomorphin; rousing; ammonia; coffee; douche; atropin; amyl nitrite; artificial respiration; external heat; battery; strychnin; potassium permanganate; oxygen.
Oxalic Acid. See *Acid, Oxalic.*			
Papaver somniferum (*Poppy*). See *Opium.*			
Paraldehyd.....	Similar to chloroform-narcosis.....	Paralysis of respiratory center.	Respiratory stimulants; coffee; atropin; battery.
Paris Green. See *Arsenic.*			
Peach-kernel—contains *Acid, Hydrocyanic, q. v.*			
Petroleum.....	Burning in course of alimentary tract; excreta covered with layer of oil; skin cold; pulse feeble, but regular; respiration sighing; thirst; restlessness.	.....	Evacuate; stimulants; warmth; stimulation of skin; artificial respiration.
Phenacetin (acetphenetidin)..	Very similar to *Antipyrin* and *Antifebrin, q. v.*		
Phenol. See *Acid, Carbolic.*			
Phosphorus.....	Vomiting and pain; vomit may be luminous in the dark; characteristic odor; after several days deep jaundice, coffee colored vomit, hepatic tenderness, failure in pulse and respiration; coma or delirium; albumin in the urine.	Failure of respiration and circulation.	Sulphate of zinc or copper; Epsom salts; *never give oil or fat.*
Physostigma venenosum (*Calabar Bean*). Eserin.	Giddiness; prostration; loss of power in the lower limbs; muscular twitching; contracted pupils; mind clear.	Asphyxia.....	Evacuate; atropin; strychnin; stimulants; artificial respiration.

POISONS, TABLE OF

Name.	Symptoms of Poisoning.	Mode of Producing Death.	Treatment and Antidotes.
Phytolacca decandra (*Poke*).	Nausea; vomiting; depression; heart, as well as respiration, slowed; tetanic convulsions.	Paralysis of respiration.	Evacuate; alcohol; opium; ether; digitalis.
Picrotoxin. See *Cocculus.*			
Pilocarpin. See *Jaborandi.*			
Pinkroot. See *Spigelia.*			
Piper cubeba. See *Cubeb.*			
Piscidia erythrin (*Jamaica Dogwood*).	Muscular relaxation; accelerated pulse; lowered sensibility; dilated pupils; deep sleep.	Asphyxia.....	Same as for *Opium, q. v.*
Pituri.....	Slightly narcotic; powerful respiratory poison.	.....	Similar to *Atropin, q. v.*
Plumbago europa (*Toothwort*).	Violent emesis.....	.....	Evacuate; demulcent drinks; heart-stimulants.
Poison-oak. Poison-vine. } See *Rhus.*			
Poke-berries. See *Phytolacca.*			
Poppy. See *Opium.*			
Potassium and its compounds.	The hydrate produces the symptoms of other caustic alkalies, *e. g.*, lime; the other poisonous compounds are to be classed under their various acids.	.....	*For caustic potash.* Vegetable acids; demulcent drinks.
Potato-fly (*Lytta vittata*). See *Cantharis.*			
Privet (*Ligustrum vulgare*)...	Purging; intestinal inflammation.....	.....	Hot water in large draughts; warmth; stimulants.
Prunus laurocerasus (*Cherry Laurel*). Prunus virginiana (*Wild Cherry*).	Both contain *Acid, Hydrocyanic, q. v.*		
Prussic Acid. See *Acid, Hydrocyanic.*			
Ptomains. See *Meat.*			
Pulsatilla.....	Lowers heart's action, reduces respiration and temperature; dilates pupils; paralyzes motion and sensibility.	Paralysis of heart..	Alcohol; opium; digitalis.
Pyrogallic Acid. See *Acid, Pyrogallic.*			
Resorcin.....	Giddiness, tingling; insensibility, profuse perspiration; tongue dry; pupils normal; teeth clenched, temperature low; urine black.	Paralysis of respiration.	Evacuate; albumin; stimulants; warmth; atropin; amyl nitrite; red wine.
Rhus radicans (*Poison-vine*). Rhus toxicodendron (*Poison-oak*).	Cutaneous irritation; itching, swelling, vesicular eruption; may involve the throat, producing cough; thirst, vomiting, colicky pains, fever, delirium.	.....	Grindelia robusta locally; also carron-oil and solution of acetate of lead; also phenol 5 percent. solution or cocain 5 percent. solution or ichthyol; rest; low diet; laxatives; opium.
Ricinus communis (*Castor-oil*).	Burning, nausea, vomiting, colicky pains, small pulse, great prostration; purging may or may not occur.	.....	Evacuate; morphin, hypodermatically; warmth; stimulants; starch and opium enemata.
Rue..... Ruta graveolens (*Rue*).	Violent gastroenteritis, extreme prostration, convulsions, strangury, suppression of urine.	.....	Evacuate; demulcent drinks; diuretics; heart stimulants.
Salicylic Acid. See *Acid, Salicylic.*			

POISONS, TABLE OF

Name.	Symptoms of Poisoning.	Mode of Producing Death.	Treatment and Antidotes.
Saliva of Rabid Animals....	Rarely come on in less than three weeks; may occur between that and years; pain in the bitten part; uneasiness, languor, difficult respiration, difficulty in swallowing, horror of water; violent convulsions; tongue swollen and often protruding; flow of viscid saliva.	.....	*Preventive:* Immediate ligature above wound; excision; cautery; inoculation. *Of hydrophobia:* Chloroform internally; morphin hypodermatically; cocain to throat; nutritive enemata.
Sambucus canadensis (*Elder*).	Emesis; purging.....	.....	Demulcent drinks; evacuate.
Sanguinaria canadensis (*Bloodroot*).	Salivation, catharsis, and vomiting, reflexes lowered; pupils dilated; temperature low; great thirst; collapse.	Paralysis of the cardiac and respiratory centers.	Evacuate; opium; amyl nitrite; atropin.
Santonin.....	Disturbance of color-vision—objects first assume a bluish tinge, then yellow; tinnitus; dizziness; pain in the abdomen; failure of respiration; convulsions; stupor.	Asphyxia.....	Evacuate; stimulants; chloral.
Savin.....	Pain, vomiting, tenesmus, and bloody stools; disordered respirations; coma, and convulsions.	.....	Evacuate stomach; castor-oil in large dose; morphin: poultices to the abdomen.
Scammony.....	Vomiting, purging, griping, tenesmus.....	.....	Evacuate; stimulants.
Scilla maritima (*Squill*).....	Vomiting, purging, strangury, bloody urine, paralysis, and convulsions.	Paralysis of heart in systole.	Evacuate; demulcent drinks; diuretics; stimulants.
Secale cornutum. See *Ergot*.			
Silver and its salts.....	Pain, vomiting, and purging; vomit white and cheesy, rapidly turning black in the sunlight; vertigo, coma, convulsions, paralysis, and marked disturbance of respiration.	Paralysis of respiration.	Salt and water; evacuate stomach; a large amount of milk; albumin.
Snake-bite. (The bite of many varieties of serpents is directly poisonous.)	Vary in severity, but are, in the main, sharp pain in the bitten part, rapidly spreading; great swelling of the wounded member, which becomes livid and gangrenous later; fainting, vomiting, and convulsions; pulse small, frequent, and irregular; breathing difficult.	Paralysis of cardiac and respiratory centers.	Removal of poison by sucking or cupping; ligature above wound; cautery or excision; ammonia to wound and internally; warmth; in some cases large doses of ammonia or whisky internally, transfusion of blood.
Soda (Sodium).....	Symptoms and treatment similar to those of other caustic alkalies, as *Lime*, *q. v.*		
Solanum dulcamara (*Bittersweet*).	Thirst, headache, giddiness, dimness of vision, dilated pupils, convulsions, vomiting, purging.	Asphyxia.....	Evacuate; stimulants; warmth.
Sorbus acuparia (*Mountain Ash*).	.....	.....	Same as for *Opium*, *q. v.*
Spanish Fly. See *Cantharis*.			
Spigelia marilandica (*Pinkroot*).	Vertigo, dimness of vision, dilated pupils, spasms, convulsions; delirium; dryness of throat.	.....	Evacuate; stimulants; coffee.
Squill. See *Scilla*.			
Stalagmitis cambogioïdes. See *Gamboge*.			
Staphisagria.....	Heart slow and feeble; breathing difficult; pupils dilated; abdomen distended and painful.	Paralysis of spinal cord and asphyxia.	Cardiac and respiratory stimulants.
Stavesacre. See *Staphisagria*.			
Stramonium. See *Datura*.			
Strophanthus (*Arrow-poison*) Strophanthin.	Weakness of pulse; increase of urine, rigidity of the muscles; spasms.	Paralysis of the heart in systole.	Cardiac stimulants.

POISONS, TABLE OF

Name.	Symptoms of Poisoning.	Mode of Producing Death.	Treatment and Antidotes.
St. Ignatius Bean..... Strychnos ignatia..... Strychnos nux vomica (*Nux romica*). Nux vomica. Strychnin. Brucin.	Tetanic convulsions coming on in paroxysms at varying intervals of from five minutes to half an hour; opisthotonos during paroxysm; eyeballs prominent; pupils dilated, respiration impeded, pulse feeble and rapid; anxiety.	Asphyxia during paroxysm, or collapse.	Evacuate stomach; tannic acid ad lib.; follow with emetic; catheterize; keep patient quiet; bromids and chloral; amyl nitrite or chloroform to control convulsions; artificial respiration if indicated.
Sulphonal.....	Giddiness, weakness, ptosis, cyanosis, suppression of urine.	.....	Stimulants; diuretics.
Sulphuric Acid. See *Acid. Sulphuric.*			
Sumach. See *Rhus.*			
Tanacetum vulgare (*Tansy*).. Tansy.	Convulsions, insensibility, dilated pupils, respirations hurried and stertorous; pulse full, gradually failing; characteristic odor of breath.	Heart-paralysis....	Heart-stimulants; evacuate.
Tartar Emetic. See *Antimony.*			
Tartaric Acid. See *Acid, Tartaric.*			
Tin.....	Metallic taste, vomiting, and diarrhea; pain; depressed action of heart.	.....	Evacuate; magnesium; mucilaginous drinks.
Tobacco..... Nicotin.	Nausea, vomiting, weakness, weak pulse, cold and clammy skin, collapse, pupils contracted, then dilated.	Paralysis of respiration; sometimes paralysis of heart.	Evacuate stomach; tannic acid; strychnin; stimulants, warmth; recumbent position.
Truffles. See *Fungi.*			
Turpentine.....	Characteristic odor; intoxication; contracted pupils; stertorous breathing; coma; collapse; tetanic convulsions; the urine has the odor of violets.	Paralysis of respiration.	Evacuate; magnesium sulphate; demulcent drinks; morphin.
Tyrotoxicon.....	Nausea, vomiting, cramps, diarrhea, collapse.	.....	Evacuate; intestinal antiseptics.
Urethan.....	Vomiting; slowing of heart; temperature lowered; muscular resolution and general anesthesia.	Asphyxia.....	Evacuate; cardiac stimulants.
Vaselin.....	Cramps in lower limbs, severe and persistent vomiting; collapse.	.....	Evacuate; stimulants.
Veratrum album (*White Hellebore*). Veratrum viride (*Green Hellebore*).	Burning and pain in course of alimentary tract; inability to swallow; vomiting and diarrhea; palpitation; slow, weak pulse; respiration labored; pupils generally dilated; may be convulsions.	Paralysis of respiratory centers.	Evacuate stomach; ether hypodermically; opium; stimulants; coffee; warmth; recumbent position.
Verdigris. See *Copper.*			
Wild Cherry. See *Prunus.*			
Wintergreen. See *Gaultheria.*			
Woorara. See *Curare.*			
Yew.....	Vomiting and delirium; pain in abdomen; irregularity of the heart's action; death may be sudden.	.....	Evacuate; quick purgation; stimulants.
Zea mays (*Maize*).....	Slow heart; dilated pupils; tonic convulsions.	Tetanus of respiratory muscles, or exhaustion.	Cardiac and respiratory stimulants.
Zinc.....	Corrosion of lips or mouth; pain and burning; incessant vomiting, the vomit blood-stained; acceleration of pulse and respiration; dyspnea; dilatation of the pupils; epileptiform convulsions; paralysis; coma.	.....	Sodium or potassium carbonate; milk; eggs; tannic or gallic acid; morphin hypodermatically; poultices to abdomen.

Household Antidotes.—When the other articles to be used as antidotes are not in the house, give 2 tablespoonfuls of prepared mustard in a pint of warm water. Also give large drafts of warm milk, or water mixed with oil, butter, or lard.

For bed-bug poison, For corrosive sublimate, For blue vitriol, For lead-water, For saltpeter, For sugar of lead, For sulphate of zinc, For red precipitate, For vermilion,	Give milk or white of eggs, large quantities.
For Fowler's solution, For white precipitate, For arsenic,	Give prompt emetic of mustard and salt, tablespoonful of each; follow with sweet oil, butter, or milk.
For antimonial wine, For tartar emetic,	Drink warm water to encourage vomiting. If vomiting does not stop, give a grain of opium in water.
For oil of vitriol, For aquafortis, For bicarbonate of potassium, For muriatic acid, For oxalic acid,	Magnesia or soap dissolved in water, every 2 minutes.
For caustic soda, For caustic potash, For volatile alkali,	Drink freely of water with vinegar or lemon-juice in it.
For carbolic acid,	Give flour and water, glutinous drinks, and a form of alcohol.
For chloral hydrate, For chloroform.	Pour cold water over the head and face, with artificial respiration, galvanic battery.
For carbonate of sodium, For copperas, For cobalt,	Prompt emetics; soap or mucilaginous drinks.
For laudanum, For morphin, For opium,	Strong coffee followed by ground mustard or grease in warm water to produce vomiting. Keep in motion.
For nitrate of silver,	Give common salt in water.
For strychnin, For tincture of nux vomica,	Emetic of mustard or sulphate of zinc, aided by warm water.
For iodin and iodids,	Prompt emetic; sclution of starch; flour and water.

POISONING, MEDICOLEGAL DUTIES IN FATAL CASES.—The duties of the medical examiner are:

1. To establish the presence or absence of conditions characteristic of any poison.

2. To preserve all necessary material for analysis, taking care that nothing thereby is done to introduce causes of error.

3. To recognize or exclude natural causes of death.

4. If necessary, to perform experiments upon animals to demonstrate the toxic effect of substances separated by the chemist.

5. To record carefully all personal observations and to state clearly the conclusions as to the cause of death.

Information as to the circumstances of the death, while guiding the medical examiner in his mode of proceeding, must not bias his scientific opinion.

The most difficult cases are those in which the postmortem appearances are negative or consistent either with disease or poison. In these, however, the postmortem evidence, though necessary, is only of indirect value. Want of harmony between the clinical, anatomic, and chemic evidence is a most serious obstacle to a decisive result in court, and witnesses for the prosecution are sometimes singularly blind to very obvious defects of this kind in State evidence. The scientific value of medical opinion in poisoning cases has been considerably overrated in the past, and when its limitations have become more clearly recognized on all sides, the present undignified conflict of scientific opinion in court will probably become a thing of the past. Overpositiveness is the root of nearly all evil in medical testimony.

In any medicolegal autopsies with negative results, poisoning should be borne in mind, and the necessary materials preserved until the case is cleared up, in case an analysis may be necessary. Finding of an immediate cause of death of another nature does not always exclude poisoning. For instance, a man may be drugged previous to a fatal assault, or the death of a sick person hastened by poison.

In making a report, after fully stating all facts established by the autopsy, but without introducing extraneous circumstances, the conclusions should be concisely drawn up. These should be limited to what is proved by the report beyond contradiction, and may usually be expressed in one or other of the following formulas:

1. The autopsy does not show cause of death. To determine whether poisoning has occurred, an analysis will be necessary.

2. Conditions found are *characteristic* of poisoning by . . . . . .

3. Conditions found *are consistent with* poisoning by. . . . . .(or *are not consistent*).

4. Death is due to. . .(natural cause), poisoning by. . . . . .is *excluded* (or *not excluded*, or *not demonstrated*).

Preliminaries.—The following general precautions are to be observed: The autopsy should be done by two medical men, with some one to take notes. Persons suspected must not be present at the autopsy, but may be represented. The identity of the body should be carefully established. In exhumations the pathologist should be present when the coffin is opened, and samples of soil above and below the coffin should be taken. Linings or shavings within the coffin, if soaked with fluid from body, should be preserved. Provide a sufficient number of clean new glass jars (the "gem" jar pattern will answer)—at least a dozen should be available. Materials for analysis should be kept under personal supervision and delivered by hand to the chemist—not sent by mail or express. Provide facilities for examining the organs without contact with substances which would interfere with chemic analysis. If new and clean porcelain dishes are not available, pieces of freshly sawed boards will answer. Decomposition is best prevented by freezing the organs. If available, a cold-storage chamber is best. When absolutely necessary to prevent decomposition, pure alcohol is recommended, a control sample being reserved for analysis (probably formalin will prove a better preservative, but its possible influence on the results of analysis is not yet known). A sample

of the jar used should be kept. The jars are to be sealed by attaching tape to both jar and cover by means of sealing-wax, the seal being retained. Jars containing decomposing tissues should be loosely stoppered to prevent bursting. A signed and dated label should be placed on each jar. By knowing the tare weight of the jars, or by using a counterpoise, organs may be weighed while in the jars.

The autopsy should be made as soon after death as possible, but preferably not by artificial light. The modern undertaker's fondness for embalming bodies is a serious inconvenience, but, fortunately, the arsenical preparations are being superseded by formalin. In some States legislative restrictions specifically forbid the embalming of bodies pending judicial inquiry.

Poisons introduced after death may diffuse through the tissues and enter remote organs, though most concentrated at point of insertion. The compounds formed by rapid putrefaction at high temperatures are less likely to be confused with alkaloidal poisons than those slowly formed at low temperature.

When practicable, the chemist may, with advantage, be present at the autopsy, but unless he is personally accustomed to postmortem work, the results of this assistance may be disappointing. Want of familiarity with ordinary cadaveric odors interferes much with the recognition of those characteristics of volatile poisons. On the other hand, the pathologist should be present at the opening and examination of the stomach and intestines if this is done by the chemist.

Technic. External Examination.—The surroundings of the body may give important information. Any substances which might contain poison found in the vicinity should be seized and preserved; the surface of the body should be examined for traces of corrosion or evidences of poison spilt. The mouth, lips, and tongue need careful examination, and the whole surface should be examined for hypodermic punctures. At all stages of the autopsy characteristic odors should be watched for. These may be masked by the odor from intestines, and hence may be best detected in the brain before the other cavities are opened. In a well-equipped laboratory facilities for making preliminary tests should be at hand.

Internal Examination.—Authorities differ as to the best order for examination of the organs. In Germany official regulations insist on the ligation and removal of the stomach and duodenum as the first step in the autopsy, to be done before opening the thorax. This has the advantage of interrupting the continuity between esophagus and stomach. French authorities insist strongly on the preservation of the blood for analysis of the dissolved gases, also on the separate preservation of the urinary organs, as in these alkaloids are found in the greatest state of purity. American toxicologists lay stress—and that rightly—upon large quantities of the tissues being preserved, and, especially in chronic poisoning, of analysis of large quantities of muscle and bone. Witthaus advises preserving, in separate jars, (1) the stomach and duodenum and contents, ligated and unopened; (2) the rest of the intestine and contents, ligated and unopened; (3) the entire liver; (4) the blood from the heart and vessels; (5) both kidneys; (6) the urine; (7) the entire brain; (8) a large piece of muscle from the thigh; portions of the bones and spleen may also be taken with advantage. Fairly satisfactory analyses, however, may be made with amounts considerably less. If only a few jars are available, group together (1) stomach and intestine with contents; (2) liver; (3) brain, blood, spleen, and kidneys, etc.; (4) bone or muscle. When the autopsy is done under very unfavorable surroundings, it may be safer simply to eviscerate all the organs, placing them in a large enamel vessel for immediate transport to the laboratory.

Proof of poisoning has been established by chemists by analysis of muscles or one kidney, when all the other tissues have been removed and got rid of by the suspected parties.

Important information as to the time of absorption is shown by the distribution of poisons in the various tissues. The unabsorbed residue is found in the stomach and intestines, plus whatever may have been excreted by the intestines. Poisons in both stomach and liver indicate a short interval between the taking and the death. Poison in the liver and organs, with none in the stomach, indicates a greater interval if the poison was taken by mouth. Most poisons remain in the liver after disappearance from the stomach, and remain longer in the muscles and bones than in any other tissue. Poisons are found in their greatest purity in the kidneys and urine. When chronic poisoning is suspected during life, a sample of urine may be quietly secured for analysis without arousing suspicion. Apart from the analysis, the stomach contents give valuable information as to the time and composition of the last meal, which may have a very important and circumstantial bearing.

In corrosive poisoning, the best results are obtained by removing the mouth, esophagus, stomach, and duodenum together. The fauces and pharynx, besides corrosion, may show foreign substances, and any particle between the teeth should be carefully examined. The crucial point of the autopsy is the opening and examination of the stomach, which should be done over a vessel suitable for receiving the contents, the mucous membrane being spread out and examined with a hand lens for lesions and suspicious substances. The cooperation and presence of the chemist at this stage is specially valuable, but the examination of the stomach by the chemist alone may lead to statements very extraordinary from a pathologic point of view.

For analysis of contained gases in blood, the bottles should be completely filled and tightly stoppered.

It must be remembered that besides the examination for poisons and their lesions, every organ must be thoroughly examined and all natural causes of death, in particular the causes of sudden death, rigidly excluded. Particular attention must be paid, therefore, to the cerebral, pulmonary, and coronary arteries, the veins and other

sources of embolism, the heart-muscle, brain, and the air-passage.

In addition no examination should be neglected which will forestall subsequent hypothetic objections, the spinal cord being best examined as part of the routine. It is most necessary that microscopic and bacteriologic studies be made when these will yield any information. Small bits of tissue preserved in formalin for microscopic examination will often give decisive information in organs too decomposed to be trustworthy to the naked eye.

Sources of Error.—The principal are: (1) Failure to recognize the existing appearances of poisoning; (2) supposed detection of characteristic appearances not really present; (3) misinterpreting, an effects of poison, lesions due to disease or to agonal or postmortem changes. In acute cases the possibility of remedial measures employed in modifying appearances must be borne in mind. The inflamed and reddened conditions of the stomach recorded for many poisons, are probably largely mistakes of observation.

The stomach in full digestion is found intensely reddened postmortem. Softening of the mucosa after death may resemble erosion, and passive or hypostatic congestion may lead to suffusion of blood in the mucous membrane, with the appearances strongly resembling those in inflammation. Due allowance must be made for the attitude of the mind when certain changes are expected. To pathologists, reddening or congestion of the stomach mucosa in itself indicates nothing important.

Anatomic Distribution of Lesions.—The following are some of the more common changes:

Surface.—Pinkish lividity, from carbon monoxid or cyanid of potassium.

Fauces, Esophagus, and Stomach.—Foreign substances, corrosion effects, odors, inflammatory exudates, ulcers, and perforation; brittleness from acids; soapiness from alkalies. The microscopic examination of sloughs shows hemorrhagic infiltration at the base, and may show crystals, as arsenic or oxalates. Diluted corrosives cause more inflammation, but less necrosis, than concentrated ones. The stomach lesions lie mostly at the greater curvature and along the rugæ. Among foreign substances, may be found matchheads, indicating phosphorus; cantharides scales, Paris-green particles, etc. Fatty change following cloudy swelling may occur secondarily in arsenic and phosphorus-poisoning.

Intestines.—Diffuse pinkish congestion, with rice-water contents in arsenic poisoning, and membranous colitis in sublimate poisoning, are highly characteristic.

Blood.—Carmin colored in poisoning by carbon monoxid and potassium cyanid; dark in prussic acid poisoning; chocolate brown, with destruction of red cells, from potassium chlorate and other reducing agents; dark, and free from clots in alcoholic or narcotic poisoning, and all conditions causing death by asphyxia. Distinctive odors may be present.

Heart.—Fatty in subacute arsenic and phosphorus-poisoning; ecchymoses of walls with phosphorus-, and subendocardial ecchymoses with arsenic, poisoning.

Lungs.—Congestion and bronchopneumonia from narcotics; carmin colored and edematous in carbon monoxid; fat emboli with phosphorus.

Kidneys.—Cyanosed in alcoholism, with the hog-back shape; cloudy swelling and fatty change in arsenic and phosphorus; congestion and glomerular and papillary hemorrhages in cantharides; methemoglobin infarcts with potassium chlorate, etc.

Liver.—Fatty with arsenic and phosphorus-jaundice in phosphorus.

Lesions Characteristic of the More Important Poisons. Concentrated Sulphuric Acid.—Blackening from carbonization in esophagus, stomach, and duodenum; perforation and charring of adjacent organs; erosion of skin.

Dilute Sulphuric Acid.—Severe gastroenteritis, with sloughing and ulceration.

Hydrochloric Acid.—Concentrated: corrosion, with gray color of the stomach; no corrosion of skin. Dilute: same as dilute sulphuric.

Nitric Acid.—Intense yellow tint from the formation of picric acid, tissues becoming very brittle.

Caustic Alkalies.—Mucosa of mouth, esophagus, and stomach swollen, translucent, and brown, soapy to the touch, and with odor of lye. In later stages intense inflammation of stomach and esophagus (croupous in the case of ammonia), followed by ulceration. Stricture of esophagus frequently follows.

Nitrous Acid Fumes.—Intense capillary bronchitis, with edema of lungs.

Corrosive Sublimate.—Severe gastroenteric with diphtheritic colitis and very marked cloudy swelling of the kidney.

Arsenous Acid.—Intense congestion and hemorrhage of stomach; diffuse pinkish congestion of small intestines, with rice-water contents, free from fetor. Subendocardial ecchymoses. In later stages, necrosis and fatty change in stomach, cloudy swelling and fatty change of kidneys, skin eruptions, and neuritis in chronic cases.

Antimony Tartrate.—In acute cases general appearances similar to arsenic; in addition sometimes pustular eruption where tissues are in contact with the solid particles, as in esophagus; greater tendency to engorgement of lungs with pulmonary apoplexy.

Silver Nitrate.—Whitish coagulum, blackening on exposure to light; blackening of skin and internal organs in chronic poisoning (very rare).

Copper Salts.—Blue discoloration and tan appearance of tissues.

Lead.—In chronic cases blue line of gums, with fibrosis of the organs and nerves (changes not constant).

Carbolic Acid.—Corrosion, with drying, hardening, and whitening of tissues; characteristic odor; stomach pinkish-gray; blood, in contact, brick-red; lungs engorged.

Oxalic Acid.—Whitish coagulation of mucosa at point of contact; severe inflammation and hemorrhage about corroded areas, if death is not im-

mediate; infiltration of tissues by octahedral oxalate crystals.

Phosphorus.—Sometimes luminosity of stomach contents; presence of match-heads, onion odor, intense jaundice, fatty degeneration of liver, kidneys, and heart; ecchymoses throughout entire body; fat embolism. In chronic forms necrosis of jaw.

Carbon Monoxid.—Bright red lividity of surface. Carmin color of blood, with persistent fluidity and characteristic spectrum. Pinkish appearance of organ from alteration in blood tint. Edema of lungs; asphyctic state, with engorgement of organs. Delayed decomposition. Color of blood unaltered on adding alkalies, tannic acid, etc.

Hydrocyanic Acid.—Asphyctic state; characteristic odor (masked in presence of ammoniacal decomposition). Blood becomes bright red on adding reducing agent.

Cyanid of Potassium.—Asphyctic state; odor as in prussic acid; blood lake-colored. Mucosa of esophagus and stomach brownish-red, swollen, thrown into folds, translucent, and slippery.

Nitrobenzol.—Intense cyanosis; odor of bitter almonds.

Potassium Chlorate.—Cyanosis and asphyxia; chocolate-brown color of blood and organs, with methemoglobin spectrum; acute hemorrhagic glomerulonephritis, with methemoglobin in kidneys, spleen, bone-marrow, and urine.

Potassium Bichromate.—Changes similar to those from potassium chlorate; decomposition delayed.

Hydrogen Sulphid.—Characteristic odor; greenish tint of blood (only found in animal experiments).

Alcohol.—Characteristic odor, specially marked in brain and liver; odor may be that of aldehyd, ether, or mercaptan. Asphyxia, engorgement of organs with blood, edema of glottis, lungs, and pia. The organs usually present stigmata of chronic alcoholism—viz., cyanotic (hog-back) kidneys, with diffuse cirrhosis; fatty or cirrhotic liver, milky opacity of pia, and chronic or acute gastritis.

Cantharides.—Inflammation of stomach and intestine, with presence of scales in the stomach; acute hemorrhagic glomerulonephritis, hemorrhagic pyelitis, and hematuria.

The following poisons have appearances which, while fairly constant and uniform, are not in themselves characteristic:

Morphin, Laudanum, Chloral, and Narcotics.—Intense cyanosis and congestion of organs, frequently bronchitis and commencing hypostatic pneumonia.

In poisoning from **strychnin, belladonna, and other alkaloids, and in most glucosids,** the postmortem conditions indicate death by asphyxia. It must be mentioned, also, that this condition is found in poisons which produce syncopal effects, such as aconite, etc., the anatomic condition described as characteristic of syncope being only a figment of medicolegal imagination. With poisoning from digitalin and ptomains diarrhea is often a prominent symptom, without inflammatory changes in the intestines.

Anesthetics.—In deaths during anesthesia the appearances are usually negative; accidental causes of suffocation should be carefully looked for, as well as evidences of organic disease. Suffocation by inhalation of vomited matters is very frequently the immediate cause of death in alcoholism and carbon monoxid poisons, and occasionally is so in other poisons.

The recent work showing that ricin, abrin, and other substances produce cell-necrosis in the liver and kidney, indicates a field in which investigation is needed, and might give valuable diagnostic results. The leukocytosis in arsenic and other poisons may prove of importance in the future. The swelling and hemorrhagic condition characteristic of snake-venom, and the cell changes produced by the bacterial toxins, have important bearings on toxicology. So also has the rôle which secondary bacterial infection plays in poisoning cases, though as yet data on this are too meager to permit of generalization.

In the foregoing article prominence has not been given to the minor technic details of autopsy routine. Those who are not thoroughly familiar with autopsy methods will probably serve best their own interests and those of the public by not attempting work of this kind. When such a person cannot avoid the responsibility, his best plan would be to remove all the organs with as little dissection as possible, and bring them, untouched and uncontaminated, into the hands of some more competent person.

POLIENCEPHALITIS.—See Brain (Inflammation).

POLIOMYELITIS, ACUTE ANTERIOR.—See Paralysis (Infantile).

POLIOMYELITIS, ACUTE IN ADULTS (*Acute Atrophic Spinal Paralysis of Adults*).—Very rarely in adults under 30 occurs a disease almost identical with the infantile form, though mistakes in diagnosis have been made, the disease being in reality multiple neuritis.

POLIOMYELITIS, SUBACUTE AND CHRONIC (*General Anterior Spinal Paralysis, Subacute of Duchenne, Subacute and Atrophic Spinal Paralysis*).—Cases have occurred, though rarely, characterized by paralysis and atrophy of all extremities without sensory disturbance, and without the severe onset of the acute form. It has often been mistaken for multiple neuritis.

POLITZERIZATION.—See Ear (Examination).

POLLANTIN (Dunbar's Serum).—An antitoxic serum from horses treated with pollen toxin derived from ragweed. It is used in the prophylaxis and treatment of hay fever. See Hay Fever.

POLYCYTHEMIA.—Marked increase in the red blood cells is generally indicative merely of concentrated blood or stasis. It occurs in health after bathing, massage, violent exercise. It is observed in high altitudes and follows the administration of certain drugs. It may occur during digestion, in blood regeneration, vomiting, profuse sweating, the removal of exudates, profuse diarrheas and, it is said, with myxedema and acute yellow atrophy. It is found in circulatory derangements, such as

organic heart disease, emphysema, stenotic dyspnea. See Blood.

POLYDIPSIA.—Excessive thirst. It is usually present in fevers and in diabetes. See Thirst.

POLYNEURITIS.—See Neuritis (Multiple).

POLYPUS.—A pedunculated tumor arising from mucous membranes. The nose is a frequent seat of polypi. Uterine polypi are of three kinds—cystic, derived from the ovules of Naboth; mucous or soft, resembling rectal polypi; and hard or fibrous, the so-called fibrous polypus of the uterus. Polypi of the ear resemble nasal polypi, springing from the tympanic membrane and from the interior of the tympanum. Intestinal polypi are of more frequent occurrence in the rectum than in any other portion of the intestinal tract. They are composed of tissue resembling that of the mucous membrane of the part, and are mostly described as adenomata. Polypi are also found in the bladder, larynx, on the gums, and sometimes in sinuses communicating with the nose. See Nose, Uterus.

POLYURIA.—Excessive secretion of urine. The causes of temporary polyuria are: excessive ingestion of fluids, cold, suppression of perspiration, the use of diuretics; it occurs in the crisis of fevers, and in certain neurotic conditions, as hysteria, and in nervous excitement. A permanent polyuria is met in diabetes mellitus, diabetes insipidus, chronic interstitial nephritis, and in amyloid disease of the kidneys. See Diabetes, Nephritis, Urine (Examination).

POMEGRANATE.—See Granatum.

POMPHOLYX.—A rare inflammation of the hands and feet generally of the palmar and plantar surface, resulting in the formation of vesicles and blebs, occurring in adults. The majority of cases are met with in neurotic women. The vesicles are deep-seated and resemble boiled sago grains; they may disappear by absorption or become purulent or coalesce to form large, flat blebs. The disease is usually symmetric and lasts from a few weeks to several months. It must not be confounded with eczema or rhus poisoning. Treatment consists in improving the general health by tonics and good food and keeping the bowels open. Soothing applications are indicated locally.

PONS, DISEASES.—**Tumors** of the pons produce symptoms chiefly of pressure. Of 52 cases, 13 had cerebral nerves involved, in 13 the limbs were affected, and in 26 hemiplegia and nerve involvement existed. Twenty-two of the latter had alternate paralysis. In 4 no motor symptoms presented.

Hemorrhage into the pons and medulla oblongata is rarer than cerebral hemorrhage and more frequent than hemorrhage into the spinal cord. Atheroma or miliary aneurysm and other factors productive of increased arterial tension are usually coincident, while cardiac hypertrophy, nephritis, excessive bodily exertion, and alcoholism may be traced.

Lesions involving the pyramidal tract cause crossed paralyses. A lesion in the lower part of the pons will cause a lower segment paralysis of the face on the same side, and a spastic paralysis of the arm and leg on the opposite side. The abducens, the motor part of the trigeminal, and the hypoglossal nerves may likewise be paralyzed. When the central fibers to the nucleus of the hypoglossus are involved, a peculiar form of anarthria follows. Swallowing is interfered with if the nucleus itself is involved. A paralysis of the external rectus muscle of one eye and of the internal rectus of the other eye, in the absence of a "forced position" of the eye-balls, is highly characteristic of certain lesions of the pons. The internal rectus may still be capable of convergence. This conjugate paralysis may be complicated by other disturbances of eye-muscle movements, and the facial nerve is often involved in these paralyses.

In lesions of the pons the patient has a tendency to fall to the side on which the lesion is situated. Still more frequent is the simple motor hemiataxia consequent upon lesion of the medial lemniscus and possibly the longitudinal bundles in the formatio reticularis. Only when the lesions are very extensive are there disturbances of hearing.

Treatment should conform to that of cerebral hemorrhage. Electricity is indicated for the paralysis.

POPLITEAL ANEURYSM.—The popliteal artery is the most common seat of aneurysm, except the aorta itself. It is peculiarly liable to atheroma; it is not supported by the structures around; it is compressed more or less in flexion of the knee, stretched out in overextension, sometimes even ruptured; and immediately below it breaks up into a number of branches, so that an embolus, if it comes down the vessel, is almost certain to lodge there. That constitutional causes are of very great importance is shown by the fact that it sometimes occurs on both sides, and that it may even develop upon the second while the patient is lying in bed being treated for the first. Fusiform dilatation occasionally occurs, but sacculated aneurysm is much more common. In some cases it springs from the anterior surface of the artery and grows forward against the bone or the posterior ligament of the knee-joint, and then it is usually slow in its course, rarely attaining a large size. In others it extends backward, and, meeting with little to oppose it, becomes immense, forming a thin-walled sac within a comparatively short space of time.

Symptoms.—Occasionally the onset is sudden, dating from some exertion; more frequently, the patient suffers from obscure rheumatic pain down the leg, with stiffness of the joint and sense of weakness, and then suddenly discovers, or has discovered for him, the presence of a pulsating swelling. Usually the expansive pulsation, the bruit conducted down the leg, and the way in which the sac empties upon compression and fills again on relaxation of the vessel are distinctive. Occasionally the tumor is harder and cannot be emptied, the pulsation is that of an artery only, and the bruit is indistinct and faint; and in some very rare instances there is no pulsation at all. Probably, in the former case, the sac is already partly filled with fibrin, and possibly in the latter it is completely solid; but as pulsation sometimes makes its appearance later, this explanation is hardly satisfactory. If the sac grows forward, synovitis of

the knee-joint sets in, the pain is very severe, and movement greatly restricted. If it takes a direction backward, the popliteal vein may be compressed and congestion and edema follow; or the internal popliteal nerve may be stretched so that there is severe neuralgia extending down the side of the limb into the sole of the foot. Sometimes a distinct difference can be made out in the two tibial pulses.

