DECUBITUS.—A term denoting a recumbent or horizontal position. Also, the position of a patient in bed. It is the German name for Bed-sore (*q. v.*). In cardiac and pulmonary diseases, in consequence of interference with the cardiac or respiratory functions, a patient is obliged to be propped or to sit up in bed, to assume the erect posture, or to bend forward. In unilateral lung-disease or in pleurisy the patient lies on the affected side. In heart affections inability to lie on the left side may exist. In acute peritonitis the patient lies on his back, the knees well drawn up and bent to relax the abdominal muscles. In spasmodic affections of the abdominal regions the patient is often doubled up, making pressure upon the abdomen. In cerebral meningitis the patient lies curled up, all the limbs bent toward the body. In spinal meningitis the head is involuntarily bent backward to relax the muscles behind. In tetanus the body is in various fixed positions, according to the muscles affected. The position voluntarily assumed by a limb may give important information as to local disease or injury, especially of the joints. The whole body may be distorted in diseases of the articulations.

DEFECATION, DISORDERS.—In some injuries and diseases of the spinal cord or brain the controlling action of volition is annihilated, and the power to restrain or induce defecation is lost. The sphincter may be irritable or subject to spasm, the muscular fibers of the rectum may lose their tone and be incapable of extruding the feces. Overdistention often results in an atonic condition of the rectum, and fecal accumulations ensue.

The treatment of fecal accumulation requires that the masses be first broken up and scooped out, since injections have no effect in softening the indurated mass, acting only on the surface and immediately returning. After the breaking up and extraction of the larger portions, injections of soap and water will be sufficient to remove the remainder.

Involuntary defecation may be caused by violent contraction of the expiratory muscles, by increased peristaltic action of the intestines, or by abnormal relaxation of the sphincter ani muscle, either reflexly, from cerebral disease, disease of the spinal cord, or local lesions. Reflex inhibition may also arise from the presence of worms, from fissure of the anus, or from vesical calculus.

The treatment is of no avail beyond removal of the cause. Worms and fecal impaction require direct treatment. Diseases of the nerve-centers are too frequently incurable, but cleanliness and such measures as permit of the escape of the discharges will relieve much distress. See Constipation, Diarrhea, Feces.

DEGENERATION, REACTION.—Decrease and loss of faradic excitability in both nerves and muscles, the galvanic excitability of the muscles remaining unimpaired, sometimes notably increased, and always undergoing definite qualitative modifications. It is due to a degenerative atrophy in the nerves and muscles, eventually in the muscles only, whose origin is always nervous, paralytic, or atrophic, and whose seat is in the peripheral nerves, motor roots, or central gray substance. Strict cerebral disease is excluded. The lesion is either in the peripheral nerves or spinal cord. This reaction is of special value in prognosis. When there is only partial reaction of degeneration,—*i. e.*, slight diminution of both galvanic and faradic excitability, "a less maximum contraction rather than a later minimum"—the disease will probably last 1 or 2 months; if complete, it will last much longer.

The reaction of degeneration embraces the following modifications of irritability: (1) Disappearance or diminution of nervous irritability to both galvanic and faradic currents; (2) disappearance of faradic and increase of galvanic irritability of muscles, generally associated with an increase of mechanic irritability; (3) disappearance of faradic and increase of galvanic mus-

cular irritability, associated generally with increased mechanic irritability; (4) tardy, delayed contraction of muscles, instead of the quick reaction of normal muscles; (5) marked modification of normal sequence of contraction.

A special variety is the so-called reaction of exhaustion, which is a condition of nervous and muscular irritability to electric excitation, in which a certain reaction produced by a given current strength cannot be reproduced without an increase of current strength.

See Electricity, Motor Points, Nervous Diseases (Examination).

DEGLUTITION, DISORDERS.—See Dysphagia.

DELIRIANTS.—Drugs that excite the functions of the higher brain to such a degree as to disorder the mental faculties, producing intellectual confusion, loss of will-power, delirium, and even convulsions. They are all narcotics (though all narcotics are not deliriants), and may be listed as follows: Belladonna, stramonium, hyoscyamus, turpentine, alcohol, chloral, ether, chloroform, cannabis indica, lupulus (at first), opium (at first), nitrous oxid gas.

DELIRIUM.—According to a well-known neurologist, delirium is a general disturbance or perversion of consciousness, characterized by an apparent exaltation of mental processes, which close examination, however, shows to be in reality a diminution or restriction in apperception, although association may be accelerated, and in consequence seemingly enriched. It manifests itself in detail by some degree of mental irritation and confusion, by more or less transitory delusions and fleeting hallucinations, by disordered, senseless speech, and by motor unrest. It varies in intensity from the slightest so-called "flightiness" to a most intense maniacal condition. The term is not to be used synonymously with insanity.

The following is the classification of Collins:

Classification.—Primary delirium—delirium acutum, delirium grave—is not a disease *sui generis*. In other words, it is not an individual affection, but a condition of varying mental disturbance, which occasionally attends different states of bodily disorder, such as collapse, intoxication, katatonia, etc., although it is often, if not always, dependent upon, or at least associated with, demonstrable changes in the cortex of the brain.

Secondary delirium is by far the more common and the least understood. It may be subdivided into the delirium of (1) infection, (2) intoxication, (3) exhaustion, (4) irritation (peripheral and central), and (5) senility.

The deliriums of infection are more common in the young and in the able-bodied. They occur particularly with the diseases that are dependent upon specific organisms, such as typhoid fever, pneumonia, scarlet fever, yellow fever, puerperal fever, pyemia, etc., although delirium occurs with analogous diseases that have not yet been proved to be dependent upon specific organisms.

Deliriums of intoxication may be subdivided into endogenous and exogenous. The endogenous comprise those dependent upon septic intoxicants, and are included under the head of sapremia, uremia, cholemia, diabetes, autointoxication, insolation, etc., while the exogenous include those due to alcohol, the drugs constituting the group of mydriatics, morphin, cocain, mineral poisons, iodoform, and the like.

The deliriums of exhaustion may be subdivided into those due to inanition; to acute anemia, such as results from hemorrhage, or from the presence in the blood of some powerful hemic dissociation substance, such as exalgin; the plasmodium of malignant forms of malaria; wasting diseases; excessive lactation, and the like.

The deliriums of central or peripheral irritation may be subdivided into those due to local injury of the brain—such as blood-clot from accidental trauma or surgical operation—to meningitis, to acute encephalitis, or to other central diseases. The peripheral irritation or excitation that may be associated with delirium is pain, a condition that could not be manifested without central interpretation. Delirium may also be due to, or associated with, states of central depression, such as those of epilepsy, hysteria, etc.

The delirium of senility requires no subdivision, for although it occurs under the apparent auspices of different exciting factors, it in reality is associated with the pathologic state of the vascular system incident to old age.

Collins summarizes the points in the treatment of delirium somewhat as follows:

Treatment.—The general indications in the treatment of delirium are (1) to secure sleep; (2) to overcome motor unrest; (3) to prop and maintain the patient's vitality by contributing to his nutrition; and (4) to discover and remove the cause upon which the delirium is dependent.

To meet the first indication hypnotics are almost always required, although it should never for a moment be forgotten that an hour's sleep induced by measures taken to fulfil the third condition is far more salutary than 3 hours' sleep obtained by the use of a hypnotic. Moreover, that in many forms of asthenic delirium, whether the asthenia is induced by infection, intoxication, exhaustion, senility, etc., sleep is more readily induced and maintained by measures directed immediately against the asthenia than against the insomnia. In the selection of a hypnotic the one least depressant to the patient's vitality, and least likely to be followed by depression, should always be given preference. The motor depressants should never be used in the delirium accompanying the asthenic state, except as the very last resort. In certain forms of sthenic delirium, and especially those in which a sedative effect cannot be produced by the external application of water, drugs that are motor depressants, and at the same time hypnotics may be used with the greatest benefit. Of these, the alkaloids of hyoscyamus are the most available. Bromids and other sedatives are used too frequently and too indiscriminately, apparently in forgetfulness of the fact that they may, by adding to the vascular depravity that is so often at the bottom of the delirium accompanying

asthenic states, intensify and prolong the duration of the symptoms for which they are given.

The second principle is that great care should be exercised in the application of mechanic restraints in all forms of asthenic delirium, lest the encroachment on respiratory capacity lead to pulmonary complications that jeopardize the life of the patient. Whenever possible, physical restraint is very much less dangerous.

The third principle is that of maintaining the patient's vitality. Alcohol and strychnin are of great value. A factor of great importance in the early stages, and much more so in the later, is the careful, judicious administration of partially or readily digested food in small quantities and of a temperature equal to that of the body. Oftentimes it is necessary to indulge in forced feeding. As in all acute asthenic conditions, stimulants must be given early.

The meeting of the fourth indication—viz., the discovery and removal of the cause of the delirium—is, after all, the most essential procedure in the treatment of this symptom.

The treatment of the secondary deliriums is further discussed under the special headings of the exciting diseases. See Alcoholism, Typhoid Fever, etc.

DELIRIUM TREMENS.—See Alcoholism.

DELIVERY.—See Labor, Fetus, etc.

DELUSION.—False judgment of objective things, as distinguished from illusion and hallucination. It is the result of an abnormal condition of the brain. An *insane delusion* is a false belief for which there is, or may be, no reasonable foundation and which would be incredible under the given circumstances to the same person if of sound mind, and concerning which his mind is not open to permanent correction through evidence or argument. A delusion may be systematized or unsystematized, the former being the more serious, and occurring in the chronically insane. See Insanity.

DEMENTIA.—A mild form of insanity marked by imperfect conception, illogic sequence of expression, loss of reflection, and impaired perception. There is partial loss of self-control and self-respect. Dementia is often a final stage of other forms of insanity. It is described under the various forms of **secondary, senile, organic,** and **alcoholic.** There is a general atrophy of the brain-substance, with a compensatory thickening of the brain membranes, and an increase of the fluid of the brain and of the neuroglia. See Insanity.

DEMENTIA PRÆCOX. (Adolescent Insanity).—This is essentially a disease, as the name indicates, associated with the time of puberty and adolescence. While it may occur spasmodically in an otherwise healthy family, heredity plays an important part in its etiology. It frequently develops in families with an insane taint, and not infrequently two or more children of the same family may be affected. While it may develop on a basis of deficient mental power it may on the other hand occur in those of unusual mental power. In the latter group of cases, the mental precocity may be ill-balanced with a tendency to an over-development of the imaginative processes. In the dull or stupid child a differentiation should be made between dementia præcox and the mental break the result of an exceptional mental stress or strain in high grade imbeciles. It is important from the medico-legal standpoint that severe physical and mental shock, hemorrhages, infection, and the mental stress following seduction and desertion may determine the onset in a predisposed individual. In addition to the infectious and toxic processes, the disturbance of metabolism associated with perversion of the internal secretions has been given as a cause for the disease.

The essential symptom of this disease is dementia. While the majority of these cases present this symptom progressively from a relatively early stage of the disease, it may become manifest in some cases only after several months or even late in the disease. Twenty to thirty percent of cases may go on to relative recovery, with, however, as a rule, some mental reduction.

Boys or girls who have previously not shown mental symptoms at the same time of adolescence begin to manifest lack of interest in themselves, their work and their surroundings. This is associated with inability to concentrate on their studies, failure or lack of attention, or abnormal, pathological moodiness. The memory is usually faulty for recent events, which may be partly due to lack of attention, or may on the other hand be the manifestation of a progressive dementia. In the latter event, there is in addition to failure of memory, a general failure of mental tone manifested by a failure of the reasoning power and the judgment. There is in addition to this a partial or usually a complete loss of emotional expression. There is no manifestation of joy or sorrow or, as far as can be determined, no expression of it. The patients usually understand what is said to them and if their attention is aroused some show a fairly normal appreciation of time, place and personality. Five different varieties have been described depending upon slight additions to or variations of the above picture:

1. Simple dementia.
2. Hebephrenia.
3. Catatonia.
4. Paranoid præcox.
5. Mixed forms.

In the *simple* forms in addition to the above symptoms delusions based on hallucinations of sight or sound may be present. These patients not infrequently present negativism—a resistance in thought and action to the commands and desires of those about them.

In the *hebephrenic* form the onset may be relatively sudden with marked mental depression, disagreeable hallucinations and delusions and a tendency to self destruction. The individuals are silly in manner and action and the delusions not infrequently center about the neurosexual sphere. Periods of depression may alternate with periods of marked excitement, which in some

cases advances to maniacal form with both homicidal and suicidal impulses.

The *catatonic* form represents a fairly definite clinical picture of mental depression followed by catatonic stupor, with marked negatism, mutism and muscular hypertension interrupted by periods of catatonic excitement. Catalepsy is frequently seen in this form.

In the *paranoid* form progressive dementia is associated with exaltation of the ego, delusions of personal grandeur, without, however, the systematized logical reasoning of the true paranoic.

Legal Relations of Dementia Præcox—Prosecution of individuals suffering with dementia præcox for incorrigibility, forgery, breach of contract, homicide and attempts at suicide not infrequently occur. In homicide cases the paranoid form presents much difficulty both as to diagnosis and the question of responsibility. In the fully developed cases, the individual is subjected to the same tests as is paranoid and other forms of insanity (Reese).

DEMULCENTS.—Substances administered for their soothing effects on mucous membranes. Their action is usually mechanic, and they are of a mucilaginous character. Applied to the skins demulcents are called emollients. The demulcents, in ordinary use are: Acacia, cetraria, barley, licorice, starch, glycerin, flaxseed, gelatin, honey, marsh-mallow, white of egg, almond, olive oil, isinglass, tragacanth, bland oils.

DENGUE (Break-bone Fever; Neuralgic Fever; Dandy Fever).—An acute, epidemic, tropical and subtropical febrile disease, consisting of 2 paroxysms of fever with an intermission. The first paroxysm is characterized by high fever, distressing pains in the joints and muscles, and a peculiar eruption; the second paroxysm is characterized by a milder fever, an eruption of different character, attended by intense itching, by some recurrence of the joint pains, and by debility. The specific cause, probably a microorganism, is as yet unknown, but it is evident that a peculiar condition of the atmosphere has some influence in its development. According to Graham, who made a study of 500 cases in Beyrout, Syria, the direct cause is a hemameba resembling the malarial plasmodium, the infectious agent being the intermediary host of the parasite, the culex fatigans, the common mosquito of Beyrout. The time of incubation is from 2 to 6 days.

Symptoms.—The onset is sudden—fever, 103° to 105° F., intense headache, burning pains in the temples, backache, severe aching and swelling of the joints and stiffness of muscles, nausea, vomiting, constipation, and the appearance of a rash resembling scarlatina, from which the disease has been mistaken for scarlatinal rheumatism. After some hours to 2 or 3 days a distinct intermission obtains, of 1 or 2 days' duration. The onset of the second paroxysm is also sudden, but the symptoms are much less severe, although the patient is greatly debilitated; it is at this time that the characteristic eruption appears, being either erythematous or rubelous, and attended by intense itching, remaining for about 2 days, when desquamation occurs and convalescence is established, but is prolonged by great debility of the patient. The average duration of the disease is 8 days. Relapses are common.

Diagnosis.—It is most likely to be mistaken for acute articular rheumatism, especially during the first paroxysm; but the course of the disease and the epidemic influence should prevent such an error. The eruption might be mistaken for scarlet fever or measles were it not for the severe joint and muscular pains and the absence of the angina of scarlet fever and the coryza of measles. It is also to be distinguished from influenza by the absence of catarrhal symptoms and the presence of the skin eruption, by the definite and intense character of the pains, by the absence of the bacillus of influenza in the nasal and bronchial secretions, and from malaria by the absence of the malarial parasites in the blood.

From yellow fever dengue is distinguished by the absence of the slow pulse with rising temperature characteristic of the former disease, by the pronounced joint pains, by the absence of jaundice, albuminuria (except rarely and then only temporarily), and black vomit. See YELLOW FEVER.

Prognosis.—Deaths practically never occur.

Prophylaxis.—This depends upon the destruction of all mosquitoes, and screening the houses and patients.

Treatment.—There is no specific. The fever must be controlled, pain relieved, and prostration combated by stimulants. See MALARIAL FEVERS.

DENTAL ANODYNES.—Substances employed locally in toothache due to caries exposing a nerve filament; such as *aconite*, *opium* and *cocain salts*, also creosote, phenol, and potassium chlorate. A solution, containing the three first named, applied on a pledget of cotton, will promptly relieve whenever the nerve is accessible.

DENTIFRICES.—Medicated powders or pastes used to cleanse the teeth and gums. Finely-powdered chalk is the basis generally used; orris-root is very popular; antiseptics, such as borax, quinin, oil of wintergreen, carbolic acid, etc., are incorporated, tincture of myrrh is an excellent ingredient, being an aromatic, stimulant, and disinfectant. All dentifrices should be slightly alkaline.

DENTITION.—The eruption of the teeth. Dentition is *primary*—that is, the cutting of the temporary or milk-teeth; and *secondary*, or that of the permanent teeth. The primary teeth are described under DENTITION (Disorders) (*q. v.*). Secondary dentition commences about the sixth year. The permanent teeth consist of 2 *incisors*, 1 *cuspid* or *canine*, 2 *premolars* or *bicuspids*, and 2 *molars* in each lateral half of each jaw. The last molar of each half-jaw is cut at an age of from 18 to 25 years, and is therefore called a *wisdom-tooth*. The upper canine teeth are popularly called *eye-teeth*; the lower canines, *stomach-teeth*. The upper central incisors are sometimes called *butter-teeth*. In structure the tooth consists of a hard *enamel*, incasing the crown, the *dentin*, within the enamel, constituting the whole of the root and

interior of the crown; and the *pulp*, a bulbous prolongation of the mucosa of the gums, which is traversed by blood-vessels and nerve filaments. The dentin of the root is surrounded by the cement or *crusta petrosa*. The exposed part of the tooth is the *crown*, the middle part the *neck*, and the part within the alveoli the *fang* or *root*. See TEETH.

DENTITION, DISORDERS.—The eruption of the temporary teeth (20 in number) begins at about the sixth or seventh month, and continues until about the twenty-fourth month.

They are usually erupted in the following order:

	Months after Birth (Approximately).
Lower central incisors	7
Upper central incisors	8
Upper lateral incisors	9
Lower lateral incisors	12
First molars	14
Canines	18
Second molars	22

The eruption of the PERMANENT TEETH in the *lower jaw* is shown in the following table, the corresponding teeth in the *upper jaw* appear a little later:

	Years.
First molars,	6
Central incisors,	7
Lateral incisors,	8
First bicuspids,	9–10
Second bicuspids,	9–10
Canines,	11
Second molars,	12
Third molars (wisdom teeth),	17–25

Variations in Temporary Dentition.—In children in other respects perfectly healthy and normal the 3 following variations are noticed as to the time and order in which the teeth appear—viz.:

1. **Early Dentition.**—A child may be born with one or more teeth. They may appear any time prior to the sixth month—in the fourth or fifth quite frequently.

2. **Late Dentition.**—The first tooth may not appear until the ninth or tenth month, or as late as the twelfth or fourteenth month.

3. **Irregular Dentition.**—They may be erupted out of the regular order.

Late or irregular dentition is very suggestive of rickets and always shows a condition of malnutrition.

The first permanent teeth (4 molars) appear at the sixth year, and the last (the wisdom teeth), completing the set of 32, the eighteenth to twenty-fifth year.

The disturbances incident to teething may be divided into:

1. **Local.**—The gums may be hot, painful, and tender. There may also occur a catarrhal stomatitis, with increased salivary secretions that, by dribbling, excoriate the chin, and may by wetting the chest cause a bronchitis.

2. **Sympathetic or Reflex.**—Any of the following complications may occur: *Eye:* More or less severe inflammation. *Ear:* Catarrhal or purulent otitis media. *Digestive tract:* Gastrointestinal disturbances. *Respiratory tract:* Bronchitis, cough, etc. *Skin:* Erythema, urticaria, eczema. *Nervous system:* Restlessness, disturbed sleep, convulsions.

Treatment.—Cleansing the mouth with boiled water or with a solution of borax, 10 grains to the ounce of water, before and after feeding, clean nursing-bottles and nipples, good hygiene, proper food, and attention to the child's general condition will usually be sufficient to prevent most, if not all, of these difficulties. When, in spite of the best care, or from carelessness or other causes, such complications do arise, they require careful treatment.

Locally, an antiseptic mouth-wash, as sodium salicylate, 10 grains to the ounce of rose-water; or, in mild cases, a borax solution should be applied with a soft cloth every 3 hours.

Internally, for digestive disturbances or bronchitis, the following powder should be given every 2 or 3 hours until the bowels are freely acted upon:

℞. Mercury with chalk,		gr. 1/6
Sodium bicarbonate, Sugar of milk,	each,	gr. j.

There may be added with benefit, if there is fever or restlessness, 1/2 grain of phenacetin or acetanilid.

When the pain is severe, the nervous symptoms prominent, and sleep impossible, chloral and the bromids will be found among the safest and most efficient anodynes.

℞. Chloral hydrate,		gr. xvj
Sodium bromid, Sodium bicarbonate,	each,	gr. xxx
Syrup of lactucarium, Water,	each,	ʒ iv.

Give one-half of a teaspoonful every hour until quiet. This amount may be given to a child 6 months old.

In exceptional cases, when the gums are swollen and inflamed from the irritation of the tooth that has not yet come through, lancing the gums may reduce the congestion and hasten the appearance of the tooth. The teeth should not be "rubbed through," nor the child given hard substances to bite upon, as is frequently done.

DEODORANTS.—Agents that destroy foul odors The *volatile deodorants* are chiefly oxidizing and deoxidizing substances, acting chemically on the obnoxious gases; while the *nonvolatile deodorants* are mainly absorbents that condense and decompose the effluvia. The deodorants in general use are the following: Formaldehyd, chlorin gas, sulphurous acid gas, hydrogen dioxid, potassium permanganate, coffee (freshly roasted), charcoal, earth, lime, and ferrous sulphate.