Left to itself it occasionally undergoes spontaneous cure. Much more frequently it grows larger and larger, leaks, and ruptures either into the knee-joint, or more usually into the cellular tissue of the leg. In either case the patient is conscious of something having given way, and becomes sick and faint with the pain and loss of blood. If the rupture takes place through the posterior ligament, the knee becomes immensely distended at once, but the bruit and pulsation do not cease altogether, and the pulse can still be felt, though feebly, in the posterior tibial. If it is into the cellular tissue, a tense swelling forms rapidly in the popliteal space, filling it completely and causing the most severe pain; the limb below becomes cold and livid, the tibials cannot be felt, and in a very short time gangrene sets in. Occasionally inflammation breaks out round the sac, the skin becomes red, edematous, and exceedingly painful, and sometimes this is followed by suppuration.

The differential diagnosis must be made from sarcoma growing either from the bones, the posterior ligament of the knee-joint, or the lymphatic glands; abscess; bursal cyst, or diverticulum from the knee-joint; and solid tumors resting upon the artery. Arterial hematoma from perforation of the popliteal artery gives rise to the same symptoms as a leaking or a ruptured aneurysm, according to the size of the opening. Sometimes there is a distinct bruit with faint pulsation along the course of the vessel.

Treatment.—Rest and diet are employed only as adjuncts, but they should never be neglected, and unless the sac is enlarging rapidly, so that there is fear of rupture, it is always advisable to submit the patient to a few days' preparation before employing any active treatment. If the aneurysm is of moderate size only, and there is no fear of immediate rupture, Reid's method with Esmarch's bandage, or digital compression, is the best, preference being given to the latter if there is much evidence of atheroma or of heart-disease; to the former if, other things being suitable, there are enlarged glands in the groin. Flexion succeeds well with aneurysms that are small or already partially solidified. If these measures fail, or if the sac is enlarging rapidly and perhaps leaking, or if inflammation has set in, or if there is any edema of the foot from pressure upon the popliteal vein, surgical treatment should be resorted to. Matas' operation of aneurysmorrhaphy has been practised with success in popliteal aneurysm, and is to be preferred to ligation of the femoral artery. See Aneurysm.

POPPY.—See Opium.

POSITIONS.—See Fetus (Positions and Presentations.)

POSTMORTEM EXAMINATION.—**The general technic** of a postmortem is as follows: First, the appearance of the body is described, including sex, height, apparent age, discoloration of the skin, rigor mortis, state of nutrition, injuries, deformities, and any peculiarities that may be observed.

An incision is then made from the top of the sternum to the pubic symphysis, the abdomen being the cavity first opened. Then the position of the viscera, their condition, the presence of hernia, if it exists, the state of the peritoneum, and the quantity of fluid are noted, but all without disturbing the relation of the contents. The thorax is now opened. In order to do this, the ribs are divided at the costochondral junction, and the sternum and clavicles disarticulated. The relation of the structures exposed on lifting up the separated portion of sternum and ribs is noted—the presence of fluid in the pleural cavity, pleural adhesions, the extent to which the lung covers the pericardium. The pericardial sac is next opened, and its condition and the quantity of fluid recorded.

The opening of the heart is the next step. This may be done in several ways; one of the best is Virchow's method. The heart is opened *in situ*. The first incision is made in the right ventricle (many open the right auricle first), along the ventricular ridge, from near the auriculoventricular groove to near the apex. The second incision opens the right auricle midway between the entrances of the venæ cavæ. In the left auricle the incision is carried from the left superior pulmonary vein to near the auriculoventricular ring. The incision through the left ventricle begins just behind the base and ends just short of the apex. It must be carried deeply through the wall of the heart. The heart is now removed. To do this the organ is grasped with the index-finger of the left hand in the left ventricle and the thumb in the right; the heart is then raised by the apex and the venæ cavæ, the pulmonary veins, and the pulmonary artery, and the aorta divided, taking care that the incisions are not too close to the heart. The next step is to open the ventricles. For this purpose the heart is placed exactly in the position it occupied in the body. One blade of the scissors is then introduced near the lower end of the incision in the right ventricle, and carried outward in the direction of the pulmonary artery. The incision for the left ventricle commences at the apex of the heart and divides the anterior wall of the ventricle close to the septum, and is continued outward.

The lungs are next removed, usually the left first. Section of these organs is made by a long sweep of the knife—in the case of the left preferably from the apex to the base; in the case of the right, from the base to the apex. Attention is now directed to the abdomen, the **spleen** being the first organ removed.

Next come the **suprarenals** and the **kidneys**. In order to gain access to these it is wise to dissect off, by a few quick cuts, the entire colon from the sigmoid flexure to the ileocecal valve. A double ligature is placed around the sigmoid, and the gut

divided between the ligatures. The removal of the kidneys is further facilitated by cutting the diaphragm loose from its costal attachments and throwing it upward, with the liver, into the thoracic cavity. The adrenals and kidneys are then exposed; the course and condition of the ureters are noted. The suprarenals may now be removed separately, or taken out with the kidneys; in either case it is best to remove the organs on the left side first. Section is made of the adrenals; also of the kidneys. In the latter the capsule is stripped off, and a note is made of the extent, if at all, to which it is adherent; also whether the renal substance is torn on removing the capsule.

The next step consists in the **removal of the intestines**. These are cut closely to their mesenteric attachment, care being taken to leave as little of the mesentery attached to the gut as possible. The fecal contents are then washed out by a running stream of water through the bowel, which is opened at the attachment of the mesentery and examined. In removing the intestines the rectum and the first and second portions of the duodenum are left *in situ*. The next step is usually the **opening of the stomach** and remaining portion of the duodenum. This is accomplished, like the opening of the intestines, by means of the enterotome. After the duodenum is opened, the **gall-bladder** is pressed until bile is made to flow from the mouth of the common duct in the duodenum. If this is impossible, obstruction exists. The gastric contents are described, and the condition of the walls noted. The **pancreas** is now examined, the condition of its duct, and the presence of cysts or stones being noted. It is then removed and incised longitudinally.

The liver is next taken out, the condition of the vessels entering the portal fissure having been noted before they were divided. The liver is weighed and measured transversely, longitudinally, and vertically, the width of the two large lobes being taken separately. A long incision is now made into the substance of the organ and the conditions noted, especially the relation of the connective tissue to the hepatic substance proper.

The pelvic organs are next removed. This is best accomplished by first making a cut into the **bladder**; into the opening a finger is inserted, while the other fingers grasp the rectum. By making the tissues tense, their separation from the bony wall of the pelvis is facilitated. After removal they are cut open; in the case of a female subject the **uterus** is opened by a longitudinal cut through the anterior wall. A fine probe is passed into the oviducts to ascertain their patulousness; they may also be opened by a delicate pair of scissors.

Nothing of importance remains now in the abdomen except the vessels and the semilunar ganglia. The latter should be examined *in situ* and also after removal. The **aorta** should be opened by a longitudinal incision extending from the beginning of the arch down to its bifurcation, thence prolonged out into the iliac arteries. The **thoracic duct** should be looked for at the side of the aorta. The **trachea**, larynx, thyroid gland, pharynx, and tongue can be removed either through a median incision in the front of the neck or from the base of the neck.

For the **removal of the brain** it is necessary to saw out a portion of the cranial vault. It is customary to divide the scalp about on a line with the coronal suture. The vault is sawed through in front and behind, a large, wedge-shaped piece being removed. The dura is then divided on a line with the sawed edge of the bone, and also separated from the attachment to the crista galli in front. The brain is then carefully lifted from its bed, the nerves passing from it divided, and the attachment of the dura to the petrous portion of the temporal bone cut loose. If possible, the pituitary body should be kept attached to the brain.

A long knife is now introduced into the spinal canal, and the cord cut as low down as possible. The brain is then lifted out and placed on a board or plate. After a careful survey of its external appearances, the organ is dissected. A number of methods are in vogue. One of the best is that known as Edinger's method; only its general features can be indicated here. The lateral ventricles are first opened; then the cerebral hemispheres are cut away from the basal ganglia. Longitudinal and transverse cuts are made into the cerebral mantle, observing always to make the incisions as near as possible at right angles to the course of the convolutions. The basal ganglia are examined by making multiple incisions into them; the cerebellum is similarly treated.

The spinal cord is generally removed from the back; special saws have been devised to cut the pedicles of the vertebræ. The cord itself is removed in its membranes from below upward, the most important point being the avoidance of traction. The membranes are opened, and the cord substance divided at short intervals by transverse cuts. The eyes, if it is necessary, can be removed without difficulty. The removal of the organ of hearing requires considerable labor. All organs should, if possible, be weighed.

POSTPARTUM HEMORRHAGE.—Hemorrhage during and after the third stage of labor. Should it occur after the first 24 hours of the puerperium, it is called puerperal hemorrhage.

Postpartum hemorrhage may be divided into: (1) Hemorrhage from relaxation of the uterus; (2) hemorrhage from rupture of the uterus; (3) hemorrhage from inversion of the uterus; (4) hemorrhage from lacerations of the lower birth canal, and (5) hemorrhage into the perivaginal tissues (hematoma).

Hemorrhage from Relaxation of the Uterus.—This is one of the most common forms of postpartum hemorrhage, and is what is meant when the simple term "postpartum hemorrhage" is used.

Causes.—Any condition which interferes with firm contraction of the uterus after the expulsion of the child might be mentioned as a cause of postpartum hemorrhage. Of these conditions may be mentioned weakness of the uterine muscle from overdistention; general disease; faulty develop-

ment; mental anxiety; retained placenta, membranes, or blood-clots; old adhesions; tumors, and distended bladder and rectum.

Symptoms.—The important symptom is hemorrhage, which may appear before or after the expulsion of the placenta. There may be sudden gush of blood, profuse enough to destroy the patient in a few moments; or there may be a succession of gushes a few ounces of blood being lost every few seconds. Not infrequently there is a steady flow of blood from the uterus, which will only end with the death of the patient or with the most active treatment. Palpation shows a large relaxed uterus, and there are marked constitutional signs of hemorrhage, such as extreme pallor, vertigo, sighing respiration, and, possibly, syncope. The pulse is extremely weak and rapid, or it may be entirely absent at the wrist.

Treatment.—The proper management of the third stage of labor, followed by the application of an abdominal pad and binder, is the best preventive treatment of postpartum hemorrhage. When one has special cause to fear hemorrhage, as in case of multiple pregnancy, hydramnios, and the like, a good precautionary measure is the hypodermic injection of 3 to 5 grains of ergotin as soon as the child's head is born.

In the majority of instances a postpartum hemorrhage may be quickly controlled by **external stimulation of the uterus.** The fundus is grasped by the hand through the abdominal wall, and is pinched, kneaded, and irritated until, in favorable cases, it becomes firm and hard and the bleeding ceases. If the placenta is not yet expelled, it should be expressed by the Credé method. If the foregoing procedure fails to control the bleeding, the disengaged hand should be passed into the uterine cavity and all placenta, membranes, and blood-clots should quickly be removed. This **internal stimulation of the uterus** will usually prove most effective. Should this fail and should the hemorrhage be rather slight in amount, **hot douching** may next be tried. A fountain syringe is filled with plain boiled water at a temperature of 120° F., and this thrown well up into the uterine cavity by means of a large two-way metal catheter. Should the bleeding be alarming in quantity or should this latter method fail, the last and most effective method of treatment is the use of the **intrauterine tampon.** The best material for plugging the uterus is 5 percent iodoform gauze. The patient is brought across the bed with the buttocks extending well over the edge; the anterior and posterior lips of the uterus are each grasped with a double tenaculum and drawn well down toward the vulvar orifice. The end of the gauze is seized with dressing forceps and, guided by two fingers of the left hand, introduced into the cervix and pushed well up to the fundus; the dressing forceps are now removed and successive portions of the gauze are carried up until the uterine cavity is firmly packed from above downward. If the packing is done properly, from 3 to 5 yards of gauze will be required. This is followed by packing the vagina, either loosely or tightly as may be indicated. In exceptional cases when the uterus is entirely atonic, it may be necessary to reinforce the vaginal tampon by a large perineal pad and binder, the two ends of the binder being firmly attached to the abdominal binder.

The subsequent treatment will depend upon the amount of blood the patient has lost, and upon her general condition. After a moderately severe hemorrhage it will be sufficient to remove the pillow from under the patient's head and raise the foot of the bed; to give some rapidly acting cardiac stimulant; hypodermic injections of ether, brandy, or carbonate of ammonium; to give frequently repeated teaspoonful doses of strong hot coffee, hot water and brandy, hot milk, red wine, or champagne; and to surround the patient with hot bottles, and cover her with warm blankets.

When the anemia is extreme, it is necessary, in addition to the preceding, to replace the lost fluid as quickly as possible. This is done most readily by the injection of a normal salt solution—about 40 grains of NaCl to the pint of warm water—into the large intestine. Two or 3 pints of this solution, if retained, will cause a very marked and rapid improvement in the pulse. If the bowel will not retain this solution, it should be given subcutaneously. A cannula about the size of a rye-straw is attached to the rubber tube of a fountain syringe; the syringe, placed about 6 feet above the patient, is filled with a sterile salt solution; the cannula is plunged directly into the cellular tissue underneath the mammary gland, starting at the outer periphery of the gland; the fluid is allowed to drain into the tissues until a pint or more has been absorbed. Both breasts may be filled with this solution, or the loose tissue in the axilla or between the scapulæ may be selected for this purpose. Autotransfusion (bandaging the extremities and thus forcing the blood into the vital organs) will be found a useful adjunct. After the patient has reacted, a hypodermic injection of morphin (1/6 grain) will quiet her, and probably induce a much-needed sleep.

Hemorrhage from Rupture of the Uterus.—Rupture of the uterus is one of the rarest accidents of labor, occurring once in about 4000 cases. The position of the rent is most frequently in the lower uterine segment. Occasionally, the rupture is an incomplete one, involving the mucous and muscular coats only.

Causes.—The most frequent cause is some serious obstruction to labor, such as grave degrees of contracted pelvis, malposition of the child, and tumors obstructing the pelvic canal. Any condition weakening the uterine wall, such as fatty degeneration of the muscle, or a previous cesarean section, predisposes toward rupture. External traumatism may be mentioned as a rare cause.

Symptoms.—Rupture of the uterus may occur at any time during labor, but it occurs most frequently during the second stage. A prolonged second stage of labor, with frequent severe pains, thinning of the lower uterine segment, and rise of the contraction ring, should be looked upon with apprehension, as they are premonitory signs of rupture. At the time of rupture there are usu-

ally violent pain and a sensation as though something had "given away." There are pronounced shock, rapid weak pulse, pallid, leaking skin, fall of temperature, and sighing respirations.

Physical Signs.—The os is widely dilated; the membranes are ruptured; the presenting part, unless it has been firmly engaged, recedes; the uterine contractions cease, and the child may plainly be felt in the abdominal cavity. It may be possible to feel the rent in the uterus, with perhaps loops of intestines projecting through it. Rupture of the uterus may occur, rarely, without any of these symptoms—the rent being discovered during efforts at the removal of the placenta. In rare instances the uterus may rupture during the puerperium as a result of pressure necrosis, septic ulceration, or malignant degeneration of the deciduæ. The symptoms and treatment are those of septic infection.

Prognosis.—This depends largely upon the extent of rupture, the amount of hemorrhage, the cleanliness with which labor has been conducted, and the treatment. The mortality is variously given at from 55 to 90 percent. The two chief dangers are hemorrhage and sepsis.

Treatment.—This will depend upon the conditions present. Rupture of the uterus can be prevented, usually, by the proper treatment of labor complicated by contracted pelves, by correction of malpositions, and the like.

If the child is delivered before the rent is diagnosed, the treatment will depend upon the amount of hemorrhage. The placenta should be delivered immediately and a hypodermic injection of ergotin administered. If the hemorrhage is slight, a strip of iodoform gauze may be introduced into the rent to secure drainage. No further treatment is necessary except the removal of the gauze at the end of 24 hours. If the child is not delivered and is still in the uterine cavity, it must be extracted immediately by forceps, version, or craniotomy. If it has been extruded into the abdominal cavity, laparotomy must be performed immediately. In all cases when the rent is large, when the hemorrhage is great, and when it is believed that septic material has escaped into the peritoneal cavity, the abdomen must be opened, the peritoneal cavity cleansed, and the uterus amputated, or the rent closed, as may be indicated. When a conservative plan of treatment is at first pursued, it may be necessary to open the abdomen later on account of the occurrence of septic infection.

Hemorrhage from Inversion of the Uterus.—This is an extremely rare accident. It may occur before or after the expulsion of the placenta.

Causes.—Effort to secure delivery of the placenta by traction on the cord is probably the most important cause. Precipitate labor and paralysis of the placental site have also been mentioned as causes.

Symptoms.—The important symptoms are shock and hemorrhage. The former is most marked, the latter is variable. Pain may be present, although it is not a constant symptom.

Physical Signs.—A soft, round, tumor protrudes from the vulva. To it may be attached all or portions of the placenta. The orifices of the fallopian tubes may be seen on either side. The finger passed along the side of the tumor at its apparent attachment feels the symmetrically reflected cervix surrounding it. Abdominal palpation shows an absence of the fundus, a cup-shaped depression, containing, perhaps, the tubes and ovaries, being felt instead.

Prognosis.—This is very grave unless the uterus can be quickly replaced. Shock, hemorrhage, and sepsis may be causes of death.

Treatment.—This consists in immediate reposition. The uterus is grasped in such a manner that the fundus rests upon the palm of the hand, the fingers and thumb surrounding the reflected portion of the cervix. The vaginal part of the cervix is gradually dilated with the tips of the fingers, and the body of the uterus is passed steadily upward and forward until reduction is complete. If the placenta is adherent, it should be removed before attempting replacement.

Hemorrhage from Lacerations of the Lower Birth Canal.—Lacerations of the lower birth canal resulting in profuse hemorrhage are situated in the cervix, anterior vaginal wall, near the urethra, or about the clitoris. Inspection of the cervix, vagina, and vulva will speedily make the diagnosis.

Treatment.—If of the cervix, a tampon of iodoform gauze packed closely around the vaginal aspect will quickly control it. In very rare cases it may be necessary to suture it. If of the anterior vaginal wall or about the clitoris, a provisional tampon may be introduced, which is subsequently removed and the tear closely sutured.

Hemorrhage into the Perivaginal Tissues.—This is a rather infrequent complication of labor. It may occur in the labia, underneath the vaginal wall, or in the broad ligament.

Causes.—A varicose condition of the veins, which is so constant an accompaniment of pregnancy, is the predisposing cause. The exciting cause is the traumatism inflicted by the passage of the child; or it may be due to the use of forceps or other manipulations in securing delivery.

Symptoms.—Sharp pain is felt at the time of rupture, and, in exceptional cases, there may be signs of internal bleeding.

Physical Signs.—A bluish tumor, varying in size from a walnut to a fetal head, may be seen at the vulva, or may be felt in the vagina. It gradually increases in size, and is elastic or fluctuating. Very rarely it may rupture externally, causing profuse hemorrhage.

Prognosis.—If properly treated, the prognosis is favorable. The most serious complication is infection of the blood-clot.

Treatment.—If the bleeding does not subside spontaneously, it should be controlled by pressure and the application of ice. Subsequently, absorption should be encouraged by absolute quiet, cleanliness, and protection. If suppuration should occur, free incisions, with irrigation and drainage, must be resorted to. In exceptional cases it may be necessary to incise the tumor, turn out the clot, and ligate the bleeding point.

POSTURE.—See Gynecologic Examination.

POTASSIUM.—K = 39; quantivalence 1; specific gravity 0.865. A metallic element, of silvery luster, and characterized by intense affinity for oxygen. Its peculiar reactions are its precipitation when converted into the acid tartrate, its precipitation by platinum perchlorid, and the violet color it imparts to the flame. Physiologically, salts of potassium are protoplasmic poisons when applied locally in sufficient concentration. They dialyze more readily than sodium salts. In the body they occur especially in the solid structures, while sodium salts predominate in the fluids. In large doses by the mouth, potassium salts act as irritants to the gastrointestinal tract. The circulation is generally depressed by potassium salts—after small doses the primary depression of the pulse-rate and arterial pressure is followed by a rise of both; large doses cause a rapid fall of pressure and pulse-rate. Injected into a vein, salts of potassium cause paralysis of the heart. Potassium salts are obtained from the ash of plants, from saltpeter, from the potassium bitartrate deposited from urine in the process of fermentation, and from the washings of sheep's wool. The action of the various salts is given under their proper headings.

Preparations.—**P. Acetas,** $KC_2H_3O_2$, an easily soluble salt having marked diuretic properties. Dose, 5 grains to 1 dram. Purgative doses, 2 to 4 drams. **P. Arsenitis, Liquor,** Fowler's solution. See Arsenic. **P. Bicarbonas,** $KHCO_3$, a salt with properties like the carbonate, to which it is preferable. Dose, 5 to 45 grains. **P. Bitartras,** $KHC_4H_4O_6$. See P. Tartras. Dose, 20 to 60 grains as a diuretic; 1/2 to 1 ounce as a purgative. **P. Bromid,** KBr, a colorless, crystalline, bitter salt, readily soluble in water. It is extensively employed as a sedative in nervous excitement, and is one of the best drugs in epilepsy. Its prolonged use causes the condition known as Bromism (*q. v.*). **P. Carbonas,** K_2CO_3, used locally in acne and acute eczema, internally in rheumatism, in the uric acid diathesis, and in jaundice. Dose, 2 to 20 grains. **P., Caustic,** potassium hydroxid. **P. Chloras,** $KClO_3$, a crystalline compound, with a saline, cooling taste. It is soluble in 15 or 16 parts of cold, and readily soluble in boiling, water. It is used as a gargle in diseases of the mouth and throat, in mercurial stomatitis, etc. Dose, 1 to 10 grains. In toxic doses it causes disorganization of the blood (converting the hemoglobin into methemoglobin) and intense irritation of the kidneys, with hematuria and blood casts. Sir James Y. Simpson recommended it in doses of 20 grains thrice daily, in threatened abortion from fatty degeneration of the placenta. **P. Chloratis, Troch.,** each containing 2 1/2 grains of the salt. Dose, 1 to 3. **P. Citras,** $K_3C_6H_5O_7.H_2O$, is used in solution as a febrifuge, a diuretic, and to alkalinize the urine. Dose, 10 to 30 grains. **P. Citratis, Liq.,** citric acid 6, potassium bicarbonate 8; filter and add enough distilled water to make 50 parts. Dose, 1/2 to 1 ounce. **P. Citras Effervescens** consists of the citrate 20, sodium bicarbonate 47, tartaric acid 25, and citric acid 16. Dose, 1 to 2 drams in a glass of water as an effervescing drink. **P. Cyanid.,** KCN, made from potassium ferrocyanid by the action of heat, sometimes with (also without) the addition of potassium carbonate and charcoal. It is very soluble in water, has active reducing powers, and is very poisonous. It has the sedative and antispasmodic action of hydrocyanic acid, and, like it, is used in gastric irritability and cough. Dose, 1/20 grain. **P. Dichromas.** Synonym of P. Bichromas. An antiseptic and escharotic milder than chromic trioxid. Internally it has been efficient in chronic nasal, gastric, or intestinal catarrh, chronic ulcers of the mouth and pharynx, chronic bronchitis, laryngitis, rheumatism, locomotor ataxia, sometimes in diphtheria. Dose, 1/10 to 1/2 grain in trituration. Locally it is used in aqueous solution (5 grains to 1 dram to the ounce). **P. et Sodii Tartras,** $KNaC_4H_4O_6.4H_2O$, "Rochelle salt," laxative. Dose, 1 to 4 drams. **P. Ferrocyanid,** $K_4FeC_6N_6+3H_2O$, yellow prussiate of potash, prepared from blood, and by heating together animal charcoal, iron, and pearl ash. It occurs in yellow crystals, soluble in water. It has many uses in chemic analysis. **P. Hydroxidum,** KHO, potassa, "caustic potash," deliquescent and very alkaline. A powerful escharotic. **P. Hydroxidi Liquor,** an aqueous solution of about 5 percent of **P. Hydroxid.** Dose, 5 to 30 minims, well diluted with water. **P. Hypophosphis.** See Phosphorus. **P. Iodid.,** KI, used in syphilis, metallic poisoning, and as an antirheumatic. Dose, 2 to 20 grains. See Iodin. **P. Nitras,** KNO_3, saltpeter, niter, crystallizing in long white prisms. Commercially, it is prepared by double decomposition of potassium chlorid and Chili saltpeter, sodium nitrate. Dose, 5 to 20 grains, well diluted **P. Permanganas.** See Manganese. **P. Sulphas,** K_2SO_4, a hepatic stimulant and laxative; soluble in 10 parts of water at ordinary temperature. Dose, 10 to 45 grains. **Pulvis Efferves. Comp.,** compound effervescing powder, "Seidlitz powder," contains in the blue paper potassium bitartrate, 120 grains, mixed with sodium bicarbonate, 40 grains; and in the white paper, tartaric acid, 35 grains.

POTT'S DISEASE.—See Spine (Caries).

POTT'S FRACTURE.—See Ankle (Fracture).

POULTICE (Cataplasm).—Generally employed as a means of applying heat and moisture to a certain portion of the body, but is sometimes medicated with anodyne, counterirritant or disinfectant agents. An excellent method of preparing poultices is to make several bags of various sizes, of either of the fabrics known as *Swiss* and *cheese-cloth*, filling each bag half full with the linseed meal or other agent used, then sewing up the open end. When wanted for use one of these bags is submerged in boiling water for a few minutes, and on taking it out the meal is found to have swelled so as to fill the bag, which should then be squeezed to rid of superfluous water, laid on the part and covered with oiled silk and a bandage.

The ordinary filthy poultice of flaxseed, slippery elm, bread and milk, has no place among the resources of the aseptic surgeon. The common poultice is a hot-bed for bacteria, and as such, it

should be discarded. In the treatment of an ordinary furuncle with poultices, almost every surgeon must have seen occasionally the development of innumerable minute daughter-furuncles in the surface covered by the poultice. In phlegmonous inflammation of the fingers or hand, the prolonged use of the poultice is followed by maceration of the skin, extensive edema of the superficial structures, a flabby condition of the granulation—in fact all the evidences which point to the poultice as a means of favoring the extension of the infectious process (Senn).

A *sinapism* is a poultice or plaster containing mustard (sinapis), used for the purpose of counter-irritation. If applied too hot and kept on too long the skin will become inflamed and ulcerated, and extensive gangrenous sores may result.

The only poultice official in the U. S. P. is the **catapalsma kaolini,** in which glycerin is the active agent. It consists of kaolin, 577 gm.; boric acid, 45 gm.; thymol, 0.5 gm.; methyl salicylate, 2 gm.; oil of peppermint, 0.5 gm.; glycerin, 375 gm.; to make 1000 gm.

Fomentations.—Flannel may be wrung very dry out of boiling water, applied, and covered with oiled silk. Spongiopiline, a fabric composed of sponge and wool, coated with india-rubber, is an excellent vehicle for the application of warmth and moisture. The inner surface is moistened with hot water, and its utility may be increased by sprinkling the moistened surface with charcoal or yeast or by saturating it with any desired lotion or liniment.

POWDER (Pulvis).—In pharmacy one or more medicinal substances reduced to a state of very fine division. Powders are usually prepared extemporaneously, but a few compound ones have been made official, the ingredients being simply rubbed together until reduced to a fine powder and thoroughly mixed. Special directions are given in a few instances. Powders are usually mixed on a slab with a spatula, but, except in the case of explosives, a much better method is trituration in a mortar.

There are 9 official powders:

Title.	Constituents.	Properties and Dose.
Pulvis:		
Acetanilidi Compositus (Antikamnia?).	Acetanilid, 70 gm.; caffein, 10 gm.; sodium bicarb., 20 gm.	Relieves pain, 8 gr.
Aromaticus.....	P. cinnamon, 35 gm.; p. ginger, 35 gm.; p. cardamon, 15 gm.; p. nutmeg, 15 gm.	Aromatic, 15 gr.
Cretæ Compositus.	Prep. chalk, 30 gm.; acacia, 20 gm.; sugar, 50 gm.	For chalk mixture, 30 gr.
Effervescens Compositus (Seidlitz powder).	Sodium bicarb., 31gm.; Rochelle salt, 93 gm.; tartaric acid, 27 gm.; mix the sod. bicarb. and Roch. salt, and divide into 12 pts. (blue papers). Divide the t. acid into 12 pts. (white papers).	Laxative, 1 set of 2 powders.
Glycyrrhizæ Compositus (licorice powder).	P. senna, 180 gm.; p. licorice, 236 gm.; washed sulphur, 80 gm.; oil fennel, 4 gm.; sugar, 500 gm.	Laxative, 60 gr.
Ipecacuanhæ et Opii (Dover's powder).	P. ipecac, 10 gm.; p. opium, 10 gm.; sugar of milk, 80 gm. Ten grains contain a grain each of the active constituents.	Diaphoretic, 8 gr.
Jalapæ Compositus.	P. jalap, 35 gm.; potass. bitart., 65 gm.	Cathartic, 30 gr.
Morphinæ Compositus (Tully's powder).	Morph. sulph., 1.5 gm.; p. camphor, 32 gm.; p. licorice, 33 gm.; precip. calc. carb., 33.5 gm.	Diaphoretic, 8 gr.
Rhei Compositus...	P. rhubard, 25 gm.; magnesia, 65 gm.; p. ginger, 10 gm.	Laxative, antacid, 30 gr.

POX.—See Syphilis.

PREDIGESTED FOOD.—See Peptonized Food.

PREGNANCY.—The state of the female corresponding to the presence within her body of the product of conception; the period from conception to delivery. When delivery is protracted far beyond the normal time and the ovum is dead, the condition of pregnancy cannot be said to exist. The normal duration of pregnancy in woman is 280 days, or 10 lunar months of 28 days each, or 9 calendar months. Various methods have been devised to estimate the probable termination of pregnancy, one of which, Ely's table, is introduced under Confinement.

PREGNANCY, DIAGNOSIS.—The signs of pregnancy may be divided into *subjective* and *objective*.

The subjective signs are those which are appreciated by the mother. Arranged in the order of their importance, they are: (1) Cessation of menstruation; (2) nausea and vomiting; (3) change in the size and shape of the abdomen; (4) change in the genitalia and breasts; (5) quickening; and (6) change in the nervous system. These signs, taken alone, are of slight importance, but when they are considered in connection with the objective signs, they become of considerable value.

The objective signs are those which are ascertained by employing the senses of sight, touch, and hearing.

Inspection shows splotches of pigmentation on the face and dark circles under the eyes. The breasts are enlarged, the nipples are prominent, the areola is widened and darkened, a secondary areola is developed, the glands of Montgomery are enlarged, and pressure on the breast from the periphery toward the nipple will cause the appearance of a drop or two of turbid fluid—colostrum. The abdomen is symmetrically enlarged, striæ are present, the umbilicus is pigmented, and after the sixth month of gestation projects from the surface of the abdomen, and fetal movements can be seen. The mucous membrane of the vulva and vagina is dark purple in color.

Palpation ascertains the size and shape of the uterus; the intermittent uterine contractions; and

in advanced cases the position of the fetal back, head, and extremities. Vaginal examination shows softening of the cervix and lower uterine segment; change in the shape, size, and consistency of the uterus; and ballottement. See BALLOTTEMENT.

Auscultation reveals the fetal heart-sounds, the uterine souffle, and at times the funic souffle.

For convenience of clinical diagnosis it is best to divide the signs of pregnancy into three groups:

1. Those manifesting themselves during the *first three months* are: Cessation of menstruation, nausea and vomiting, enlargement of the breasts, soft cervix and lower uterine segment, and change in the size, shape, and consistency of the uterus.

2. During the *second three months* there are, in addition to the foregoing, intermittent uterine contractions, ballottement, fetal movements and heart-sounds, and purple discoloration of the vaginal mucous membrane.

3. During the *last three months*, in addition it is possible to ascertain the position of the back, head, and extremities, and to determine the presenting part.

Of these signs, ballottement, fetal heart-sounds, and fetal movements are considered absolutely diagnostic.

PREGNANCY, DISEASES.—These are considered under their appropriate headings. See AMNION, CHORION, ECLAMPSIA, COLON BACILLUS INFECTION, NEPHRITIS OF PREGNANCY, etc.

PREGNANCY, DURATION.—See CONFINEMENT.

PREGNANCY, EXTRAUTERINE OR ECTOPIC.—See EXTRAUTERINE PREGNANCY.

PREGNANCY, FALSE.—See PSEUDOCYESIS.

PREGNANCY, MULTIPLE.—Two or more fecundated ova or fetuses occupying the uterus at the same time. Twin births occur once in about 100 cases, triplets occur once in about 8000, and quadruplets once in about 400,000 cases. Twin pregnancy occurs when 2 ova are fecundated at or near the same time; or two fetuses may develop from a single ovum. If the twins are developed from 2 ova, each twin has its own amnion, chorion, and placenta; if from 1 ovum, there is but one chorion and placenta.

The diagnosis of multiple pregnancy is difficult, and is usually not made until birth. Irregularity in the shape and excessive size of the abdomen would be suggestive. Edema of the lower part of the abdominal wall and lower extremities is a common sign, while the presence of an abnormal number of extremities would be almost diagnostic. The only positive signs are: The existence of 2 fetal heart-sounds, of different rates, heard with greatest intensity at different points on the abdomen; and the palpation of two heads, two breeches, or multiple extremities.

The prognosis for both mother and child is somewhat graver than in single pregnancy. The dangers to the mother are albuminuria and eclampsia, postpartum hemorrhage, and a long, tedious, and complicated labor. The children are likely to be ill developed from lack of room; monsters, from anastomoses between fetal and placental vessels, frequently occur, and usually there are serious complications at birth.

The treatment of labor in multiple pregnancy is the same as in ordinary pregnancy until the first child is born. After this has occurred the cord should be ligated and the position and presentation of the second child determined. If this is faulty, as it frequently is on account of the roominess of the uterus, it should be corrected immediately, and a dram of the fluidextract of ergot administered. The second child is usually born within an hour after the first; a longer delay than this demands some artificial interference.

PREGNANCY, PERNICIOUS VOMITING.—The variety of vomiting occasionally seen in pregnancy that becomes so excessive as to threaten the patient's life.

Causes.—The causes of pernicious vomiting are extremely varied. The most common are: (1) Reflex disturbance, caused by the rapid growth and distention of the uterus, with irritation of its contained nerve endings; (2) some pathologic condition of the uterus or its adnexa, such as endometritis or inflammation of the tubes and ovaries; (3) some pathologic condition of the gastrointestinal tract, such as gastritis or gastric ulcer; (4) excessive sexual intercourse; (5) kidney insufficiency.

Symptoms.—The ordinary physiologic vomiting of pregnancy becomes exaggerated until the patient vomits almost continuously. Anything taken into the stomach is immediately vomited, and with it bile-stained mucus. Blood is not infrequently mixed with the vomited material. The mere sight or thought of food is enough to provoke an attack of vomiting. There is intense thirst; the patient becomes extremely weak and emaciated; the temperature is usually subnormal; the respirations are rapid; the pulse becomes rapid and feeble; coma supervenes, and death occurs from profound exhaustion.

Diagnosis.—The diagnosis of the condition is easy, while that of the cause of the condition is difficult. From the fact that it occurs early in pregnancy, usually from the second to the fourth month, the existence of pregnancy may be overlooked. Should the vomiting occur late in pregnancy, kidney disturbance should be suspected.

Prognosis.—The prognosis is grave. In general practice the mortality ranges from 25 to 50 percent.

Treatment.—The patient should be confined to bed in a quiet, darkened room. The bowels should be kept freely open, and a suitable diet given. This should consist of easily digestible foods, such as milk, broths, eggs, and the like. Sexual intercourse must be prohibited. Should any local exciting cause be found, it should, if possible, be removed. Thus, a displaced uterus should be replaced; erosion of the cervix or inflammation of the cervical canal should be treated by the application of a solution of silver nitrate (20 grains to the ounce); inflammation of the tubes and ovaries may be treated by the careful use of tampons and douches. Drugs that allay nervousness are sometimes beneficial; grain doses of the aqueous extract of opium by suppository, or 10-grain doses of sodium bromid in a dessertspoonful of camphor

water may be given 3 or 4 times daily. Other drugs that have been found useful at times are: Cocain (1/4 of a grain), silver nitrate (1/4 of a grain), oxalate of cerium (10 grains), hydrobromid of hyoscin (1/120 of a grain), antipyrin (8 grains), tincture of aconite (6 minims), tincture of iodin (2 minims), tincture of nux vomica (10 minims), and creosote (1 minim).

If the patient cannot retain any food by the mouth, all efforts in this direction should cease and she should be fed by the rectum. If this is properly done, life may be sustained for days or even weeks. The following rules should be observed in rectal alimentation: (1) The enema must consist of predigested food. A very good one is the following: Three ounces of peptonized milk, 2 ounces of liquid peptonoids, 1/2 of an ounce of whisky, and 15 drops of tincture of opium. (2) The enema should not exceed 6 ounces in quantity. (3) It should be given regularly at intervals of 4 or 5 hours. (4) It should be preceded by irrigation of the lower bowel with a normal salt solution.