For removing the fetid exhalations emitted by the feces, the following powder is a very efficient and cheap deodorizing and disinfecting agent: Zinc sulphate, 2 pounds; sulphuric acid, 1 1/2 to 2 1/2 drams; essence of mirbane, 1 dram; indigo blue, 2 grains. About a dessertspoonful of this salt is placed in the bed-pan or chamber utensil before it

is used. Contact with urine or with a liquid stool causes its prompt solution, deodorization is instantaneous, the liquid excreta are at once sterilized, and the fetor is changed to a rather agreeable odor. Oil of eucalyptus has the property of spreading rapidly over water in a thin film, and if a few drops are sprinkled over the water in the pan of a water closet before using the latter, no fecal odor will arise therefrom. See FECES.

DEPILATORY.—A substance used to destroy the hair, usually a caustic alkali. The agents most commonly used are arsenic, calcium sulphid, barium sulphid and quicklime. See ELECTROLYSIS, HYPERTRICHOSIS.

DEPLETION.—The process of diminishing the quantity of any tissue or fluid of the body, especially the blood. It is practised in such affections as cerebral congestion, uremia, acute poisoning with lead, acetanilid and other blood poisons, venous turgescence, engorgement of the portal system, pulmonary congestion, renal ischemia, aneurysm, or general plethora. The agencies are blood-letting, general and local; purging; vomiting; sweating; and abstinence from food and drink. General blood-letting is the most powerful, and is serviceable in engorgement of the right heart and venous system, from disease of the heart or of the lung, or from impaired respiratory movement, and also in visceral congestion and arterial turgescence. See VENESECTION. Local blood-letting is accomplished by CUPPING, LEECHING, AND SCARIFICATION (*q. v.*).

Free purging by hydragog cathartics relieves the turgid vessels. Elaterin, scammony, jalap, senna, magnesium, sodium sulphate, croton oil, gamboge, mercury, antimony, and resin of podophyllin are useful. See CATHARTICS.

Antimony, used as an *emetic*, has depressant as well as depletory effects; and when emetics are used as depletents, this depressant action should be borne in mind.

Sweating will reduce arterial tension, and is of especial service in renal disease. Active exercise, hot air, Turkish bath, vapor bath, wet packing, pilocarpin nitrate, antimony, Dover's powder, and spirit of nitrous ether, or a judicious combination of these measures with copious drafts of hot liquids, are measures of depletion through the action of the skin. Depletion through abstinence is employed in the treatment of aneurysm.

DEPRESSANTS.—Medicines that retard or depress the physiologic action of an organ; sedatives. Cardiac depressants lower the action of the heart. Cerebral depressants arrest the functions of the cerebrum. Motor depressants lower the activity of the spinal cord and motor apparatus.

Cardiac depressants.—See CARDIANTS.

Cerebral depressants include the NARCOTICS, ANESTHETICS (General), and several ANTISPASMODICS (*q. v.*).

The principal **motor depressants** are curare, physostigma, conium, gelsemium, opium, morphin, apomorphin, belladonna, atropin, stramonium, hyoscyamus, muscarin, pulsatilla, grindelia, phytolacca, pilocarpus, quebracho, aconite, veratrum, tobacco, lobelia, digitalis, arnica, ailanthus, saponin, spartein, ergot (at last), quinin (large doses), camphor, alcohol (large doses), ether (large doses), chloroform (large doses), chloral, bromids, potassium salts, many metallic salts, amyl nitrite, nitroglycerin, hydrocyanic acid, potassium cyanid, methylstrychnin, many methyl compounds, ammonium cyanid, ammonium iodid, many compound ammonias, galvanism, and cold.

Hepatic depressants are agents that lower the functional activity of the liver, reducing the quantity of bile secreted, and lessening the production of glycogen and urea. They are as follows (Potter)—viz.:

Lessening Bile.—Lead acetate, atropin, calomel, chloral, castor oil, gamboge, magnesium sulphate.

Diminishing Glycogen.—Opium, morphin, codein, phosphorus, arsenic, antimony.

Lessening Urea.—Opium, morphin, codein, colchicum, alcohol, quinin.

Many purgatives act as hepatic depressants and diminish the secretion of bile by lowering the blood pressure in the liver, and by carrying off the materials from which bile might be formed.

Renal depressants directly diminish the activity of the renal cells, and lessen or suspend the secretion of urine. Morphin, quinin, and ergot act in this way through the circulation, and digitalis may arrest the renal circulation by contracting the vessels. Strychnin and caffein in large doses have similar action, and it is well to combine with them drugs that dilate the renal arteries, such as alcohol or nitrous ether.

Respiratory depressants are cold, opium, physostigma, muscarin, lobelin, gelsemium, aconite, veratrin, hydrocyanic acid, conium, alcohol, ether, chloroform, chloral, saponin, caffein, colchicin, nicotin, quinin, camphor, and carbolic acid.

Uterine depressants lower the activity of the nervomuscular apparatus that controls the uterine contractions. The most important are opium, bromids, cannabis, viburnum prunifolium, chloral, chloroform, tartar emetic, tobacco, copper sulphate, emetics, and piscidia erythrina.

DERMATITIS. Definition.—Dermatitis, or inflammation of the skin, is a cutaneous disorder characterized by heat, redness, pain, and swelling; in other words, by the ordinary phenomena of inflammation. The term is restricted to acute inflammations the result of known irritants. It is classified as follows:

DERMATITIS CALORICA.—See BURNS, FROST BITE, etc.

DERMATITIS EXFOLIATIVA (Acute General Dermatitis; Pityriasis Rubra).—A rare inflammation of adults, especially men, often ushered in with some constitutional disturbance. After a more or less general erythema with more or less infiltration has been present several days, exfoliations appear, grayish-brown scales on a red shiny skin. More or less itching is present. The disease may be grafted upon a squamous eczema or psoriasis. Gout, rheumatism, tuberculosis and certain drugs seem to be predisposing factors. The disease lasts from several weeks to a few months and tends to recur. The acute type is very similar to erythema scarlatinoides, but the

latter is markedly acute and shows no infiltration of the skin. General treatment is symptomatic and local, and consists of soothing applications. There are two varieties that are probably infectious:

(1) **Dermatitis exfoliativa epidemica** has been observed in institutions chiefly among elderly men. It is accompanied by loss of hair and nails and conjunctivitis.

(2) **Dermatitis exfoliativa neonatorum** (Ritter's disease) occurs during the first weeks of life. The disease may take on a suppurative form and death may occur from septicemia or marasmus.

DERMATITIS GANGRENOSA INFANTUM. Synonyms.—Varicella gangrenosa; multiple disseminated gangrene of the skin in infants, pemphigus gangrenosus, ecthyma gangrenosa.

A gangrenous eruption of infants and young children following usually varicella and also frequently vaccinia, measles or pemphigus, and sometimes arising spontaneously in debilitated infants. The disease is undoubtedly due to some microorganism, such as the streptococcus pyogenes or the bacillus pyocyaneus, each of which has its advocates. When it follows a vesicular or pustular eruption the lesions of the primary disease persist, become crusted and ulcerate. These ulcers are "punched out" in appearance and may coalesce. Constitutional symptoms may be severe. There may be high fever, vomiting, diarrhea, heart and lung complications, and septicemia. Indelible scars are left.

The prognosis is guarded, depending upon age, number of lesions, and character of complications.

The treatment is supportive. The general health should be built up by proper nourishment, fresh air, tonics. Crocker advises quinin in 1- or 2-grain doses, in milk every 4 hours. Complications should be treated as they arise. Locally, antiseptics are necessary, such as bichlorid solution (1 to 5000) or ichthyol ointment (5 to 10 percent).

DERMATITIS HERPETIFORMIS. Synonyms.—Duhring's disease; hydroa; herpes gestations.

Definition.—Dermatitis herpetiformis is an inflammatory disease of the skin, characterized by grouped erythematous, papular, vesicular, pustular, and bullous lesions occurring in varied combinations. It is accompanied by burning and itching, and runs a chronic course with remissions.

Symptoms.—In severe cases there are elevation of temperature, malaise, chilliness, etc. The eruption may appear gradually or suddenly.

The erythematous, vesicular, bullous, pustular and multiform eruptions are the common varieties of the disease. There is a distinct tendency for one variety to pass into another variety—for, instance, for the vesicular to become pustular or bullous, or the reverse. Burning and itching are practically always present, and in some cases are intense.

Erythematous Variety.—This form occurs in marginate patches or in diffuse efflorescences, resembling erythema multiform. Urticaria-like edematous infiltrations may also occur. The color may be raspberry-red, mottled and tinged with yellowish, brownish, or variegated, with later a variable degree of pigmentation. Erythematopapular and vesicular lesions often coexist. Itching and burning are marked.

Vesicular Variety.—This is the most common form. It is marked by pinhead- to pea-sized, flat or raised, irregularly shaped or stellate, distended vesicles, frequently without an inflammatory areola. They are usually aggregated in clusters of 3 or 4 lesions. They often tend to coalescence, but not to rupture. Itching is severe, often intense, but abates considerably upon rupture or laceration of the vesicles. The eruption appears in crops.

Bullous Variety.—The lesions consist of distended, irregular-shaped, angular bullæ, occurring in groups of 3 or more, often without areola. Small pustules frequently appear in the neighborhood, and erythematous and vesicular lesions may likewise be present. Itching and burning are severe.

Pustular Variety.—Two kinds of pustules appear: the one small (miliary), pin-point to pinhead-sized, and perfectly flat; the other large, elevated, rounded or acuminate, and situated upon an inflammatory base. There is a tendency to arrangement in clusters of 3 or 4 pustules. Vesicles and blebs may complicate the eruption, although the pustular type often remains as such, even throughout successive outbreaks.

Papular Variety.—Rare. It is the mildest expression of the disease. More commonly papulovesicles, resembling an abortive herpes zoster, develop.

Multiform Variety.—In this form erythematous patches, papules, vesicles, blebs, pustules, and pigmentation are commingled in various combinations.

The course of dermatitis herpetiformis is variable, but in nearly all cases is chronic, lasting for years in the form of relapses; or, indeed, at times continuously.

Etiology.—The disease occurs generally between the ages of 30 and 60. It is due to various causes, among which may be mentioned physical and psychic nerve shock, pregnancy, disordered menstruation, puerperal septicemia, and renal insufficiency; the nervous system, however, is directly responsible for the cutaneous manifestations. There is, in most cases, a lowering of the general nerve tone.

Pathology.—There is an acute inflammation of the papillary layer of the corium, with the formation of vesicles between the corium and epidermis, and the exudation of large numbers of polynuclear leukocytes and eosinophiles. The epidermis is but secondarily involved.

Diagnosis.—The polymorphism and herpetiformity of the eruption, the intense itching, and the history, course, and chronicity of the disease will aid in distinguishing it from pemphigus, erythema multiforme, and impetigo herpetiformis—diseases that it at times closely resembles.

The vesicles and blebs of dermatitis herpetiformis are peculiar in that they are of marked irregular outline—sometimes stellate, quadrate, or oblong, etc. In drying they are likely to present a puckered appearance.

They are herpetiform in that they occur in

groups, have inflammatory bases, and do not tend to spontaneous rupture, resembling in these respects herpes zoster.

Prognosis should be guarded. The disease is persistent and is refractory to treatment. In addition there is a strong tendency to recurrence. In rare cases the pustular or bullous type may prove fatal.