If the patient fails to improve under this course of treatment, the induction of abortion is indicated. This final step in the treatment of pernicious vomiting must not be delayed too long or the exhaustion will become so great that it will fail. If vomiting continues after 6 or 8 days of rectal feeding; if her temperature rises or remains subnormal; if her pulse becomes rapid and weak; if, in short, she presents the picture of pronounced exhaustion, abortion should be induced immediately in the manner already described. Dilatation of the cervical canal and internal os with the finger has been tried with benefit in a certain proportion of cases. It should be given a trial just previous to the induction of abortion.

PREMATURE LABOR.—See Labor (Premature).

PRESBYOPIA (Old-age Sight).—A condition of the eye in which the power of accommodation is either partially or wholly lost by age. Properly speaking, presbyopia implies diminution of the accommodative power in adults past middle life to such an extent as to interfere with near vision. Presbyopia usually occurs between 40 and 50 years of age. As a hyperopic eye is obliged to exert a portion of its power of accommodation to overcome its refractive error, it necessarily has less accommodative power in reserve, and consequently becomes presbyopic sooner than an emmetropic or myopic eye. An uncorrected myope may never exhibit the signs of presbyopia, as he can read at his far-point, but if he wears a distant correction, he will have the same need for a reading glass about the presbyopic age as the enmetrope or hyperope. See Ametropia.

Cause.—The direct cause of presbyopia is the diminishing elasticity of the lens, simultaneously with the solidification and sclerosing conditions which take place elsewhere in the body with advancing age. As a consequence of the changes in the lens-structure, it gradually loses its power to become convex, and hence to refract diverging rays from a near-point so that they will meet directly on the retina and give a clear image. This diminution in the refractive power of the lens is physiologic, and when it has advanced to such a point that rays at the average reading distance—about 13 inches—are no longer refracted exactly on the retina, presbyopia is said to have commenced.

Notwithstanding the fact that each patient should be studied individually, and no arbitrary rules can be constructed by which we can estimate the relative range of accommodation to age, for convenience it is desirable to have the following tables in the mind in refracting presbyopes:

Age in Years.	Accommodation in Diopters.	Age in Years.	Accommodation in Diopters.
10,	14	45	3.5
15,	12	50	2.5
20,	10	55,	1.75
25,	8.5	60,	1
30,	7	65,	0.75
35,	5.5	70,	0.25
40,	4.5	75,	0.

	Additional Glass Required to Produce a Comfortable Working Point.
45,	+1 D.
50,	+1.75 D.
55,	+2.50 D.
60,	+3 D.
65, or over,	+3.50 D.

Symptoms.—The chief symptom of recession of the near-point beyond the ordinary working distance is dimness of vision for near-work, the patient particularly complaining of inability to read, write, or sew, without holding the work at an uncomfortably increased distance. The ordinary symptoms of accommodative asthenopia are very often present, and it is quite likely that the headaches, dyspepsia, and neurotic conditions in women about 45 years of age, so often attributed to the menopause, are really directly due to eye-strain. The gradual progress of presbyopia, together with the attempt of nature to remedy the defect by narrowing the pupil, somewhat delays the marked symptoms, and, unfortunately, most presbyopes unconsciously undergo considerable eye-strain before seeking the oculist.

Diagnosis rests on the age of the person, the history of failing near vision, the recession of the near-point as tested with the Jaeger types, and the acceptance of a convex lens at close range. A loss of accommodation disproportionate with the age is indicative of ciliary palsy or insufficiency.

Treatment.—In every case it is necessary to detect and properly correct the hyperopia, myopia, or astigmatism that may exist; and for this purpose, in strong, vigorous persons under 50 the administration of a mydriatic is necessary. Following the ordinary method of prescribing lenses for distance in the kind and degree of ametropia detected, we correct the presbyopia by adding to the distant correction a convex spheric lens that gives the best vision at an ordinary working distance. If allowed to choose the glass and distance, the presbyope will usually select a strong glass at a close reading point, and thus lead the

examiner into error. Always try the test-lenses with the reading card at least 13 inches from the eye. Again, it must be constantly borne in mind that the patient's occupation is an important factor to be considered in prescribing presbyopic glasses; the engraver needs stronger glasses than the seamstress, and, conversely, persons working at a comparatively long distance, such as musicians, artists, ministers in the pulpit, etc., need weaker glasses in the pursuit of their occupations than they do for ordinary reading.

PRESCRIPTION-WRITING.—Although prescriptions in good English are preferable to those written in incorrect or badly abbreviated Latin, the classic formulas of prescription-writing, taken from Potter, are given below:

A prescription should begin with the name of the person for whom it is designed, and the date on which it is written. Then follows the Latin word *Recipe*, usually abbreviated to the sign ℞, and signifying "Take," or "Take thou;" next the names and quantities of the ingredients to be used, which are also expressed in Latin; then the directions to the compounder, followed by the directions to the patient, the last being now usually expressed in English; and, finally, the signature and address of the prescriber.

A prescription then has four component parts —viz.:

Superscription—consisting of the name of the party for whom it is designed, the date, and the sign ℞, signifying "Take thou."

Inscription—the body of the prescription, consisting of one or more of the following subdivisions —viz.:

Basis—or chief active ingredient.

Adjuvant—to assist the action of the basis.

Corrective—to correct some injurious quality of the other ingredients.

Vehicle or excipient—giving the prescription a suitable form.

Subscription—the directions for the compounder, usually expressed in contracted Latin.

Signature—the instructions for the guidance of the one administering the medicine, in English, followed by the signature of the prescriber.

A prescription may, however, contain the base alone, or the base with the adjuvant, or the base with a simple vehicle or diluent. A single ingredient may serve a double or treble office, as the syrupus rhei aromaticus with quinin, in which case the syrup serves as an adjuvant to increase the action of the quinin, as an excipient to cover the taste, and as a vehicle to facilitate the administration of the dose directed. Again, the basis may need no aid in doing its work, and may require no corrective of its action, nor any special vehicle. On the other hand, there is no limit to the number of ingredients which may be used, provided that the prescriber has a clear idea of something to be accomplished by each one, and also provided that there is no chemic or medical incompatibility between them. The tendency of the present age is toward monopharmacy, rather than polypharmacy. However, proper combinations of medicines will often produce effects for the patient's good which could not be obtained from the use of any one remedy.

Procedure in Writing a Prescription.—In writing an extemporaneous prescription, the first step is to write the patient's name and address, the date, and the sign ℞. The physician's registration number is also necessary if the prescription contains opium or cocain, or any salt or derivative of opium or cocain. (See HARRISON LAW). Then the title of each ingredient should be written in Latin and in the genitive case, except that when a certain number only of an ingredient is ordered, the name of the ingredient should be in the accusative case: for example, *Vitellum unum*, "one yolk of egg." Next, the quantity of each ingredient sufficient for one dose should be mentally determined and multiplied by the number of doses which the mixture is to contain, and the result set down in signs and Roman numerals. The directions to the pharmacist and patient being added, and the prescriber's name or initials affixed, the prescription is completed; but when very active agents are used, it is a good plan to go over the calculations a second time before letting it leave the hands of the person most responsible for its action. For pills or powders the same process should be employed, slightly varied according to the requirements of each case. Frequently, the ingredients and quantities for but one pill, powder, or suppository are named, with instructions to make a certain number after the formula. When an unusually large dose of any poisonous drug is prescribed, it is customary to underline the quantity.

An example will perhaps make the foregoing more comprehensible, and at the same time serve to indicate the style of Latin writing formerly employed. The following formula is that ordered in the U. S. P. for the preparation known as Black draft, but officially styled the compound infusion of senna, approximate weights and measures being substituted for the pharmacopeial metric weights:

For Mrs. John Black. *January* 1, 1911. *Recipe*, Take,—		Superscription.
(Basis.)	*Sennæ, semiunciam,* Of senna, half an ounce. *Magnesii sulphatis,* Of magnesium sulphate.	Inscription.
(Adjuvant.)	*Mannæ, ana unciam unam,* Of manna, of each an ounce.	
(Corrective.)	*Fœniculi, drachmam,* Of fennel, 1 dram.	
(Vehicle.)	*Aquæ bullientis, fluiduncias octo,* Of boiling water, 8 fluidounces.	
Macera per horam in vase clauso, deinde cola. Macerate for an hour in a closed vessel, then strain.		Subscription.
Signetur, Let it be entitled—*A wineglassful every 4 hours until it operates.* *Charles White, M. D.*		Signature.

The above prescription abbreviated would read.

For Mrs. John Black. *January* 1, 1911.

℞. Sennæ, ℥ ss
Magnesii sulphat.,
Mannæ, āā ℥ j
Fœniculi, ℥ j
Aquæ bull., ℥ viij.

Mac. per hor. in vase clauso, deinde cola.

Sig.—A wineglassful every 4 hours, until it operates. *C. White, M. D.*

Explanation.—*In writing a prescription* look for the dose of the ingredient (say 1/20 grain) in the column headed by the size of your mixture (6 ounces); then on that line, in the left marginal column, is the quantity (2 1/2 grains) you must put into the entire mixture to get your dose in each dram thereof. *In reading a prescription* find the quantity of any ingredient called for in the left marginal column (say 3/4 grain), and on the same line, in the column headed by the number of ounces in the mixture (3 ounces), you will find the quantity (1/32 grain) in each dram dose. Of course, when the dose is more or less than 1 dram, the result must be proportionately multiplied or divided accordingly.

As the result of the above is nearly identical with the official preparation, we might write the same prescription more simply, as follows:

℞. Infusi Sennæ Compos., ℥ viij.

with the proper superscription and signature; this being the manner of prescribing the official preparations.

A rule for writing a prescription in metric terms by one who is not practised in the use of the system is the following, by Potter:

Write as though prescribing but one dose of each ingredient in grains or minims and decimals thereof; then substitute the term "grams" or "cubic centimeters" for grains or minims, and the prescription is correct for 15 doses in metric terms.

Of course, when writing for a mixture or solution, the proper quantity of vehicle must be added to complete the one dose, and must also be expressed first in grains or minims. For example:

	One Dose.	15 Doses Metric.
℞. Quininæ sulphatis,	gr. j,	1
Strychninæ sulphatis,	gr. $\frac{1}{64}$ or 0.016,	016
Fluidextr. glycyrrhizæ,	♏ iv,	4
Syrupi,	♏ lx,	60

This gives a two-ounce mixture approximately, of which the dose would be a teaspoonful.

	One Dose.	15 Doses Metric.
℞. Quininæ sulphatis,	gr. j,	1
Massæ ferri carb.,	gr. ij,	2
Extr. nucis vomicæ,	gr. $\frac{1}{4}$ or 0.25,	25

Ft. pil. no. xv.

Sig.—One pill thrice daily after meals.

See Dosage; Latin (Medical); Incompatibility.

PRESENTATIONS, FETAL.—See Fetus (Position and Presentation).

PRESSURE.—Pressure is a less ambiguous term than compress or compression. Illustrations of the mechanic uses of pressure are: Coaptation of divided parts, crushing and dispersion of a ganglion on the wrist, truss retention of hernia, dilatation of strictures by bougies, and injections of air or oil by the rectum in cases of intussusception. The therapeutic uses of pressure, in combination with immobility and rest, antiseptics, and styptics are hemostatic, antispasmodic, and antiphlogistic in nature. In arresting hemorrhage, by most methods, in preventing and in treating acute inflammation when from a bruise or injury to a joint, gentle, equable, and elastic pressure conduces powerfully to the balance of innervation and circulation. In chronic inflammation pressure is a powerful agent. The patient's comfort is the usual measure of the degree of pressure in each case. When pressure causes pain, it must at once be lessened. Well-adjusted and elastic pressure is of service in the treatment of simple flesh wounds, complicated fractures, ingrowing toe-nail, in burns, bubo, carbuncle, whitlow, and arthritis. Bandaging is the most usual form of applying pressure, with or without padding, while elastic bandages, india-rubber strapping, air-cushions and water-cushions, and bags filled with sand or shot are other means. Digital pressure may sometimes be useful in compressing an artery. Successive layers of collodion make considerable pressure.

PRESSURE SYMPTOMS.—1. Nervous symptoms due to pressure upon the brain or spinal cord. In general if the pressure is light, the symptoms are those of irritation of the area pressed upon, manifesting themselves as spasmodic movements, tonicity of the muscles, pain, hyperesthesia, etc.; if the pressure is great, there results paralysis—motor or sensory or both—of the parts innervated by the areas pressed upon. See Brain, Spinal Cord. 2. The symptoms produced by an aneurysm or a tumor, as of the pelvis, adjacent organs being impinged upon.

PRIAPISM.—See Penis, Spine (Injuries).

PRICKLY HEAT.—See Sweat Glands.

PRISMS.—See Eye-muscles.

PROCTITIS.—See Rectum (Inflammation).

PROCTOCLYSIS.—Continuous rectal irrigation, popularized by Murphy, has proved of inestimable value in the treatment of peritonitis, hemorrhage, and shock. It is also recommended in typhoid, scarlatina, eclampsia, and the first stage of pneumonia. The nozzle of the apparatus is bent in order that it may be inserted without pressure against the posterior rectal wall as the patient sits up in bed. An adhesive strip fastens the tube to the thigh. The tube may remain in position several days. Murphy introduces a pint and a half of the solution (1 dram each of sodium chlorid and calcium chlorid to the pint of water) into the rectum in about an hour, then after an interval of an hour, a similar quantity is introduced. A modified form of irrigator has an electric heater attached to the douche so that the water entering the rectum can be kept at a constant temperature of 100° F. Saline solution may be administered by the drop method by means of a special instrument, containing a glass sight tube and a hard rubber regulator, designed to eliminate the disadvantages of the continuous flow method (back flow of fluid, regurgitation of feces, difficult retention of fluid in some cases). Through this contrivance, too, gases can readily escape. The Elbrecht apparatus, recommended by Dr. Murphy as fulfilling all indications, is adapted for either the continuous or the drop method. See Peritonitis.

PROFESSIONAL NEUROSIS.—A neurosis caused by continuous exercise of one set of muscles. See Occupation Neuroses.

PROGRESSIVE MUSCULAR ATROPHY.—Chronic anterior poliomyelitis in which the large ganglion cells of the anterior horns, the motor and trophic cells of the muscles, are gradually destroyed. See Muscles (Atrophy).

PROLAPSE.—See Anus, Ovary, Rectum, Umbilical Cord, Uterus, etc.

PROSTATE GLAND, HYPERTROPHY.—The term hypertrophy of the prostate is applied to that form of enlargement of the gland which takes place after middle life, rarely before the fiftieth year, and more frequently after the age of 60, developing

slowly and without inflammatory symptoms. The enlargement may be general, affecting the entire organ equally, or it may take the form of a circumscribed growth involving only one portion of the gland. Thus, the so-called middle lobe alone may be involved. Overgrowth in this situation may take the form of a pedunculated tumor or of a sessile hypertrophy. In other cases there is a hyperplasia of the lateral lobes without any involvement whatever of the median portion. Sometimes one lateral mass is much more affected than the other.

In one form of this affection there is a marked overgrowth in a transverse direction, just at the vesical orifice, which gives rise to an upward projection that offers a great impediment to the emptying of the bladder. To this particular condition the term "collar" has been applied. There are two distinct types of prostatic hypertrophy. In one the overgrowth affects chiefly or entirely the glandular elements, forming a tumor of the type of the adenomata. In the other form the increase affects the stroma, which results in the formation of a fibroma-like tumor. Between these two types there is every gradation of simultaneous involvement of both gland and stroma.

Etiology.—The etiology of this form of prostatic enlargement has not been definitely determined. Many theories have been advanced, but, so far, none of them is susceptible of complete demonstration. Thus Launois advanced the hypothesis that the condition is merely a part of a universal arteriosclerosis, or local sclerosis affecting the urinary organs, and Ciechanowski endeavored to prove that it is the terminal result of chronic gonorrheal inflammation. Neither of these theories, however, has been generally accepted, and in fact good evidence has been adduced to show that they are wrong. Other supposed causes such as chronic constipation, sexual excesses, gout, rheumatism, the abuse of alcohol, etc., are so fanciful as to require no consideration whatever.

Symptoms.—The symptoms of enlargement of the prostate are not referred to the organ itself, but to the function of urination. In a certain percentage of cases with a moderate degree of hypertrophy there will be no symptoms to direct the patient's attention to the presence of this condition. As the overgrowth is of slow and gradual formation, so the symptoms are usually so insidious that the patient does not notice the change until the condition is well advanced. Usually, the earliest symptom is an increase in the frequency of urination. The difference in the beginning is very slight, but as the condition goes from bad to worse, the patient may be called upon to empty the bladder as often as every hour, half-hour, or even 15 minutes. In some cases this increased frequency is more particularly noted during the hours of sleep. There is also more or less hesitation in the beginning of micturition and absence of the usual force, which results in the loss of the usual parabolic curve, and, finally, an incomplete stoppage. Pain is a marked symptom in some instances, and is absent in others. It is particularly marked in the cases complicated with acute inflammation of the bladder. Some forms of prostatic hypertrophy obstruct the outflow of urine to a marked degree, while others seem to offer no obstacle to this function. In the former class the patient is unable entirely to empty the bladder. The urine that remains after the patient passes as much as possible is termed "residual." In some instances the patient is unable to void any urine voluntarily; in other cases it collects until the bladder is filled to its utmost capacity, after which there is an involuntary "dribbling," which flows as fast as the secretion is discharged from the kidneys. If cystitis is superadded, the urine will contain pus and mucus proportionate in amount to the grade of the inflammation, and blood will very frequently be present also. In a few cases the very first symptom will be absolute retention, which is the result of cold or some other condition, producing an acute congestion of a gland already the seat of a marked hypertrophy.

Diagnosis.—The diagnosis of hypertrophy of the prostate is usually to be made by digital palpation through the rectum. This examination reveals enlargement of the lateral lobes only, but will not always detect with certainty an overgrowth of the median portion. It is necessary, however, to exclude other sources of obstruction and other disturbances of the function of urination. Among the conditions from which prostatic enlargement is to be distinguished are: Stricture of the urethra, atony and paralysis of the bladder, tumor of the bladder, calculus, and cystitis. Stricture of the urethra will be detected readily by the usual examination for this condition. Atony of the bladder results from prolonged overdistention or from profound depression of the general health. Paralysis of the bladder would be accompanied by other evidences of degenerative changes in the spinal cord. Tumors of the bladder and tuberculosis are more difficult to distinguish from hypertrophy of the prostate. A careful study of the history and the symptoms is necessary, and, finally, the usual examination for the latter condition will generally enable one to determine its presence or absence. Vesical calculus will be detected by careful examination with the proper instrument. It should not be forgotten, however, that vesical calculus and prostatic hypertrophy frequently coexist, the latter condition predisposing to the formation of stone. The differentiation from simple cystitis must be made again by excluding enlargement of the prostate.

The positive evidence of prostatic enlargement is determined, as already indicated, by digital examination through the rectum, and, in addition, by careful instrumental examination of the urethra. In making the latter examination the following points should be noted: (1) The distance the catheter passes before urine begins to flow; (2) whether the point of the catheter deviates to either side or is otherwise obstructed as it reaches the prostatic portion of the urethra; and (3) whether it is necessary to depress the shaft more than usual between the thighs before the point of the instrument enters the bladder.

This exploration is in most instances best made

with a full-sized metal catheter (24 to 28 of the French scale) that has been properly sterilized and lubricated. It is also necessary to pass a catheter immediately after the patient has voided as much urine as possible voluntarily, in order to determine whether there is any residual urine. If the catheter passes freely and if urine is withdrawn when the instrument has been passed 7 1/2 inches, it is to be presumed that marked enlargement does not exist. If it is necessary to introduce a catheter 8 or 9 inches, or even further, before urine flows, and if, in addition, it is necessary to depress the shaft forcibly, prostatic enlargement is probably present. In certain cases it will be found impossible to introduce the ordinary form of metal catheter. In these cases it will be necessary to employ the metal "prostatic" catheter, which has a larger curve and a longer shaft than the ordinary instrument. In other instances, on account of the irregular overgrowth and consequent tortuosity of the urethra, some of the forms of flexible catheters must be employed. The information obtained by the foregoing examination will be confirmed or disproved by digital examination through the rectum. In making this examination the patient should lie in the dorsal position. The middle finger is the most suitable for this exploration. The physician should, of course, be familiar with the size of a normal prostate—which is usually described as being about that of the common horse-chestnut —in order to detect the presence of any enlargement. It is well, at the same time, to determine as far as possible the character of the growth, whether uniform or affecting principally one lateral lobe; and also whether it is hard or soft, hardness indicating fibrous overgrowth and softness glandular hypertrophy. Every grade of hypertrophy exists, from a degree scarcely to be detected, to the size of an orange or even larger. A gland that is twice the normal size must be considered the seat of distinct enlargement. It is to be remembered that the degree of obstruction and the urgency of the other symptoms do not depend entirely upon the extent of the enlargement.

The cystoscope, if skilfully used, will impart much information concerning the condition of the prostate. The projection of the enlarged gland into the bladder can be plainly seen, as can also the narrow channel formed by the convergence of the right and left lobes toward the median line; in lesser degrees of hypertrophy the irregular margin of the sphincter is shown. The so-called third lobe may also be distinctly seen, jutting out into the bladder. In addition the state of the bladder may be ascertained.

Treatment.—The treatment of these cases is to be determined by the symptoms and not by the degree of the enlargement of the prostate. As in the treatment of every other condition, no rules can be given that will be of universal applicability. Particular indications must always receive due consideration. Casper has truly stated that great knowledge and much patience is required of the surgeon who assumes the responsibility of treating prostatic cases. Attention to hygiene is of great importance. The diet should be plain but nutritious, a moderate amount of exercise taken, the bowels kept regular, and everything known to predispose to congestion and engorgement of the prostate avoided. Consequently exposure to cold and dampness must be guarded against as it often precipitates an attack of acute retention. Many prostatics get along excellently by following this regimen of living. If in course of time occasional attacks of pain, strangury and difficulty in urinating occur, relief will often be afforded by rest in bed, the use of hot applications to the hypogastrium, together with hot sitz-baths and the internal administration of anodynes and urinary antiseptics. In these attacks of incomplete retention recourse to the catheter is frequently necessary, but there are cases, as already stated, in which the trouble subsides promptly under the treatment above indicated.

In cases of complete retention regular catheterization must of course be practised. Great care is necessary in this procedure, which must be carried out under the strictest aseptic precautions, with the greatest gentleness, and by means of properly selected instruments. As a rule soft catheters should be used, and of these the French silk-web ones are an excellent type. The preliminary injection of a weak cocain and adrenalin solution, followed by an injection of warm sterilized olive oil or 20 percent gomenol oil, just before the catheter is inserted into the urethra, will facilitate the passage of the instrument and also lessen the pain incident to the procedure. In exceptional cases other instruments such as Mercier's, Guyon's, Brodie's, or an ordinary English catheter bent to a certain curve, will render good service, but it is advisable that they be used only by one who is well skilled in the manipulation of urethral instruments, lest a false passage be made. After the urine is withdrawn the bladder may be washed out with hot normal salt solution. A saturated solution of boric acid or weak permanganate solution, for instance 1 : 8,000. In cases in which there is an associated purulent cystitis, nitrate of silver solution is of value.

For those patients who are more or less dependent upon the catheter, the internal administration of such drugs as urotropin, arbutin, salol, opium and hyoscyamus or belladonna will prove helpful if they are selected in accordance with the indications present in the individual case. They are especially valuable during temporary retention in the comparatively early cases as they render the urine aseptic and relieve irritability and pain. Permanent catheterization is of decided value in certain cases, but no fixed rules can be laid down with regard to its employment. When the passage of an instrument is very painful to a patient suffering with prolonged complete retention, the permanent catheter may be tried. If it produces so much irritation that the patient cannot be made comfortable with a moderate amount of opium, it is well to discontinue its use. Patients vary greatly with reference to their toleration of this

instrument, and each case must be decided upon its own merits.

Acute complete retention may demand capillary puncture of the bladder if an instrument cannot be passed through the urethra after a reasonable effort has been made to get one through. This little operation is free from danger. The skin is incised above the symphysis and the trocar plunged quickly and forcibly downward and backward.

With regard to operative treatment suprapubic and perineal prostatectomy chiefly require consideration. They are to be welcomed as a decided advance in the therapy of prostatic hypertrophy, inasmuch as they afford relief in a class of cases not otherwise amenable to treatment. They are not without danger, however, and therefore should not be employed indiscriminately nor undertaken lightly, being reserved for those cases in which milder measures prove futile (Casper).

When catheterization fails or has to be frequently repeated owing to smallness of the bladder produced by thickening of its walls, when it is very painful or is followed by hemorrhage, and when severe cystitis is present or frequent attacks of retention occur, then one of these radical operations is to be considered (Casper). Although both operations have ardent advocates, it is probable that each has its own particular sphere of applicability. Thus it may be stated that the large, soft adenomatous prostate which projects up into the bladder can be better attacked and removed through the suprapubic incision, and that the small, hard, fibrous prostate which does not rise into the bladder for any distance can be better removed by the perineal route. Naturally those operators who have had unusual experience in the performance of one or the other operation can do it successfully under conditions which would make its performance very difficult to a surgeon of less experience. The suprapubic operation still has a higher death rate than the perineal, but it is claimed by many that the results obtained by it are better and more permanent than those which follow the perineal operation.

The Bottini operation, or galvanoprostatotomy, is rarely employed at present. Casper states that as a rule it is only palliative, although in a few specially selected cases it affords permanent relief. Castration for the purpose of producing atrophy of the enlarged prostate is a relic of the past, and division of the vasa deferentia is employed only in case of patients who suffer from prostatism or recurring epididymitis due to catheterization. When advanced arteriosclerosis, grave cachexia, bilateral renal disease, or other serious organic trouble is present so that a radical operation is not possible relief may be obtained by the establishment of a suprapubic fistula.

PROSTATE GLAND, INFLAMMATION.—Inflammation of the prostate may be either *acute* or *chronic*. Two forms of each are described—namely, *follicular* and *parenchymatous*. In the former the pathologic process affects the follicles chiefly or solely, while in the latter all the structures of the organ are involved.

Acute Prostatitis

Etiology.—Acute prostatitis probably does not occur as an "idiopathic" affection. Among the causes assigned are such external influences as exposure to cold and wet, and traumatism of the perineum; such local factors as injury from instrumentation, calculus, or foreign body; and such general conditions as gout and the acute infectious diseases. It is probable that all the cases are due to infection, and that the factors mentioned act chiefly by establishing a focus of diminished resistance. The majority of cases of inflammation of the prostate are secondary to extension backward of a specific urethritis. The prostate is also involved in some cases of cystitis, the condition being known as "prostatocystitis." Acute prostatitis may develop during the course of smallpox, scarlet fever, typhoid fever, typhus, etc., or it may occur as a sequel to one of these diseases. Prostatitis of tubercular origin is occasionally met with. There appears to be no evidence that horseback riding and bicycle riding, under proper conditions, have ever caused inflammation of the prostate. The cases that have been reported as originating from these causes may have depended upon other factors that were not manifest. This expression is not intended to convey the idea that the use of a saddle constructed upon principles that are grossly wrong anatomically and injudicious riding may not exert some unfavorable influence upon structures adjacent to the perineum. These are factors, however, that may be eliminated, and should not be allowed to weigh against the many advantages to be derived from judicious riding. It has seemed well to speak emphatically upon this point, inasmuch as the question is so frequently asked, and because some difference of opinion exists.

Symptoms.—The symptoms of acute prostatitis are: A sensation of heat and of weight in the perineum or in the rectum; micturition is more frequent than normal and may be attended with tenesmus; if there is great swelling of the gland, retention may result; pain soon becomes a prominent symptom and is frequently very severe—it may be throbbing in character, it is worse on motion, and the usual sitting position is uncomfortable if not impossible; a constipated stool is attended with very acute suffering; pressure on the perineum causes pain; digital examination of the prostate, per rectum, shows the gland to be somewhat enlarged and tense, and pressure causes very acute pain. There is always some constitutional disturbance in these cases; the temperature ranges from 100° to 103° F., and the pulse is proportionately accelerated.

In the higher grade of inflammation pus is likely to form. The occurrence of suppuration is often announced by a chill, and digital examination at this stage will sometimes reveal an area of softening at some point of the gland or distinct fluctuation may be felt. The abscess may remain localized until it is evacuated, it may discharge spontaneously, or the whole gland may break down rapidly. In connection with the last termi-

nation the constitutional disturbance is usually pronounced. Septicemia and pyemia are rare terminations of acute prostatitis, and are especially liable to occur in the cases in which the periprostatic tissues are involved with secondary thrombosis of the prostatic plexus of veins.

Diagnosis.—Acute prostatitis must be distinguished from acute posterior urethritis; from acute cystitis, especially that form affecting chiefly the vesical neck; from cowperitis, and from stricture of the urethra and hypertrophy of the prostate Acute posterior urethritis may present all the urinary symptoms observed in acute prostatitis; the constitutional symptoms, which are usually marked in the latter, will, however, be absent, or nearly so, in the former; swelling and tenderness of the prostate, as determined by rectal palpation, will be absent in urethritis. Acute cystitis would likewise cause no change in the prostate gland; the condition of the prostate is the chief distinguishing feature between these two diseases. Cowperitis would be detected by the presence of a slight, very tender swelling on one side of the perineum (unless the disease were bilateral); the absence of change in the prostate would exclude inflammation of this structure.

Stricture of the urethra would not be accompanied by the local evidences of inflammation of the prostate gland or the accompanying febrile symptoms. Hypertrophy of the prostate almost never occurs before the age of 50, and is not usually observed until the sixtieth year or later. The absence of acute inflammatory symptoms would exclude acute prostatitis.

Treatment.—In common with all other acute inflammatory processes the treatment of acute prostatitis should include absolute rest and a position that will favor emptying the part of blood as much as possible. Therefore, rest in bed—with the hips elevated upon pillows to a higher level than the shoulders—is to be insisted upon. In the more acute cases the local abstraction of blood by means of leeches applied to the perineum and around the margin of the anus will be followed by marked amelioration of the pain. Hot sitz-baths or hot compresses applied to the hypogastrium and perineum act beneficially by withdrawing the blood from the deeper parts to the surface. Hot-water clysters are likewise useful.

If there is marked fever, a prescription similar to the following should be used:

℞. Boric acid, Potassium bromid, } each, ʒ j
Potassium citrate, ʒ ij
Tincture of aconite, ♏ lxxij
Tincture of belladonna, ʒ ss
Sweet spirit of niter, ℥ ss
Water, add enough to make, ℥ vj.

One tablespoonful every 3 hours.

If pronounced vesical irritation is present, the administration of some such mixture as the following will give marked relief:

℞. Boric acid, Sodium bromid, } each, gr. clx
Tincture of belladonna, ss ʒ
Solution of citrate of potassium, add enough to make ℥ viij.

One tablespoonful to be taken every 3 hours.

If the pain is severe, 1 grain of morphin sulphate may be added to the foregoing mixture with advantage, or suppositories may be administered. A common and useful formula for the latter is:

℞. Extract of belladonna, gr. iij
Watery extract of opium, gr. vj
Cacao-butter, add enough to make 12 suppositories.

One of these may be introduced into the rectum 2 or 3 times a day, according to the severity of the pain.

Straining, either at stool or during micturition, should be avoided, as it increases the congestion in and about the prostate and aggravates the symptoms. If the patient is unable to pass his urine naturally, it should be drawn, preferably with a Nélaton catheter of medium size (14 to 18 of the French scale). The bowels should be kept acting rather freely by the use of salines or other laxatives. The diet should be restricted to milk as nearly as possible. Stimulants should not be given unless indicated by some other condition, and then in moderation only.

If abscess of the prostate forms, the pus should be evacuated as soon as detected. The incision should be made through the perineum, except in those rare instances in which the pus appears just beneath the mucous membrane of the rectum, when the incision may be made in this situation. To reach a collection in the prostate through the perineum, the index-finger of the left hand should be introduced into the rectum and the abscess located; then a straight bistoury, with the cutting-edge directed upward, is introduced into the perineal raphe, about 3/4 of an inch anterior to the anus, and carried forward toward the tip of the finger in the rectum until the abscess is reached. Neither the urethra nor the rectum should be wounded in this operation. The incision should be enlarged upward sufficiently to give free exit to the pus. It is always well to explore with the finger, to be certain that the drainage is free, and also to break up any partitions that may exist. Thorough irrigation with an antiseptic solution and moderate packing with iodoform gauze complete the operation. In the event of profuse hemorrhage following the operation, the packing should be firm. The gauze should first be removed on the second or third day, after thorough soaking with antiseptic solution. The dressings are to be repeated daily thereafter. Sometimes a urethroperineal or a urethrorectal fistula will persist; but with proper attention to the care of the wound this will be rare. A prostatic abscess will usually be evacuated through the urethra, either spontaneously or as the result of passing a catheter. This is to be considered a favorable termination, but in severe cases with marked local and con-

ritus ani), the vulva (*pruritus vulvæ*), and the scrotum (*pruritus scroti*).

Pruritus is far more common in advanced life (*pruritus senilis*).

The form of pruritus occurring during the cold months of the year is designated *pruritus hiemalis*.

Etiology.—Generalized pruritus may be caused by Bright's disease, diabetes, hepatic affections, digestive and intestinal disturbances, nervous disorders, pregnancy, uterine and ovarian disease, ingestion of certain medicaments, etc.

Pruritus vulvæ is not infrequently produced by irritating vaginal discharges. It is a common symptom in diabetes. Pruritus ani may be caused by hemorrhoids, fissures, seat-worms, etc., or may be due to digestional disorders, gout, or some other consitutional condition.

Diagnosis.—Pediculosis corporis may usually be differentiated from pruritus by the localization of the scratch marks and the presence of the parasites in the garments.

Prognosis.—Guarded. Depends upon the nature and removability of the cause.

Treatment.—The cause must be assiduously investigated and treated. In all patients who present themselves for the treatment of this disease, it is of the utmost importance that the urine be examined carefully for sugar as pruritus is frequently a symptom of diabetes. It is also at times associated with lymphatic disturbances and many other internal derangements. In many cases, it is absolutely impossible to attribute it to any known cause and certain symptoms make it seem as though it were the result of some mental disturbance. A very thorough examination of all the organs may elicit the cause of this troublesome condition and the treatment should be along this line, and internal medication and diet governed entirely by such findings. Alcohol in any form is usually contraindicated.

Internal Treatment.—Diet and hygiene should be carefully regulated. The various visceral diseases must receive appropriate treatment. In obscure cases the mineral acids, quinin, strychnin, atropin, gelsemium, pilocarpin, and arsenic may be variously tested.

Local treatment is designed to give merely temporary relief from the distressing itching.

The following are some of the best antipruritic lotions:

℞.	Phenol,	ʒ j to iij
	Glycerin,	ʒ ij
	Alcohol,	ʒ iv
	Water, add enough to make	O j.
℞.	Liquor carbonis detergens,	ʒ ss to ij
	Water,	O j.
℞.	Thymol,	ʒ ss to ij
	Solution of potassa,	ʒ ij
	Glycerin,	ʒ ss
	Water,	O j.

For pruritus vulvæ one may use: (1) Saturated solution of boric acid; (2) compound tincture of benzoin (painted on); (3) vaginal injections of alum zinc sulphate, etc.

For pruritus ani:

℞.	Phenol,	gr. x to xx
	Calomel,	gr. xx to xxx
	Zinc oxid ointment,	ʒ j.
℞.	Mercuric chlorid,	gr. viij to xvj
	Water,	ʒ viij.
℞.	Morphin sulphate,	gr. x
	Flexible collodion,	ʒ j.

See Anus, Vulva.

PRUSSIC ACID.—See Cyanids.

PSAMMOMA (Sand Tumor).—A fibrosarcoma, containing calcareous material, observed rarely in the meninges, pineal gland and choroid plexus.

PSEUDOCYESIS (False Pregnancy).—The belief in the existence of pregnancy on the part of a woman, accompanied, perhaps, by more or less vague subjective signs. This condition occurs in nervous, hysteric women as a rule. It is seen most frequently in unmarried girls who fear the results of illicit sexual connection, or in sterile married women who are approaching the menopause and who very much desire offspring.

It is accompanied usually by such common symptoms of pregnancy as nausea, enlargement of the abdomen, and sometimes cessation of menstruation. A careful vaginal examination (preferably with the aid of anesthesia), will reveal an absence of the characteristic signs of true pregnancy.

Treatment should be directed toward the general nervous condition. Sedatives, tonics, and change of food, air, and scene will be found most beneficial.

PSEUDOLALIA.—See Speech Defects.

PSEUDOLEUKEMIA.—See Lymphadenoma.

PSEUDOLEUKEMIA, SPLENIC.—See Splenic Anemia.