Treatment.—The first effort should be directed toward the removal or modification of the underlying cause, if ascertainable. The nervous system is, in most cases, at fault, and remedies should be administered with a view of restoring the normal nerve tone. There are no specifics, but arsenic often acts in a gratifying manner. In other cases, however, it is of no value. Phenacetin, cannabis indica, and belladonna may be tried; and such tonics as quinin, strychnin, and iron are sometimes of value.

Local Treatment.—Blebs should be incised or punctured, and the contents evacuated. Lotions containing tar, carbolic acid, ichthyol, and resorcin are useful. These may be followed by an ointment of salicylic acid. In the vesicular and pustular forms (particularly the chronic) Duhring advises the use of a strong sulphur ointment, well rubbed in.

DERMATITIS MEDICAMENTOSA.—See DRUG ERUPTIONS.

DERMATITIS REPENS.—A spreading dermatitis generally on the upper extremities starting from an injury or surgical operation. Beginning as it usually does on the finger or hand it may gradually involve the whole arm and even the trunk. It may possibly be due to a peripheral neuritis associated with parasitic infection. The disease is readily differentiated from eczema rubrum and pompholyx.

Treatment.—After removal of the loose skin, applications should be made of a saturated boric solution containing 2 to 5 grains of resorcin to the ounce.

DERMATITIS TRAUMATICA.—See BRUISE, WOUNDS (Contused), etc.

DERMATITIS VENENATA.—See IVY-POISONING.

DERMATITIS, X-RAY.—Repeated exposure to X-rays has resulted not infrequently in a chronic dermatitis. Some observers believe that not the rays but the current has been responsible. The best treatment is prophylaxis. With the care and the means for protection of both patient and operator that are now employed X-ray dermatitis should now be a thing of the past.

DERMATOL.—Dermatol is a trade name for bismuth subgallate, a substitute for iodoform. It forms a fine, yellow powder, without odor or hygroscopic properties. It contains about 55 per cent of bismuth oxid. It is practically insoluble. It is employed pure as a powder, united with other desiccants, or exhibited in the form of an ointment or collodion (1.5 : 10). Dermatol is protectant, desiccant, and antiseptic. See BISMUTH.

DERMOID CYSTS.—See CYSTS.

DESCEMETITIS.—See IRITIS (Serous).

DETERGENTS.—Substances that cleanse the skin. They are used to remove dirt or epidermal scales. The principal detergents are water, soap, alkalies, ox-gall, milk, vinegar, alcohol, charcoal, sand, oatmeal, sawdust, pumice-stone, oil, and borax. Warm water is the chief detergent, greatly aided by soaps and chemicals, or by mechanically acting substances, such as oatmeal and sand. Oil or alcohol aids in the removal of resinous deposits adhering to the skin after the removal of plasters. Borax and elderflower water are preferable to irritating soaps to remove scurf, when the skin is tender.

DIABETES INSIPIDUS.—Diabetes insipidus is the term applied to simple continued polyuria unassociated with glucose. It is to be distinguished from simple polyuria, which is a temporary condition often occurring in nervous people.

Its **etiology** and **pathology** are as little understood as are those of diabetes mellitus. It has even more rarely been found associated with lesions of the nervous system, or, indeed, of any part of the body, though associate tumors and other new formations in the brain have been described. It is a much less serious condition than diabetes mellitus. It occurs in the adolescent, the adult, and the middle-aged, rather than in the very old or very young, and is about three times as frequent in males as in females. Heredity is also a recognized factor and syphilis has caused diabetes insipidus. Nervous shock is an acknowledged exciting cause. This may be sufficient to account for the effect of blows and falls. Pregnancy has been assigned as a cause.

Of **symptoms**, there is little to add to thirst, occasional dryness of the skin, and polyuria. As in diabetes mellitus, weakness and emaciation ensue, though they are not so marked or so rapid as in the latter disease. The quantity of water ingested and passed even exceeds that in diabetes mellitus. The specific gravity of the urine is sometimes as low as 1000, often 1002 to 1005, and it contains neither albumin nor sugar. The 24 hours' urea is commonly increased, owing to the polyuria. Often the health is very slightly impaired. Intermissions occur, during which the quantity of urine is diminished, while the effect of intercurrent disease is also to diminish the flow of urine.

The diagnosis is commonly easy. The persistent polyuria, with absence of sugar and albumin, belongs to no other disease.

The prognosis is uncertain as to recovery, but the condition is not incompatible with long life and attention to business. It sometimes disappears spontaneously, and occasionally in response to remedies administered. A patient rarely dies of its effects.

Treatment.—Water should be allowed in reasonable amount, as no advantage is derived from its restriction. Indeed, such a course increases the discomfort, and hence tends to exhaust and weaken the patient. Potassium iodid is without doubt an efficient remedy; at least as long as its administration is continued. The dose must be determined by its effect: 10 grains and upward to adults, less to children. Valerian is, however, the remedy that has the best reputation. It may be

combined with the bromids. Any one of the preparations may be used, as the fluidextract in 10-minim doses, or the valerate of zinc in 15-grain doses, or valerate of ammonium. The last is the most suitable preparation, in combination with the bromid of ammonium. Ergot, in the form of the fluidextract, gallic acid, and antipyrin are said to have cured cases. Belladonna, either alone or in combination, has some reputation. Tonics are useful aids, especially iron and strychnin. Opium does not appear to be so useful in diabetes insipidus, nor is its use so safe.

DIABETES MELLITUS.—Diabetes mellitus is a constitutional disease, characterized especially by hypersecretion of urine highly charged with sugar. Allen has defined diabetes as a "specific deficiency of the power of assimilating food."

The pathology is still obscure; for although glycosuric polyuria is found associated with lesions of the nervous system and lesions of the pancreas in a noteworthy number of cases, there remains a decided majority in which no lesion is discoverable, and the affection must still be regarded as a symptomatic one.

The etiology is also uncertain. It is a disease of the rich rather than of the poor, and is more frequent in men than in women. It is especially frequent in the Hebrew race, and is unusual among negroes. More frequently than not no cause is discoverable. Physical and mental overwork are assigned as causes. Heredity is an acknowledged factor, or, at least, several members of a single family may be subjects. Unrestricted eating and drinking are probable factors, in view of the fact that it is found more among the rich than the poor, and among well-to-do Hebrews rather than among those in the humble walks of life.

Symptoms.—In addition to the polyuria and glycosuria already mentioned, thirst and dryness of the mouth, and, at times, also dryness of the skin, are characteristic. They vary in intensity with the severity of the disease. In some cases "gallons of water" are drunk—to use the expression of the patient—and as much may be passed, although more often smaller quantities are ingested too variable to permit of precise statement. The specific gravity of the urine varies from 1020 to 1040 or higher, and the percentage of sugar from 2 to 10 percent or more, although the latter percentage is not often reached.

An abnormally large appetite is likely to be present in the early stages, notwithstanding which the patient loses flesh, and in advanced stages emaciation is often extreme. With this is associated a corresponding weakness and debility. Boils and carbuncles are frequent and sometimes initial symptoms—the very first to attract attention. The urine should, therefore, be examined in all cases in which boils and carbuncles are present. The same is true of pruritus, and especially of pruritus vulvæ, though the same symptoms also occur on the genitals of men. Eczema in various situations on the body, and in varying degrees of severity, is also at times a symptom.

A like manifestation of nutritional disturbance is gangrene, which is sometimes the result of diabetes when least suspected. It is extremely difficult to heal, and is not infrequently a cause of death. Cataract is a rarer symptom, similarly caused. Cataract is of most significance when it occurs among the young, as the usual causes of cataract may operate in the aged diabetic. Neuritis often causes much suffering. In advanced stages the knee-jerks are often absent; not because of any demonstrable lesion in the spinal cord, but probably because of a toxic effect of the sugar-laden blood. Loss of sexual desire is a symptom often named.

Diabetic coma is a terminal symptom that is justly dreaded. The most characteristic symptom is deep inspiration. It is sometimes ushered in by cramp-like pains in the epigastrium; at others by drowsiness that gradually increases until the patient is profoundly comatose. The presence of acetone, and especially of diacetic acid, as shown by the ferric chlorid reaction, is often a forerunner of impending coma. Convulsions may supervene toward the end. The condition is probably the result of a self-infection due to the absorption of poisons in some way engendered in the body of the diabetic. The phenomena of diabetic coma are not confined to diabetes.

Complications.—There are few complications of diabetes. Pulmonary tuberculosis is perhaps the most frequent one, the diabetic state favoring its development. Some conditions mentioned under the symptomatology may be regarded as complications—viz., eczema, furuncle, and gangrene—but these are direct consequences rather than true complications. Albuminuria occurs in connection with a certain number of cases of diabetes, generally late in the disease, and is probably the result of slight degree of degeneration from excessive function. In a few instances it is the result of associated interstitial nephritis, which is probably a coincidence. In like manner visual symptoms, when present, are more often a result of a complicating interstitial nephritis than a result of the diabetic condition, excepting always cataract, which has been alluded to. See Acidosis.

In this connection some mention should be made of the relation of gout to diabetes mellitus. Undoubtedly, the milder forms of the disease have some relation to gout, being sometimes substituted for it; though more frequently, perhaps, gout is replaced by diabetes. Sometimes the two are interchangeable. There is no satisfactory explanation of the relation.

The diagnosis is usually easy. Polyuria and glycosuria are key-notes. Diabetes mellitus only exists when grape-sugar is permanently present in the urine. If polyuria is not actually present, the presence of any one of the foregoing symptoms should suggest an immediate examination of the urine for sugar. Tests for acetone and diacetic acid should also be frequently made, as their presence indicates the probable onset of diabetic coma. See Urine (Examination), Glycosuria.

The prognosis of diabetes varies with the severity of the case and the age of the patient. A well-developed case in a child under 12 years of age

probably never recovers, though amenable to treatment to a degree. Mild cases in persons over 50 are so far amenable to treatment that they may be regarded as curable—at least, as long as a suitable diet can be maintained.