PSEUDOLEUKEMIC ANEMIA OF INFANCY.—A chronic anemia of infants and young children described by von Jaksch, characterized by marked leukocytosis and marked reduction in the red cells and hemoglobin, greatly enlarged spleen, sometimes moderately enlarged liver with sharp edges and at times enlarged lymphatic glands. The disease is not to be confounded with pseudoleukemia, in which there is no leukocytosis, nor with leukemia, in which there is not so marked a reduction of hemoglobin or in the number of red cells but a greater increase in the number of leukocytes. The leukocytes are characterized by their varied shape and unusual size. The red cells display a high degree of poikilocytosis, while white cells inclosing red cells and fragments of red cells are also found, together with occasional eosinophilic leukocytes and large multinuclear neutrophilic leukocytes and nucleated red cells. All of these modifications of the blood-corpuscles, however, may occur in leukemia. Prognosis is only guardedly favorable, for death often occurs from intercurrent disease.

PSILOSIS.—See Sprue.

PSOAS ABSCESS.—Chronic collections of tuberculous fluid, which form in the cellular substance of the loins, behind the peritoneum, and descend in

the course of the psoas muscle; if the disease forms on the side of the vertebræ, instead of the fore part, it is termed lumbar abscess.

Etiology.—This disease arises generally from cold, strains, or falls, and from general debility, and not infrequently from spinal affections.

Symptoms.—At the beginning there is little or no pain, no inflammation, nor is there febrile disturbance; but previous to the appearance of any other symptom the patient has an unaccountable feeling of weakness across the loins, accompained by pains, usually giving no indication of the seat of the disease, and likely to be regarded as rheumatic. The tuberculous fluid is formed slowly and imperceptibly, and occasions, at first, no manifest swelling or fluctuation. When the lower dorsal or upper lumbar vertebræ are diseased, the pus enters the sheath of the psoas, or the substance of the muscle, and is firmly bound down in front by the fascia covering this muscle and the iliacus. The abscess proceeds as far as the tendon of the muscle by Poupart's ligament, where its further progress will probably be arrested. When it has attained considerable magnitude, it passes under Poupart's ligament, between the femoral vein and the symphysis pubis.

The diagnosis is difficult when the abscess is unattended by an external tumor. The swelling takes place in various situations and assumes different aspects; it may appear beneath the femoral fascia, or it may descend as far as the knee and form a prominent swelling; sometimes it will make its way downward into the pelvis and occasion a swelling in the neighborhood of the anus, or it may appear in the vicinity of the vertebræ, or, again, it may make its way through the abdominal muscles.

Treatment.—A psoas abscess should be opened, if possible, before it leaves the abdomen, just about Poupart's ligament, external to the line of the vessels. If it points at the inner side of the thigh, an incision may be made in that situation, in addition to the one above Poupart's ligament. Under antiseptic precautions, the sooner the abscess is opened, the better, for the abscess cavity is then smaller than if the surgeon waits until the fluid has burrowed its way into the thigh. Free drainage should be established from the groin to the lumbar region. The same principal of treatment must be applied to lumbar abscesses. Antiseptic dressings must be continued as long as there is discharge. General tonic and alterative treatment is indicated. See also Spine (Caries).

PSORIASIS.—A common chronic inflammatory disease of the skin, characterized by variously sized lesions, having red bases, covered with white scales resembling mother-of-pearl. It affects by preference the extensor surfaces of the body. The lesions are infiltrated, elevated, clearly defined, covered with white, shining, easily detachable scales which, upon removal, reveal a red, punctate, bleeding surface. The eruption is absolutely dry, and itching is usually absent. The recognition of psoriasis depends upon a clear comprehension of the many manifestations exhibited by this cutaneous affection. The lesions observed in the early stages of an attack may not always be sufficiently distinct to the casual observer to obviate error. Those noted in the later periods of the condition are usually characteristic.

Symptoms.—Early in its inception psoriasis is observed to present lesions of a papular nature and of diminutive size. Scattered here and there over the body surface there are noted pinhead-sized or smaller lesions, each of which very early in its life becomes tipped with a minute scale of a pearly white color. They are slightly raised above the surrounding healthy skin, and while showing a pinkish-red coloration directly at the point of attack, the amount of inflammation is not of a high grade, and does not extend beyond the borders of the individual papule. Enlarging by gradual periphearl extension—either slowly or quickly—they soon become easily discernible and characteristic.

Later in their course they have been known to attain varying dimensions—from the diminutive lesion to those occupying areas one inch or more in diameter, or when two or more in close proximity have coalesced, forming patches the size of one's hand, or even covering the greater part of one limb, or occasionally the major part of the back or chest. The edges of these lesions are distinct and stand out prominently, being, with the entire patch, raised somewhat above the surrounding areas. They are always dry and covered with abundant, pearly white, shining scales, which are arranged one upon the other in an imbricated manner. The removal of the scale often presents some bleeding points upon the affected areas. The patches often assume grotesque outlines—being in some instances annular or circinate, and in still others semicircular or arranged in bands—to each of which descriptive names are applied. Although rarely giving sensitive impression of their existence, they occasionally give rise to intolerable itching in certain nervous constitutions.

Psoriasis may remain stationary at any stage of its process, but, generally seen, all stages may be depicted in any given case. While the affection may be observed at any point of the body surface, it usually accepts certain points, such as the scalp, elbows, and knees, as its most formidable positions. It may be observed at any age, although early adult life presents the greater number.

Diagnosis.—The special points of value in reference to diagnosis are: Lesions of variable dimensions, all being capped with the pearly white scales; borders severely outlined; tendency to coalescence, with the presentation of bleeding points upon removal of scale.

In differentiating psoriasis from **eczema** care should be exerted to observe the dry character of lesions which are scattered over the entire body surface; their tendency to coalescence, with the appearance of characteristic scale; the chornic course, with existence of but slight, if any, itching; the well-marked borders and regularly rounded outline of each lesion. In eczema there is always a history of moisture, with occasionally crusting and scaling; the patches always fade into surrounding areas, and are continually changing; itching is

usually severe, while the inflammation is more of an acute nature.

In contradistinction to syphilis, psoriasis gives no history of initial lesions; there is no enlargement of glandular structures; lesions are symmetric, present a tendency to uniformity and coalescence, with abundance of pearly white scaling. Itching is occasionally present, although of but slight degree. Syphilis presents a history of contamination, with enlargement of cervical, inguinal, and epitrochlear glands. The lesions are asymmetric and multiform, but retain their contour. Itching is not a usual accompaniment. The scale is of a grayish tint.

Erythematous lupus is more often limited to the face and neck. The lesions number but two or three, are paler in tint, and covered with a fine yellowish or grayish scale; the center is depressed beneath the surrounding edge of the patch, and is more whitish in appearance than surrounding healthy areas. Upon removal of the scale, small sebaceous plugs may be observed emerging from the follicles.

Tinea circinata rarely occurs over a great surface. It is an acute affection, and gives a history of contagion. Lesions are usually annular, and extend upon the periphery while the center is healing. Vesicles may often be noted upon their periphery. Psoriasis, while clearing in the center, presents a tendency to peripheral disappearance.

Treatment.—While internal and external measures may both be demanded in most of the cases of this affection, there are many in which either plan may prove curative, and therefore it is advisable to acquaint one's self with the therapeutic agents of both classes.

Internal Treatment.—By far the greatest benefit may be received from the use of arsenic in one of its many forms; and while it has been supposed to possess specific properties for the removal of this affection, this cannot be proved, on account of its many failures. In the choice of this remedy it is advisable to select those cases in which there is not decided inflammation, as is often encountered in its early history, or those more chronic, wherein the drug has not been used. Arsenic seems to lose its power over the affection when used continuously or when repeated attacks are placed under its influence. One of the following plans may often prove beneficial: In one set of cases the best results follow the administration of 4 or 5 drops of the solution of arsenite of potassium, given 3 times daily for an indefinite period (arsenous acid, in doses of 1/20 grain, possesses a similar property). In another set of cases it may be found advantageous to increase the dose by 1 drop daily until near a point of tolerance, but not reaching that point.

Cod-liver oil is efficacious in cases of lowered vitality, and is best administered in the maximum dose, according to the age of the affected individual. The oil of copaiba, in doses of from 5 to 30 drops, thrice daily, may be most judiciously advised in many cases of long standing or when the degree of inflammation is high. Potassium iodid, in 5-grain or 10-grain doses, given for indefinite period; the salicylates, in similar dosage, produce good effects. Iron and strong tonics are demanded in certain depressed constitutions. Numerous other drugs are omitted, owing to the many chances of failure following their use.

Sea-water injections are said to have been used with some success.

External Treatment.—The first essential point in the external treatment is the removal of the scales; and to accomplish this, recourse must be had to the use of either baths or emollients. The ordinary bicarbonate of sodium or, preferably, the carbonate of potassium may be used in strengths varying from 1 to 3 ounces to each bath of 30 gallons. Olive oil or liquid petrolatum may produce a similar effect, possibly without fear of irritation in injudicious subjects.

Ordinary soap and water, applied thoroughly by means of a coarse towel, may likewise remove the abundance of scales, and thus present a clear base upon which to apply the chosen unguent. It may be found advisable to apply one of these measures frequently during the treatment of a case, owing to the tendency to reaccumulation of scales.

Ointments or pigments may possibly be the preferable plan of using external drugs, although liquid applications may give as good results. Salicylic acid, in from 3 to 10 percent ointments, with petrolatum applied twice daily, may be satisfactorily borne by many patients, but care must be exerted not to produce too much irritation of the underlying skin or contiguous parts. Tar—in the form of the oil of cade, oil of birch, or ordinary liquid tar—in the proportion of 1 or 2 drams to the ounce of ointment, may be judiciously advised in many long-standing cases. Ichthyol proves beneficial in many instances, and may be used in strengths varying from 1 to 3 drams to the ounce, and applied once daily during the whole course of the disease. This class of remedies may also be used in watery solutions, in strengths similar to those mentioned.

Chrysarobin produces excellent results in ointment form, in the strength of from 10 to 60 grains to the ounce of petrolatum, in those cases wherein much thickening has been induced by the process. It may also produce good effects when applied dissolved in the strength of from 10 to 60 grains to the ounce of either traumaticin or chloroform. Either of these plans will demand careful attention, owing to the inflammation that may be induced; and if applied near the eye, violent iritis may follow.

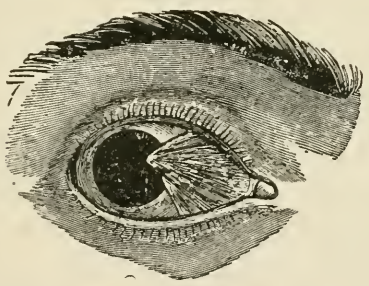
Pyrogallic acid may be used advantageously in a manner similar to the foregoing, and with less likelihood of producing ill effects. When psoriasis is observed upon the face or upon other visible parts of the body surface, it should be treated by some form of inunction, such as by ammoniated mercury, that does not give evidence of its presence. This remedy, used in the strength of from 10 to 40 grains to the ounce of petrolatum, will usually suffice.

PSOROSPERMIASIS.—Psorosperms (sporozoa cytozoa) belong to the lowest forms of the pro-

tozoa. The most important psorosperms are the *coccidium cuniculi* and the *coccidium hominis*. The latter is reported to have caused a few cases of intestinal disease in man. The former has been found in man usually in the liver. Its presence gives rise to inflammation of the ducts followed by the formation of tumor-like nodules with a cheesy center containing pus, débris, coccidia and shed epithelial cells. These nodules with the massing of epithelial cells have led to the opinion that they are associated with cancer formations. The cutaneous lesions that sometimes occur simulate verrucose tuberculosis, mycosis fungoides or carcinoma.

PSYCHOSIS POLYNEURITICA (Korsakow's Psychosis, Polyneuritis).—See MULTIPLE NEURITIS.

PTERYGIUM.—A triangular patch of thickened conjunctiva, most common on the nasal side; the apex of the growth points toward the pupil, and the fan-shaped base radiates toward the canthus. As it continues to grow it resembles a mass of flesh; and as years go on it partly atrophies, becomes pale, and appears tendinous. It is loosely attached at the limbus, and in this position a probe can be passed under its edges. On the cornea the growth is firmly adherent and must be torn or dissected away. If the pterygium grows over the cornea, it may drag the conjunctiva and caruncle with it to such a degree as to interfere with the movements of the eyeball, besides becoming unsightly. This affection is frequently found in elderly persons who have endured exposure in years of outdoor occupation. It is common in sailors. One eye is usually affected, although the growth has been seen simultaneously in both eyes, and in rare instances has developed from the outer canthus.



PTERYGIUM.

Treatment.—If the growth has not extended upon the cornea and shows no sign of progression, it may be left undisturbed. A flat, stringy head indicates a cessation of growth, and excision need not be resorted to. A vascular head means active progression. The operation of removal is as follows: Grasp the neck of the pterygium with fixation forceps, making traction perpendicular to the surface; dissect up the head, and make two converging incisions into the body with a pair of scissors. The parts between these incisions are dissected away and the lozenge-shaped wound closed by a suture applied about the middle of the wound. Another method of removal is by *transplantation*. The growth is split longitudinally and is fixed in an upper and a lower conjunctival pocket with a suture. *Ligation* has also been recommended; a large part of the pterygium between the sclerocorneal margin and the base of the growth is strangulated by sutures in the manner shown in the illustration. It has been suggested that the whole trouble in pterygium lies in the apex, and curetting the affected cornea or the application of the galvanocautery has produced good results. Under the old operations pterygium was liable to occur, and sometimes repeated operations caused limitation of the ocular movements. Electrolysis is the most recent treatment proposed.

PTOMAIN.—A basic nitrogenous compound, resembling the alkaloids, and produced by the action of bacteria on organic matter. As they are usually formed in putrefactive processes, ptomains have also been termed *putrefactive alkaloids*. The name *cadaveric alkaloids* has also been given to them, but applies properly only to those obtained from the dead animal body. Some of the ptomains are poisonous; many are not. As a rule, each distinctive ptomain is produced by a different microorganism, but there are instances of several bacteria producing the same ptomain. The dependence of a ptomain upon microorganisms may be indirect and complicated by or dependent upon purely chemic changes. The kind of ptomain produced depends somewhat upon the stage of putrefaction, as ptomains are "transition products in the process of putrefaction." Their production is also influenced by the media in which the bacteria grow. A ptomain that is formed by a certain bacterium in one medium may not be produced by the same bacterium in another medium. Ptomains have been found in foods, as in mussels, oysters, eels, sausage, ham, canned meats, cheese, milk, ice cream, etc. The pathogenic action of certain bacteria may be due to their production of ptomains. In addition to the well-known ptomains, a number of unnamed substances have been studied that possess reactions and physiologic effects similar to or identical with those of well-known vegetable alkaloids. These at present can only be called after analogs —*e. g.*, **coniin-like substances**; others are called **atropin-like, delphinin-like, digitalin-like, morphin-like, nicotin-like; strychnin-like, veratrin-like**, etc. See LEUKOMAIN, PTOMAIN-POISONING.

PTOMAIN-POISONING.—Infection of the organism through the medium of the gastrointestinal tract.

Etiology. Exciting Causes.—Certain varieties of food which have partially undergone putrefaction, such as oysters, ice-cream (made of milk containing tyrotoxicon), sausage, meat, mussels, fish, and cheese. Sausage poisoning is not uncommon in Germany. Ham poisoning not due to trichina has been reported, and many cases of poisoning from canned meats are recorded, though these may be due to the chlorids of lead or tin. Milk, cheese, and ice-cream poisonings are not rare, although

tyrotoxicon is not always the active cause. The mussel furnishes the most frequent source of poisoning from the shell-fish. See PTOMAIN.

These foods contain a variety of poisonous ptomains after decomposition, such as tyrotoxicon (in milk), neurin, mydatoxin, methyl-guanidin (in meats), mytilotoxin (in mussels), and a poisonous base in fish isomeric with ethylidene diamin ($C_2H_4(NH_2)_2$).

Predisposing Causes.—(1) A catarrhal condition of the stomach and intestines; (2) dilatation of the stomach; (3) certain diseases, as typhoid fever, enteritis, peritonitis; (4) idiosyncrasy toward certain kinds of food.

Pathology.—In a case of ptomain-poisoning from milk observed by Vaughan and Prescott, the following lesions were found 15 hours after death: "The mucous membrane of stomach and intestines normal (bile-stained); the small intestine distended with gas; the jejunum ashy green in color; the ileum purplish green; the cecum, ascending, transverse, and descending colon empty; the circular fibers tightly constricted; the salivary glands distinct but not inflamed; Peyer's patches normal; the liver and spleen normal." Rigor mortis is usually quite marked.

In other cases of ptomain-poisoning the mucous membrane of the stomach and intestines has been found red and swollen, presenting the picture of acute inflammation; the large vessels filled with dark blood; the kidneys congested; spleen enlarged; the heart either empty or filled with dark blood.

It would seem, therefore, that the *materies morbi*, while primarily acting as a gastrointestinal irritant, after being absorbed spends its force chiefly upon the nervous system.

Symptoms and Clinical Course.—The symptoms of ptomain-poisoning usually manifest themselves in from 2 to 24 hours after the food has been taken.

Nervous Symptoms.—Sense of chilliness, coldness of extremities, headache, vertigo, dryness of mouth, extreme thirst, constriction of the throat, difficult deglutition, intense pains in the abdominal region and calves of legs, muscular weakness, twitching of eyelids and muscles of face, shoulders, and hands, tingling sensations, hallucinations, mental anxiety, imperfect vision, dilatation of pupils, strabismus, dyspnea, convulsions, and coma.

Gastrointestinal Symptoms.—Abdomen retracted, sense of heat in stomach, excessive nausea, persistent vomiting, usually watery diarrhea. Constipation is present in some instances.

Cutaneous Symptoms.—Scarlatinal rash, urticaria.

Circulatory Symptoms.—Heart feeble and quick, often 140 to a minute; violent throbbing of abdominal aorta.

Temperature.—In many cases there is a subnormal temperature (95° F.), but if the case is protracted, the temperature is somewhat elevated (100° to 102° F.).

Respirations are hurried (dyspnea), 35 to 40 a minute.

Diagnosis.—

Acute Gastrointestinal Autointoxication.	Cholera Morbus.	Mineral Poison.
1. Onset often from 2 to 24 hours.	1. Onset usually at night or early morning hours.	1. Onset within half an hour.
2. Results from eating animal (nitrogenous) food.	2. Results from eating fruits or vegetable food.	2. History negative.
3. Nervous symptoms marked (twitching of facial muscles, tingling sensations, dilated pupils, convulsions).	3. Nervous phenomena, as seen in autointoxication, absent.	3. Nervous phenomena, as seen in autointoxication, absent.
4. Early dyspnea, cyanosis.	4. Respirations normal.	4. Dyspnea comes on late in mineral poisoning.
5. Temperature often subnormal.	5. Temperature often elevated a degree or two.	5. Temperature often elevated a degree or two.
6. Dryness of mouth and fauces, often bitter taste.	6. Bitter or sour taste in mouth.	6. Metallic taste in mouth.
7. Vomitus contains mucus, contents of stomach, or bile.	7. Vomitus has a sour or bitter taste without blood.	7. Vomitus variable, often tinged with blood, and containing trace of poison.
8. Generally watery diarrhea, sometimes constipation.	8. Diarrhea and tenesmus; feces greenish in color.	8. Feces may contain blood and trace of poison.
9. Various cutaneous eruptions (scarlatinal eruptions, urticaria).	9. Cutaneous eruptions absent.	9. Cutaneous eruptions absent.

Prognosis is guardedly favorable.

Treatment.—After the diagnosis has been fully determined, the first attempt should be directed toward the removal of the cause of the evil by aid of the stomach-tube, emetics (if needed), irrigation of the bowel with long rectal tube attached to a fountain syringe; and, subsequently, remedies to control the pain, to combat the symptoms of shock, and intestinal antiseptics to keep down intestinal putrefaction.

The stomach-tube may be introduced at once, and 1 1/2 pints of lukewarm water allowed to run in; the funnel of the tube should then be lowered and the fluid drained away. The process may be repeated until the stomach is thoroughly cleansed. See LAVAGE.

The rectal tube is then inserted into the bowel its full length and attached to a fountain syringe, and from 1 to 2 quarts of lukewarm water introduced. After the fluid has been expelled, the operation may again be repeated.

If emesis is not sufficient to expel the gastric contents and time is lost in procuring a stomach-tube, apomorphin (1/4 of a grain) may be given hypodermically. Should the bowels be constipated and the stomach retentive, magnesium sulphate (6 drams), Rochelle salt (6 drams), or solution of citrate of magnesia (10 ounces) may be given at once. Pain is best relieved by morphin (1/4 of a grain) hypodermically.

If collapse threatens, it must be combated with hypodermics of atropin (1/100 grain), strychnin

(1/30 grain), nitroglycerin (1/75 grain), whisky, inhalations of ammonia, nitrite of amyl, and hot applications to abdomen and extremities. After the stomach and bowels have been thoroughly cleansed by means of irrigation and purgatives, the following prescription may be given:

℞. Codein, gr. iij
Naphthalin, } each, ʒ j.
Bismuth subnitrate, }

Divide into 8 powders. One powder every 2 hours.

Naphthalin (10 grains) or naphthol (4 grains) may be given every 4 hours for 2 or 3 days. Salol (5 grains) may be substituted for the other intestinal antiseptics.

PTOSIS.—Drooping of the upper eyelid. It may result from any effusion or inflammation weighing down the upper lid. Excessive deposits of fat in the lid may cause it to droop. Ptosis also results from injury to or paralysis of the levator palpebræ muscle. It is one of the symptoms of palsy of the third nerve.

The treatment of ptosis consists in removing the cause if possible. In paralysis of the levator muscle strychnin and the galvanic current are useful. Several ingenious lid elevators have been devised for the relief of this condition. Operative interference has for its object the removal of a piece of the skin of the upper lid, or the insertion of silver wire to hold the lid up. The tendon of the levator muscle may be advanced, or the tarsus may be sutured to the temporal muscle. The patient can often relieve ptosis by learning to use the temporal muscle, or by throwing the head backward in order to see better.

A simple and effective operation for ptosis consists in passing a stout silk ligature vertically under the skin from the eyebrows to the margin of the lids, and firmly tying the ends. The noose formed in this manner is tightened every day, until it has cut its way through the confined tissues; the resultant cicatrix draws the lid to its normal position.

PTYALAGOGS.—See Sialagogs.

PTYALISM.—See Mercury (Salivation).

PUBERTY.—1. The period at which the generative organs of the male or the female become capable of exercising the function of reproduction. 2. The changes in the generative organs and in the general system that accompany the inauguration of this period.

Puberty occurs earlier in warm climates, in sanguine temperaments, and in highly cultivated and luxurious states of society. It cannot be estimated by age alone, and it is modified by family or hereditary peculiarities and the influence of various diseases. In the male the voice becomes bass, while about the same time hair grows on the face, pubes, and other parts of the body. Before this the male genital organs develop; the testes enlarge, as do other parts of the sexual apparatus; seminal and other accessory fluids are secreted, and there is an out-burst of sexual feelings and instincts. The changes are so slowly proceeding that they are not completed until full age has been passed.

In the female the individual passes from childhood to womanhood. The external genital organs enlarge, the uterus, ovaries, and breasts develop, and the commencement of the periodic menstrual discharge is marked. This time is usually, in this climate, between 13 and 15 years. The nonappearance of menstruation may be due to some constitutional disease or some general condition, the rational treatment of which rather than any uteroovarian stimulation should receive the physician's attention. Many of the ailments common about the period of puberty are but forerunners and accompaniments of the functional and organic changes about to commence, especially in the female sex. The influence of excessive mental stimulation during puberty is a subject deserving attention. The mind should not be goaded or overstrained at this time. See Adolescence, Anatomic Age.

PUERPERAL CONVULSIONS.—See Eclampsia.

PUERPERAL FEVER.—Fever occurring in women during the first few days after childbirth. It is of two varieties—(1) infectious and (2) noninfectious.

Noninfectious puerperal fever may be due to a variety of causes. The most common are emotion, constipation, exposure to cold, and reflex irritation.

PUERPERAL INFECTION.—Infectious puerperal fever may be divided into—

A. That class in which the infecting agent—bacteria or ptomains—gains entrance to some part of the genital tract or its vicinity.

B. That class in which the infection enters the body at some point distant from the genital tract, as the infectious fevers, erysipelas, and malaria.

Class A

Etiology.—The varieties of microorganisms capable of producing infection are the streptococci, which are the infecting agents in 80 to 95 percent of the cases; the staphylococci, the colon bacilli (see Colon Bacillus Infection), the gonococci, and, in short, any of the germs capable of causing local inflammation or general disease. In addition to these the saprophytes of decomposition, by the manufacture of ptomains, play an important rôle in the commonest form of puerperal sepsis—sapremia. These germs gain entrance to the genital canal by the hands of the physician, nurse, or other attendant; by instruments used in or about the parturient tract; by the water used to wash and douche the patient; by the bed-clothing, personal clothing, vulvar pads, and material used to cleanse the vulva; and by the atmosphere, laden with dust or vitiated by bad hygienic conditions. Putrescible material contained within the genital tract, such as decidua, pieces of placenta, and blood-clots, forms a suitable area for their multiplication, growth, and dissemination. Finally, a certain small proportion of cases may be traced to autoinfection—*i. e.*, to the action of germs resident in the body and not introduced from without

during or after labor. Such cases may arise from the rupture, during labor, of an old pyosalpinx or a suppurating cyst.

It should be remembered that while a large proportion of vaginal secretions contain pathogenic bacteria, these bacteria are frequently incapable of producing disease, since they are in a condition of diminished or absent virulence. It should also be remembered that the vagina possesses certain natural resisting powers against pathogenic invasion. These powers depend upon a special bacillus (Doederlein's) which, by the production of lactic acid, is antagonistic to pathogenic bacteria; the leukocytosis which is always present, due to chemotactic action; the anatomic structure of the mucous membrane of the vagina, resembling skin; the plug of cervical mucus; and the bloody discharge during the first few days of the puerperium.

Classification and Pathology.—The most convenient classification is that one which is dependent upon the part of the genital tract or its vicinity which is most extensively involved. Thus, we have the following:

1. **Endocolpitis, endometritis, and salpingitis**—inflammation of the mucous membrane of the vagina, uterus, and tubes. This is most frequently of the superficial or suppurative variety; it may, however, be ulcerative or phlegmonous.

2. **Metritis and cellulitis**—inflammation of the uterine walls and pelvic connective tissue. The former is the result of septic endometritis, the inflammation having extended beyond the mucous membrane and attacked the muscular wall. Cellulitis is usually the result of direct extension from the uterus; it not infrequently terminates in abscess formation.

3. **Peritonitis.**—This is the result, usually, of an extension through the tubes or a pelvic cellulitis. As a rule, the inflammatory process is limited to the pelvis; occasionally, diffuse peritonitis is seen.

4. **Uterine and Parauterine Phlebitis.**—This is caused by infection of blood-clots at the placental site. These may be disintegrated and swept into the circulation, producing pyemia. Rarely, phlebitis may occur from infection of the wall of the vein as it passes through a septic area.

5. **Sapremia.**—This is due to absorption of ptomains. The ptomains are generated by the putrefaction, in the uterus or vagina, of blood-clots, decidua, membranes, or placenta. It is the most common cause of fever after childbirth.

6. **Septic Cystitis, Ureteritis, and Pyelitis.**—This is frequently caused by infection from a dirty catheter. The condition becomes exceedingly grave when the kidney is involved. The inflammation may be suppurative or ulcerative in character.

7. **Septic Proctitis.**—This is a rare form of infection. It may be suppurative or ulcerative.

Symptoms.—The symptoms may be divided into local and general.

The local symptoms are (1) Putrid discharge; this is not invariably present, but it is seen in the majority of instances. (2) Diphtheritic patches; these ulcerated areas about the cervix, vagina, and vulva are seen in the severer class of cases. (3) Edema of the vulva; usually present in more or less marked degree. (4) Localized pain and tenderness. (5) Abdominal distention. (6) Inflamed tubes and ovaries. (7) Subinvoluted uterus. (8) Pelvic exudates and, later, perhaps, signs of pelvic abscess.

The general symptoms are: (1) Rigors or chill, followed by rise of temperature. The temperature usually ranges between 101° and 104° F.; the chill is not infrequently absent. (2) Rapid pulse; this is an almost constant symptom. (3) Prostration, delirium, and usually constipation.

All of these symptoms are not to be expected in every case of septic infection. Rise of temperature and rapid pulse may be only evidences of the condition.

Differential Diagnosis.—It is desirable to differentiate the various forms of sepsis. Unfortunately, this is not always possible; indeed, two or more of them not infrequently occur together. There are, however, certain distinctive signs which are of value:

1. **Endocolpitis, Endometritis, and Salpingitis.**—In the former speculum examination will reveal a red, swollen mucous membrane, and probably patches of ulceration about the vulva, vaginal vaults, and cervix.

2. **Metritis and Cellulitis.**—The uterus is large, boggy, and tender; the discharge is foul and copious; exudate may be felt through the vaginal vaults; the uterus is firmly adherent.

3. **Peritonitis.**—There is a very rapid, running pulse; the abdomen is greatly distended and very tender; constipation is a marked symptom.

4. **Phlebitis.**—The symptoms usually occur late in the puerperium; there is high and very irregular fever, with marked remissions, sometimes lasting 4 or 5 days; prostration is profound; phlegmasia alba dolens is commonly present; there are no severe local symptoms.

5. **Sapremia.**—This variety of sepsis should be expected if there are moderate fever, rapid pulse, and no other well-defined symptoms. A thorough disinfection of the birth canal will cause a rapid disappearance of these symptoms.

6. **Septic Cystitis, Ureteritis, and Pyelitis.**—There are pain and tenderness in the lumbar and hypogastric regions; urination is frequent and painful; blood and pus may be found in the urine.

7. **Septic Proctitis.**—There are pain in the rectum, diarrhea, and bloody stools; examination will reveal areas of ulceration on the mucous membrane of the bowel.

Treatment.—The treatment naturally divides itself into the (1) preventive and (2) curative.

1. **Preventive treatment** comprises care to avoid all sources of puerperal infection. It is considered under the management of labor. Careful attentions should be paid to the hygiene during pregnancy and to the sanitary condition of the lying-in chamber. Asepsis of patient, physician and accessories is imperative. No more internal examinations should be made than are absolutely necessary. See LABOR.

2. **Curative treatment** may be subdivided into constitutional, local, and special treatment.

Constitutional Treatment.—Give (1) calomel (1/2 grain) every hour until 4 grains have been taken. Follow this with Rochelle salt (1 dram) every half-hour until free catharsis is produced. (2) Milk (4 to 6 ounces) with lime water (1 fluid-ounce) and whisky (1/2 ounce) every 4 hours. Broths and beef-tea may be given during intervals if the patient can assimilate them. (3) Tincture of digitalis (10 drops) and sulphate of strychnin (1/20 grain) 4 times daily as long as the pulse is above 120 a minute. (4) Suppositories of quinin (5 grains) and pyrophosphate of iron (3 grains) twice daily. (5) Ergot is indicated to promote involution, thereby reducing the absorbent power of the uterus. (6) Inhalations of oxygen are of great value.

In addition to the foregoing, certain drugs that produce hyperleukocytosis, such as nuclein, may be tried. Nuclein, in some cases, has appeared to give very satisfactory results. Unguentum Credé, (a harmless remedy) may be used. Various results have been obtained from the intravenous infusion of formaldehyd solution. Pryor had excellent results with iodoform gauze packing subsequent to operation.

For reduction of the temperature hydrotherapy is valuable especially in the form of the wet pack or cold sponge. The ice-bag or coil applied intermittently is advocated for local tenderness.

The subcutaneous injection of a normal salt solution, a pint or more 2 or 3 times daily, has given good results. It probably acts by causing a hyperleukocytosis. Saline enteroclysis may be of service.

Serum Therapy.—Injections of antistreptococcic serum have given varied clinical results. If the streptococcus be present it may be used, but in conjunction with other treatment, as previously mentioned. The method of administration is as follows: 20 c.c. of reliable serum are injected deeply into the tissues as an initial dose. The daily dose in a desperate case should be 60 c.c. The serum may be tried as a last resort even in the absence of a microscopic examination of the lochia.

Local Treatment.—This consists in thorough disinfection of the parturient tract as follows: (1) Bring the patient in the lithotomy position across the bed, with the buttocks projecting well over the edge. (2) Sterilize vulva, vagina, instruments, and hands. (3) Seize the anterior lip of the cervix with a double tenaculum, and draw it well down to the vulva. (4) Curette thoroughly, using only the force of thumb and forefinger. (5) Remove any tabs of decidua or placenta digitally if possible —if not, by means of placental forceps. (6) Curette again carefully. (7) Irrigate with warm sterile water. (8) If the discharge has been very offensive, inject into the uterine cavity an emulsion of sweet oil (2 ounces) and iodoform (2 drams). (9) If the uterus does not contract firmly or if it is displaced, insert a light drain of iodoform gauze.

This constitutional and local treatment should be instituted in every case of puerperal sepsis. In addition it may be necessary to resort to the following:

Special Treatment. 1. **Endocolpitis, Endometritis, and Salpingitis.**—For the first two, repeated douches of sterile water or a 50 percent solution of alcohol should be given. If ulcerated areas of mucous membrane are present, they should be touched with nitrate of silver solution (1 dram to 1 ounce). In suppurative salpingitis laparotomy will be required.

2. **Metritis and Cellulitis.**—For the former, frequent intrauterine douches are required; in grave cases hysterectomy will be necessary. Cellulitis will yield in most cases to free purgation, counter-irritation, poultices, and douches; if abscess should occur, laparotomy must be performed and the abscess cavity evacuated and drained. If after the abdomen is opened it is found that the inflammation is confined to the pelvic connective tissue, the wound should be closed and the infected area opened and drained through the vaginal vault or above Poupart's ligament.

3. **Peritonitis.**—Salines, stupes, and free stimulation will be sufficient in mild cases. If active symptoms persist far beyond 48 hours, it is probable that suppuration has occurred. In such a case the abdomen should be opened, abscesses evacuated and drained, and diseased tubes and ovaries removed. It may also be necessary to perform hysterectomy.

4. **Phlebitis.**—Prolonged rest in bed, free stimulation, and an abundance of good nutritious food is required. If complications occur, such as septic pneumonia or arthritis or phlegmasia alba dolens, they must be appropriately treated. If one is certain that he has to deal with a pure phlebitis, local treatment is unnecessary or even harmful.

5. **Sapremia.**—Though disinfection of the parturient tract will cause a disappearance of symptoms in from 24 to 48 hours.

6. **Septic Cystitis, Ureteritis, and Pyelitis.**—Irrigate the bladder every 4 hours with boric acid solution (15 grains to 1 ounce). Use hot stupes, salines, and stimulation. Urotropin should be given. Abscess of the kidney may necessitate evacuation and drainage.

7. **Septic Proctitis.**—Irrigate the rectum with sterile water, and apply nitrate of silver solution (1 dram to 1 ounce) to ulcerated areas.

Class B

The most common varieties of infectious puerperal fever, in which the infecting agent enters the body at some point distant from the genital tract, are malaria, typhoid, and erysipelas. To eliminate the first as the cause of fever, give blue mass (8 grains) followed by quinin (15 grains); next morning give a brisk saline purge and repeat the quinin.

PUERPERAL INSANITY.—This is a somewhat rare complication of childbirth, occurring once in about 400 cases. It commonly manifests itself as mania, melancholia, or dementia—the former being the most frequent. It usually makes its appearance during or just after labor, less frequently during lactation, and rarely during pregnancy.

Causes.—The reduction in physical and mental power caused by the strain of gestation might be

considered the predisposing cause. Exciting causes are profound emotion, dystocia, anemia, albuminuria, and septicemia.

Diagnosis.—The diagnosis is not difficult, although it is important to distinguish it from the temporary delirium of labor, the delirium of fever, and delirium tremens.

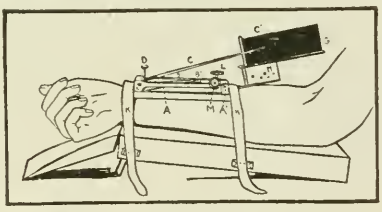
Prognosis.—With appropriate treatment about 66 2/3 percent recover their reason in the course of a few months. Of the remainder, a small proportion die from infection or exhaustion, and the rest remain permanently insane.

Treatment.—This consists in the administration of tonics and nutritious food; a change of scene, open-air exercise, and general hygienic precautions are most beneficial. The patient must be constantly watched, lest she attempt some injury to herself or child.

PULMOTOR.—A recent appliance for producing artificial respiration in cases of asphyxia. By appropriate mechanism, which acts automatically, and alternately by pressure and suction, oxygen is pumped into the lungs, and then by negative pressure an outflow from the lungs is caused. The apparatus has already achieved great results and is most valuable. See NEW-BORN INFANT (Asphyxia Neonatorum).

PULSE.—Much information of the action of the heart, of the blood, and of the artery itself may be gained by a simple examination of the radial pulse.

The physicians in olden times gave much careful attention to the pulse, and the amount of information to be gained from its study is astounding. By the introduction of percussion, and auscultation, the interest in the study of the pulse was decidedly lessened. This interest was further diminished by the introduction of the *sphygmograph;* and the clinical thermometer dealt a deathblow to the painstaking study of the pulse.