Dietetic Treatment.—By far the most important treatment is dietetic, and a choice between medicines and diet promptly discards the former. The recognition that there is a lowered functional capacity not only for the assimilation of carbohydrates, but also for proteins and fats is the basis for whatever dietetic restrictions are instituted. The object of the treatment, therefore, should be the supplying of a diet below the assimilation limit, thereby resting what Allen emphasizes as the underlying cause, namely, a weakened pancreatic function. The diabetic who constantly indulges in dietetic excesses tends to progressively weaken pancreatic function and become progressively worse. A diabetic who is given a diet within the tolerance limit will gradually manifest an increase in the tolerance and an improvement in the condition. Allen, who has studied the question of the treatment of diabetes extensively, has formulated a plan of treatment which may be outlined as follows: (1) A preliminary fast until the urine is free from sugar. (2) Following the fast, carbohydrate food is gradually added, at first in the form of green vegetables. (3) Coincident with the addition of carbohydrate, or in place of it, if the carbohydrate tolerance is very low, protein is added to the diet in small but gradually increasing amounts until glycosuria occurs, or a sufficient amount of protein is taken to cover the basal requirement. (4) The addition of fats in small amounts during the time of addition of carbohydrates and protein. Subsequently, a sufficient amount of fat is added to make up the fuel requirements of the body, provided this amount can be tolerated without the appearance of glycosuria or acidosis. (5) Frequent urine examinations are made, either by the medical attendant or by the patient himself, and the appearance of glucose is taken as an indication for a fast of sufficient length to cause a cessation of the glycosuria. Feeding is subsequently begun with not more than one-half of the carbohydrate contained in the diet at the time of the appearance of glycosuria. Subsequent carbohydrate increase is made very gradually. (6) At intervals, the patient is fasted for a day or else takes a greatly restricted diet. (7) Body fat is reduced to a minimum and the adult diabetic is not allowed to gain weight; children may gain, but the gain must not be adipose tissue. (8) Active daily exercise carried to the point of healthy fatigue is advocated. The length of time of the preliminary fast is usually less than five days, although in exceptional instances it may be as long as eight or ten days. During this time water is allowed freely and tea or coffee (without sugar or cream) in moderate amounts. Alcohol, in the form of whiskey, from 1 to 2 ounces daily is given by some, but is not considered an essential in the treatment. Rest in bed may be necessary for weak patients, but the more vigorous ones may exercise with benefit, and in some instances it seems that the duration of the fast may be shortened thereby. If during the fast, symptoms referable to severe and progressive acidosis occur the fast must be temporarily terminated and the acidosis treated. The fast is terminated and feeding cautiously begun when the urine is sugar free for twenty-four hours. Two essentials for the preparation of the diet are a scale for the weighing of the food and a knowledge of the percentage values of the food principles in the different types of food. The latter has been tabulated in a practical form by Joslin and is reproduced herewith:

JOSLIN'S DIET TABLE.

Strict Diet—Meats, Fish, Broths, Gelatin, Eggs, Butter, Olive Oil, Coffee, Tea and Cracked Cocoa.

Foods Arranged Approximately According to Percentage of Carbohydrates.

Vegetables.

5 Percent.	10 Percent.	15 Percent.	20 Percent.
Lettuce Spinach Cauliflower Sauerkraut String beans Celery Asparagus Cucumbers Brussels sprouts Sorrel Endive Dandelions Swiss chard Sea kale Tomatoes Rhubarb Egg plant Leeks Beet greens Watercress Cabbage Radishes Pumpkin Kohlrabi Broccoli Vegetable marrow	Onions Mushrooms Squash Turnip Carrots Okra Beets	Green peas Artichokes Parsnips Canned lima beans	Potatoes Shell beans Baked beans Green corn Boiled rice Boiled macaroni

Fruits.

Ripe olives (20 percent fat) Grapefruit	Lemons Oranges Cranberries Strawberries Blackberries Gooseberries Peaches Pineapple Watermelon	Apples Pears Apricots Blueberries Cherries Currants Raspberries Huckleberries	Plums Bananas

Nuts.

Butternuts Pignolias	Brazil nuts Black walnuts Hickory Pecans Filberts	Almonds Walnuts (Eng.) Beechnuts Pistachios Pinenuts	Peanuts 40 Percent Chestnuts

5 Percent

Miscellaneous.—Unsweetened and unspiced pickles, clams, oysters, scallops, liver, fish roe

Reckon *actually available* carbohydrates in vegetables of 5 per cent group as 3 percent, of 10 percent group as 6 percent

DIABETES MELLITUS

Thirty grams or 1 ounce, of each of the following contain approximately:

	Protein, Gm.	Fat, Gm.	Carbohydrates, Gm.	Calories.
Oatmeal, dry weight	5	2	20	110
Meat (uncooked)	6	2	0	40
Meat (cooked)	8	3	0	60
Broth	0.7	0	0	3
Potato	1	0	6	30
Bacon (cooked)	5	15	0	155
Cream, 40 percent	1	12	1	120
Cream, 20 percent	1	6	1	60
Milk	1	1	2	20
Bread	3	0	18	90
Butter	0	25	0	240
Egg (one)	6	5	0	75
Brazil nuts	5	20	2	210
Orange (one)	0	0	10	40
Grapefruit (one)	0	0	10	40
Vegetables, 5 and 10 percent groups	0.5	0	1	6

1 gm. protein, 4 calories.
1 gm. fat, 9 calories.
6.25 gm. protein contain 1 gm. nitrogen.
30 grams (gm.) or cubic centimeters (c.c.), 1 ounce.
A patient "at rest" requires from 25 to 30 calories per kilogram body weight.
1 gm. carbohydrate, 4 calories.
1 gm. alcohol, 7 calories.
1 kilogram, 2.2 pounds.

The day **the feeding is started** the patient is given from 150 to 200 gm. of the vegetables of the 5 percent group. These so-called "green vegetables" contain a very small quantity of available carbohydrate (approximately 5 gm.) and only traces of protein and fat. Their bulk serves to fill the stomach and allay, to a certain extent, the hunger, and by their residue tends to prevent constipation. If no glycosuria occurs 5 gm. of carbohydrate are added every day until 20 gm. are given, then every other day until the patient is receiving as much as 3 gm. of carbohydrate per kilogram of body weight in 24 hours (Joslin). After the first day or two carbohydrates may be given in the form of vegetables of the 10 percent group, followed subsequently by those of the 15 and 20 percent groups. Fruits are then added and ultimately if glycosuria has not supervened, bread and oatmeal. Ordinary bread is but seldom included in the dietary of the diabetic. There are on the market a large number of brands of "gluten" and "diabetic" flour which contain relatively little carbohydrate and much protein. Bread made from such flour, provided the composition is accurately known, may be eaten. These special brands of flour, however, are expensive and many are fraudulent. The patient's longing for bread may, in a measure, be satisfied by bran biscuits. These contain no carbohydrate and serve as a convenient vehicle for the administration of butter or other fats. The bulky residue fills the stomach and relieves constipation. The appearance of glucose in the urine means that the patient's assimilative limits have been exceeded and a fast must be instituted until the glycosuria ceases. Following the fast, the carbohydrate ration should bd diminished by one-half and not increased beyone this amount for some days and then very cautiously. The amount should be kept well within the limit of tolerance previously determined for a considerable period of time. Subsequently, if there is reason to suppose the patient can assimilate more carbohydrate, the limit of tolerance may again be determined by gradual addition of carbohydrate, even to a point in excess of the former tolerance. **The addition of protein** to the diet may be made in most cases during the period when the carbohydrate tolerance is being tested. At first one egg, then two, three, four eggs, and lean meat until the patient receives about 1 gm. of protein per kilogram of body weight. Later this may be increased to 1 1/2 gm. and in children 2 gm. of protein per kilogram. In exceptionally severe cases of diabetes it may be necessary to test the protein tolerance by feeding exclusively protein foods until glycosuria appears; in the same way the carbohydrate tolerance is tested. **The fats are added** to the diet when the amount of protein fed has reached 1 gm. per kilogram body weight. These are added in increasing amounts (25 gm. a day) until the caloric requirement of from 25 to 40 calories per kilogram of body weight is covered by the total food intake. Patients who are exercising require a higher caloric intake than when resting, and growing children up to as much as 50 or 60 calories per kilogram, depending on the age. The caloric intake should eventually be such that a progressive loss of weight does not occur. On the other hand, the patient must not gain in weight, or, more correctly, he must not gain in adipose tissue, though muscular development is allowable. Fat, besides that obtained in the eggs and meat fed, may be supplied in the form of bacon, cream, olive oil or butter. If acidosis appears, it is advisable to substitute olive oil for butter and cream or to use washed butter. **Weekly Fast Days.**—For a long time it has been recognized that days of partial or complete fasting are of benefit to the diabetic. Joslin's rule is to fast all patients once a week whose tolerance for carbohydrates is less than 20 gm. When the tolerance is between 20 and 50 gm., 5 percent green vegetables and one-half the usual quantity of protein and fat are allowed on the fast days; when the tolerance is between 50 and 100 gm. of carbohydrates, the 10 and 15 percent vegetables are allowed as well. If the tolerance is more than 100 gm. of carbohydrate, the carbohydrate intake is halved on the weekly fast days. The treatment of **Acidosis** is seldom necessary with proper diet regulations, because under these conditions the development of acidosis of a serious grade is unusual. A few patients do develop a severe acidosis during the fasting period and the indications are to break the fast by allowing a diet strictly of green vegetables. In such cases subsequent fasting frequently causes acidosis to disappear. The dietetic treatment outlined above, however, usually prevents any tendency toward progressive acidosis. In order to check acidosis temporarily, especially if it threatens life, it may be necessary to administer alkalies. This is accomplished by giving **sodium bicarbonate** by mouth, intravenously or subcutaneously (rarely). A half to one

dram is given by mouth every 3 or 4 hours until the evidences of acidosis lessen (the estimation of the carbon dioxid tension of the alveolar air is extremely simple with the use of the Marriott apparatus and is recommended as the easiest and most reliable method of estimating the degree of acidosis and the influence of alkali therapy). If the patient is unable to retain the alkalies by mouth or has approaching coma, the intravenous injection is used. For this purpose a 4 percent solution of sodium bicarbonate may be used and as much as 500 mils at one time is injected slowly. The injection may be repeated as often as the symptoms would indicate or dependent upon the concentration of the carbon dioxid tension in the alveolar air.

Criteria of improvement are: Retention of body weight; obesity; the urine remaining without sugar; carbohydrate tolerance; and absence of fatigue, vomiting, restlessness, drowsiness, listlessness, nausea, vertigo, headache.

Medicinal Treatment.—Of medicines, only 2 have borne the trial of experience: viz., arsenic and opium. The former drug is efficient in mild cases. Fowler's solution, in 5-drop doses, is the most convenient and trustworthy preparation. It should be intermitted at times. Opium is a much more efficient drug, but it has its disadvantages, and should be used only when dietetic treatment and arsenic do not suffice. Any one of the preparations of opium are efficient, but codein is commonly preferred, because its use is attended with fewer of the inconveniences of the other preparations: it constipates less, nauseates less, produces less of the uncomfortable head symptoms so often caused by the use of opiates, and there is decidedly less danger of forming the opium habit. It may be used beginning with 1/4 of a grain 3 times a day, and increased 1/4 of a grain a day until the desired effect is obtained, or until 10 grains a day are given. It should then be as gradually reduced. Much larger quantities have been used. All other drugs are practically useless so far as specific effect on the diabetic process is concerned. Lactic acid, nitrate of uranium, benzosol, antipyrin, antifebrin, and jambul are equally useless. Tonics are required as in other diseases that tend to weaken and exhaust the patient. The continuous use of alkaline mineral waters is helpful. In lieu of such waters, solutions of alkalies—viz., citrate of potassium and sodium bicarbonate—may be given. Aperients are necessary when there is a tendency to constipation. Mercurial purges are especially useful, as engorgement of the liver tends to aggravate the disease, and mercurials relieve this. Salines may be used.

Hygiene is important. The patient should be kept in well-ventilated rooms, should spend as much time as possible out of doors, and should dress suitably in woolen underclothing; for the diabetic is very susceptible to cold, and lung complications often cause his death. Walking and cycling in the open air are especially wholesome if the patient is not too weak and exhausted.

The treatment of diabetic coma promises little, but the patient should immediately be put on milk and Vichy, and potassium citrate in 30-grain doses hourly, well diluted—the more water, the better. Hypodermoclysis with a 0.6 percent solution of sodium chlorid should be practised, and a pint should be introduced at one point and another pint at another. Or, in lieu of this, an alkaline injection, of the strength of 2 ounces of sodium bicarbonate to the pint, should be given by the rectum. The rectum should first be washed out, or, if time permit, an aperient should be given. The reviving effect of hypodermoclysis is magic, but, unfortunately, it is only temporary. This same treatment used in the prodromal stage is more efficient, and the further development of the condition has not infrequently been arrested.

DIABETIN.—Levulose. Fruit sugar. As it is more easily consumed in the system than the other sugars, it is used with advantage in diabetes. Dose, 1 to 2 ounces daily.

DIAPHORETICS.—Remedies that increase the action of the skin and promote the secretion of sweat. When they act energetically, so that the perspiration stands in beads upon the surface, they are known as *sudorifics.* They may be subdivided into the following groups—viz.:

1. **Simple diaphoretics,** which enter the circulation and are eliminated by the sudoriferous glands, which they stimulate to increased action.

2. **Nauseating diaphoretics,** which produce relaxation and the dilatation of the superficial capillaries.

3. **Refrigerant diaphoretics,** which reduce the circulation, at the same time acting directly on the sweat-centers in the spinal cord and medulla.

The principal diaphoretics are enumerated as follows, the figures referring to their respective supposed modes of action, as indicated above (Potter)—viz.:

Aconite.[3]	Camphor.[1]
Veratrum.[3]	Cocaine.[3]
Tobacco.[2,3]	Ammonium acetate.[1]
Lobelia.[2,3]	Ammonium citrate.[1]
Alcohol.[2,3]	Potassium salts.[3]
Ether.[2,3]	Mezereon.[1]
Nitrous ether.[2,3]	Sarsaparilla.[1]
Salicylates.[1]	Guaiacum.[1]
Pilocarpus.[1,3]	Serpentaria.[1]
Pilocarpine.[1,3]	Sassafras.[1]
Ipecacuanha.[2]	Senega.[1]
Opium[2,3](large doses).	Vapor bath.[2]
Dover's powder.[2]	Turkish bath.[2]
Tartar emetic.[2]	Wet pack.[2]
Sulphur.[1]	Warm drinks.[2]

DIAPHRAGM, AFFECTIONS.—These are due to physical interference with the diaphragm, to displacement, to functional disorders—either paralysis or spasm—and to organic lesions.

Displacement may be partial or complete. Pleuritic effusions, empyema, pneumothorax, emphysema of the lungs, abundant pericardial effusion, enlargement of the heart, and tumors are the chief thoracic causes. The abdominal causes of displacement of the diaphragm are distended stomach, tympanites, ascites, peritonitis, pregnancy, large fecal accumulations, and ovarian,

hepatic, splenic, or renal tumors. Tight lacing may embarrass and alter the position of the diaphragm.

Symptoms.—Instead of actual pain, there is a sense of constriction, tension, or tightness of the lower part of the chest. Respiration is more or less impeded, hurried, and oppressed and labored. Spasmodic cough may ensue. The exact position of the parts can be determined only by carefully noting the physical signs.

Paralysis.—When the spinal cord is destroyed at the origin of the phyrenic nerve, or if this nerve is cut, injured, or destroyed on one or both sides, or if severely compressed, either one lateral half or the entire diaphragm will be paralyzed. It may also be affected by diphtheritic paralysis, by lead-palsy, or in hysteria. Death speedily ensues from impediment to the respiration when the entire diaphragm is paralyzed. When one-half is paralyzed, coughing and sneezing cannot be performed, and sputa cannot be easily expelled, while defecation and vomiting are ineffectual or impossible. The lower parts of the lung are more or less collapsed and congested, and if bronchitis sets in, grave danger is at hand. A peculiar dysphonia, in which the voice loses power as the day advances, is developed.

Spasm, either tonic or clonic, may depend upon disorder of the nerve-center, or may be the result of irritation of the phrenic nerve, from direct or reflex excitation of the diaphragm. Tonic spasm is chiefly observed in tetanus, poisoning by strychnin, and in hydrophobia. A form of asthma has been attributed to spasm of the diaphragm; and spasm may result from immoderate laughter. Hiccup is probably due to clonic spasm of the diaphragm, and a spasmodic cough may be due to spasm of this muscle. See Hiccup.

Organic Lesions.—The diaphragm may be perforated, lacerated, or ruptured. Rupture may result from violent strain, as in persistent vomiting or during parturition, or from efforts to suppress cries of pain; or the perforation may be congenital. It may result from empyema, from pulmonary, hepatic, or other abscesses, from aneurysm, or from gastric ulcer. Portions of the thoracic or abdominal viscera may pass through and form a **diaphragmatic hernia.**—See Chest (Injuries). This form of rupture is of little practical interest, since the condition is seldom diagnosed, and, even when diagnosed, the hernia is not very amenable to treatment. The serous covering of the diaphragm is not infrequently involved in pleurisy or peritonitis, and lesions may be caused by extension from pericarditis. Direct injury may cause inflammation of the substance of the muscle. Ulceration and gangrene have been noticed, and chronic inflammation may occur. The symptoms are obscure and ill defined. Muscular rheumatism may affect the diaphragm, causing much pain in coughing and defecation and a sense of aching. Progressive muscular atrophy may involve the diaphragm as well as other muscles. Fatty and fibroid degeneration are the forms most encountered. Brawny induration has been noticed in scurvy. In progressive muscular atrophy the fatal termination may result from paralysis of this muscle. Malignant disease usually involves this structure from extension.

Treatment.—Little can be done in the way of direct treatment, even when a diagnosis is made. Indications are to get rid of any mechanic obstruction to respiration or to the action of the diaphragm. The disease causing functional disturbance is to be treated. Dry heat, fomentations, bandages and supports, and anodynes may relieve the painful affections, while an acute inflammation is to be treated on general principles. Paralysis may call for electric treatment through the phrenic nerve, although this is particularly dangerous from the proximity to the pneumogastric nerve. Hiccup may be relieved by various remedies.

DIARRHEA.*—An abnormal frequency of the evacuation of feces, thin in consistence, and connected with tenesmus.

Etiology.—It is due mainly to two morbid factors: (1) Increased amount of water in the feces, on account of the rapid passage through the jejunum and ileum not permitting of absorption, and on account of abundant secretion and transudation from the vessels and glands; (2) an increase in the rate of peristalsis in the small or large intestine. When bile pigment can be detected in the feces, it is suggestive of diarrhea originating in the small intestine. When the diarrhea is due exclusively to disturbances in the colon, bile pigment is, as a rule, absent from the evacuations.

Classification.—It has been suggested to drop entirely the clinical conception of diarrhea and to class all such symptoms with enteritis and other anatomic alterations of the intestines. This would be incorrect, for there are diarrheas that run their course without any anatomic lesions whatever. Increased peristalsis of the small intestine need not cause diarrhea if the large intestine is not involved; but increased peristalsis of the colon alone causes severe diarrhea when the small intestine is quiescent. If both small and large intestines are involved, the stools will contain more and more undigested food the further up the small intestine is involved. Etiologically, diarrheas may be considered under three headings, viz.: (1) those in which the irritations arise from the intestinal contents; (2) from the nervous system; and (3) from the blood.

Under the first group the following types may be conveniently considered: (*a*) dyspeptic, (*b*) cathartic, (*c*) stercoral, (*d*) entozoic diarrhea.

Dyspeptic Diarrhea.—Caused by certain articles of food—fruits, cucumbers, turnips, and sour milk. Sometimes the diarrhea depends upon the combination of certain foods; for instance, fruit and beer, or milk and cucumbers. Spoiled articles, such as cider and sour beer, and unripe fruit are more detrimental. In some persons milk causes diarrhea, and in others constipation. The gases formed in fermenting food—CO_2, H_2S, CH_4—increase peristalsis. Catarrhal changes of the intestines do not occur in the beginning, but may

*See also the remarks on diarrhea in the article on Constipation.

develop later on. The diarrhea in this case is a curative effort, and should not be checked by constipating medicines.

Cathartic Diarrhea.—This type is due to the ingestion of purgative medicines that act chiefly by increasing the peristalsis. Alkaline salts act by causing an endomosis from the blood-vessels into the intestine, and also by increase of peristalsis. The stools produced by purgatives differ from normal stools mainly in their greater percentage of water—the rapid peristalsis inhibiting absorption.

Stercoral Diarrhea.—This form exists when alternating diarrhea and constipation constitute the main symptoms; it may even exist when there is no history of constipation, but retention of fecal matter occurs that, by its irritating effects on the mucosa, brings about diarrhea. The gases CO_2, CH_4, H_2S, when produced during chronic habitual constipation, may bring on an exaggerated peristalsis. In the beginning stercoral diarrhea is not associated with enteritis, but supervenes when diarrhea is not treated properly or when errors of diet are continued.

Entozoic Diarrhea.—It is very probable that entozoa, certain worms, and infusoria may cause diarrhea, perhaps by mechanic irritation, or, more likely, through chemic toxins that they produce. The relation of certain amebas and cercomonas to DYSENTERY (*q. v.*) is considered under that head. It is not definitely known whether the unicellular protozoa cause diarrhea, but the thread-worm oxyuris and trichocephalus may occasion this symptom, though not invariably.

Nervous Diarrhea.—When the previously mentioned forms can be excluded, this type of diarrhea may be suspected, though it is occasionally difficult to distinguish from the stercoral type. Nervous diarrhea may be caused by (*a*) increased irritation of the nerves that excite peristalsis, (*b*) paralysis of the nerves that inhibit peristalsis, (*c*) increased serous transudation, and (*d*) excitation of the peripheral nervous apparatus contained in the walls of the intestine. Diarrheas that occur after intense fright, fear, or terror belong to this type. They are generally acute attacks, but nervous diarrhea may also constitute a chronic disease. It is usually accompanied by other nervous phenomena, such as giddiness, vertigo, cerebral oppression and congestions, a sensation of alternating heat and cold in various parts of the body, fear, feeling of oppression around the heart, rapid breathing, palpitation—all of which symptoms rapidly disappear after a diarrheic passage has occurred. The number of passages may vary from 2 to 20 in the day, consisting of liquid intestinal contents with very little mucus. The passages are often preceded by active peristaltic unrest and accompanied by tenesmus and borborygmus. Diarrhea occurs very frequently complicated with hysteria, neurasthenia, migraine, and diseases of the genitourinary apparatus. The diagnosis is based upon exclusion of other forms of diarrhea or diseases of the digestive tract, absence of abnormal constituents in the stool, and presence of nervous symptoms. It may, however, occur in individuals that show no signs of nervousness or neurasthenia.

Diarrhea after Taking Cold.—This form is probably brought about by reflex vascular hyperemia of the intestinal mucosa, accompanied by increased serous transudation and mucous secretion. This reflex is mediated through the cutaneous nerves.

Diarrhea Caused by Irritants Acting from the Blood.—Under this heading may be classed the diarrhea occurring in uremia, malaria, septicemia, croupous pneumonia, erysipelas, influenza, and cholera. It is supposed that the poison formed in these diseases is absorbed into the blood-vessels, and reaches the intestinal glands with the blood, causing an enormous increase of secretion. In this way diarrhea may occur in typhoid fever long before enteritis or intestinal ulcers have developed.