MAREY'S SPHYGMOGRAPH.—(*Greene.*)

A. Steel spring. *B.* First lever. *C.* Writing lever. *C'.* Its free writing end. *D.* Screw for bringing *B* in contact with *C*. *G.* Slide with smoked paper. *H.* Clockwork. *L.* Screw for increasing the pressure. *M.* Dial, indicating the pressure. *K, K.* Straps for fixing the instrument to the arm and the arm to the double inclined plane or support.

To take the pulse, the physician should be seated by the side of the patient, who should be in a sitting or recumbent posture, with arm extended and resting on some support. The physician should lightly place the 4 fingers of his right hand over the left radial artery of the patient, with his index-finger nearest patient's hand; the little finger will thus be the first to receive the stroke. The pulse should always be taken at each wrist, for reasons to be given later. By so doing the presence of aneurysms may often be suspected and frequently verified. Pressure should be made and relaxed alternately. Points to be noticed are: (1) The size of the artery; (2) pulse rate or frequency; (3) regularity of rhythm; (4) uniformity of strength; (5) synchronism and equality of the right and left radial pulses; (6) the force required to obliterate them (tension); (7) abnormal thickening of the artery (arteriosclerosis). A strong pulse is characterized by volume and vigor; a weak one by the reverse conditions. The number of pulsations to the minute, which can generally be counted accurately by means of a watch, is the least important of all the points to the experienced clinician, who cares little whether the heart contracts 75 or 100 times a minute. He is mainly "interested in the dynamics of the viscus rather than in the derangement of its running-gear." Above all things should the family physician be familiar with the pulses of his patients in health, for, as is well known, some families have abnormally slow and others fast pulses.

The pulse may be modified (1) as to frequency, (2) rhythm, (3) volume, (4) tension.

Frequency.—The normal pulse-rate in the male adult may be said to be 76 a minute and 80 for the female; at birth it has been placed at 120 to 130, and 100 at the second year.

The frequency of the normal pulse may be increased by excitement—such as fright—emotion, by violent exercise, and by the use of drugs, such as stimulants. An increased frequency of the pulse is spoken of as **tachycardia,** (*q. v.*). It is often greatly increased (1) in fevers, as scarlet fever, and diphtheria; (2) shock from loss of blood; (3) exophthalmic goiter; (4) pressure on the base of the brain; (5) organic heart-disease, angina pectoris, etc.

Bradycardia, (*q. v.*), or a **slow pulse,** is seen in (1) jaundice; (2) atheroma; (3) lesions of the cerebral centers; (4) fatty degeneration; (5) often after the use of such drugs as aconite, digitalis, and opium; (6) Stokes-Adams syndrome. A slow pulse is often a physiologic phenomenon.

Rhythm.—Often the interval between the beats is disturbed, and there will be (1) an intermittent pulse or (2) an irregular pulse (arrhythmia).

Intermittent pulse is often seen in those who habitually use tobacco, or after hearty eating. It is commonly due to reflex causes, as constipation and diseases of the stomach, liver, or kidneys. The rheumatic or lithemic diathesis may give rise to a slow pulse.

Irregular pulse is often found in disease of the heart-muscle or in disease of its valves. It is very common in mitral regurgitation.

Dicrotic pulse is a condition of the pulse in which the first impulse as it strikes the finger is quickly followed by another impulse or a secondary wave. It is found often in conditions of marked exhaustion or toxemia as in typhoid fever, and in other febrile diseases.

Quick pulse (*pulsus celer*) or **water-hammer pulse** (*Corrigan's*) is a condition of the pulse characterized by a short, sharp, strong impulse, which seems to collapse under the finger. It is best detected by holding the arm erect. It is almost

diagnostic of aortic regurgitation under certain conditions. It also occurs in anemia and fevers when the arterioles are relaxed.

Pulsus paradoxus is a pulse in which the wave is small and imperceptible during full inspiration. It is seen sometimes in health and often in adherent pericardium.

Volume.—When the beat of the pulse is large or strong, it is known as a **full pulse,** such as is found in plethora or in the robust. If the beat is weak, it is known as a **small pulse,** such as is found in debility or exhaustion.

Strength.—A **strong pulse** is one in which there are little compressibility and a strong impulse, such as is found in hypertrophy of the heart. Its opposite is a **weak pulse,** as in adynamic states.

Tension or Resistance.—It may be either hard or soft. A **hard pulse** is one of high tension, or one in which there is great contractile power; it is often seen in hypertrophy of the left ventricle, interstitial nephritis, septicemia, angina pectoris, arteriosclerosis; certain intoxications like gout, lead poisoning, diabetes in elderly persons. It is observed in apoplexy and at times in anemia. A small, hard, **wiry pulse** is noted in the early stage of peritonitis. A **soft pulse** is of low tension and easily compressible, indicative of a loss of tone in the arterial coats. It is found in low fevers, such as typhoid, the later stages of pneumonia, and in adynamic conditions in general. It is sometimes hereditary and may be observed in obesity. See HEART-DISEASE (Functional).

PULVIS.—See POWDER.

PUMPKIN SEED.—See PEPO.

PUPIL, CHANGES IN MOTILITY.—Mydriasis, or extreme dilatation of the pupil, occurs under the effects of drugs possessing a mydriatic action, such as atropin, homatropin, hyoscyamin, etc.; in glaucoma; in optic nerve atrophy; in diseases of the orbit; after fright; in neurasthenia; after irritation of the cervical sympathetic, as by an aneurysmal tumor; and sometimes in idiots. Permanent mydriasis has occurred after the instillations of a mydriatic have been suspended. Mydriasis of distinctly cerebral origin is caused either by irritation due to some lesion in the brain or cervical portion of the spinal cord, or by paralysis of the oculomotor center due to hemorrhage, thrombosis, tumor, or abscess of the brain.

The treatment of mydriasis consists in remedying the cause, if possible; locally, pilocarpin or eserin is indicated, and the galvanic current is sometimes of use. Exercise of the eyes with convex lenses upon near objects may be of value.

Miosis, or permanent contraction of the pupil, occurs under drugs possessing miotic action, such as eserin, pilocarpin, etc.; in paralysis of the cervical portion of the spinal cord, particularly in locomotor ataxia; in paretic dementia; in cerebral syphilis; and in bulbar palsy, with progressive muscular atrophy. Persons who continually use their eyes on fine objects, such as watchmakers and engravers, sometimes suffer from miosis. In opium-poisoning the pupil is reduced to the size of a pinpoint, dilating just before death. Nicotin and alcohol in poisonous quantities may produce miosis. As contraction of the pupil may result from irritating cerebral lesions similar to those causing dilatation, it is important to have some means of differential diagnosis. Berthold mentions that miosis occurs in a sudden attack of paralysis due to embolism, and mydriasis in an attack due to ophthalmia. Idiopathic cases are said to result from syphilis, tuberculosis, rheumatism, and other systemic disorders.

Treatment is virtually the same as that for iritis, although atropin must be used with caution, as it is often very poorly borne. Plastic and purulent cyclitis must be treated rigorously with mercurial inunctions. For the reduction of tension, the local use of eserin, diaphoretics, and paracentesis are indicated. In purulent cyclitis, especially after operations, antiseptic douches are indicated. On account of the uncertain prognosis, the possibility of relapses, disorganization of the vitreous, and sympathetic ophthalmia, the patient may be carefully watched, and expectant treatment continued after the symptoms have subsided.

Anisocoria, or **inequality in size of the pupils,** may occur in perfect health. In fact, it is much more common than text-books indicate. It is sometimes seen in eyes of widely dissimilar refraction, diseases of the brain and nervous systems, and in insanity. It is not uncommon in tabes, disseminated sclerosis, and paretic dementia.

Wernicke's sign, or **hemiopic pupillary inaction,** is mentioned in the discussion of HEMIANOPSIA (*q. v.*). Light is carefully thrown on the blind side of the retina; if there is reflex contraction, the lesion is behind the pupillary centers; if there is no reflex obtained, the lesion is at or in front of the pupillary centers.

The Argyll Robertson pupil is a name given to a reflex pupillary rigidity producing loss of reaction to light stimulation, although the action to accommodation and convergence may still be present. It is a diagnostic sign of value in locomotor ataxia, but has been noticed in general paralysis of the insane, in cerebral syphilis, and is the result of poisoning by bisulphid of carbon.

The orbicularis pupillary reaction refers to contraction of the pupil when a forcible effort is made to close the lids.

Hippus is the name given to the oscillations occurring after contraction to light. It is exaggerated in hysteria, disseminated sclerosis, epilepsy, and in the early stages of acute meningitis.

Iridodonesis is a tremulous condition of the iris, due to lack of a normal support of the lens. It is seen in conditions in which the lens is dislocated posteriorly, in atrophy of the vitreous, in overripe cataract, and after cataract extraction.

PURGATIVES.—See CATHARTICS.

PURPURA (Peliosis Rheumatica).—A hemorrhagic disease characterized by the appearance on the skin of variously sized and shaped reddish-purple macules, not disappearing under pressure.

Varieties.—There are 3 chief varieties, distinguished by the premonitory and concomitant constitutional symptoms, by the extent of hemorrhagic extravasation, and by the cause: (1) Purpura simplex; (2) purpura rheumatica; (3) purpura hæmorrhagica.

Purpura Simplex

The eruption usually appears suddenly and consists of pinhead-sized to bean-sized, round, oval, irregular, claret-red or purplish spots. They are circumscribed, smooth, and nonelevated, and are symmetrically distributed, tending particularly to occur upon the lower extremities. Subjective symptoms are, as a rule, absent. There is commonly no systemic disturbance, and the disease tends to a favorable termination in the course of a few weeks.

Purpura Rheumatica (Peliosis Rheumatica)

This form is ushered in with fever, lassitude, anorexia, and severe rheumatoid pains, particularly in the lower extremities, the joints of which may be swollen. The eruption consists of well-defined, splitpea-sized to finger-nail-sized hemorrhagic patches which may be slightly elevated or level with the skin. At first of a pinkish, reddish, or purplish color, they later pass through the color transitions of all ecchymoses. The eruption is more or less generalized, but is most marked upon the extremities. The disease may last a few weeks or persist, in the form of relapses, for several months. It is sometimes associated with erythema multiforme.

Purpura Hæmorrhagica (Morbus Maculosus Werlhofii; Land Scurvy)

The onset of the hemorrhagic form is signalized by the occurrence of fever and symptoms of systemic depression. The eruption consists of hemorrhagic patches varying in size from that of a small coin to that of the palm of the hand, which come out suddenly and in considerable numbers. The trunk and extremities are the regions usually involved. At the same time, bleeding from the mouth, gums, nostrils, bowels, bladder, etc., may take place. The disease may terminate in a fortnight or may continue for weeks. In a certain number of cases it proves fatal.

Etiology.—The causes of purpura are obscure. The disease, especially the hemorrhagic type, occurs more often in debilitated individuals. Some look upon the vasomotor apparatus as the agency primarily at fault; others believe purpura to be an infectious disease. Such drugs as arsenic, potassium iodid, chloral, quinin, and the salicylates may produce hemorrhagic eruptions.

Pathology.—As a result of an alteration in the blood or blood-vessel walls an extravasation of blood takes place into the tissues. After a variable period of time this undergoes resorption, the changes in the blood pigment producing the varying colorations. The process is not attended with inflammation.

Diagnosis.—The evident hemorrhagic nature of the lesions and their failure to disappear upon pressure distinguish them as purpuric. Purpura hæmorrhagica may be confounded with scorbutus:

Scorbutus.	Purpura Hæmorrhagica.
1. Occurs in those subject to lack of vegetable food and to bad hygiene.	1. No such etiologic relationship.
2. Definite premonitory symptoms: weakness, impaired circulation, etc.	2. Premonitory signs slight or absent.
3. Onset slow.	3. Onset sudden.
4. Gums spongy, swollen, and bleeding; teeth loose.	4. Gums often bleeding but not swollen.
5. Severe muscular pains.	5. Less marked.
6. Brawny infiltration of lower extremities.	6. Not present.
7. Hemorrhages from mucous membranes not, as a rule, profuse.	7. Hemorrhages from mucous membranes often so severe as to prove fatal.

Prognosis.—In purpura simplex and rheumatica the prognosis is favorable, recovery taking place in several weeks or months. In purpura hæmorrhagica the prognosis is more guarded, a certain number of cases succumbing to internal hemorrhage.

Treatment.—The treatment of purpura must be adapted to the exigencies of the individual case. Ergot, tincture of the chlorid of iron, quinin, turpentine, and the mineral acids are useful in all forms of the disease. In purpura rheumatica and hæmorrhagica the patient should be confined to his bed and placed upon a nutritious and easily assimilable diet. Locally, astringent lotions and ice, if necessary, may be employed.

PUS.—See Suppuration.

PUSTULANT.—See Counterirritation.

PYELITIS (Pyelonephritis).—Inflammation of the mucous membrane of the pelvis of the kidney. Except in the mildest cases, the kidney proper becomes simultaneously involved. To the former condition the term pyelitis is applied; to the latter, pyelonephritis.

Etiology.—(1) Renal calculus; (2) secondary to urethritis or cystitis; (3) tuberculosis; (4) after infectious diseases, such as typhoid fever, scarlet fever, diphtheria, small-pox; (5) carcinoma.

Microorganisms may gain access to the kidney either through the blood stream or through the urinary tract. When infection occurs in the former way it is called hematogenous; when in the latter, urogenous. See Colon Bacillus Infection.

Pathology.—The mucous membrane of the pelvis of the kidney is swollen, turbid, and often shows minute extravasations. The epithelium has in certain areas undergone degeneration, forming mucus or pus. The suppurative process may finally extend into the kidney structure, giving

rise to pyelonephritis, and a large abscess may occupy the entire area of the kidney. In certain instances the fluid material may be entirely absorbed, leaving a putty-like material.

Symptoms and Clinical Course.—There is pain in the lumbar region and also anteriorly, detected on deep pressure. The fever is irregular, occasionally accompanied by hectic symptoms, with sweat and chill. In some cases the disease may simulate typhoid fever. The urine is clear at times, but generally has a turbid color, with a heavy precipitate containing a large amount of mucus, pus-cells, red blood-corpuscles, and pelvic epithelium. Blood-clots may be passed.

The purulent material renders the urine albuminous.

Diagnosis.—

Pyelitis.	Nephritis.	Cystitis.
1. History of case.	1. Increased micturition; sweat and chills rare.	1. Micturition accompanied by tenesmus; often burning pain.
2. No tube casts...	2. Albumin and various kinds of casts.	2. No tube casts.
3. Pus in urine....	3. Pus rare.....	3. Blood often at end of micturition.
4. Dropsy rare....	4. Dropsy common... 5. Urea diminished.	4. No dropsy.

Prognosis.—The prognosis is variable; simple pyelitis may exist for years without the substance of the kidney itself becoming involved. Pyelonephritis, as a rule, gradually leads to destruction of the kidney and therefore must be considered a serious disease.

Treatment.—The treatment of acute pyelitis consists in the employment of antiphlogistic measures and the administration of narcotics and urinary antiseptics. Of the latter urotropin is the most valuable. Regular evacuation of the bowels should be secured. If threatening symptoms persist, such as high fever and chills, and if an exact diagnosis can be made as to which kidney is diseased, or at least as to which one is the more diseased a brilliant curative effect can sometimes be secured by splitting the kidney. This applies to pyelitis as well as pyelonephritis, but is only of value in the ascending forms of the disease.

In chronic pyelitis, and pyelonephritis, the use of urinary antiseptics and the employment of hygienic measures are also indicated. For pyelitis due to infection with the gonococcus or colon bacillus Casper recommends irrigation of the renal pelvis with a solution of silver nitrate 1:1000. In chronic pyelonephritis nephrotomy often brings about a cure. See Kidney (Injuries, Surgery), Nephritis.

PYEMIA.—Phlebitic septicemia, with the presence of pyogenic microorganisms in the blood and with the formation, wherever they lodge, of secondary embolic or metastatic abscesses. It is characterized by intermittent fever, with recurrent rigors, profuse sweats, a sweetish odor to the breath, a dry, brown tongue, and rapid emaciation. Slight jaundice frequently develops; sometimes, also, a purpuric eruption; the temperature may be very high—105° F., or even more. It usually terminates in death. See Sepsis.

PYLORUS.—See Stomach.

PYOKTANIN.—See Methyl-violet.

PYOMETRA.—See Hematometra.

PYONEPHROSIS.—Pyonephrosis is the distention of the pelvis and calices of the kidney with pus, and the subsequent destruction, more or less complete, of the medullary and cortical substance, the whole kidney being at length converted into a large multilocular suppurating cyst. This cyst may rupture into the peritoneal cavity or colon, or into the surrounding tissue, causing a perinephritic abscess.

Etiology.—Infective nephritis with retention of pus is a very common cause, but some cases of pyonephrosis are due to infection of a hydronephrosis.

Symptoms.—In addition to a tumor in the abdomen with characters similar to those of hydronephrosis, there will be pain in the tumor, especially on pressure, and if the obstruction of the ureter is incomplete, pus in the urine, septic fever varying with the absorption.

Treatment.—Nephrotomy, with removal of any obstruction discovered in the pelvis of the kidney or ureter. If after nephrotomy, however, the cyst does not shrink and cease to suppurate, and the opposite kidney is sound and working well enough, nephrectomy may have to be done, as otherwise lardaceous disease may carry off the patient, or blood-poisoning may ensue from the discharge becoming septic, or, as sometimes happens when the obstruction of the ureter is relieved to some extent by the nephrotomy, the decomposing pus may make its way into the bladder, set up cystitis, and the other kidney become affected. When the disease is bilateral both kidneys are drained through the loins. See Pyelitis.

PYORRHŒA ALVEOLARIS.—Riggs' Disease, Phagedenic Pericementitis (Black), **Interstitial Gingivitis** (Talbot), **Phagedenic Pericemental Alveolitis** (Logan).

Definition.—A chronic destructive disease of the supporting structures of the human tooth.

Etiology.—The usual *systemic predisposing* causes are diseases of the heart and vessels, diabetes and Bright's disease. Chronic rheumatism and digestive disturbances are held to be the most serious predisposing factors. *Local predisposing causes:* Lack of maintenance of proper hygiene; absence of normal contacts and masticatory influences; excessive irregularities and malocclusion of the teeth. *Local exciting causes:* Presence upon the crown and root surfaces of teeth of inorganic and organic deposits of a fatty glue-like substance impregnated with pyogenic bacteria; lodgment of food in the interproximal spaces; the presence of pyogenic organisms that chronically involve the pericemental alveolar structures which normally support the teeth. The *entamœba buccalis* has been found in many cases.

Diagnosis.—This disease exists whenever serumal deposits are found upon the exposed cementum, and a septic chronic destructive inflam-

mation coexists in the pericemental and alveolar structures, providing this exposed cementum resulted from some disturbance that had its origin of irritation in the gums. This disease exists also when we find a chronic septic destructive process beginning at the gums and progressively involving the pericemental and alveolar tissues in such a manner as to create well defined pockets in the form of narrow routes at the expense of the pericemental tissues and the inner surface of the alveolar structures some distance in advance of the alveolar rim involvement. According to the above diagnostic findings phagedenic pericemental alveolitis exists without serumal deposits being found in the pockets as well as with them. However, in over 90 percent of the advanced cases serumal deposits are present.

Subjective Symptoms.—Patients as a rule not aware of the presence of the disease until it has progressed to a serious stage; then low, dull, gnawing pains are experienced in the part for a few days at a time, with variable periods of rest from discomfort. In advanced cases tenderness is felt when masticating food.

Objective Symptoms.—Deep dark red discoloration of the gums and adjacent soft tissues overlying the bone structure about the roots involved. Excessive hemorrhage from gums from the slight irritations caused by thorough examination, the usual brushing, and the mastication of food. Sufficiently pronounced hemorrhage occurs sometimes during sleep to saturate the pillow. In advanced cases pus can be forced up around the necks of the teeth involved from practically all of the pockets found. The teeth eventually become abnormally mobile and permanently shift from their normal positions causing characteristic deformities. The roots gradually become exposed as the supporting structures are progressively destroyed.

Treatment, operative, consists in the removal of all deposits found upon the exposed cementum in the pockets. Smooth the roughened cementum with sharp instruments and polish with pumice and orangewood point all exposed tooth surfaces. **Surgical,** remove all degenerating pericemental fibers from the tissues forming the borders of the pockets, carefully examining remaining alveolar process and if carious areas are found, these areas are to be curetted. **Medicinal,** irrigate pockets during operative and surgical treatment with a physiological salt solution, which is to be made fresh for every patient. Senn's solution should be employed for the final medicinal treatment in the pocket. Tincture of iodin for local application to be applied upon the gums and overlying structures is sometimes beneficial in causing the acute inflammation to subside. The constant use of astringent mouth washes acts against rather than in favor of gaining and maintaining control of this disease. Tooth powders and mouth washes should never be relied upon to cure this condition; still proper oral and dental cleanliness is necessary for the prevention of the beginnings of excessive dental caries and diseased conditions of the gums. The use of emetin has been recommended but it is impossible to say, as yet, whether it will always give the good results which have been claimed for it. Dilute sulphuric acid (in 20 to 30 minim doses, has also been advocated.

Prosthetic Treatment.—A reestablishment of all lost contacts and the fixation of the abnormally loose teeth is to be brought about by the constructing of metal splints that are to be cemented into place.

Prognosis for *single rooted teeth* when only the gingival third is involved, is good; when the middle third is extensively involved prognosis is only fair; when the apical third is extensively involved the tooth should be immediately extracted. **Prognosis** of *multiple rooted teeth* when gingival third is involved is good; but when middle third is extensively involved the tooth should be extracted or one of the roots excised.

PYOSALPINX.—See Fallopian Tubes.

PYOTHORAX.—See Pleurisy (Purulent).

PYRAMIDON.—A derivative of antipyrin in which an H-atom of the pyrazolon group is replaced by a dimethylamido group. It forms a yellowish-white, tasteless, crystalline powder, soluble in water (1:10). This solution gives a violet fugitive color with Fe_2Cl_6. Nitrous acid gives an evanescent violet. In the urine pyramidon is best detected by the ferric chlorid test. The action of pyramidon upon the nervous system is analogous to that of antipyrin, but it is active in much smaller doses. It is much milder, more gradual and lasting in its influence than antipyrin. Dose, 2 to 8 grains. For consumptives and in hectic fever the minimum dose should not be exceeded. *P. Acid Camphorate* and *P. Neutral Camphorate.* The acid and neutral salts combine the antipyretic action of pyramidon with the antihidrotic action of camphoric acid, the former action predominating in the neutral salt, the latter in the acid salt. It is said that the tonicity of pyramidon is thereby reduced, while the camphoric acid has greater antihidrotic power. They are especially efficacious in the night-sweats of phthisis. Dose of the neutral salt, 8 to 12 grains; of the acid salt, 12 to 15 grains.

P. Salicylate is antipyretic, analgesic and antiseptic, combining the activity of its components, pyramidon and salicylic acid. It is recommended in rheumatic and gouty affections, neuralgia, pleuritis, etc. Dose, 8 to 12 grains.

PYRETHRUM (Pellitory).—The root of *Anacyclus pyrethrum.* It contains an alkaloid *pyrethrin,* also inulin, tannin, mucilage, etc., with a brown *resin* and two fixed oils. When taken into the mouth, it increases the flow of saliva, and is used as a masticatory in dry conditions of the mouth, in relaxed states of the throat, and in aphonia; also in headache and facial neuralgia. It is valuable mainly as a masticatory and sialagog. Dose, 10 to 45 grains. **P., Tinct.,** 20 percent; used externally. *P. roseum,* Persian pellitory. The powdered flower-heads are used as an insecticide.

PYROGALLOL. $C_6H_3(OH)_3$.—A triatomic phenol obtained chiefly by dry distillation of gallic acid, occurring in light, white, shining laminæ or fine needles; of bitter taste, but soluble in water,

alcohol, and ether. Dose, 1 to 2 grains. It is a powerful reducing agent, and is used as a disinfectant in 1 to 2.5 percent solutions. As an ointment (1 dram to 1 ounce) it ranks next to chrysarobin, for use in psoriasis, while in lupus and epithelioma it is supposed to attack only the diseased nodules, leaving uninjured the adjacent skin. By the mouth, for internal hemorrhage, it has been used in 20-grain doses. Large doses may produce hemoglobinuria and general disorganization of the blood-corpuscles.

PYROPLASMOSIS HOMINIS.—A peculiar fatal disease of certain parts of Idaho, Wyoming, Montana, Nevada, occurring during the spring and early summer, apparently only in persons who have been bitten by ticks. Certain observers believe it to be due to the *pyroplasma hominis*, which is closely related to the pyrosoma bigeminum, the cause of Texas cattle fever, and is believed to be transmitted by means of the bite of a tick (though the latter may be overlooked by reason of its presence at times only in the hair above the genitals). This organism is found in the patient's blood.

Symptoms.—After an incubation period of from 3 to 10 days, headache, nausea, muscular soreness, and a chill or chilliness and nose-bleed are followed by a rapidly rising fever and unduly rapid pulse and respiration. On the third day a rash, macular, bright red, in severe cases petechial, appears first on the forehead and extremities, later on the chest, abdomen, and back. It is profuse except on the abdomen. Desquamation may follow. Albumin is present in the urine. In fatal cases rapid anemia appears with sustained high temperature and rapid weak pulse. About the twelfth day the temperature falls by lysis in favorable cases, but 70 to 90 percent terminate fatally.

Prophylaxis.—It is wise not to live in these districts during the spring and early summer. Tick bites should be guarded against, but if incurred, ammonia, kerosene or turpentine should be applied, followed by cauterization with pure phenol.

Treatment is stimulating and symptomatic.

PYROSIS (Heartburn).—An affection of the stomach characterized by a burning sensation, accompanied by eructations of an acrid, irritating fluid. See Gastric Neuroses, Gastritis.

PYROXYLIN (Soluble Gun-cotton).—Chiefly tetranitrate of cellulose, used for preparing collodions. Collodion rapidly dries on exposure to air by evaporation of its ether and leaves a transparent film of pyroxylin on the surface to which it has been applied. This film, if the flexible collodion be used, will not contract or crack on drying.

PYURIA.—See Cystitis, Pyelitis, Urine (Examination).

Q

QUARANTINE.—The time (formerly 40 days) during which a vessel from ports infected with contagious or epidemic diseases is required by law to remain outside the port of its destination, as a safeguard against the spreading of such disease. The necessity and means of quarantine in infectious diseases are discussed under the separate headings of the different diseases. The methods of disinfection are considered under the heading DISINFECTION (*q. v.*).

QUASSIA.—The wood of *Picrasma excelsa*, or of *Quassia amara;* the former is known commercially as Jamaica quassia, and the latter as Surinam quassia. The wood is turned into cups, which are sold under the name of quassia- or bitter-cups. It contains a bitter principle, *Quassin*, $C_{31}H_{42}O_9$, which is crystalline, soluble in hot alcohol and in chloroform, slowly in cold water, faster in alkaline or acidulated water. Dose of the powdered wood, 5 to 15 grains. Quassia is fatal to flies and fish, and makes an excellent anthelmintic enema against the thread worm. The lower bowel should be washed out with soap and water, and from 1/2 to 1 pint of an infusion, made by adding 1 or 2 ounces of quassia chips to a pint of water, should be injected and retained for some minutes. Several such injections will invariably kill seat-worms or thread-worms, but enough fluid should be injected to reach high up in the rectum, and the washing with soap and water should not be omitted. Quassia contains no tannin, and may be prescribed with salts of iron. In atonic dyspepsia, with pain after eating and regurgitation of food, and to promote appetite and digestion, it is much employed.

A bitter tonic:

℞. Extract of nux vomica, gr. iv
Extract of quassia, gr. xx
Sulphate of quinin, gr. xl.
Make into 20 pills. One pill 3 times daily after meals.

Preparations.—**Q.-cup,** a cup made of quassia wood, called also *bitter-cup,* from which water may be drunk, the bitter principles becoming dissolved in the water. **Q., Ext.,** its properties are due to a bitter principle, *quassin.* Dose, 1 to 3 grains. **Q. Fluidextract.** Dose, 5 to 15 minims. **Q., Infus.,** quassia chips, 1 dram; water, 10 ounces. Dose, 1 to 3 ounces. **Q., Tinct.,** 20 percent in strength. Dose 5 minims to 1 dram.

QUEEN'S-ROOT.—See STILLINGIA.

QUERCUS (White Oak).—The bark of the white oak tree. It is astringent and tonic, but seldom used internally, its action being that of tannic acid. A decoction or infusion is much used as a cheap astringent application in leukorrhea, vaginitis, gonorrhea, prolapsus ani, hemorrhoids, etc., and as a gargle in faucial inflammations and for prolapsed uvula. It stains the clothing very slightly. *Q. tinctoria* stains the clothing very badly, but it is equally efficient. As an astringent poultice, the powdered bark is used to check discharges of freely running sores. An infusion of 1 ounce to a pint of water is of sufficient strength. **Q. Fluidextract.** Dose, 5 to 20 minims.

QUICKENING.—The first sensation of the movements of the fetus in a pregnant woman. It usually occurs at about the twentieth week. Some women experience it earlier than this, and in some it appears to be entirely absent. It has been likened in character to the fluttering of a bird held in the partly closed hand. It is one of the important subjective signs of pregnancy. See PREGNANCY (Diagnosis).

QUICKSILVER.—See MERCURY.

QUILLAJA (Soap Bark).—The inner bark of *Quillaia saponaria.* Its properties are due to a glucosid, *saponin.* It is a sternutatory, irritant to the mucous membranes, and an expectorant having an agreeable taste. Dose of a 5 : 200 decoction, 1 to 2 drams, according to age.

QUINIDIN.—A cinchona alkaloid, isomeric with quinin, with which it corresponds in therapeutic effects; but it is thought to produce less unpleasant symptoms in the head. **Q. Sulph.,** readily soluble in acidulated water and alcohol; it is an excellent antipyretic and antiperiodic. Dose, 20 to 60 grains or more. **Q. Tannate,** used in diarrhea, nephritis, and malaria. Dose, 2 to 12 grains twice daily.

QUININ.—Quinin is a finely crystalline or amorphous white alkaloid obtained from various species of CINCHONA (*q. v.*). It is odorless, very bitter, alkaline in reaction, and soluble in 1600 parts of cold water or 0.6 parts of alcohol. It is a valuable tonic, antiseptic, antipyretic, and antiperiodic. Quinin and its salts are distinguished from all other alkaloids, excepting quinidin and quinicin, by the emerald-green color given to their solution by chlorin water followed by ammonia.

Therapeutics.—Quinin finds its principal field of action in the malarial diseases, over which its influence is specific, by reason of its power to prevent the development of the plasmodium to which malaria is due. In intermittent fevers a 10-grain dose of the sulphate should be given in the sweating stage, and again 5 hours before the expected time of the next paroxysm. In the intervals arsenic is better used, as quinin may cause a daily exacerbation of temperature if long continued. In remittent fevers 20- to 30-grain doses should be administered once or twice a day until the temperature is reduced to the normal point. In pernicious remittent fevers large doses (30 to 40 grains) are necessary to the safety of the patient.

In chronic malarial poisoning quinin has considerable power, but chinoidin is more effective. Quinin (5 to 10 grains daily) is efficient as a prophylactic against malaria. See MALARIAL FEVERS.

As an antipyretic, quinin is used with the best results, especially in septic fevers, typhus, typhoid, variola, pneumonia, and acute rheumatism. Inflammations may, at their inception, be aborted by 15- or 20-grain doses, combined with morphin, which in this respect is synergistic to quinin. Acute tonsillitis and acute catarrh may sometimes be aborted by a full dose. In surgical fevers, pyemia, and exhausting suppurative conditions, also in septicemia, hectic fever, and before surgical operations, quinin is much employed. Neuralgias of malarial origin are amenable to it, as also neuralgia of the ophthalmic division of the fifth nerve. In eruptive fevers—especially scarlet fever, erysipelas, and measles—it is advantageously administered throughout their course. In some skin-diseases—particularly erythema nodosum—it is quite efficient, also in whooping-cough and hay-fever. In the latter affection a solution of 6 grains to the ounce of the neutral hydrochlorid is a very useful local application. Of internal antipyretics, the safest and best is quinin, next in order being phenacetin. Quinin hydrobromid has recently been recommended for use in exophthalmic goiter.

Warburg's tincture has obtained a very high reputation in the hands of Indian army-surgeons in the treatment of remittent and other malarial fevers of the most malignant types, in malarial neuralgias, acute nervous exhaustion, and sudden collapse without organic disease.

Poisoning.—The heart and the arterial tension are somewhat stimulated by small doses, but depressed by large ones (40 to 80 grains), which slow and enfeeble the pulse by direct action on the cardiac ganglia. The brain is rendered hyperemic and exhilarated by small or moderate doses, but large ones produce a sense of fulness and constriction in the head, cerebral anemia, pallor, tinnitus aurium, vertigo, staggering gait, amaurosis and deafness, great headache, dilated pupils, delirium, coma, and, in animals, convulsions. The eyes and ears are very rarely injured permanently. These symptoms collectively are termed CINCHONISM (*q. v.*).

Preparations.—**Quinina,** a white, amorphous or minutely crystalline powder, of alkaline reaction and very bitter taste, soluble in 1670 of water and in 0.6 of alcohol at 59° F. and readily in dilute acids. Dose, 1 to 20 grains, or 40 grains in special cases. Is insoluble in saliva. **Q. Bisulphas,** clear, colorless efflorescent crystals or small needles, of very bitter taste and strongly acid reaction, soluble in 10 of water with blue efflorescence, and in 32 of alcohol at 59° F. Dose, 1 to 20 grains, or even 60 grains in special cases. **Q. Hydrobromidum,** colorless needles, of very bitter taste, soluble in 54 of water and in 0.6 of alcohol at 59° F., very soluble in boiling water and in boiling alcohol. Dose, 1 to 20 grains. **Q. Hydrochloridum,** white needles in tufts, of very bitter taste, soluble in 34 of water and in 3 of alcohol at 59° F., in 1 of boiling water or alcohol. Dose, 1 to 20 grains. An excellent salt which should be more generally used; 5 to 10 grain doses are antipyretic. **Q. Hydrochloridum Acidum** (B.P.) is soluble in less than its own weight of water, and may be used hypodermically. Dose, 1 to 10 grains. **Q. Salicylas** is soluble in 77 of water, in 11 of alcohol, in 37 of chloroform, and in 110 of ether, at 77° F. It contains 70 percent of quinin. Dose, 1 to 20 grains in pill or capsule. **Q. Sulphas,** very light, snow-white, fragile crystals, of bitter, persistent taste, soluble in 740 of water and in 65 of alcohol at 59° F., more soluble in acidulated water. Dose, 1 to 20 grains, or even 40 grains in special cases. **Tinctura Pyrexialis, Tinctura Antiperiodica,** or **Warburg's Tincture** (Unofficial) is a celebrated and formerly secret preparation. The formula, published by the originator, included over 60 ingredients, one of which (Confectio Damocratis) contained many drugs which are not now obtainable. The tincture contained quinin bisulphate, 2 percent, with aloes, rhubarb, camphor and several aromatic herbs. Dose, 1 ounce (about 9 1/2 grains of quinin bisulphate) in 2 doses given 3 hours apart. Hager's modification of the original formula is—quinin sulphate 1, Spt. camphoræ 2, Tinct. aloes et myrrhæ 22, alcohol 16. Dose, as above. Some of the preparations now sold under this name contain few, if any, of the original ingredients. The so-called *Warburg's Pill* is a most irrational form in which to administer this complex medicine, even if it contains the proper constituents. See CINCHONA, EUQUININ.

QUININ HYDROCHLORID AND UREA.—Quinin carbamid hydrochlorid or urea-quinin. Recently this drug has been highly recommended as a local anesthetic in operations on the nose and throat and in ano-rectal surgery. A 1 percent solution is injected locally or a 10 to 20 percent solution is applied locally to the mucous membranes. The resulting anesthesia is claimed to be considerably prolonged. As a palliative measure a 20 percent solution has been applied in tuberculous ulcers of the larynx with excellent results. Quinin hydrochlorid and urea has also been used with good effect in hydrophobia. An intravenous injection of 15 grains of the drug in 3 c.c. of normal saline solution is used. This is twice repeated at intervals of two hours. More injections may be used if necessary, but the intervals between injections must be greatly increased.

QUINSY.—See TONSILLITIS.

R

RABIES.—See Hydrophobia.

RACHITIS.—See Rickets.

RADIOTHERAPY.—See Radium.

RADIUM.—Radium is one of the newer elements. It is a radioactive substance, obtained from pitch blende, and discovered by Madame Curie and her husband in 1898. It is of high atomic weight; extremely rare and expensive, being almost unobtainable in the pure state. It is of interest because of its wonderful radioactive emanations. These are of three kinds, and are designated as the *Alpha*, *Beta*, and *Gamma* rays. The *Alpha rays* have very slight penetrating qualities and are chiefly or entirely absorbed by the container. The *Beta rays* are the most numerous and have only a moderately penetrating effect, being absorbed chiefly by the skin and subcutaneous tissue. The *Gamma rays*, on the other hand, correspond rather closely to the Roentgen rays, and are very penetrating, probably more so than the Roentgen rays.

Therapeutically its exact value has not yet been determined, but it has been used successfully in the treatment of various obstinate skin diseases, such as epithelioma, rodent ulcer, and nevus. It has also been used with some degree of success in the treatment of deep-seated malignant disease, particularly when located in the cavities, which are not easily reached by the Roentgen rays.

It is used as a paste for external applications or in tubes. These tubes are often introduced into cavities; or even, by surgical means, into the tumors themselves.

RADIUS.—See Forearm.

RAILWAY INJURIES.—These are of greatest interest from their medicolegal aspect. Trivial railway injuries might be immediately followed by loss of memory, defective sight, pain in the back, and the usual symptoms of nerve shock, and subsequently by the most formidable array of nervous symptoms. On the other hand, very severe injuries may be followed by prompt and complete recovery. The more serious results are dependent upon the great weight and impulse of the train, the sudden arrest of momentum, and direct traumatism. Serious spinal injuries and violent shock have occurred to persons sitting in a train not in motion that has been struck by a moving train from behind. It is the sudden and violent character of the occurrence, the alarm and fright, the general jar and commotion of the whole body, and possible local damage that make the main features of railway injuries.

Direct results of railway accidents are various, but ligamentous lesions are perhaps the most characteristic. Death has resulted from sheer fright. The indirect results are also numerous and varied. It must always be borne in mind that a chronic inflammation may be lighted up by an accident; syphilitic, gouty, tubercular, and even cancerous diseases may follow and complicate the symptoms arising from the injury. Chronic inflammatory conditions of the cord or its membranes may be induced. Certain indefinite phenomena constantly render the diagnosis and prognosis of railway injuries difficult. When no local lesion of importance exists, neurasthenic conditions are likely to occur which are doubtless expressions of an exhausted nervous system. The temperature in these cases is often subnormal and the pulse slow. Asthenopia, with difficulty in, or real loss of the power of, accommodation, may impair the vision. Physical changes in the retina and optic disc are extremely uncommon, and generally follow organic lesions of the spinal cord and membranes. Functional disturbances, probably of cerebral origin, are often added to this neurasthenic condition, and in such cases there are frequently medicolegal controversies. The common "railway spine" is considered under the head Spinal Cord (Injuries) (*q. v.*).

Every medical attendant, as well as medical officer of any railway, should familiarize himself with all the circumstances of an accident and its results. Apart from the accident itself, the approximate speed of the train, the position of patient in the carriage and of carriage in the train, the presence of other uninjured passengers, the condition from the time of the accident to the time of examination, and the symptoms complained of, should be noted fully and filed away for reference. The general condition of the patient, especially as to appetite, capacity for work or sleep, and previous habits, the possible existence of organic disease, and the condition of urine are to be investigated. Bruises or signs of local injury are to be noted, and when injury to the spine is alleged, the amount of mobility or rigidity noticed when undressing, the effects of digital pressure or percussion, and the application of hot or cold sponges should be noted. The circumference of limbs should be measured, the electric excitability of muscles tested, the existence of spasm or tremor and the condition of reflexes, superficial and deep, ascertained. Cutaneous sensibility should be investigated, and an ophthalmoscopic examination may be made to determine the existence of local lesions of the fundus.

The medical attendant should form an opinion on the following points: Has the patient been really injured? What is the nature of the injury? Is the injury a possible or probable result of the accident as described? Are the symptoms consistent with the history and objective signs?

Railroad surgeons are usually given sufficient directions by the corporation that employs them, according to the views of their chief officers or in compliance with the law prevailing in the district where such accidents may occur.

The treatment of railway accidents is mostly surgical, and differs in no way from the treatment of similar injuries received in other ways, and which are fully discussed in other portions of the book under their various headings. Immediate treatment, even by the train crew and passengers, is necessary. Hemorrhage should be prevented by the prompt application of pressure. A handkerchief, belt, or suspender tied around a limb or twisted tight by a stick, or direct pressure with the finger, will usually suffice.

Fractures should be placed in improvised splints from umbrellas, walking-sticks, cushions, newspapers, broken pieces of wood, etc., and fixed by straps or suspenders, handkerchiefs, etc.

Simple dislocations should be reduced as early as possible, and simple fractures prevented from becoming compound.

Shock, collapse, and fright require great caution to maintain the vital powers until reaction sets in. The temperature of the body, the strength and rate of the heart's action, together with the respiration, are to be maintained by external warmth and by internal stimulants. Overstimulation is also to be guarded against. See Collapse, Shock.

Exposure to cold and wet should be prevented and shelter provided as soon as possible, followed by early removal to a hospital or place of rest. Subsequent treatment of railway injuries requires absolute rest for a long time, especially if spinal lesions are suspected; change of scene and moderate exercise often are beneficial, especially when neurasthenic conditions supervene. See Abdomen (Injuries), Chest (Injuries), Fractures, Spinal Cord (Injuries), Spine (Injuries), etc.

RAILWAY SPINE.—See Spinal Cord (Injuries).

RÂLES.—The sounds caused by the breaking of air through impediments or passing over obstructions in the lungs and bronchi. They vary in character according to the consistency of the surrounding lung tissue. Sometimes a distinction is made between râles and rhonchi. The first word is applied to sounds generated by vibrations set up in fluids; the second, to sounds generated in the narrowed or obstructed lumen of tubes. See Chest (Examination).

RALES, TABLE OF

Variety.	When Heard.	How and Where Produced.	Size and Character.	Condition in Which Heard.
Amphoric.....	Inspiration and expiration.	By movement of air in a tense-walled cavity containing air and communicating with a bronchus.	Large, musical, and tinkling.	In tuberculous and abscess cavities.
Bubbling, large.	Inspiration and expiration.	By passage of air through frothy mucus in the trachea and larger bronchi.	Larger than the medium bubbling; moist.	Bronchitis and pulmonary engorgement.
Bubbling, medium.	Inspiration and expiration.	By passage of air through mucus in the larger tubes.	Larger than the small bubbling; moist.	In capillary bronchitis especially in children.
Bubbling, small.	Inspiration and expiration.	By passage of air through mucus in the bronchioles.	Small; moist; like the bursting of soft bubbles.	In capillary bronchitis, especially in children.
Cavernous....	Inspiration and expiration.	By passage of air through a small cavity with flaccid walls, which collapse with expiration.	Hollow and metallic....	In the third stage of pulmonary tuberculosis.
Clicking.....	Inspiration only....	By passage of air through softening material in smaller bronchi.	Small; sticky.....	The apex in pulmonary tuberculosis.
Consonating ..	Inspiration and expiration.	When bronchial tubes surrounded by consolidated tissue.	Bright, clear, ringing..	Tuberculous pneumonia.
Crackling, dry.	In inspiration.....	By the breaking down of lung tissue.	Sharp, short, and clicking.	In the second or softening stage of pulmonary tuberculosis and in pulmonary gangrene.
Crackling, large.	Inspiration and expiration.	By fluid in very small cavities....	Larger than the medium crackling; dry.	In pulmonary tuberculosis and pneumonia, after formation of small cavities.
Crackling, medium.	Chiefly in inspiration.	By fluid in the finer bronchi.....	Larger than the small crackling; dry.	Softening of tuberculous deposit or pneumonic exudation.
Crackling, small.	Chiefly in inspiration.	By fluid in the finer bronchi.....	Small; dry; like the breaking of small shells.	Softening of tuberculous deposit or pneumonic exudation.
Crepitant.....	End of inspiration only.	By passage of air into vesicles collapsed, or containing fibrinous exudation. Usually at the base of the lungs.	Small; like rubbing the hair between the fingers.	Pneumonia, early stage; edema of lungs; hypostatic pneumonia; localized in pulmonary tuberculosis.

RALES, TABLE OF

Variety.	When Heard.	How and Where Produced.	Size and Character.	Condition in Which Heard.
Dry.....	Inspiration and expiration.	By narrowing of the bronchial tubes, from thickening of the mucous lining, from spasmodic contraction of the muscular coat, viscid mucus within, or pressure from without.	Large and sonorous, or small and hissing, or whistling.	In bronchitis, asthma, and localized in beginning pulmonary tuberculosis.
Extrathoracic.		In the trachea or larynx.		
Friction.....	Inspiration and expiration; most distinct at the end of inspiration.	By the rubbing together of serous surfaces, roughened by inflammation or deprived of their natural secretion.	Grazing, rubbing, grating, creaking, or crackling.	In pleurisy and pericarditis.
Gurgling.....	Inspiration and expiration.	By the passage of air through fluid in cavities, on coughing.	Larger than the large bubbling; moist; like the bursting of large bubbles.	Pulmonary tuberculosis, after formation of cavities.
Guttural.....	.....	In the throat.		
Moist.....	.....	By the passage of air through bronchi containing fluid.		
Mucous (of Laennec).	Inspiration and expiration.	By viscid bubbles bursting in the bronchial tubes.	A modification of the subcrepitant.	Pulmonary emphysema.
Râle redux, râle de retour.	Inspiration and expiration.	By the passage of air through fluid in a bronchial tube.	Crackling and unequal..	In pneumonia in the stage of resolution.
Sibilant.....	Inspiration and expiration.	By narrowing of the smaller bronchi from viscid mucus adhering to the walls, from thickening of the lining membrane or spasmodic contraction.	High-pitched and even hissing or piping.	In bronchitis, asthma, and localized in beginning pulmonary tuberculosis.
Sonorous.....	Inspiration and expiration.	By lessened caliber of the larger bronchi, from spasm, tumefaction of mucous lining, or external pressure.	Low-pitched and snoring.	Most frequent in bronchitis and spasmodic asthma, but may occur in any pulmonary disease.
Subcrepitant..	Inspiration and expiration.	By passage of air through mucus in the capillary bronchial tubes.	Small; moist.....	Capillary bronchitis.
Subcrepitant (of Hirtz).	Inspiration and expiration.	By passage of air through mucus in the capillary bronchial tubes.	Moist; metallic.....	Tuberculous softening.

RANULA.—A cystic tumor beneath the tongue, connected with the duct of the sublingual salivary gland.

Varieties.—*True ranula*, found in the floor of the mouth, from the size of a walnut to a pigeon's egg, and containing glairy, tenacious contents.

Mylohyoid, found between the mylohyoid and buccal mucous membrane, often as large as an orange, and filled with cheesy contents.

Etiology.—The common form of ranula has thin walls, and contains a fluid somewhat resembling saliva, and hence formerly supposed to be a dilatation of the duct of the submaxillary gland. It may be that this is true in those instances in which the duct is occluded by a salivary calculus, but in the majority of cases the ranula appears to be a distinct cyst.

Symptoms.—If the ranula has attained some size before it is noticed, it may be large enough to crowd the tongue against the hard palate, so that swallowing is interfered with, and sometimes even breathing becomes difficult, especially if there is concomitant coryza; or there may be convulsive attacks of dyspnea, simulating croup.

Prognosis is favorable, though the disease is prone to recur; rarely spontaneous cures have been known to follow suppuration.

Treatment.—If complicated with croupy attacks, the following operation should be immediately performed: Open the sac sufficiently to cauterize thoroughly its inner walls, which must be repeated often enough to prevent union, except from the bottom of the sac. If this is not obtained, relapses will occur.

RAPE.—The carnal knowledge by a boy or man of a female forcibly and unlawfully and without her conscious and free consent. If a woman is incapable of giving consent, as in idiocy, imbecility, or any mental unsoundness, either temporary or permanent, sexual intercourse with her is rape. If at the time of the act the victim is unconscious of the nature of the act, and this fact is known to the defendant; if her resistance is forcibly overcome or prevented by fear of immediate and great bodily harm, which she has reason to believe will be inflicted upon her; or if she is prevented from resisting by stupor or mental weakness produced by intoxicating, narcotic, or

anesthetic agents administered by or with the privity of the person accused of the crime, the offense constitutes rape. It is immaterial whether the victim is a virgin or a common prostitute.

Age of consent is the age below which a female is incapable of giving legal consent to sexual connection, and such connection on the part of a man is rape, in spite of her consent or desire.

The age of consent in the various States is given in the following table (compiled by the New York Society for the Prevention of Cruelty to Children):—

State.	Age of Consent.				
	12	14	15	16	18
Alabama		14			
Arkansas				16	
California				16	
Colorado				16	
Connecticut				16	
Delaware					18
Florida					
Georgia		14			
Idaho					18
Illinois				16	
Indiana				16	
Iowa			15		
Kansas					18
Kentucky				16	
Louisiana					18
Maine				16	
Maryland				16	
Massachusetts				16	
Michigan				16	
Minnesota				16	
Mississippi		14			
Missouri					18
Montana					18
Nebraska					18
Nevada					18
New Hampshire				16	
New Jersey		14			
New York					18
N. Carolina		14			
N. Dakota				16	
Ohio				16	
Oklahoma				16	
Oregon				16	
Pennsylvania				16	
Rhode Island				16	
S. Carolina		14			
S. Dakota				16	
Tennessee					
Texas			15		
Utah					18
Vermont				16	
Virginia	12				
Washington				16	
W. Virginia					
Wisconsin					18
Wyoming					18

Indecent assault may include various factors of an attempt to commit rape, comprising, in the case of a child, putting the hands on the external genitals or even feeling the legs.

Legal rape may be committed only when there is physical capacity in the direct perpetrator. A boy under 14 cannot commit rape according to the law in some countries and States, and no evidence is admissible if he is under that age, even though the fact could be shown that he had capacity. The presumption of capacity is rebuttable in Ohio, Massachusetts, New York, and Tennessee.

A boy under 14 cannot be convicted of rape in California, but in North Carolina and Florida courts the English law is followed. In Louisiana there is no foundation for the presumption of incapacity. Here the law conforms to the medical knowledge. It is not essential to prove emissions, as mere touching of the vulva by the penis suffices to establish the fact of carnal knowledge.

If the victim is under years of discretion, her evidence, even when unsupported, if believed by the jury sufficient to leave no reasonable doubt of guilt, will justify a conviction.

It is a matter of doubt whether rape is possible upon a woman of fair size and strength when committed by an unaided man. If in the enjoyment of her faculties, she is capable of offering an amount of resistance well-nigh insuperable, and if she has offered a decent resistance, the person of the ravisher should bear evidence of it. Rape is most often committed on children of tender-years, but it is well to be on one's guard against error. Purulent discharges from the vagina are not uncommon in ill-fed, dirty, and scrofulous children.

The *medical evidence* is based on: (1) Marks of violence about the woman's genital organs; (2) wounds, bruises, or other marks of injury on the woman or on the accused; (3) blood stains and seminal stains on the person or clothing of either party; and (4) the presence of any venereal disease on either party.

For examination for spermatozoa, see Seminal Stains.

RASH.—See Exanthems, Skin-diseases.

RATION, EMERGENCY.—One with high force-value and with sufficient available nitrogen for the needs of hard labor, prepared in compact form and designed for occasions when the use of the regular ration is impracticable.

UNITED STATES ARMY EMERGENCY RATION

	Quantity (in Ounces).	Protein (Grams).	Fats (Grams).	Carbohydrates (Grams).	Full Value (Calories).

RAY FUNGUS.—See Actinomyces.

RAYNAUD'S DISEASE (Symmetric Gangrene;

Sphaceloderma).—A rare disease, characterized by a local stagnation occurring at the periphery of the circulation, producing symmetrically distributed gangrenous spots on the body. The disease occurs in 3 well-defined grades, which are, in the order of severity, *local syncope*, *local asphyxia*, and *local gangrene*. The so-called "*dead finger*," frequently seen in females, is an example of the first grade.

Local syncope is observed most frequently in the extremities, and produces the condition known as dead fingers or dead toes; it is analogous to that induced by intense cold.

Local asphyxia, which usually follows local syncope, but may develop independently. Chilblains are the mildest manifestation of this condition. The fingers, toes, and ears are the parts usually affected. In the most extreme degree the parts are swollen, stiff, and livid, and the capillary circulation is almost stagnant.

Local or Symmetric Gangrene.—The mildest form follows local asphyxia. Small areas of necrosis appear on the pads of the fingers and of the toes, also at the edges of the ears and tip of the nose. Occasionally, symmetric patches appear on the limbs or trunk, and in severe cases terminate in extensive gangrene.

Raynaud suggested that the local syncope is produced by contraction of the vessels; the asphyxia is probably caused by dilatation of the capillaries and venules, with persistence of the spasm of the arterioles. The condition is probably due to some disturbance of the vasomotor nerve-center or in some instances to a peripheral neuritis. Two forms of congestion occur, which may be seen in adjacent fingers, one of which may be swollen, intensely red, and extremely hot; the other swollen, cyanotic, and icy cold (Osler).

Pain is the most prominent symptom of the disease, which usually attacks children or adults under 30 years of age. Women of the neurotic temperament are more liable to be affected, and especially does it occur after some sudden mental shock. The disease is frequently associated with hemoglobinuria. Scleroderma and edema, probably angioneurotic, may be observed. There may also be cerebral symptoms, impaired vision, arthritic swelling, tingling and formication due to peripheral neuritis.

Treatment.—When seen early, galvanism, with one electrode applied to the spine and the other immersed with the affected part in water, is the best treatment. Friction with stimulating liniments, as for frost-bite, is also of value. Nitroglycerin is highly recommended. See GANGRENE.

REACTION OF DEGENERATION.—See DEGENERATION (Reaction), NERVOUS DISEASES (Examination).

RECTOCELE.—Protrusion of the anterior wall of the rectum and posterior wall of the vagina into the vagina or through the vaginal ostium. The condition is due to injury of the perineum that takes away the support of the posterior vaginal wall. The bulging of the vaginal wall causes a distinct tumor, which is readily recognized on separation of the vulva. Straining or bearing-down efforts cause an increase in the size of the tumor. The patient feels during defecation as though the feces were about to pass through the vagina. Pressure on the rectocele will easily replace it.

The treatment of rectocele consists in repair of the perineum by Emmet's operation. See PERINEUM.

RECTOVAGINAL FISTULA.—See VAGINAL FISTULA.

RECTUM, ABNORMALITIES.—The only congenital malformation needing mention here is imperforate anus. The anus may be entirely absent; it may be present but separated from the rectum by a membrane; or the rectum may open into the bladder, prostatic urethra, or vagina.

Treatment.—When only a thin membrane intervenes, its division is all that is necessary. When there is no apparent outlet to the re tum, careful dissection is made upward to the bowel from a spot where the rectum is normally situated. Mayo Robson advises continuing the dissection in the perineum, opening the peritoneum, pulling the end of the gut down and fixing it to the skin. In some cases left inguinal colotomy is necessary. See ANUS (Preternatural).

RECTUM, ADMINISTRATION OF MEDICINE BY.—See MEDICINES (Administration).

RECTUM, EXAMINATION. Interrogation.—After the patient has concluded the description of the ailment, the following are the principal queries which may be asked with advantage (Adler):

1. **In Reference to Pain.**—Is there any pain? If so, of what character? Is it situated in the rectum? What is its relation to the act of defecation? Is it worse during an evacuation, shortly afterward, or some time after the movement? Is itching, a sense of fullness, or heat experienced?

2. **Regarding Protrusion.**—Is there any swelling or protrusion at the anus? Does this occur only at defecation, or is it independent of this act? Does it bleed? Does it go back spontaneously, or has the patient to return it?

3. **As to the Presence of a Discharge.**—Is there any discharge? If so, what is its nature (bloody, mucous, or purulent)? Is it offensive? Does it occur before or immediately after defecation, or is it independent of the action of the bowels?

4. **As to the Regularity of the Action of the Bowels.**—Is there a daily movement, or does constipation or diarrhea exist? What is the character of the fecal evacuation as to color, size, and consistence?

5. **General Interrogations.**—Does the patient cough, have night-sweats, spit blood, or has there been a loss of flesh? What are the habits of life, especially with reference to the use of alcoholic liquors, tobacco, and to indulgence in venery? Is there any specific history? Lastly, inquire as to any hereditary tendency to rectal trouble, malignant disease, kidney, liver, or heart affection. In women inquire into the condition of the sexual organs, etc. Whenever the idea of any operative procedure is entertained, the urine should be examined, and a thorough physical inspection of the patient made.

Having obtained the subjective symptoms and being satisfied as to the existence of rectal disease, we proceed to confirm the provisional diagnosis and to obtain positive information upon which to base the prognosis and to guide the treatment by making a thorough local examination. If possible, the patient should have the bowel emptied by an enema immediately before an examination is attempted. In the case of female patients especially the neglect of this will often render a thorough investigation impossible, without recourse to anesthesia, owing to the fear of an accident occurring—such as the escape of flatus. Under such circumstances the sphincter muscles may be so tightly closed that the surgeon is frustrated in the attempt to explore the parts. When a specular examination is necessary, as in the case of an investigation of the higher portions of the rectum or of the sigmoid flexure, it is absolutely essential that the contents of the bowels are removed.

Postures.—There are various postures in which this examination may be made. Some surgeons prefer the patient to lean over the back of an ordinary chair; others, to have them kneel upon a table with the head of the patient placed on his folded arms, by which means the buttocks are elevated and the intestines are allowed to gravitate from the seat of investigation; others, the lithotomy position; but for general use Adler thinks that the most comfortable as well as the most delicate posture for the patient, and that most convenient for the examiner, is for the patient to lie on a firm couch on the left side, the right shoulder turned away from the surgeon, the left arm brought behind the body, and the right thigh well flexed upon the abdomen. In examining for the presence of strictures or growths situated above the lower 4 inches of the rectum, by directing the patient to stand and strain, the diseased part will be brought nearer to the anus, so that at least an inch or more of the bowel may be explored than can be done when the patient assumes the usual position, even though directions are given to bear down.

Light.—Either natural or artificial light may be used. By means of a head-mirror (the operator sitting facing the light and the patient's back being from the same) the light may be concentrated upon any particular point requiring observation.

The instruments usually required are: A flexible probe made of silver, useful for the exploration of fistulous tracks; an exploring needle, or a small trocar, by means of which can be ascertained the nature of the contents of any swelling or fluid collection; Kelly's short and long proctoscope and his sigmoidoscope; sponge-holders; basins; and possibly a hypodermic syringe, with a flexible silver cannula attached, which is useful in detecting whether a fistula is complete or otherwise. Plenty of towels and cotton should be on hand.

Inspection of the Condition of the External Parts.—On separating the buttocks, the orifice of the anus will come into view. The radiating folds should be separated by the fingers, and cracks, excoriations, and fissures should be looked for. External hemorrhoids will also be noted, if present. By passing the finger around the anus and making pressure, any induration that exists will be detected; this may be due to a fistula or an abscess. If the parts are covered with a discharge, it should be wiped away and its source traced, as to whether it is from an external opening of a fistulous track, etc. Eruptions of any kind—eczematous, syphilitic, or otherwise—must also be noticed.

Digital Examination of the Interior of the Rectum.—The method of making the examination is as follows (Adler): The nail of the index-finger, being well-trimmed and the finger lubricated with carbolized linseed oil, is introduced into the bowel by a slow boring motion, in a direction at first slightly forward. This should be done gradually, so as to allow the sphincters time to relax; if attempted too hurriedly or in too forcible a manner, spasm of the muscles will to a certainty be induced. As the finger enters, the condition of the sphincters is noted. The strength, measured by the power of resistance, will be found to vary greatly in different people. In the aged or debilitated it is likely to be very weak; and just the reverse in the strong and healthy. In persons of a specially nervous tendency and in cases of irritable ulcer of the anus, a contraction may be met with, which, owing to the pain, will render an examination impossible without the use of an anesthetic.

The finger should now be passed its full length up the bowel, unless an obstruction exists, and by instructing the patient to bear down forcibly the rectum can be explored for a considerable distance. Additional length may be gained by passing the other fingers of the examining hand backward along the intergluteal groove, instead of closing them in the palm, as is generally done, and pressing the knuckles against the soft parts. The knuckles, in the latter procedure, prevent the full passage of the index-finger. In this manner about 3 1/2 or 4 inches of the rectum may be explored, together with the prostate, the neck of the bladder, the uterus, the anterior surface of the coccyx and the lower part of the sacrum, the ovaries and tubes, and the broad ligament. With an exceptionally long finger it may be possible to feel the seminal vesicles and the vasa deferentia.

In making an examination of the rectum it must be borne in mind that frequently two or more rectal affections coexist: as, for instance, a polypoid growth complicating a fissure, or malignant disease existing with fistula and hemorrhoids, etc.

Malignant infiltration, or stricture, can be detected if situated within reach. By sweeping the finger around the mucous membrane, its condition can be noted: a general smoothness, and absence of the normal folds indicating atony; ulceration can be recognized, and the attachment of polypi can be felt. In examining for a polypus it is important that the finger should be brought from above downward; as otherwise the growth may be pushed out of reach owing to the length of the pedicle, which is often considerably elongated. Fecal masses in the rectal pouch can be recognized without difficulty.

The finger is now to be partly withdrawn, passing the palmar surface around the entire surface of the mucous membrane as this is done, in order to note the existence of internal openings of fistulæ, the seat of ulcers, etc. As the outlet of the bowel is approached, internal piles may be perceived; but the fact should always be remembered that unless they are thickened by inflammatory changes they are extremely hard to recognize by the touch; in point of fact, the sensation conveyed to the finger is more apt to deceive the surgeon than any other rectal trouble.

The Use of the Speculum.—In the large majority of rectal diseases digital and ocular examination is sufficient for purposes of diagnosis; but for some cases the use of the speculum is desirable. This instrument is made in a variety of forms; the length of the tube to be selected depending on the portion of the bowel to be explored. Before being introduced into the rectum the speculum should be warmed and well-lubricated; it should then be inserted into the anus, and gently but slowly directed a little forward and upward for a distance of about an inch, as if to pass from the perineum to the umbilicus, in order that it may follow the course of the anal canal; having reached this depth, which is somewhat greater in the male than in the opposite sex, the point should be inclined backward, first slightly, and afterward to a greater extent, until the instrument is fully inserted. Should the interior view of the rectum be obstructed by blood, mucus, or feces, a mop of cotton attached to a holder, made for the purpose, should be used to cleanse the parts. With these instruments the interior of the rectum and the sigmoid flexure can be examined, and the exact condition of affairs ascertained. Some forms of speculum are furnished with blades or plates, which can be separated to the requisite extent by means of a screw attachment.

The use of the rectal bougie for diagnostic purposes Adler condemns. The introduction of these instruments is one of considerable difficulty, and requires greater practice than the passage of a urethral catheter; the danger of perforation is as great, and the result of such an accident is very much more serious, than in the urethra. In one case a fatal peritonitis will likely be started, while in the other a false passage will probably be the sequence. The use of the Kelly tube has obviated the necessity of employing the rectal bougie for the purpose of diagnosis.

Rectal Eversion as a Means of Diagnosis.—In examining the rectum in females, Stover has recommended eversion of the bowel by the fingers placed into the vagina. This method is useful in women who have borne children, but not in the young and unmarried. A portion of the anterior wall may thus be exposed.

The introduction of the hand into the rectum is a procedure which may be a means of exploration open to the surgeon, but it is doubtful if the amount of information obtainable by its use is sufficient to warrant the practice.

Exploration with a silver probe 7 or 8 inches in length is of value in detecting blind, external, internal, or complete anal fistula. Being flexible, it may be bent to any desired form.

Injections of various fluids, such as peroxid of hydrogen, a 2 percent solution of creolin, milk, or a weak iodin solution, often serve a useful purpose for detecting the internal opening of a fistulous tract.

RECTUM, INFLAMMATION (Proctitis).—**Catarrhal inflammation** of the mucous membrane may arise from various causes: Gonorrheal infection, especially in women; syphilis during the secondary stage; abuse of purgatives; gout; errors in diet, etc. Except when it is due to the first of these, it is rarely severe; there is a sense of heat and weight in the perineum, with a constant desire to defecate. The sphincter is in a state of painful spasm; the anus is hot and tender; the amount of mucus is increased, and this, escaping externally, leads to excoriation and perhaps superficial ulceration. As a rule, the symptoms subside as the cause is removed; sometimes, however, they become chronic; and occasionally, when severe, painful catarrhal ulcers develop, requiring special treatment.

Ulceration of the rectum is much more serious, not only for itself but from the way in which it leads to stricture and fistula. In some cases it is the result of injury, the introduction of foreign bodies, the use of enema tubes, or the passage of hard scybalous masses, especially as the circulation is often sluggish and the tissues badly nourished from the presence of varicose veins. In others it arises directly from thrombosis and inflammation of the veins, or from dysentery involving the rectum as well as colon. When this occurs, the ulcers formed are of a peculiarly irregular character; they spread in all directions, forming little islands, which, as cicatrization takes place, stand out as hard warty excrescences; or they undermine the mucous membrane, so that it leaves rigid cords passing across the interior from one part to another; and the scars are of such extreme density that not improbably many of them have been mistaken for scirrhus.

In other cases ulceration is due to syphilis. In its earlier stages this attacks the anus chiefly; condylomata and superficial sores occur around the margin, leaving irregular folds of skin between which are painful fissures, not unlike those at the angles of the nose and mouth. In the latter it breaks out on the mucous membrane, some distance from the anus, forming deep serpiginous sores, which may extend almost around the bowel. Tubercle is still more common, beginning in the adenoid tissue between and beneath the follicular glands. Little nodules make their appearance first, not larger than millet seeds, and only slightly raised above the surface; after a time these become caseous and break down, leaving shallow depressions, which grow larger and deeper, until at length they become circular sores with overhanging edges. In other cases the caseous deposit seems to infiltrate the adenoid tissue in the mucous and submucous layers before the surface gives way, and deep, irregular ulcers are formed, which almost at once become the orifices of tuberculous fistulæ.

Ulceration somewhat similar in character is not infrequently associated with albuminuria; probably it originates as catarrhal inflammation; after a time the lymphatic follicles become affected and break down; and then, as there is no longer any protection against septic infection, the deeper tissues become inflamed as well. In many cases it is difficult to distinguish this from the preceding; they both occur in patients whose health has failed and whose tissues are badly nourished; and they both lead to ulceration, and not infrequently to fistulous channels of very much the same description. In addition to these lupoid ulceration may attack the skin around the anus and the mucous membrane of the rectum. It is essentially destructive in character, and cicatrization is unusual. The edges and base are not hard, as in malignant disease; and the former are undermined and overhanging. Sometimes it remains stationary for a time, and is apparently beginning to heal; then it all breaks down again. It is only met with in tuberculous subjects, and probably is itself tuberculous. The only treatment that has proved of any use is scraping and the actual cautery; sometimes the pain, at least, can be relieved in this way for a time.

Symptoms.—In acute inflammation of the rectum the patient complains of a sense of heat and weight in the perineum, spreading over the back and thighs, and of violent straining and spasm of the sphincter. The skin is dry and feverish; the anus is very tender; the finger, if it is introduced, is tightly gripped; and the mucous membrane feels burning hot. In severe cases the constitutional symptoms are very marked; the pain radiates over the whole of the lower part of the body, and there is nearly always retention of urine.

The symptoms of ulceration depend upon its situation. When the anal margin is involved, they are so striking and so severe that this affection is described as *fissure of the anus* (see ANUS (Fissure)); when, on the other hand, they are higher up—above the level of the external sphincter—they are at first very vague. Diarrhea is the most prominent; as soon as the patient gets out of bed there is an immediate desire to go to the closet, and a small quantity of liquid feces, with some mucus like white of egg, comes away. The same thing occurs perhaps once or twice in the morning; and then, if the ulceration is not far advanced, the rest of the day is passed in comparative comfort; the rectum is empty and there is nothing to irritate it. In all but the slightest cases, however, there is a constant sense of fulness and tenesmus; normal motions are never passed; the amount of discharge increases; it loses its simple mucous character, and becomes dark, like coffee-grounds. Control over the sphincter is lost; the skin around the anus is constantly moist; it becomes covered with vegetations and excrescences, between which fissures form. Then the pain becomes more severe; after each motion it is intense, and in the intervals there is always a constant dull aching. Finally, the diarrhea becomes almost continuous; health and strength fail; the appetite is lost; colicky spasms and pains over the lower part of the abdomen grow more frequent; abscesses and fistulæ form around the bowel; the emaciation becomes extreme; and the patient sinks from exhaustion, if he is not carried off by some intercurrent disorder.

Diagnosis.—In advanced cases the appearance of the anus at once suggests the presence of more serious mischief. The thickened and pigmented folds, with deep and painful ulcers in between, and the eczematous condition of the skin, can only be caused by long-continued irritation; but the diagnosis can be made only with the finger or the speculum. The former is usually sufficient; the latter can only be used with an anesthetic, and with either the utmost gentleness is essential. Immediately inside the anus the mucous membrane is generally unaffected, though both in syphilis and advanced tubercular or lupoid disease it may be nearly as bad as the rest; higher up, the normal soft character of the bowel is entirely lost. The surface is rough and irregular; hard nodules project here and there; in some places the walls are dense and thick, like stricture tissue, and the passage is narrowed; in others there are soft smooth patches, surrounded with overhanging edges, which bleed at the least touch; and the finger, when it is withdrawn, is smeared with blood-stained mucus. Sometimes it is possible from this alone to form an opinion both as to the extent and cause of the disease. Syphilitic ulceration is often accompanied by other signs; tubercle rarely leads to the formation of dense cicatrices, and fistulæ generally make their appearance very soon. Dysentery, on the other hand, may destroy all trace of normal mucous membrane, and often extends far beyond the reach of the finger. In the majority, however, a careful inquiry into the history and into the other symptoms that are present is essential; and even then it is sometimes difficult to exclude the idea of malignant disease.

Treatment.—Rest is the first consideration. The patient must lie down for at least the greater part of the day, with the foot of the bed raised to prevent venous congestion. The feces must be kept as soft and as small as possible; everything that is stimulating or indigestible, or likely to leave a bulky residue, must be strictly avoided. Pure milk diet for a time is often advantageous. All straining must be prevented; the bowel must be washed out night and morning with warm water or an astringent lotion—nitrate of silver in the case of dysentery, lotio nigra for syphilis; and after this a simple unirritating ointment (calomel—10 grains to about 1 ounce—subnitrate of bismuth, iodoform, or nitrate of mercury) may be applied, either as a suppository or with a suitable ointment introducer. Starch and opium injections are excellent means of controlling the diarrhea.

In the meanwhile constitutional treatment must not be neglected. Potassium iodid must be given in syphilitic cases. Cod-liver oil, if the patient can take it, often answers better than anything, as there is nearly always great loss of flesh and strength, and it tends to keep the motions soft; if iron is given, care must be taken that the bowels are not confined. In a few cases, when the

ulcer is low down and the spasmodic contraction of the sphincter is severe, perfect rest may be obtained by subcutaneous division of the muscle or by stretching it; but this is seldom beneficial in the more severe forms. In these, when all local treatment fails, colotomy is the only resource (Moullin).

Periproctitis.—Inflammation around the rectum may occur at the anus, in the ischiorectal fossa, or higher up in connection with the insertion of the levator ani and the rectovesical fascia.

Inflammation around the margin of the anus in many cases is symptomatic of some deeper infection. There is a constant offensive discharge from the anus, the parts are continually moist, the epidermis is macerated, and the deeper papillary layer of the skin is exposed. Inflamed external hemorrhoids, small cutaneous boils, suppuration in connection with the hair follicles, and syphilitic eruptions are not uncommon. Of itself, it may be trivial in character, but it becomes of great importance from the tendency it has to leave behind it painful fissures and superficial fistulæ.

Ischiorectal abscess is more serious. It may be acute or chronic. In the former case the symptoms closely resemble those of proctitis. It may commence with a rigor; the pulse is quick, the tongue furred; there is the most intense throbbing in the perineum; sitting down is almost impossible; the rectum feels as if it was loaded with feces, but the least attempt at relief brings on the most violent pain and straining. On examination there is a hard brawny swelling by the side of the anus; the skin is red and edematous, pitting on pressure; and if the finger is introduced into the bowel, the hardness can be felt through the wall for some distance above. Sometimes the inflammation is even more acute than this, and a form of gangrenous cellulitis, which may prove fatal, sets in. In the chronic form, on the other hand, the swelling is painless, and often lasts for weeks. There is merely a soft, fluctuating swelling, filling the whole of the ischiorectal fossa and extending up by the side of the bowel, covered by a thin layer of discolored skin. Not infrequently the patient is almost unaware of its existence, and it may attain a very large size and burrow for a considerable distance before the skin gives way. When this happens, the opening is always large and ragged, with thin overhanging edges, like those of a scrofulous sore, and a fistula is almost certain to be left. The frequency with which these abscesses occur is accounted for by the ease with which septic absorption takes place through abrasions of the mucous surface, partly owing to the anatomy of the region. Owing to the rapid variations in size of the bowel, the tissues are badly supported; the circulation is feeble; there is a large amount of loose fat, with dilated veins; and the vessels have even a greater tendency to become varicose than those of the lower extremities.

Phlegmonous inflammation is rare, except in patients who are thoroughly broken down; most of the cases recorded have been in persons who were suffering from specific fevers. Acute abscess may usually be traced to injury; perforation of the mucous membrane from the inside by a fish-bone or other foreign body; tearing of the mucous surface from straining or the passage of hardened feces; or bruising of the subcutaneous tissue, leading to extravasation in the ischiorectal fossa or to venous thrombosis. The chronic form is probably due in a very large number of cases to the breaking down of tubercular deposit in connection with the adenoid tissue of the rectum; or it may be a complication of stricture, beginning either from an ulcer on the mucous surface or, independently of this, in the inflammatory exudation surrounding the bowel. In addition to this, suppuration may extend into the ischiorectal fossa from distant organs. Urinary abscess is not uncommon; necrosis of the sacrum or coccyx occasionally gives rise to it; coccygeal dermoid cysts may cause it; and it has been known in caries of the lumbar vertebræ.