Treatment.—The treatment of diarrhea might be briefly summed up as follows: Rest, diet, external heat, castor oil, calomel, and opium. If the disease has not disappeared under the simultaneous use of these means, it is certain that it is not a simple diarrhea, but one of the forms of enteritis or colitis, the treatment of which is considered under its proper heading. The treatment of the dyspeptic diarrhea consists in excluding all food for 24 hours, and giving a saline purge, such as a tablespoonful of Epsom salts, 1/2 of an ounce of castor oil, or 1/10 of a grain of calomel every hour. External warm applications should be made to the abdomen, and the patient should keep very quiet. The cathartic diarrhea produced by the abuse of purgative medicines should not be treated at all, but permitted to recover spontaneously. The stercoral diarrhea should be treated like the dyspeptic form, with castor oil or calomel, though in this case an enema with 1 quart of water is especially beneficial. The entozoic diarrhea is best controlled by diet, rest, warmth, and colon enemas consisting of 5 to 10 grains of nitrate of silver to 1 quart of water; 1 to 2 drams of quinin to the quart of water is an effective injection in diarrhea due to amebæ. The treatment of nervous diarrhea must remove the cause of the fundamental neurasthenia. Hydropathic and electric management may be followed by improvement. Of medicines, the bromid of strontium in doses of 15 grains 4 times a day, and Fowler's solution of potassium arsenite, are occasionally of value. Fowler's solution should be given in doses of 2 drops 4 times a day, gradually increased to 12 drops.

In diarrhea caused by irritants acting from the blood, the underlying causative condition will require careful investigation, and the means of treatment are stated under the headings in which these causative conditions are considered.

The Diet.—The best diet in diarrhea is milk; if the patient is weak, milk and whisky. For chronic diarrhea the following bill of fare is recommended:

Morning:

8 ounces of chocolate boiled in milk.
1 soft egg.
1 piece of toast.

Forenoon, about 11 A. M.:

8 ounces of a decoction of whortleberry (2 1/2 ounces dried berries and 1 pint of water); or—

8 ounces of soup made of toasted flour and bouillon with 1 egg added.

150 grains of scraped lean meat.

2 ounces of well-boiled rice.

Afternoon, 3 P. M.:

8 ounces of whortleberry decoction.

Evening:

8 ounces of maltoleguminose soup with 1 egg.

5 ounces of finely minced breast-meat of boiled chicken.

During the entire day 2 1/2 ounces of toast and 8 ounces of Burgundy or whortleberry wine may be added.

It is useless to consider the endless number of drugs recommended for diarrhea, but discussion may be limited to the use of the cardinal remedy—opium. There is no remedy that checks peristalsis, inhibits excessive secretion, and reduces intestinal pain so well as opium. The denarcotized extract of opium, in doses of 1/2 of a grain combined with 5 grains of tannigen, 3 or 4 times daily, will rarely disappoint in severe cases if used in connection with diet and a preceding dose of castor oil. The discussion of the use of intestinal disinfectants and astringents will be found under other diseases affecting the intestines. See ENTERITIS, etc.

DIARRHEA, INFANTILE.—This is most frequent in children under 2 years of age, though, as is well known, it may occur at any age. It is most prevalent during the summer. The poorer classes in the larger cities are affected in the greatest numbers, although bad hygiene is not essential, as diarrheal affections are not uncommon among the well-to-do in the cities as well as in the country.

Children with lowered vitality from malnutrition or any wasting disease are most subject to attacks, but strong and healthy children are not exempt. In some cases teething seems to be the exciting cause, and in others exposure to damp or cold brings on the attack.

That the food plays an important part in the etiology is shown by the fact that severe cases are very rarely seen in nursing infants, but occur so frequently in those who are hand-fed, and in older children whose diet is not properly selected or regulated.

The milk fed to infants may be impure—spoiled from long standing or contaminated from contact with filthy cans or surroundings and from foul nursing bottles; or, if pure, it may not have been properly modified to meet the requirements of the child's age and powers of digestion. Again, the amount given may be too large or the intervals of feeding too short.

In infants, as well as in older children, overfeeding and food that is not digestible are common causes of diarrheal complaints. Infants are allowed to partake of table food when consideration of their age should eliminate from the diet-list all but properly modified milk; older children consume in large quantities indigestible food or fruit, and fruit that is unripe or partially decayed.

Pathology.—In simple diarrhea there are no anatomic lesions. It is produced by a hypersecretion of the gastric and intestinal glands, and by increased peristalsis, when caused by improper food; the latter being a conservative measure of nature. In the more severe forms (as acute gastrointestinal catarrh, enterocolitis, dysentery) there may be a catarrhal inflammation of the digestive tract, or there may be the various stages of congestion, inflammation, and ulceration, depending in degree upon the severity of the infection and upon the duration of the attack.

Symptoms.—The symptoms are principally an increase in the number of stools—which may reach as high as 20 or more in a day—and a change in their character, the color and consistency varying in different cases or in the same case at different times. In infants they are frequently green, resembling chopped spinach, or they may be very light and contain curds or fat from undigested milk. They usually become, later, very thin, acid, and irritating, excoriating the skin about the anus and buttocks. The odor may be sour or very foul and penetrating. In both infants and older children, when the diarrhea continues for any considerable time, the stools become mucous in character and streaked with blood.

In mild cases the onset may be gradual, with loss of appetite and fretfulness, and the symptoms throughout the attack may be very slight. In more severe cases, however, the onset is more likely to be sudden, with vomiting, high temperature, a hot, dry skin, great thirst, pain, and all the symptoms of a serious illness. The child may be dull, or, on the contrary, restless and excitable; and in infants convulsions are not unusual at any time during the attack.

The course varies greatly—one child recovering in a few days, rapidly regaining its accustomed health, while another will suffer for a period of a week or longer.

In severe cases emaciation is rapid, the face becomes drawn and pinched, the eyes are sunken in their sockets, the anterior fontanel is depressed, and the abdomen is retracted or ballooned up with gas, and is hot, while the rest of the body may be bathed in a cold perspiration. The temperature remains elevated—100° to 103° F., or higher. The tongue is coated, and stomatitis is often present. The urine is scanty and high-colored. Pain, especially before a bowel movement, is a prominent symptom, and is shown in an infant by an agonized expression of the face, by crying, and by twisting and writhing movements of the body, rigid flexion of the legs upon the abdomen, and spasmodic contraction of the extremities.

The prognosis in the simple, noninflammatory diarrheas is favorable, but recurrences are frequent, and there is always danger, unless the attack is cut short, that a more serious form will develop. When enterocolitis is present the prognosis is not so good, many cases terminating fatally. Complications that would influence the recovery of

the patient are convulsions, bronchitis (which is very common), bronchopneumonia, nephritis, and various skin eruptions, as urticaria and eczema.

As sequels there may, and frequently do, occur chronic intestinal catarrh and marasmus.

Prophylaxis consists of improved hygienic surroundings and care, the wearing of woolen clothing next to the skin for those who are susceptible to atmospheric changes, and in all cases a proper regulation of the diet. Since experiments have shown that the house-fly is a carrier of infection, the house, dishes, food, and infants should be screened from flies.

All soiled napkins and clothing of the patient should be disinfected by soaking in a carbolic acid solution 1:40, or some other antiseptic, and should be removed from the room. When the child is soiled from discharges, it should be carefully washed and dried. To prevent the skin about the anus from becoming excoriated, it should be anointed with such preparations as the ointment of zinc oxid or carbolized vaselin, which will act as a protective and be found more efficacious than the usual dusting-powders, which are sufficient when the bowel movements are normal and non-irritating.

Treatment.—For the attack the treatment should be, first, rest for the body by confinement to bed, and rest for the digestive organs by withholding all food for a period of from 12 to 36 hours, according to the indications, giving for this period water or ice to quench the thirst, and bland drinks, such as barley-water, albumin water, or toast-tea in small quantities, frequently repeated. To these may be added every 1 or 2 hours, when the child is weak, 10 or 15 drops of brandy.

Warm baths should be given 2 or 3 times a day, as they assist in the elimination of waste-products from the system, stimulate the cutaneous circulation, and thus have a tendency to lessen the local congestion of the digestive organs.

For the abdominal pain, which may be severe, turpentine stupes, a spice poultice, or a mustard plaster applied to the epigastrium will often give relief.

As stated, food should be withheld until there has been time to clear the alimentary tract of the irritating material that it contains and until the organs have regained to some extent their normal condition. When food is then given, it must at first be administered very weak and in small quantities. For a child under 2 years old a suitable formula to begin with would be 1 ounce consisting of equal parts of whey and water, 10 grains of sodium bicarbonate, and 30 grains of milk-sugar, fed from a bottle every hour; and if this is found to agree with the child, the strength of the mixture may be gradually increased by adding cream, also increasing the amount and the intervals of feeding. Older children may be cautiously fed on such light diet as milk, meat-juice, broths, soft-boiled eggs, and toast in very small quantities at first, not allowing coarse food, such as vegetables, fruit, etc., until the system has regained its normal tone.

Medicinal Treatment.—The first indication for medication is to aid nature in her efforts to clear the alimentary canal. If the stomach has not been emptied by vomiting, and there is reason for assuming that it contains undigested food, an emetic, as a teaspoonful of syrup of ipecacuanha, should be given. Following this, or at first in cases when an emetic is not necessary, some laxative should be given, one of the best being castor oil, or equal parts of castor oil and aromatic syrup of rhubarb, in teaspoonful doses every hour, until the bowels are freely acted upon. Calomel may be used instead of castor oil, and in many cases its action is most beneficial—1/2 of a grain, with 1 grain of bicarbonate of sodium, should be given every hour for 4 or 5 doses, or until its action is shown on the stools.

The colon should be irrigated once or twice a day as long as there is any irritating material left in the bowels.

When improvement is not marked and the diarrhea continues after the treatment outlined has been followed for from 24 to 36 hours, astringents or intestinal antiseptics, or a combination of the two, should be given. One of the following formulas will at this time be found useful for a child 1 to 2 years old, giving smaller doses for a younger child:

℞. Sodium bicarbonate, gr. xxx
Aromatic syrup of rhubarb, ʒ jss
Peppermint water, ʒ v.
One-half to 1 teaspoonful after each bowel movement.

℞. Aromatic sulphuric acid, gtt. xvj
Camphorated tincture of opium, ʒ j
Mucilage of acacia, ʒ iv
Brandy, q. s. ʒ j.
One-half of a teaspoonful after each bowel movement.

℞. Compound tincture of lavender, ʒ iv
Sugar, gr. xxx
Camphor water, ʒ ij.
One or 2 teaspoonfuls every 3 hours.

℞. Salicylate of bismuth, ʒ ij
Glycerin, ʒ ij
Listerine, ʒ iv
Chalk-mixture, q. s. ʒ iij.
One teaspoonful every 2 or 3 hours, as necessary.

℞. Subgallate of bismuth, ʒ ij
Chalk-mixture, ʒ iij.
One teaspoonful every 3 hours.