Treatment.—Ischiorectal abscesses should be opened at once, and freely, or a fistula is almost certain to form. Even if there is merely a tense, hard, and painful swelling, it is better to run the risk of not finding pus. If the abscess is small and close to the rectum, so as to give rise to the suspicion that it is really intramural, the patient should be placed upon his side, with the knees drawn up, and the finger introduced into the bowel to fix the swelling and make it project toward the skin. Then a straight bistoury is introduced, and an incision, sufficiently free to give exit to the pus, made radially from the anus. Some of the outer fibers of the external sphincter are divided, to prevent the opening from closing too soon. True ischiorectal abscesses, on the other hand, must be laid freely open by a longitudinal incision, parallel to the anus, midway between it and the ischium; and as soon as the pus has escaped, the finger must be introduced, the cavity explored, and the partitions inside broken down. Afterward, the opening must be kept patent to insure the abscess healing from the bottom. Lint should be avoided, as the discharge is liable to collect behind it, and its removal is very painful. Guttapercha tissue, folded irregularly so as to fit inside the orifice without blocking it, is the most convenient. The cavity, if the dressing does not come away easily, can be syringed out behind it, and it does not absorb the discharge. The patient should be kept in bed, or at least lying down, until the abscess has healed. If it is an acute one this will not be many days; if it is chronic, the greatest care is necessary to prevent it degenerating into a fistula. The bowels should be well opened once, and then kept confined for several days, the diet being very light, so that there may not be an accumulation of feces. When they are opened, an effectual purge should be given to avoid straining.

Inflammation on the Visceral Surface of the Levator Ani.—This is nearly always caused by extension from some of the neighboring viscera, and if it involves the rectum, is nearly always associated with stricture. Occasionally it originates from the bowel; much more frequently from the uterus, following parturition or metritis, and probably it is for this reason that stricture of

the rectum is so much more common in women than in men. The inflammation may be acute, attended with high fever, and soon ending in suppuration; or chronic, spreading from one part to another until they are firmly bound down to each other and to the pelvis by bands of cicatricial tissue, which may be almost of cartilaginous hardness. When it starts from the region of the uterus, the anterior surface of the rectum is first involved. The inflammatory exudation spreads into the substance of the muscles until the fibers become atrophied and the walls hard and unyielding; the mucous membrane becomes rigid and unable to unfold itself; the constant irritation caused by the passage of the feces gradually leads to hyperemia and thickening of the submucous tissue; and, at length, a definite stricture is formed, which may either be tubular in shape, extending for some distance along the bowel, especially on the anterior surface, or sharp, well-defined, and annular, about 1 1/2 or 2 inches above the anus. If suppuration occurs, the abscesses may break into the bladder or vagina, or they may extend through the sacrosciatic foramina, or even burst into the peritoneal cavity (Moullin).

RECTUM, INJURIES.—Injuries of the rectum occasionally occur from falls upon sharp-pointed bodies, or from incautious attempts to pass a long enema tube or bougie. Should the peritoneal cavity be perforated, death is the almost invariable consequence, especially if any injection has been absorbed by the peritoneum before the mistake is discovered.

Treatment.—Opening the abdomen, flushing out the peritoneum, and sewing up the rent in the gut affords the only hope of cure.

Foreign Bodies in the Rectum.—Foreign bodies of many differing kinds have at times been accidentally or intentionally introduced into the rectum. Fish-bones that have been swallowed not infrequently become impacted just within the anus, there giving rise to much irritation or pain, and often causing an ischiorectal abscess. The removal of some of these bodies, when of large size, is frequently attended with considerable difficulty, requiring an anesthetic, dilatation of the sphincter, and the use of various forceps, or even the passage of the whole hand.

RECTUM, PROLAPSE.—Prolapsus recti is the protrusion of the mucous membrane of the lower part of the rectum, and, more rarely, of the muscular coat as well, through the anus. It is most common in children, but may occur at any age.

The causes are either a relaxed state of the sphincter, induced by general weakness; residence in hot climates, etc.; or excessive straining due to stricture of the urethra, phimosis, stone, ascarides, constipation, piles, or polypus.

Symptoms and Diagnosis.—It commonly appears as an irregular ring of mucous membrane, or when much is protruded as a cylindric, elongated swelling. When recent, it has the color of healthy mucous membrane; but if not soon reduced it may become livid and congested, in consequence of constriction of the blood-vessels by the sphincter. The strangulation may proceed to such an extent that the prolapsed portion may undergo mortification and slough away. In old-standing cases it becomes indurated and leathery from exposure. It may be diagnosed from polypus by the presence of a central aperture, and from intussusception by the mucous membrane being continuous with that of the sphincter. In intussusception a sulcus exists between the protruded part of the bowel and the sphincter.

Treatment.—Should the bowel be protruded or strangulated, an attempt should be made to reduce it. If it has only been prolapsed a short time, this is easily accomplished by gentle pressure, the parts having been well smeared with vaselin, and the buttocks raised. When of longer standing, firm pressure must be exercised on it for 10 minutes or so, or the finger may be introduced into the orifice and the bowel pressed back. If reduction fails and the part is much inflamed, an ice-bag may be applied, and another attempt subsequently made, when, if still unsuccessful, nothing remains but to allow the protruded part to slough off or to excise it. If the muscular coat protrudes, no operation should be done, lest the peritoneum be wounded. Having reduced the bowel, the cause of the prolapse should, if possible, be removed; and to prevent a recurrence, the nates may be strapped together, or a pad and T-bandage worn, and the motions passed at bedtime instead of in the morning, the patient lying on his side or back during defecation. Astringent lotions or ointments of sulphate of iron, galls, or tannin should be applied, or the mucous membrane painted with nitrate of silver, while any pendulous folds of skin may be snipped off, so as to cause some amount of contraction of the anus. In the meanwhile the motions should be rendered soft with gentle laxatives. Should these means, after being well persevered in, fail, a more serious operation may become necessary. Comparatively recently the main active treatment of rectal prolapse consisted in chemical or thermal destruction of protruding mucous membrane or of portions of the dilated anus, the scar contraction incident to healing leading to narrowing of the anus and support of the gut. Strangulation of the protruding tissues by means of ligatures was also recommended and often gave good results. All such measures ought to be discarded, as chemical and thermal action are difficult to regulate and the strangulation by ligature is distinctly dangerous. There are three distinct principles, each of which is the base of a modern method of operative treatment.

1. When the prolapse is due to sphincteric atony or looseness, the principle of treatment is to overcome this condition by narrowing the sphincter.

2. When the prolapse is due to want of superior support, such support must be provided.

3. When there is excess of rectum and much tissue is prolapsed, the protruded mass should be excised. Generally this excision must be supplemented by narrowing the sphincter.

Thus according to the indications in the individual case plastic operations may be performed upon the sphincter ani, the lumen of the rectum

narrowed, the rectum or sigmoid raised to a higher level and retained by sutures. The operation of sigmoidopexy, in which the peritoneal cavity is opened and the sigmoid flexure sutured to the abdominal walls is advocated by a number of surgeons. Excision of the prolapsed bowel is not advised.

RECTUM, STRICTURE.—Stricture of the rectum may be divided into the simple and the malignant.

The simple or fibrous stricture may be caused by the fibroid contraction of inflammatory products in the mucous and submucous coats, or of cicatrices following simple, syphilitic, or dysenteric ulceration; by injury, or operation on the bowel; or it may be the result of pelvic inflammations.

Pathology.—The stricture is generally situated from 1 to 2 inches from the anus, but may occur at any part. It may involve only a narrow, ring-like portion, when it is called annular; or it may include an inch or more of the gut, when it is sometimes spoken of as tubular. The strictured portion of the bowel consists in great part of fibrous tissue. The syphilitic variety is often combined with condylomata or ulceration about the anus, and the mucous membrane between the anus and the stricture is frequently ulcerated. The bowel above is generally distended with feces, the muscular coat hypertrophied, and the mucous membrane ulcerated; while in the neighborhood of the stricture the coats are often so thin that the least force causes them to give way. Fistulæ often form below the stricture, and hemorrhoids are a frequent concomitant.

Symptoms and Diagnosis.—Pain and difficulty in passing a motion, constipation, and, later, constipation alternating with diarrhea. The motions, when the stricture is near the anus, become small, ribbon-like, and streaked with discharge. There is a frequent desire to defecate, but little passes except gas and mucus, or pus, and the bowel feels as if it had not been emptied. In tight strictures or in strictures with ulceration fistulæ may sometimes form about the anus, and the patient gets worn out; and after many years, perhaps, of suffering may die of an attack of peritonitis or obstruction. The stricture is readily detected on passing the finger, but is often so tight that only the tip can be inserted. When this is the case, on no account should the finger be passed through it, as the slight force of passing the finger may rupture the attenuated walls, and peritonitis and death may follow.

Treatment.—As a rule, gradual dilatation by means of bougies should be first attempted, and will generally be successful; but the stricture must be kept dilated by the subsequent occasional passage of a bougie. In exceptional cases, when the stricture is very resistant, a bougie may be tied in. When the parts are much riddled by fistulæ, a division of the stricture may be necessary. This may be done by what is called internal or external **linear proctotomy.** In the former operation the knife, guided by the finger, is introduced through the stricture, which is then divided in a posterior direction; in the latter, the stricture, together with the external sphincter and other intervening soft parts, are completely divided down to the coccyx.

Malignant or Cancerous Stricture.—Cancer in all its forms may occur in the rectum, but the most common is a variety of carcinoma known as the columnar or adenoid. It occurs either as a fungating, more or less distinct tumor projecting into the lumen of the bowel; or as a laminar, nodular, or ring-like infiltration of its coats. In either case it is at first covered by apparently unaltered mucous membrane, which, however, is sooner or later destroyed by ulceration, leaving an ulcer with an uneven, proliferating, or excavated surface, everted edges, and an indurated base. As the disease extends, it involves the muscular coat, and subsequently the surrounding structures and organs, gluing them, as it were, to the rectum, and finally converting the whole into a cancerous mass. The lymphatic glands in the pelvis, and later the inguinal glands and others more removed, become affected, and the carcinoma may finally be disseminated, secondary growths being more especially met with in the liver.

The symptoms are often very insidious. At first there may be merely some uneasiness, hardly amounting to pain, about the anus; then more or less pain on defecation is noticed; the feces may be streaked with mucus or with blood, and a slimy discharge may be present. Later, the motions become small, flattened, or pipe-like when the stricture is near the anus, or scybalous when some distance above. The patient strains at stool, and feels as if his bowel had not been emptied; then there is constipation, alternating with diarrhea, and an offensive sanious discharge. Emaciation and cachexia now come on, with more local pain, and the patient dies of exhaustion, peritonitis, or during an attack of acute obstruction.

The diagnosis can only be arrived at by a local examination. The anus generally appears healthy, though probably patulous, and a healthy strip of mucous membrane generally exists between the anus and the growth. When the growth can be felt, its indurated base, and when ulceration has occurred, the everted edges of the ulcer, and the sanious and foul discharge, render the diagnosis generally easy. When beyond the reach of the finger, it may at times be brought down by the patient straining. The fungating form may be mistaken for a villous growth; the annular, for a simple fibrous stricture. A *villous growth* may be distinguished by its velvety and supple feel, by the fact that it does not ulcerate nor break down, by the absence of induration, by the thin and mucoid discharge, by the brightness and scarcity of the blood, by the unattached rectum, and by the duration of the disease. A *fibrous stricture* may be known by its longer duration, by being less indurated than the cancerous form, by the bowel not being fixed, and, when due to syphilis, by the absence of a healthy strip of mucous membrane between the growth and the anus.

Treatment.—If the disease is seen sufficiently early, and before it has involved the surrounding parts, if it is not situated too high up in the rectum, and if the general condition of the patient is other-

wise favorable, excision of the growth with the lower end of the rectum should be undertaken, as in this way the whole may be removed, and not without reasonable hope, in some of the less malignant forms of the disease, of its not returning. Some cases have been reported in which it has not done so for upward of 4 years. Previous to removal of the rectum it may be wise to perform inguinal colotomy, since after this operation there is less risk of the wound left by the excision becoming septic. When removal seems impracticable, or otherwise inadvisable, such palliative measures should be adopted as may render the last few months or years of the patient's life as comfortable as possible. Thus, the bowels should be kept gently relaxed, the diet regulated, and the pain relieved by morphin suppositories. In this way the patient can often follow his occupation in comparative comfort and with little inconvenience. Should, however, there be very frequent calls to defecate, much pain and irritation on the passage of feces, or obstruction threaten or have already occurred, colotomy should be performed. This operation should not, as is too frequently the case, be regarded merely as a last resource, to be undertaken when obstruction has come on, as then the danger of the operation is greatly increased. Nor should it be undertaken in every instance, since the inconvenience caused by the cancer is not always sufficient to justify the patient undergoing the risk (Walsham).

Excision of the rectum may be performed if the finger can be passed beyond the growth, if the growth is movable, if the glands are not involved, and if the patient is otherwise fairly healthy. The patient having been placed in the lithotomy position, and a staff introduced into the bladder, a curved bistoury should be passed along the finger up the rectum, and its point made to emerge near the coccyx, and the intervening tissues cut through in the middle line. By this incision a free exposure is obtained. Lateral incisions are next made on each side of the anus, meeting in front, and the bowel is rapidly cleared, either with the finger or with the handle of the scalpel, from the tissues of the ischiorectal fossa. The lower part of the rectum is now dissected more carefully from the urethra and prostate, and when it has been sufficiently freed, the ecraseur is placed above the growth, and the rectum removed, care being taken that the cord when tightened is not pulled down below the spot where it is intended to sever the bowel. If preferred, the scissors may be substituted for the ecraseur, the vessels being then tied as they are cut. When the growth does not involve the whole of the bowel, a strip of mucous membrane should, if possible, be left. The wound should be plugged for 24 hours with iodoform gauze if there is much oozing, and the parts subsequently irrigated frequently. More of the rectum may be removed by resection of the coccyx and lower part of the sacrum, the incision extending backward and to the left side (Kraske's operation).

RECTUM, TUMORS. Polypi.—The term polypus has been erroneously applied to almost any outgrowth from the mucous membrane that projects into the cavity of the bowel. A polypus should be pedunculated, but it may be sessile, provided the base is relatively small; and it may be a new growth altogether—adenoma or fibroma—or a mere overgrowth of the normal tissue of the part. Generally, polypi are single, growing within a short distance of the anus, from the dorsal surface of the bowel; but sometimes there are 2 or 3, and in a few instances there have been hundreds. As a rule, their size is not large; the fibrous ones are seldom larger than a walnut, and adenomata in most instances are not so large; but when there are 2 or 3 together, they have been known to block up the interior, and give rise to symptoms of obstruction. The soft polypus is most frequent in children. It is generally the size of a raspberry, bright red in color, smooth or slightly granular on the surface, and bleeds at the least touch. It is composed mainly of tubules lined with columnar epithelium, like Lieberkühn's follicles, held together by a delicate connective tissue, and dilated in places into cysts; sometimes there is a little more fibrous tissue, and occasionally a few unstriped muscular fibers. At first they are sessile, but as they rarely give rise to symptoms until they protrude from the anus, a long and slender pedicle is generally present by the time the diagnosis is made. Fibrous polypi, on the other hand, are rare except in adults. They spring apparently from the submucous layer, and are composed of fibrous tissue, which may be so hard as to creak when divided with a knife. It has beeen suggested that they are really adenoid polypi, which in course of time have become hardened and condensed by constant irritation. Occasionally, it is almost impossible to distinguish them from internal hemorrhoids.

Beside these, polypoid outgrowths of mucous membrane, hypertrophied from persistent irritation, are often present in cases of fissure just inside the anus.

Symptoms.—These are not definite until the pedicle is long enough to be grasped by the bowel. In children, bleeding from the anus is often the first thing noticed, and in the absence of injury may be regarded as almost conclusive. Sometimes the growth is extruded during defecation, and is caught by the sphincter, giving rise to pain and spasm; and it may even slough off, and undergo spontaneous cure. In adults hemorrhage is not so conspicuous, but there is usually a considerable discharge of mucus, like thin starch or white of egg, not only with the motions but in the intervals. If the polypus comes down, the pain and irritation may be very severe, and it may drag the bowel down with it so as to cause prolapse, or, if it is situated higher up, intussusception.

A protruding polypus can be recognized at once by its appearance. If it is not visible at first, an injection may be given, and the part examined immediately after. When the finger is introduced, it is advisable to pass it up to its full length at once, and search the mucous membrane as it is withdrawn; otherwise a polypus with a slender pedicle may be pushed up in front of it and missed.

Treatment. –Polypi may be removed by torsion

and ligation. The former answers very well in children, and if the pedicle is really twisted off, is not followed by hemorrhage; the latter is better if the pedicle is of any size, or if the growth is fibrous. An anesthetic is advisable. If a ligature is used, precautions should be taken to avoid ulceration.

Villous growths, similar to, but rather coarser than, the fimbriated papilloma of the bladder, are occasionally met with in the rectum. Allingham, who has had the widest experience with this condition, describes these growths as forming soft, lobulated, spongy masses, either sessile or with a pedicle formed from the subjacent mucous membrane. In most cases they grow from the posterior wall rather high up, and by far the greater number occur in people over 50 years of age. In some they cause severe hemorrhage, and the growth occasionally becomes prolapsed; but the most striking feature is the constant discharge of large quantities of thin watery mucus. The diagnosis, unless some portion of the growth is forced out through the anus, is exceedingly difficult, owing to the peculiarly soft, velvety feel of the mass, which prevents distinguishing it from the natural folds of the mucous membrane. The only treatment is free excision; and this is especially necessary, as in a large proportion of cases malignant disease follows (Moullin).

Nevus of the rectum is occasionally met with, and may give rise to very profuse hemorrhage.

Hemorrhoids.—See HEMORRHOIDS.

REFLEXES.—Reflex movement is caused by the stimulus of an afferent nerve, and the transference or return, by a center, of the impulse through an efferent nerve, resulting in movement or function of a peripheral organ. Reflexes may be motor, sensory, secretory, tactile, or inhibitory. See NERVOUS DISEASES (Examination). A table of reflexes is herewith appended.

REFLEXES, TABLE OF

NAME.	DEEP OR SUPERFICIAL.	HOW OBTAINED.	EFFECT PRODUCED.	SIGNIFICANCE.
Abdominal	Superficial	Sharp, sudden stroking of abdominal wall from margin of ribs downward.	Contraction of muscles about umbilicus.	Shows integrity of cord from eighth to twelfth dorsal nerve.
Ankle-clonus	Deep	By sudden complete flexion of foot, by pressing hand against sole.	Clonus contractions of tendo Achillis, dependent upon alternate contraction and relaxation of anterior tibial and calf muscles.	As in knee-jerk.
Argyll Robertson		See Robertson, Argyll.		
Babinski	Deep	Irritation of the skin of the sole of the foot.	Extension instead of flexion of the toes.	Lesion of pyramidal tract. Found in organic, but not hysteric, hemiplegia.
Biceps	Deep	Tapping tendon of biceps.	Contraction of biceps muscle.	Same cases as increased knee-jerk.
Ciliospinal	Superficial	By irritation of the skin of the neck.	Pupillary dilatation.	
Conjunctival (corneal).	Superficial	Irritation of conjunctiva	Contraction of orbicularis palpebrarum.	Abolished by complete anesthesia, deep stupor coma.
Cremasteric	Superficial	Stimulation of skin on front and inner aspect of thigh.	Retraction of testicle on same side.	Shows integrity of cord between the first and second lumbar pairs of nerves.
Crossed	Deep	Stimulation of one side of body.	Reflex on opposite side of body.	
Deep		Reflexes developed by percussion of tendons or bones.		
Dorsal	Superficial	Same as *Erector spinæ*.		
Elbow-jerk.				
Epigastric	Superficial	Stimulation of skin in fifth or sixth intercostal space near axilla.	Dimpling in the epigastrium, due to contraction of the highest fibers of the rectus abdominis muscle.	Shows integrity of cord from fourth to seventh dorsal nerves.
Erector spinæ	Superficial	Stimulation of skin along border of erector spinæ muscle.	Local contraction of these muscles.	Integrity of dorsal region of cord.

REFLEXES, TABLE OF

Name.	Deep or Superficial.	How Obtained.	Effect Produced.	Significance.
Front-tap	See *Tendo Achillis*.			
Gluteal	Superficial	Firm sudden stroking of skin over buttock.	Contraction of glutei	Shows integrity of cord at fourth and fifth lumbar nerves.
Interscapular	Superficial	See *Scapular*.		
Iris-contraction	Superficial	See *Pupillary*.		
Jaw-jerk, or jaw-clonus.	Superficial	Downward stroke with a hammer on the lower jaw hanging passively or gently supported by the hand.	Clonic movements of inferior maxilla.	Rarely present in health.
Knee-jerk	Deep	By striking patellar tendon after rendering it tense by flexing the knee at right angle.	Contraction of quadriceps muscle, foot jerked forward.	Normal in health. *Absent* in locomotor ataxia, destructive lesions of lower part of cord, alcoholic paraplegia, affections of the anterior gray cornua, infantile paralysis, † meningitis, diphtheritic paralysis, atrophic palsy, pseudohypertrophic muscular paralysis, diabetes, etc. *Increased in* diseases of the pyramidal tracts, in spinal irritability, tumors of brain, cerebrospinal sclerosis, lateral sclerosis, after epileptic seizures or unilateral convulsions.
Laryngeal	Superficial	Irritation of fauces, larynx, etc.	Cough.	
Lumbar	Superficial	Same as *Erector spinæ*.		
Nasal	Superficial	Irritation of Schneiderian membrane.	Sneezing.	
Obliquus	Superficial	Irritation of skin below Poupart's ligament.	Contraction of fibers of external oblique in females; corresponds to cremasteric in males, although it can also be caused in males.	
Ophthalmic (supra-orbital).	Superficial	Blow struck over supra-orbital nerve.	Slight contraction of orbicularis palpebrarum muscle.	
Palatal	Superficial	Irritation	Swallowing.	
Palmar	Superficial	Tickling of palm	Contraction of digital flexors.	Shows that cervical region of cord is normal
Patellar	Deep	Same as *Knee-jerk*.		
Patellar, paradoxic.	Superficial	Percussing patellar tendon with the patient in the dorsal decubitus.	Contraction of the adductor, but not of the quadriceps muscle. If the patient be in the sitting posture the normal reflex is elicited.	Spinal concussion.
Penis-percussion	Superficial	See *Virile*.		
Periosteal	Deep	Tapping the bones of the forearm or leg.	Sharp contractions of the muscles.	Indicates disease of the spinal cord (amyotrophic lateral sclerosis).
Peroneal	Superficial	Stroke on peroneal muscles when tense or when the foot is turned inward.	Reflex movements.	

REFLEXES, TABLE OF

Name.	Deep or Superficial.	How Obtained.	Effect Produced.	Significance.
Pharyngeal	Superficial	Irritation	Swallowing	
Plantar	Superficial	Stroking sole of foot.	Contraction of toes	Muscular exertion.
Platysma	Superficial	Pinching the platysma myoides muscle.	Dilatation of pupil.	
Pupillary		Exposure of retina to light.	Contraction of iris	Absent in basal meningitis, etc.
Paradoxic Pupillary.		Stimulation of retina by light.	Dilatation of pupil	In rare abnormal states.
Paradoxic Patellar.	See *Patellar, Paradoxic.*			
Reinforced	Any reflex is heightened by coincident muscular exertion of other parts than those being tested or by mental distraction.			
Robertson, Argyll		Light and accommodation.	Pupil reacts in accommodation, but not to light.	Locomotor ataxia.
Scapular	Superficial	Irritation of interscapular region.	Contraction of scapular muscles.	Shows integrity of cord between upper two or three dorsal and lower two or three cervical nerves.
Skin	Superficial	See *Platysma.*		
Sole		Same as *Plantar.*		
Spinal		Those reflex actions emanating from centers in the spinal cord.		
Superficial		Such as are developed from irritation of the skin.		
Tendo Achillis, or front tap contraction.	Superficial	By striking muscles on anterior part of leg, while in extension, the foot being extended by the hand upon the sole.	Reflex contraction of gastrocnemius.	Considered by Gowers as a delicate test of heightened spinal irritability.
Toe (great)	Superficial	Strong flexion of great toe.	Involuntary flexion of foot, then flexion of leg, and, lastly, flexion of the thigh on the pelvis.	Met with in cases in which the knee-jerk and other tendon-reflexes are strongly developed.
Virile	Superficial	Sharp percussion of back of penis, the sheath having been made tense.	Retraction of bulbocavernous portion.	Occurs in health.
Wrist-clonus	Deep	By pressing hand backward, causing extreme extension.	A series of jerking movements of the hand.	In the late rigidity of hemiplegia.

REFRACTION OF THE EYE.—The case of test-lenses should contain a set of + spheric lenses and − spheric lenses in pairs from 0.12 D. to 20 D.; a set of + cylinders and − cylinders from 0.12 to at least 6 D., and a set of prisms from 0.5 degree to at least 20 degrees; several plain-colored glasses, opaque glasses, blanks, stenopaic discs, etc., and a trial-frame.

Trial-frames for test-lenses are of several varieties. The most common form consists of an arrangement whereby the nose-piece may be rapidly adjusted by means of a screw, so as to make the frame conform to any height or depth of the bridge of the patient's nose. A vertical and horizontal adjustment by a rack-and-pinion movement on the nose-piece enables us to quickly and perfectly adjust the frame to any peculiarity of the patient's face. A millimetric scale with a pointer moved by a double rack-and-pinion device gives the distance between the pupils at a glance. The lens-holder consists of two hollow grooves, with a slot in each eye-piece to permit rotation of cylindric lenses with handles. On the outside of each eye-piece are hooks for adjusting an additional lens or a blinder. The markings on the eye-pieces begin at zero at the nasal side, and run to the temporal side to 180 degrees. The axis at which the cylinder is inclined is found by comparing the axis marked on the test-cylinder with the coinciding number on the trial-frame. However, as the trial-frame is not often perfectly adjusted, it is well for the surgeon to learn to estimate the angle, particularly in the vertical and horizontal meridians, with his eye. In placing strong lenses in the trial-frame it is well to have the convex surface of convex lenses turned away from the eye, and the concave surfaces

of concave lenses turned toward the eye. In all cases the lenses should be placed as near the eye as possible.

Practical Procedure with the Test-lenses.—Having been assured that all the accommodation is suspended, seat the patient to the left of the table containing the test-lenses, and commence the examination with the right eye, covering the left with an opaque lens or metal disc. Then ask the patient to read down the card situated at 5 or 6 meters' distance, until he comes to the letters that are indistinct; then commence the application of the lenses. Experience will give a good idea what lens to start with, by noting the amount of interference with vision after mydriasis. If the patient is able to recognize only the largest letters on the card, he is either amblyopic, myopic, or highly hyperopic, and is quite likely in every case astigmatic. If the patient is amblyopic from intraocular disease or other cause, the application of a pin-hole perforated disc will not increase his vision, and it is not likely that glasses will improve his sight. If the trouble is only refractive, he will at once notice an improvement in vision through the small perforation. If he is astigmatic, he will select the stenopaic disc (a blank disc with a small open slit, described under ASTIGMATISM (*q. v.*)) at an angle corresponding to the axis of his astigmatism, and the two meridians may be refracted separately by spheric lenses alone.

It is perhaps well to assume the simplest examination of a moderate degree of ametropia. First using a low power + spheric lens (0.25), inquire if the confused letters are improved by it; if the patient answers yes, try a corresponding strength astigmatic lens starting at axis 90 degrees, and inquire if the vision is still better; then rotate the cylinder in the frame, finding the axis at which the letters are seen best. If the patient prefers the cylinder to the spheric lens, put on the cylinder at the axis preferred, and determine the line read with this correction. A low power + spheric lens (0.25) is held in front of the eye that is already corrected by a cylinder, and inquiry is made whether or not the vision is improved, and also whether a correspondingly low + cylinder still further improves the vision; if the spheric lens is preferred to the cylinder, it is put in the trial-frame, back of the cylinder first applied, and the same mode of procedure further pursued, testing with a low spheric lens and then a low cylinder until the vision can no longer be improved. The result is then noted and the examination of the other eye commenced in the same manner.

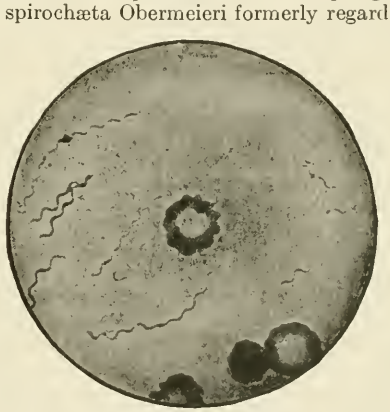
If, however, neither a + spheric nor a + cylinder lens improves the vision, a − spheric and a − cylinder are used in the preceding manner. It sometimes happens that a + cylinder is accepted, but further improvement cannot be obtained by an advance in the strength of a cylinder, or by the addition of a + spheric lens; in such case immediately resort to a − spheric lens or a − cylinder, placed at an axis at right angles to the position at which the + cylinder was preferred. Occasionally rotating a cylindric lens of one eye, with both eyes corrected and participating in vision, will definitely determine a doubtful axis better than if the fellow-eye is excluded by an opaque disc.

An exact knowledge of the correct method of using the test-lenses can only be obtained by long experience; a few other practical points are given in the discussion of the various forms of ametropia. See ASTIGMATISM, HYPEROPIA, MYOPIA EYESTRAIN.

Other Methods of Determining Refraction of the Eye.—In this discussion the many other ingenious methods devised will be left to the numerous text-books on ophthalmology. For practical purposes it is only necessary to describe the ordinary and universally used subjective method with test-cards and test-lenses, and the objective methods of importance—namely, refraction with the retinoscope, with the ophthalmoscope, and the estimation of corneal astigmatism by the ophthalmometer. See OPHTHALMOMETER, OPHTHALMOSCOPY, RETINOSCOPY, VISION (Tests).

RELAPSING FEVER (Febris Recurrens; Spirillum Fever; Famine Fever; Seven-day Fever; Typhus Icterodes).—An acute infectious disease characterized by two or more febrile relapses separated by periods of total remission, and caused by the inoculation and multiplication of the spirochete of Obermeier.

Etiology.—The specific cause of relapsing fever is the spirochæta Obermeieri formerly regarded as



SPIRILLA OF RELAPSING FEVER FROM BLOOD OF A MAN.—(*Kolle and Wassermann.*)

a bacterium of the genus spirocheta but now regarded as probably a protozoan parasite—a trypanosome. First discovered by Obermeier in the blood of cases, it is known by his name. It is a narrow spiral about 0.025 to 0.05 mm. (1/1000 to 1/500 inch) in length; that is, its length is from 3 to 6 times the width of a red blood-disc. It is found floating among the blood-discs during the fever. Before the crisis and in the intervals the organism is not found; but small, glistening spherules, said to be its spores, take its place. Confirmation of the contagious nature of the disease is found in the fact that it has been communicated from one human being to another by inoculation of blood, and to monkeys in the same way. It may be supposed that the organism is given off in the breath or from the skin. The operation of the cause is undoubtedly favored by overcrowding,

by filth, and by destitution. Yet the disease is not confined to the poorly fed. Neither age, sex, nationality, nor season are factors in its causation.

There is no essential morbid anatomy, and such as is found corresponds with that of typhus. Most conspicuous is enlargement of the spleen.

Symptoms.—The period of incubation varies greatly, so that it is put down at from 2 to 14 days. According to Murchison there may actually be no interval between exposure and the invasion. The latter is sudden by a chill, fever, intense pain in the back and limbs, with dizziness. This abrupt invasion is a distinctive feature, and in perhaps none of the contagious diseases is it as a rule so marked. Exceptionally only is there a short period of malaise with loss of appetite. On invasion the temperature rises rapidly and quickly reaches 104° F. The patient cannot retain his feet and promptly takes to his bed, feeling very sick rather than profoundly weak; there may be nausea and vomiting and even convulsions in the young; the pulse rises rapidly, more rapidly than in typhus, reaching 140 on the second day, and later 150 and 160. The patient may be delirious, but the typhoid symptoms are not usually so profound as in typhus, and the tongue remains moist. Jaundice appears in a certain number of cases on the third or fourth day, usually in 1 out of every 12 cases, occasionally as often as 1 in every 4 or 5. The temperature during the paroxysm fluctuates slightly, being higher in the evening. Sweating and sudamina are often present and occasionally petechiæ, but there is no characteristic eruption. Rarely, a roseolous rash appears in small spots, or it may be a mottling like that of typhus, which, however, always disappears on pressure, and disappears altogether in 3 or 4 days, differing in these respects from the similar eruption of typhus. Herpes may be present. There is occasionally abdominal tenderness in the epigastric or iliac region and the enlarged spleen may be easily detected, but there are no active intestinal symptoms. The liver is also slightly enlarged, extending lower than in health. The spirillum is to be found in the blood and should always be looked for. It may readily be detected with a power of 500 diameters without any special preparation of the blood, care being taken simply to secure a thin film.

If the invasion of relapsing fever is sudden, its termination is not less so. It is by crisis, beginning usually with sweating. After 5 or 6 days of unabated fever, sweating sets in, which soon becomes profuse, the temperature falls rapidly to normal or even subnormal, the various discomforts fade away, and in the course of a few hours the patient is apparently well. Rarely the crisis may be ushered in by a diarrhea, an epistaxis, or the appearance of menstruation. The crisis does not always take place at the same stage of the disease. It may occur as early as the third day or not until the tenth, and even the fifteenth, but most commonly on the seventh. While the crisis is ordinarily followed by some relaxation and faintness, there soon ensues a rapid recovery of natural and healthful feeling. Occasionally, however, the depression is greater, and a feeling as of collapse occurs, especially in delicate or elderly persons. Again, in a week from the crisis—generally on the fourteenth day from the primary chill—another occurs, or a series of them, with fever, and the paroxysm repeats itself, to be again succeeded by a crisis at a somewhat shorter interval. There may be a third or even fourth and fifth paroxysm; more commonly they are limited to two or at most three. Each succeeding attack is shorter than the previous one. Occasionally there is no relapse, the disease terminating with the first crisis. Convalescence, usually rapid, is sometimes prolonged, and the duration of the entire illness may be put down at from 18 to 90 days, and the patient rarely returns to work within 6 weeks. One attack does not confer immunity from another (Tyson).

Complications.—Among the complications may be mentioned bronchitis, pneumonia, nephritis, and hematuria. The spleen may enlarge until it ruptures. It may attain a weight of 4 1/2 pounds, and may be the seat of infarcts. Albuminuria occurs as in other fevers characterized by high temperatures. Pregnant women usually abort in the relapse, and the child, if not still-born, survives but a few hours. Postfebrile paralysis may occur, and troublesome ophthalmia succeeds in some epidemics.

Diagnosis.—**Yellow fever** has many points of resemblance, but has a shorter febrile stage, remission not so complete, vomiting late and characteristic, normal spleen, and the late appearance of yellow color.

Remittent fever begins with a decided chill, followed by fever and sweats, and not the progressive rise of temperature until the fifth or seventh day. Examination of the blood will reveal a different organism from that of relapsing fever.

Prognosis.—Recovery is the rule, but protracted, and decided emaciation results.

Treatment.—The febrile paroxysm demands much the same treatment as typhus: Careful nursing; sponging or cool bathing; nutritious, easily assimilable food, and stimulation, although the latter is less important than in typhus. No drug has the power to prevent the recurrence of the relapse, although quinin is indicated, and, as in other adynamic fevers, is useful as a roborant. It is reasonable to expect that acetphenetidin, acetanilid, or antipyrin will relieve the muscular pains. Should they not suffice, morphin, hypodermically, can be relied upon. A serum has been elaborated from the blood of infected horses and the results following its use seem gratifying.

REMITTENT FEVER.—See Malarial Fevers.

RENAL CALCULUS.—See Kidney (Stone).

RENAL INSUFFICIENCY.—See Phenolsulphonephthalein Test.

RESINOL.—A product obtained by the destructive distillation of resin. It occurs as a yellowish oily liquid, and is used as a solvent for phenol, aristol, iodol, camphor, cocain, carbolic acid, creosote, phosphorus, and many alkaloids. Its physiologic action and uses are those of tar. In chronic scaly skin-diseases, especially psoriasis and chronic eczema, it is serviceable.

RESINS (Resinæ).—The proximate principles called by this name are neither the commercial resins nor the resins of pharmacy, all of which are complex bodies, but include only the chemical individuals of resinous character existing in nature, as those in copaiba, cannabis, gamboge, guaiac, gurjun, etc. Even these, in their commercial form, are accompanied by other principles. It is difficult to define the resins correctly, but they are generally considered to be oxidation products of hydrocarbons, such as terpenes. They are mostly brittle, amorphous, uncrystallizable solids, insoluble in water, but soluble in alcohol, ether, chloroform, benzin, etc. Most of them are of acid character, combining with alkalies to form a kind of soap, these "resin-soaps" being soluble in water and giving up their resins again to the action of acids. They soften or melt when heated and solidify again on cooling.

The substances ordinarily called resins are usually classified as follows:

True resins are hard, compact products of oxidation, and are made up chiefly of resin acids. Such are copal, damar, mastic, sandarach, dragon's blood, gum-lac and amber. **Gum-resins** are natural mixtures of gum and resin. When they are rubbed up with water the gummy matter dissolves and the resin is suspended in the form of an emulsion. Such are olibanum (frankincense), myrrh, ammoniac, asafetida, galbanum and tragacanth. **Oleo-resins** include all mixtures of volatile oils and resins of whatever consistency, also the balsams or mixtures of resins with benzoic and cinnamic acids. Such are copaiba, crude turpentine, storax, and the true balsams—benzoin, balsam of Peru and balsam of Tolu. See Oleo-resins. **Pharmaceutical resins** are solid preparations obtained by precipitating the resinous principles of plants from their alcoholic solutions by the agency of water. They differ from alcoholic extracts in containing only those principles which are soluble in alcohol and insoluble in water, while the extracts contain all principles which are soluble in alcohol. Including resina itself, which is the residue left after distilling off the volatile oil from turpentine, there are 4 official resins: Resina; R. Jalapæ; R. Podophylli; R. Scammonii.

RESORCINOL.—$C_6H_4(OH)_2$. Metadioxybenzene, a substance produced from different resins, and from umbelliferous gum-resins on fusion with caustic potash. It is isomeric with hydroquinon. It crystallizes in colorless rhombic prisms or plates, melts at 118° C., and boils at 276° C. It resembles carbolic acid in many of its properties, but it is less toxic; it is odorless, antiseptic, and a powerful germicide. It is valuable chiefly as an antipyretic in malarial fevers, and locally as a lotion in diphtheria and certain skin-diseases. Dose, 1 to 10 grains; as an antipyretic, 5 grains every 2 hours, or 15 to 30 grains not repeated. It is readily soluble in water, alcohol, and ether. In dyeing it yields a fine purple-red coloring-matter, and several other dyes of commercial importance.

Poisoning.—Toxic doses (15 grains to each 35 ounces of weight) paralyze the motor tracts in the spinal cord, but do not affect the general sensibility. It is eliminated chiefly by the urine, which it colors a bluish-violet hue. The best test of its presence is the solution of the perchlorid of iron, which produces with it a dark-violet, almost black, color. Atropin and other cardiac and respiratory stimulants, cerebral excitants, and agents that raise the arterial tension are physiologically antagonistic.

In subacute or chronic eczema:

R. Resorcin, Zinc oxid,	each,	ʒ j
Cold cream,		ʒ x.

Apply to the affected parts twice daily.

RESPIRATION.—See Artificial Respiration, Chest (Examination).

REST CURE.—What is known as the "rest cure" or "rest treatment" was perfected in this country by S. Weir Mitchell. The treatment is especially directed toward the restoration of the vitality of the feeble or overworked by a combination of isolation from friends, rest in bed, and excessive or forced feeding, together with the thorough use of massage and electricity. The cases best suited for this treatment are those in which an enfeebled condition has resulted from an infectious disease, from pneumonia, etc., those of chronic dyspepsia, malarial toxemia, neurasthenia, spinal irritation, and hysterics.

By this method an entire change in surroundings, diet, and mode of life is instituted with the hope that "routine" may be combated and mental activity reduced to the minimum. From 4 to 6 weeks absolute rest in bed is required in most cases.

During the first week only milk is allowed, 4 ounces of which are given every 2 hours and gradually increased until 10 to 12 ounces are given every 3 hours. Stimulating drugs are prohibited, the dominant idea being to place the whole nervous system in a state of profound rest. Nutritive tonics and digestants only are permitted.

To counteract depression and exhaustion, which necessarily ensues from confinement to bed, massage and electricity are employed daily. Proper periods are chosen for massage, usually selecting some period an hour or two after meals. The patient lying in bed, the operator, first beginning at the toes, carefully kneads the parts in all directions; the muscles of the foot are then similarly treated, then the ankles, legs, and body, while at the same time the joints are bent in all directions.

It is essential that the anatomic relations of the muscles should be known in order that passive exercise of each may be encouraged. From 20 minutes to 1 hour are spent in this exercise. In treating the larger muscles they should be grasped firmly, pressed downward, and then kneaded. All massage movements should be in the direction of the heart, in order that the circulation may be naturally stimulated. The form of electricity employed is the faradic current of very moderate intensity with a slow interrupter. A space of 4 or 5 inches should interpose between the two poles, and sufficient time allowed to elapse in order that a full muscular contraction may ensue. After the arms and legs have been treated in this manner for some time, the rapid interrupter is used;

one pole is applied to the neck, the other to the heel for 10 minutes, then to the other heel for an equal length of time. Forty minutes should be given to this application.

Proper mental and bodily habits are demanded. The patient is aroused about 7 A. M., given a cup of coffee, tea, or cocoa, and subsequently a cold bath while in bed, bathing each limb alternately; an hour later a generous breakfast is allowed, and at 10.30 milk, broth, or soup is given. At 11 A. M. massage is employed, followed by a glass of milk. At 1 P. M. a liberal dinner is given, and at 3 P. M. liquid food. At 6 P. M. a moderate supper is served, and at 9 P. M. a glass of milk. Frequently, a dry scrub-bath may be given before the patient is allowed to sleep.

In 3 or 4 weeks the patient may be allowed to sit up out of bed for an hour or two, and a few days later may take excursions out of doors for from a half or three-quarters of an hour. At the end of 6 weeks the patient is advised to spend several months at the seashore, and, if possible, a short period in the mountains.

RETENTION OF URINE.—See URINE (Retention).

RETINA, DISEASES.—Hyperemia of the retina is detected by an increase in the size of the retinal vessels, particularly noticeable over the disc, which appears pinkish in contrast. It is caused by stasis or irritation. In stasis-hyperemia the thickness of the veins in comparison with the arteries is noticed. Irritation-hyperemia usually accompanies inflammation of some other portion of the eye, or it may be a sign of eye-strain. It is quite common in persons with some uncorrected refractive error or muscular imbalance, who use their eyes to excess.

Treatment should be directed to correction of any ametropia or muscular trouble, and the eye should be put at rest and shielded with protective glasses. If the hyperemia is supposed to be a local expression of cerebral congestion, the treatment for the latter affection should be instituted.

Retinal hemorrhage is seldom an independent affection, but is usually associated with some disease or injury of the retina; or it may be the result of some condition provocative of hemorrhage in any other organ, such as atheroma of the arteries, hypertrophy of the left ventricle, scorbutus, hemorrhagic purpura, nephritis, diabetes, pernicious anemia, etc. In such conditions the immediate cause may be muscular strain, violent coughing, or sudden change in the intraocular tension after operation. Hemorrhage following occlusion of the retinal vessels will be mentioned later.

Diagnosis with the ophthalmoscope is easy if the media are clear and if the remaining portion of the retina and disc is unaffected. In such a case a fresh clot appears as a bluish-red blotch on a white background; or, if the clot is old, a brownish-red blotch is seen; or the only remnants of the hemorrhage may be a spot of yellowish-white degeneration, perhaps associated with pigment deposits. The hemorrhage is flame-shaped when in the internal layers, rounded when in the external layers, and massive when between the retina and hyaloid membrane of the vitreous (subhyaloid). If other blotches are seen in the retina and the whole fungus is hazy, the condition is called hemorrhagic retinitis.

Prognosis depends on the cause and recurrence of hemorrhages; unfortunately, the prognosis of affections causing retinal hemorrhage is usually bad. The amount of visual disturbance depends on the location and size of the clot. Hemorrhage in the macula is serious. Multiple hemorrhages may cause a glaucomatous condition, producing blindness.

Treatment must be directed to the general causative condition. Patients should be put to bed and the eyes bandaged. Congestion may be relieved by leeches or dry cups to the temples. Mercurials and iodids, together with diaphoresis, may promote absorption.

Retinitis.—It is probable that idiopathic retinitis never occurs. Inflammation of the retina is generally due to some disease of the general system, such as syphilis, renal disease, diabetes, leukemia, etc. In cases of prolonged exposure or excessive use of the retina the resultant affection is more in the nature of a functional trouble than a true inflammation. Retinitis may be due to an extension of inflammation from the neighboring structures, principally the ciliary body, choroid, and optic nerve. Panophthalmitis produces an immediate suppuration of the retina.

The subjective symptoms of retinitis are usually dimness of vision, scotoma, metamorphopsia, etc. **The objective symptoms** elicited by the ophthalmoscope are sometimes quite characteristic of the causal trouble, although differential diagnosis is at times very difficult. However, the condition discovered is often a valuable indicator in substantiating systemic evidence of the general disease, and is an important factor in prognosis.

Albuminuric retinitis is almost always bilateral, although a number of unilateral cases are recorded. The light-sense, color-sense, and visual field are usually undisturbed. Dimness of vision progresses slowly, and sometimes it is difficult for the patients to count fingers. This affection often accompanies the nephritis of pregnancy. Uremia, coincident with renal disease, may cause complete blindness, but this cannot be attributed to retinitis, but rather to a transient effect upon the cuneus lobe by the uremic poison.

Ophthalmoscopic changes differ in the various stages, although they are most marked in advanced renal disease. The changes in the fundus are generally confined to the posterior pole and region adjoining. Hyperemia is at first noticed, but in the advanced disease white spots or patches are seen about the papilla, and later fine white dots are noticed grouped about the macula in the shape of a star with the fovea in the center. Finally, hemorrhages and fatty degeneration, with paleness of the disc and contraction of the vessels, may occur just before death. In some cases, instead of white spots, there may be numerous widespread hemorrhages, or, again, only congestion and simple redness of the disc.

Prognosis.—The exact relation between retinitis

and the coincident renal disease is not definitely established. However, it may usually be said that a definite case of albuminuric retinitis will have a fatal issue within 2 or 3 years, although the visual disturbance may not increase, and may even improve in fatal, chronic cases. Cases have been observed in which the patients have lived from 5 to 10 years after typical albuminuric retinitis had been established. In interstitial nephritis particularly, retinitis is a serious sign. After recovery from acute nephritis an associate retinitis may clear up and the vision become normal. The prognosis of both life and vision is better in the albuminuric retinitis of pregnancy, and in cases in which only one eye becomes involved.

Treatment must be that of the original disease. In hemorrhagic cases, rest, bandaging of the eyes, and possibly the instillation of atropin, in weak solution (1 grain to 1 ounce), are advisable. The appearance of albuminuric retinitis in pregnancy is regarded by many as an indication for the induction of abortion. See NEPHRITIS.

Diabetic retinitis is often indistinguishable from albuminuric retinitis by the ophthalmoscope alone. The diagnosis can only be made by the test for glycosuria. The prognosis is probably not so bad as in the foregoing disease, and dietary and hygienic treatment may establish a cure.

Syphilitic retinitis is a diffuse instead of a local inflammation, as in the preceding diseases, and may be unilateral or bilateral. A general cloudiness, most apparent at the optic disc, and gradually shading off into the periphery of the fundus, is noticed. White lines may be observed along the course of the blood-vessels. There are numerous dust-like opacities in the vitreous. Hemorrhages are less frequent than in the preceding forms. The treatment is purely constitutional.

Leukemic retinitis is characterized by the pale-yellow appearance of the fundus, always bilateral. There is a marked tendency toward hemorrhages; sometimes circular white clots and prominent blood-bordered spots are seen at the periphery of the retina. Diagnosis should be substantiated by microscopic examination of the blood. The treatment is that of leukemia.

Retinitis of pernicious anemia presents an edematous condition of the retina, diffuse retinitis, with distended veins and pallid blood. The disc appears dirty greenish-white, against a yellowish eye-ground.

Retinitis Pigmentosa.—A pigmentary degeneration of the retina sometimes found in descendants of consanguineous marriages, or of syphilitic parents. It occurs commonly in members of the same family.

Symptoms and Diagnosis.—The chief subjective symptoms are night-blindness, due to the reduced sensitiveness of the retina; concentric contraction of the field of vision, often coupled with nystagmus, causing the patient great inconvenience from inability to find his way, although his central vision may be acute. The constant bowing of the head in walking is a characteristic sign. The fundus has a very characteristic appearance. The disc is yellowish and its edge is somewhat obscured, and the vessels are narrowed, accompanied by fine bands, and fade off into the periphery. Dark streaks of pigmentation, beginning at the periphery, trail over the fundus, and gradually progress toward the macula. In appearance these have been compared to the Haversian bone-canals. Cases of retinitis pigmentosa without the distinctive pigmentation are occasionally found. There is evidence of pigment-atrophy at the periphery, slightly subnormal night-vision, narrowed color-field, etc.

Treatment is useless. All that can be done is to keep the patient in good health and spirits, and surround him with hygienic conditions conducive to the arrest of any degenerative process.

Thrombosis and Embolism of the Retinal Vessels.—Embolism of the central artery of the retina is rare. Both the ophthalmic and central retinal arteries branch at right angles from their parent stems, and an embolus is easily swept by them. The characteristic subjective symptom is sudden blindness in one eye, probably after some slight exertion. There may be temporary improvement during the succeeding weeks, but the prognosis is very unfavorable. The differential diagnosis between thrombosis and embolism with the ophthalmoscope is sometimes difficult. Hemorrhages are more numerous in thrombosis, and there is intense swelling of the nerve and retina. There is pallor of the disc and retina in embolism, and marked diminution in the size of the vessels. The veins become tortuous and very irregular. The central portion of the retina becomes hazy and grayish, the macula standing out in sharp contrast by its maintenance of the normal red color, the classic "cherry-red spot," supposed to be due to the non-existence of the nerve-fiber layer at the fovea, allowing the choroidal vessels to show through. Finally, atrophy of the disc and retina ensue, and the vessels become obliterated and replaced by white streaks. Involvement of only a branch of the central artery is followed by an anemic and degenerated sector-like area supplied by the affected artery. The diagnosis should be confirmed by the discovery of some systemic source of embolus or thrombus, such as endocarditis, or other organic heart affection, phlebitis, pyemia, etc.

Treatment is of little avail; but sometimes in very recent cases it may be possible to remove the embolus by massage of the eyeball, or by reduction of the internal tension, as by sclerotomy. General treatment is, of course, indicated.

Detachment of the Retina.—The most common cause is disease of the choroid consequent upon myopia of high degree. Chronic inflammation of the eyeball or of the retina alone, fluid effusions or hemorrhage between the retina and choroid, injuries, new growths, diseases of the vitreous, removal or dislocation of the lens, and parasites, are other causes. Any condition in which the intraocular tension is suddenly lowered—as, for instance, by the rapid escape of vitreous after a corneal section—predisposes to retinal detachment.

Symptoms and Diagnosis.—The premonitory signs are flickerings and the appearance of dazzling sparks before the eyes, and attacks of momen-

tary blindness. The detachment takes place suddenly, and the field of vision is obscured by what seems to be a dark cloud before the eyes. The detachment is only partial at first, and the retina is still nourished by its own vessels, its functions being impaired rather than destroyed. Naturally, the refractive condition of the eyes is more hyperopic, but as the detached portion of the retina constitutes irregular folds, which constantly move with every movement of the eye, metamorphopsia and other anomalous visual disturbances are present. By the ophthalmoscope there is absence of the red reflex in the region of the detachment. In advanced cases a bluish-gray curtain is seen floating freely in the vitreous, and many even be seen by the naked eye. The picture may be confused by vitreous opacities, which frequently accompany this condition.

Prognosis is dependent on the cause. If caused by intraocular tumor, the case may be considered hopeless. If due to pronounced myopia, one eye is usually attacked after the other, and blindness is unavoidable. In the other conditions the progress of the detachment may possibly be arrested, but we can hardly hope for improvement, although instances of alleged reattachment without treatment have been reported.

Treatment consists of prolonged rest in bed with protection of the eyes from light by a pressure-band age. Antiphlogistic measures should be adopted; diaphoresis with the salicylates, or by hypodermic injection of pilocarpin, may prove of benefit. Several cases are reported to have been cured by a course of tuberculin treatment. See TUBERCULOSIS (Ocular).

The operative treatments that have recently been recommended are puncture through the sclerotic, allowing escape of the subretinal fluid, injection of an artificial vitreous in front of the prolapsed retina, or injection of a few drops of iodin in the vitreous. The real value of these measures is doubtful.

Glioma of the Retina.—A malignant tumor, soft and highly vascular, developing in the retinal connective tissue (sometimes designated neuroglia).

Symptoms.—It occurs chiefly in children from 1 to 4 years old. On account of the youth of the patient and the absence of pain, the early subjective symptom—visual disturbance—escapes unnoticed. The child may be totally blind for some time without the parents' knowledge, attention to the eye first being called by the bright shimmer in the pupil, the so-called "cat's eye." In the first stage of the disease the ophthalmoscopic examination shows a yellowish prominence surrounded by small nodules, toward which dilated retinal vessels converge. In the second stage there is probably increased tension, and the growth begins to push its way forward, carrying the retina, lens, and iris with it. The cornea and the aqueous may become opaque, and the conjunctival vessels intensely congested. Internal inflammation progressively increases, and the tumor may escape through a perforation in the cornea or penetrate the sclera, and appear as a spongy bleeding mass between the lids. The final stage is extension along the optic nerve, or metastasis to the neighboring structures.

Diagnosis is easy after the second stage is reached. In their early stages suppurative choroiditis or hyalitis may produce symptoms so closely resembling glioma that they have been called pseudoglioma. However, in choroiditis inflammation precedes the blindness, and the eye is soft. If there is doubt as to the diagnosis, the case should be treated as glioma, to prevent an error, which may prove fatal.

Prognosis.—Unfortunately, it is usual for the child to be brought for treatment after the disease has progressed sufficiently to cause the "cat's eye" or other prominent objective symptoms, and it may be too late even to save the child's life. There is absolutely no hope of preserving the affected eye.

Treatment.—Not only should the affected eye be immediately enucleated, but the optic nerve should be divided as far back as possible, and if there is the slightest sign of invasion of the orbital tissues, they must be removed and the orbit cauterized.

RETINOSCOPY (Shadow-test).—The method of estimating the refraction of an eye by reflecting into it rays of light from a plane or concave mirror, and observing the movement that the retinal illumination makes by rotating the mirror. To avoid confusion, the description of retinoscopy that follows will apply to the plane mirror, which is to be preferred to the concave mirror, as it is decidedly more satisfactory for general use and convenience.

The principle of retinoscopy is the finding of the point of reversal, or myopic far-point. Should the eye under examination be emmetropic or hyperopic, it must be given an artificial far-point.

Advantages.—Of all the objective methods of refraction, retinoscopy in the hands of the expert is the most exact, but, like all objective methods, its results should, when possible, be confirmed with the trial-lenses.

Retinoscopy offers the following advantages:

1. The character of the refraction is quickly diagnosed.

2. The refraction is estimated without the verbal assistance of the patient.

3. No expensive apparatus is necessarily required.

4. Little time is taken to estimate the refraction.

5. It is of inestimable value in the young, in the feeble-minded, the illiterate, in cases of amblyopia, nystagmus, and aphakia; and in such cases the retinoscopic correction may be ordered.

The retinoscope, or mirror, is of varying form and size. The one recommended is the small plane mirror, 2 cm, in diameter, on a 4 cm. metal disc, with a 2 mm. sight-hole at the center of the mirror, made by removing the silvering and *not by* cutting a hole through the glass.

The light should be steady, clear, and white, and secured to a movable bracket. For general use the Argand burner is best. As only a small portion of the flame is used, it is necessary to cover most of it with a screen.

The screen, or cover-chimney, is made of thin asbestos and of sufficient size to fit easily over the glass chimney of the Argand burner. The opening used, generally 1 cm. in diameter, should be opposite to the brightest part of the flame. An asbestos cover-chimney is used in preference to metal, as it intercepts most of the heat.

The room for retinoscopy must be darkened, and the darker the better; all sources of light except the one in use must be excluded. This must be insisted upon, as darkness offers the best contrast to the test.

Position of the Light and Mirror.—The rays of light coming out of the opening in the light-screen should be 5 or 6 inches in front and to the left of the observer, so that the rays may pass in front of the left eye and fall upon the mirror held before the right eye, thus leaving the observer's left eye in comparative darkness; or this may be reversed if the observer is left-handed. The observer should keep both eyes wide open.

In order to see the movements distinctly the observer should wear his correcting glasses, but need not make any note of his accommodation as in using the ophthalmoscope.

The patient must have his accommodation thoroughly relaxed with a reliable cycloplegic, and be comfortably seated in front of the observer, *preferably at* 1 *meter distance*, with his vision steadily fixed on the observer's forehead just above the mirror; or, even better, the patient may concentrate his vision on the edge of the metal disc of the mirror, but never directly into the mirror, as that would soon irritate and compel him to close his eye. In cases of squint it is particularly necessary to cover one eye while its fellow is being refracted.

To Find the Point of Reversal.—In observing the retinal illumination, the most important thing to study is the direction in which it moves, or whether it moves at all. For example, having determined at 1 meter distance, with a + 2.00 D. lens before the patient's eye, that the retinal illumination moves in the same direction in which the mirror is tilted, and then, substituting a + 2.25 D., and the illumination appears to move in the opposite direction, the observer will know at once that the difference in the strength of these lenses, + 2.12 D., would bring the emergent rays to a focus on his retina and that no movement of the retinal illumination could be made out, and this point, when found, is the point of reversal or artificial far-point.

Emmetropia.—The rays of light from an emmetropic eye proceed parallel, and by reflecting the rays of light into such an eye from a distance of 1 meter the observer sees a small bright retinal illumination, which moves rapidly in the same meridian through which the light is passed. By placing a + 1.00 D. lens in front of such an eye all apparent movement in the pupillary area ceases, showing that the + 1.00 D. has bent the emergent rays and brought them to a focus on the observer's retina. This + 1.00 D. has made this emmetropic eye myopic just 1 D., so that in taking the patient thus refracted from the dark room to test his vision at 6 meters, this 1 D. of artificial myopia must be removed, thus proving the emmetropic condition.

Hyperopia.—In hyperopia the same conditions hold true as in emmetropia. For example, having placed a + 3.00 D. in front of the eye and found that the previously slow movement with the mirror has ceased, and substituting a + 3.25 D. makes it move opposite, it will be known at once that the + 3.00 D. was the correcting glass for 1 meter; or, in other words, that the original divergent rays proceeding from the eye were bent by the + 3.00 D. and brought to a focus on the observer's retina. Two D. of this + 3.00 D. would have made the eye emmetropic, but the additional + 1.00 D. made the eye myopic just that amount, and taking the patient from the dark room this 1.00 D. of artificial myopia must be taken from the dark-room result, which would leave + 2.00 D. as the amount of the hyperopia.

Myopia.—The rays of light from a myopic eye always proceed convergently, and to the observer seated at 1 meter distance the retinal illumination appears to move opposite to the direction in which the mirror is moved *if* the myopia exceeds 1 D., and to move *with* the movement of the mirror if the myopia is *less* than 1 D. An eye that is myopic just 1 D. has its emergent rays focusing at 1 meter, and the observer with his eye at this point does not recognize any apparent movement in the pupillary area.

For example, an eye that is myopic 4.00 D. has its emergent rays focusing at 10 inches, and the observer at 1 meter has the apparent movement of the retinal illumination moving opposite to the movement of the mirror. If a −3.00 D. is placed in front of this eye, the emergent rays than focus at 1 meter, at which point the observer does not appreciate any movement of the retinal illumination. It will thus be seen that the eye that is myopic more than 1.00 D. retains 1 D. of its myopia when tested at 1 meter, and this 1.00 D. must be supplied in taking the patient from the dark room to test his distant vision.

If the observer will remember to always use a plus lens when the retinal illumination moves with the movement of the mirror, and a minus lens when it moves opposite, and allow for the 1. D. of myopia **when working at 1 meter,** he will have the following rule to guide him: namely, **to add a minus 1.00 D. to the dark-room result in every instance**—*i. e.*,

Dark room	0.00 D.	+0.25 D.	+0.50 D.	+0.75 D.	+1.00 D.
add	−1.00	−1.00	−1.00	−1.00	−1.00
Result	−1.00	−0.75	−0.50	−0.25	−0.00

Regular Astigmatism.—The presence of this condition when looking in the eye before any neutralizing lens has been placed in position, can be determined when a band of light is seen extending across the pupil, or when it is possible to note a difference in the rate of movement of the retinal illuminations of any two meridians at right angles to each other. If the spheric error is high and the cylinder a low one, then it will not always be possible to recognize the characteristic band of light (astigmatism) until the approximate neutralizing sphere has been added.

The axis subtended by the band of light after the requisite sphere has corrected the meridian of

least ametropia is the axis for the cylinder in the prescription to be given.

The better way to neutralize cases of astigmatism is to use spheric lenses in preference to cylinders, for by so doing the difficulty of placing cylinders on the exact axis is avoided; for example, in the following formula, +S. 2.00+C. 1.00 axis 90 degrees, it will be found that a + 3.00 sphere in the dark room will correct the 90 degrees meridian and partly correct the 180 degrees meridian; and that a +4.00 sphere will correct the 180 degrees and overcorrect the 90 degrees meridian, making a difference in the strength of the two spheres employed of 1.00 D., which is the amount of the cylinder required. After thus obtaining the result, the observer may, if so disposed, confirm it by placing the spherocylinder combination.

Irregular Astigmatism.—This condition is either in the cornea or lens, generally in the former, making it difficult in any instance to study the refraction, as the reflex is more or less obscured by areas of darkness, so that to study the condition the observer may have to change his working distance toward or from the eye. The kinetoscopic picture obtained by moving the mirror so as to make the light describe a circle around the pupillary edge of the iris is quite diagnostic of the corneal condition. Whatever result is obtained, the observer must take care to refract in the area of the cornea that will correspond to the small pupil when the effects of the cycloplegic pass away. It is best in these cases to retain the correction found as a guide in a postcycloplegic manifest refraction.

Conic Cornea.—In this condition the observer is impressed at once with the bright, round, central illumination that moves opposite to the movement of the mirror, the peripheral movement being with the mirror, unless the margin is myopic also, but of less degree. The best way to refract a case of this kind is to follow the suggestion given for refracting cases of irregular astigmatism.

RETROFLEXION.—See Uterus (Retrodisplacements).

RETROPERITONEAL TUMORS.—There are certain rare tumors which arise behind the peritoneum, having a fixed attachment to the back of the abdomen and the intestines in front. Among these may be included kidney, suprarenal, pelvic, and pancreatic tumors, which are elsewhere described. Of rarer occurrence are the retroperitoneal lipoma, cysts of obscure origin, whether multilocular or dermoid, and lymphadenomatous and lympho-sarcomatous tumors of the lymphatic glands. The diagnosis of such conditions can only be completed by exploration, when it has been found possible in simple cases to shell them out (Spencer and Gask).

RETROPHARYNGEAL ABSCESS.—Abscess behind the pharynx or esophagus. It is due to caries of the cervical vertebræ, or, more rarely, to suppuration of the retropharyngeal lymphatic glands. Again, it may have an idiopathic origin, as is the case with scrofulous, tuberculous, and rachitic children. See Spine (Caries).

Symptoms.—At first there is difficulty in swallowing, and to this are soon joined stiff neck, tenderness of the cervical vertebræ, and the snuffling voice. Later, the head is bent strongly backward as far as possible to prevent dyspnea; respiration becomes difficult and stertorous, but not whistling, as in croup, while the facial muscles twitch, and speech is unintelligible. The posterior wall of the pharynx, at first only reddened and somewhat swollen, soon evidently protrudes as a fluctuating tumor, which sometimes crowds forward the uvula. Finally, the abscess opens, and an enormous quantity of pus is poured forth into the mouth, and if this happens during sleep, the pus may flow down into the larynx and result possibly in suffocation.

Prognosis is serious, though not necessarily fatal.

Treatment.—The patient should be put to bed and small pieces of ice used locally. Timely incision must be employed after the abscess forms, in consequence of suppuration of the lymphatic glands; but if the abscess arises from caries of a cervical vertebra, incision must be delayed until there is real danger from suffocation. After opening, rest in bed, lying on the back, for months is necessary. Iodid of iron may be prescribed.

RETROVERSION.—See Uterus (Retrodisplacements).

RHACHITIS.—See Rickets.

RHAGADES.—Linear cracks or fissures in the skin, whether due to injury or to disease. They are most frequently seen on the palmar and plantar surfaces of the hands and feet, at the angles of the mouth, at the anus, and at the flexures. They are painful on movement. They are often the early manifestations of congenital syphilis, the secretions from these lesions being very virulent, and consitute a frequent source of infection.

RHAMNUS PURSHIANA.—See Cascara Sagrada.

RHATANY.—See Krameria.

RHEUM.—See Rhubarb.

RHEUMATISM, ACUTE ARTICULAR.

Synonyms.—Rheumatic fever, inflammatory rheumatism.

Rheumatism is an acute infectious disease characterized by high fever, inflammation of the large joints, acid sweats, and a disposition to cardiac involvement.

Etiology.—No specific bacterium has yet been discovered and the distinct causative factor is still unknown. There is evidence of some severe poison circulating in the system, having a predilection for the joints, endocardium, and other serous membranes.

Heredity, damp climate with sudden changes in the temperature, exposure to the cold and wet, lowered vitality, are all conducive to rheumatism. It is a disease of young adults and has a tendency to recur. Of the different theories that have been advanced as to the causes of rheumatism may be mentioned (1) metabolic, (2) nervous, and (3) germ theory. Most authorities at the present time admit that the disease is infectious.

Various microorganisms have been isolated from the exudate of the joints of rheumatic

patients, which have caused arthritis and endocarditis in lower animals. Probably, as Flexner and Barker have suggested, acute articular rheumatism may be caused by the infection of the blood by any one of several species of pyogenic organisms, at a time when the conditions were not favorable to the development of a general septicemia, but which may produce an inflammation of one or more serous membranes; hence may occur a pericarditis, pleurisy, or peritonitis of rheumatic origin.

H. C. Wood, Gurich, etc., have shown that suppurative conditions in the tonsils or teeth may be the fundamental cause of acute articular rheumatism and other general conditions.

Other affections, such as scarlet fever and gonorrhea, are associated with a synovitis which closely resembles acute rheumatism, but are due to the specific cause of each of those diseases, and are not truly rheumatic.

Pathology.—The membranes and ligaments show a high grade of inflammation, being reddened, swollen, and there is an effusion of albuminous fluid into the joint-cavity, containing many leukocytes and flakes of fibrin. The inflammatory process producing an increased amount of fibrin in the circulating medium is one of the marked characteristics of this disease.

Usually, the attack ends in recovery, but there may be a hyperplastic proliferation of the synovial membrane, fibrous metaplasia of the cartilage, and fibrocartilaginous ankylosis of the joint.

The blood changes in rheumatism are very marked. Rapid anemia develops early and the red cells may show a loss of 1,500,000 per cubic millimeter; there is a corresponding loss of the hemoglobin, which may be reduced to 50 percent; leukocytosis is the rule, and the white blood-corpuscles may run as high as 39,000 per cubic millimeter. The fibrin is greatly increased. Lactic acid is in excess.

Symptoms and Clinical Course.—The onset is usually quite sudden, although there may have been a history of anorexia, sore throat, pains in the affected parts, or a general body "ache." The inflammatory process first attacks the larger joints, which become reddened, swollen, and excessively tender. Often the inflammation may subside quickly in one joint to attack another. The parts most often affected are the joints of the knee, elbow, shoulder, wrist, and ankle. Occasionally, however, one joint alone is involved. There is a sudden onset of high fever, 103° to 104° F., and the pulse is usually greatly accentuated. With the onset of fever acid sweats occur, and the patient may be bathed with the excretion almost constantly. The sour odor is quite characteristic. The urine, as in gout and lithemia, is high-colored, scanty, and loaded with an excess of uric acid and urates.

Complications.—(1) Hyperpyrexia; (2) endocarditis (very common); (3) pericarditis; (4) myocarditis; (5) pneumonia; (6) pleurisy; (7) cerebral symptoms, as delirium, convulsions, meningitis; (8) cutaneous symptoms—scarlatiniform rash, urticaria, purpura; (9) rheumatic nodules; (10) peritonitis.

Sequels.—Chorea, acute nephritis, exophthalmic goiter and chronic joint changes.

Diagnosis.—The following table illustrates the characteristic points of the affections likely to be confused with rheumatism:

Gout.	Septic Arthritis.	Osteomyelitis.
1. Occurs late in life.	1. Septic focus, tending to suppuration, present. Onset slower.	1. History of long-continued pain, which is worse at night.
2. Fever not high.	2. Hyperpyrexia not marked.	2. Moderate fever.
3. No acid sweats.	3. No acid sweats...	3. Acid sweats absent.
4. Affects small joints.		4. Often affects long bones.
	5. Heart-lesions rare.	5. Heart-lesions rare.

Other forms of infectious arthritis such as scarlatinal, gonorrheal, and also tuberculous and traumatic must be eliminated.

Prognosis is guardedly favorable. Complications are very common. Recurrence and a crippled heart are to be feared. Occasionally the disease becomes subacute, all the symptoms becoming less prominent but more prolonged. Rarely it may become chronic. The subacute type may exist independently of any previous acute attack and is markedly resistant to treatment.

Treatment.—The parts must be placed at absolute rest, and the patient should lie between blankets. It is well to envelop the affected joint in soft wool or flannel.

The diet should be composed of light broths, soups, beef-juice, milk, while there is fever; tea and coffee should be restricted to the minimum; vegetables and fruits of all kinds may be allowed with each meal.

The hyperpyrexia should be constantly watched, and is best controlled by the cold bath or cold packs. The remedy which seems to be most curative is some pharmaceutic preparation of salicylic acid, such as sodium salicylate:

℞. Sodium salicylate, Aromatic elixir, each, ʒ iij
Water, add enough to make, ʒ iij.

One teaspoonful every 4 hours.

If not well borne by stomach, the salicylates may be given by rectal injection of 20 to 40 grains.

The bowels should be evacuated with fractional doses of calomel—1/4 grain may be given every hour until 6 doses have been taken—followed by 1/2 ounce of Rochelle salt. Rochelle salt (1/2 ounce) may be given every 2 days to keep the bowels open.

The function of the kidneys should be carefully considered, and diuretics are distinctly indicated.

℞. Lithium citrate, ʒ jss
Sweet spirit of niter, ʒ v
Solution of potassium citrate, ʒ ij
Simple elixir, ʒ iv
Water, add enough to make ʒ iv.

Two teaspoonfuls every 3 or 4 hours.

℞. Potassium citrate, ℥ iij
Peppermint water, ℥ j
Water, add enough to make ℥ iv.
Two teaspoonfuls every 3 or 4 hours.

Conjointly with the salicylates and alkalies, phenacetin may be used for the pain. Sometimes morphin may be necessary.

Aspirin (*q. v.*) in doses of 5 to 15 grains has been proved to be a most efficient substitute for the older salicylates, as it has the advantage of not producing the unpleasant effects of the latter.

A healthy action of the skin may be preserved by the use of flannel bedding and hot drinks, such as lemonade, hot beef-juice, and soups.

Local Treatment.—A piece of flannel may be dipped in a mixture of lead-water and laudanum, applied to the affected part, and the whole enveloped in wool or flannel and kept at rest.

℞. Tincture of opium, ℥ iv
Solution of lead subacetate, ℥ iijss.
One tablespoonful to a pint of water.

℞. Belladonna liniment, ℥ iv
Soap liniment, add enough to make ℥ iij.
Apply on flannel cloth once daily.

Either of these local applications may be covered with oiled silk. A liniment containing salicylic acid is often very efficacious. Oil of gaultheria in olive oil (1:2) is excellent for local application.

Should endocarditis supervene, successive blisters should be applied over the heart. An ice-bag over this area often relieves pain, lowers the temperature, and lessens the frequency of the heart-beat.

As soon as the patient is able to be out of bed, massage and electricity applied to the joints are valuable, and tonics are necessary:

℞. Strychnin sulphate, gr. j
Quinin sulphate, ℥ ij
Mass of carbonate of iron, ℥ jss.
Make into 50 pills. One pill after each meal.

℞. Elixir of phosphates of iron, quinin, and strychnin, ℥ iv.
Teaspoonful after each meal.

RHEUMATISM, CHRONIC ARTICULAR.—A chronic inflammation of the soft parts of the joint, not due to trauma, or tuberculosis or septic infection.

Etiology.—Same as acute, except that it occurs usually late in life and especially among the working-class. Though as a rule appearing independently, it may be a sequel to the subacute form or it may be followed by an acute or subacute attack. Present research is pointing to microbic origin.

Pathology.—Similar to the acute but more pronounced. The capsule, tendons, and their sheaths are thickened and cause increase in size of the joint. Neuritis and muscular atrophy may supervene about the joint. Ankylosis may occur.

Symptoms.—The main symptoms are pain increased by movement and stiffness diminished by exercise. These are augmented by cold and damp weather. Tenderness and slight swelling may be found. Later ankylosis may occur. Fibrous changes of the heart muscle and valves are frequent.

Prognosis.—While life is not shortened, the disease generally progresses.