℞. Deodorized tincture of opium, gtt. xvj
Dilute nitric acid, ʒ j
Glycerin, ʒ iv
Chloroform water, q. s. ʒ ij.
One teaspoonful every 3 or 4 hours.

℞. Arsenite of copper, gr. 1/8
Camphor water, } each, ʒ j.
Cinnamon water, }

During convalescence the following pepsin mixture will be found a useful aid to digestion:

℞. Pepsin, ℥ j
Dilute hydrochloric acid, ℥ ij
Glycerin, ℥ iv
Water, q. s. ad ℥ iij.

One teaspoonful, well diluted with water, after meals.

Tonics, such as tincture of nux vomica, tincture of gentian, iron, etc., are frequently indicated following the attack, and great care should be exercised to keep the child in a healthy condition by proper food, bathing, outdoor exercise, change of air, etc., to guard against recurrences, which are so likely to occur.

DIASTASE.—A nitrogenous vegetable ferment that converts the starch of bread or other farinas into grape-sugar or glucose. It may be used to form a syrupy mixture with preparations of iron or cinchona. It is put in the form of a light yellow powder as a distinct product by manufactures, or contained in extracts of malt.

Taka-diastase is a brownish powder, almost tasteless; soluble in water and insoluble in alcohol. It is a powerful starch digestant, absolutely free from sugars, and is used in amylaceous dyspepsia in small doses—1 to 5 grains.

DIAZO-REACTION.—See Typhoid Fever.

DIETETICS.—Dietetics is the science of the systematic regulation of the diet for hygienic or therapeutic purposes.

Classification of Foods (Yeo).—

Organic — Nitrogenous:
1. Albuminates.—Nitrogenous substances having the same or nearly the same chemic composition as albumin. *Examples.*—Albumin, fibrin, syntonin, myosin, globulin, casein, from the *animal* kingdom; gluten and legumin, from the *vegetable* kingdom.

(*a*) *Subordinate* nitrogenous substances referred to this class, and known as—
Gelatigneous substances: Gelatin. Casein. Chondrin.

Organic — Nonnitrogenous:
2. Fats, or Hydrocarbons, containing carbon, hydrogen, and oxygen; the proportion of oxygen being insufficient to convert all the hydrogen into water. *Examples.*—Olein, stearin, margarin. (Butter is a familiar one.)

3. Carbohydrates, containing carbon, hydrogen, and oxygen; the two latter elements in the proportion to form water. *Examples.*—Starch, dextrin, cane-sugar, grape-sugar, lactose, or milk-sugar.

(*a*) The *vegetable acids*, oxalic, tartaric, citric, malic, acetic, and lactic, are by some authors referred to this class.

Inorganic:
4. Mineral.—Water. *Salts.*—Sodium and potassium chlorids, calcium and magnesium phosphates, iron, etc.

The special diet-lists for such conditions as constipation, diabetes, nephritis, etc., are considered under the special headings of the diseases to which they refer. See Typhoid Fever (Coleman-Shaffer diet).

Constituents of Foods.—The following table (by Atwater and Bryant) shows the composition of some of the more common articles of diet:

	Water Percent	Protein Percent	Fat Percent	Carbohydrate Percent	Ash Percent
Beef, round	73.6	22.6	2.8	.....	1.3
Pork, loin	52.0	16.6	30.1	.....	1.0
Salmon	63.6	17.8	17.8	.....	1.1
Eggs	73.7	13.4	10.5	.....	1.0
Milk	87.0	3.3	4.0	5.0	0.7
Cheese	31.6	28.8	35.9	0.3	3.4
Butter	11.0	1.0	85.0	.....	3.0
Bread (White)	33.2	10.9	1.3	53.6	1.0
Bread (Corn)	38.9	7.9	4.7	46.3	2.2
Rice	12.3	8.0	0.3	79.0	0.4
Oatmeal	7.3	16.1	7.2	67.5	1.9
Beans (Dry)	12.6	22.5	1.8	59.6	3.5
Potatoes (White)	78.3	2.2	0.1	18.4	1.0
Potatoes (Sweet)	69.0	1.8	0.7	27.4	1.2
Strawberries	90.4	1.0	0.6	7.4	0.6
Watermelon (Edible portion)	92.4	0.4	0.2	6.7	0.3

A liquid diet is indicated in many acute conditions, particularly in those of febrile character. The following is an appropriate list:

Soups.—Raw-meat juice, clam broth, chicken broth, vegetable broths, mutton broth, broth with egg, broth of gelatin, beef-tea, clear soups, fruit soup.

Eggs.—Beaten up with water or stimulants.

Foods.—Peptonized milk, malted milk, any of the prepared foods, liquid peptonoids, milk-toast, arrow-root, Indian-meal gruel, oatmeal gruel, ground rice, pounded raw meat, oysters; later, meat and calf's-foot jellies.

Beverages.—Skim-milk, 2 quarts daily; buttermilk, whey, koumiss, barley-water, rice-water, toast-water, jelly-water, gum-arabic water, lemonade, pure nonpurgative mineral waters, fruit-juices, egg lemonade, egg-nog, cocoa.

A Light Diet. Soups.—Any clear soup not highly seasoned.

Meats.—Scraped beef or mutton, pounded raw meat, sweetbread, beef-juice, liquid peptonoids.

Eggs.—Raw, lightly boiled, poached.

Farinaceous.—Crackers, toast, rice boiled with milk, arrowroot, tapioca, sago, well-boiled gruel; brandy or port wine may be added to the arrow-root or gruel.

Dessert.—Milk foods, milk and egg puddings if not sweetened.

Beverages.—Sterilized or pasteurized milk, skim-milk, milk with lime-water, peptonized milk, strong tea, lactic acid water, toast-water, rice-water, koumiss, egg lemonade, and nonpurgative mineral waters.

Articles Prohibited.—Vegetables, soups, new bread, brown and Graham bread, oatmeal, cooked or raw fruits, fried foods, fish, sweet foods, nuts, salt meats, veal, pork.

A sufficient though restricted diet, such as might be called for in convalescence or in persons with impaired assimilation, is as follows:

Soups.—Clear soups.

Fish.—Fresh fish, oysters, and little-neck clams; none of these may be fried.

Meats.—Meat-juice, roast or broiled beef, mutton, chicken, venison, tongue.

Eggs.—Raw, soft-boiled, poached on toast, omelet combined with chicken or oysters.

Farinaceous.—All kinds of bread at least 1 day old; Zwieback, crackers, cream crackers, cracked wheat, rice, sago, tapioca, macaroni, arrowroot, corn-meal, hominy, wheaten grits, Graham grits, vermicelli, rolled rye, rolled oats.

Vegetables (best made into purée by passing through a colander or mashing).—Greens—spinach, lettuce, water-cresses—French beans, sweet corn, green peas, asparagus, celery, artichokes, baked tomatoes, potatoes (sparingly).

Dessert.—Fruit, rice, tapioca, Indian, and farina puddings; custards, orange charlotte, gelatin creams, blanc-mange, baked and stewed apples and pears, grapes, and all ripe fruits except bananas and pineapples. No rich sauces may be used.

Beverages (drinks should be taken near the end of meals).—Hot water before meals, milk, lime-water, pure mineral waters, weak tea (1/2 of an ounce to the pint), koumiss, weak cocoa, peptonized cocoa and milk, butter-milk, acid wine (if acidity).

Articles Prohibited.—Rich soups and chowders, all fried foods, veal, pork, liver, kidney, hashes, stews, pickled and corned meats, preserved and potted meats, turkey, goose, duck, sausage, salt mackerel, bluefish, sturgeon, eels, shrimps, sardines, lobster, crabs, cabbage, cauliflower, cucumbers, string-beans, parsnips, egg-plant, turnips, carrots, squash, oyster-plant, sweet potatoes, beets, pastry, pies, made dishes, nuts, dates, jams, dried and candied fruits, candies, cheese, strong tea, ice water, malt liquors, sweet and effervescent wines, spirituous liquors.

The feeding of infants is considered under the headings of INFANT FEEDING and MILK (*q. v.*).

Recipes for the Sick-room Dietary (Thomas):

Toast-water.—Toast 3 slices of stale bread to dark brown, but do not burn; put into a pitcher; pour over them a quart of boiling water; cover closely and let stand on ice until cold; strain. Wine and sugar may be added.

Rice-water.—Pick over and wash 2 tablespoonfuls of rice; put into a granite saucepan with 1 quart of boiling water; simmer 2 hours, when the rice should be softened and partially dissolved; strain, add saltspoonful of salt; serve warm or cold. Sherry or port, 2 tablespoonfuls, may be added.

Gum-arabic Water.—Dissolve 1 ounce of gum-arabic in a pint of boiling water; add 2 tablespoonfuls of sugar, wineglassful of sherry, and juice of 1 large lemon; cool, add ice.

Barley-water.—Wash 2 ounces (wineglassful) of pearl barley with cold water; boil 5 minutes in fresh water; throw both waters away; pour on 2 quarts of boiling water; boil down to a quart; flavor with thinly cut lemon-rind; add sugar to taste; do not strain unless at the patient's request.

Egg-water.—Stir the whites of 2 eggs into 1/2 of a pint ice-water without beating; add enough salt or sugar to make palatable.

Flaxseed Tea.—Flaxseed, whole, 1 ounce; white sugar, 1 ounce (heaping tablespoonful); licorice root, 1/2 of an ounce (2 small sticks); lemon-juice, 4 tablespoonfuls. Pour on these materials 2 pints of boiling water; let stand in hot place 4 hours; strain off the liquor.

Sterilized Milk.—Put the required amount of milk in clean bottles (if for infants, each bottle holding enough for one feeding); plug mouths tightly with rubber stoppers; immerse to shoulders in kettle of cold water; boil 20 minutes; or, better, steam 30 minutes in an ordinary steamer; push stoppers in firmly; cool bottles rapidly, and keep in refrigerator; warm each bottle just before using.

Peptonized Milk. *Cold Process.*—In a clean quart bottle put 1 peptonizing powder (extract of pancreas, 5 grains; bicarbonate of sodium, 15 grains) or the contents of 1 peptonizing tube (Fairchild); add one teacupful of cold water, shake; add 1 pint of fresh cold milk, shake the mixture again; place on ice; use when required without subjecting to heat. *Warm Process.*—Mix peptonizing powder with water and milk, as previously described; place bottle in water so hot that the whole hand can be held in it for a minute without discomfort; keep the bottle there 10 minutes; then put on ice to check further digestion. Do not heat long enough to render milk bitter.

Milk and Egg.—Beat milk with salt to taste; beat white of egg until stiff; add egg to milk and stir.

Peptonized Milk-toast.—Over 2 slices of toast pour a gill of peptonized milk (cold process); let stand on the hob for 30 minutes. Serve warm, or strain and serve fluid portion alone. Plain light sponge cake may be similarly digested.

Baked Flour Porridge.—Take 1 pint of flour and pack tightly in small muslin bag; throw into boiling water and boil 5 or 6 hours; cut off the outer sodden portion, grate the hard core fine; blend thoroughly with a little milk and stir into boiling milk to the desired thickness.

Kumyss.—Take an ordinary beer-bottle with shifting cork; put in it 1 pint of milk, 1/6 of a cake of Fleischmann's yeast, or 1 tablespoonful of fresh lager-beer yeast (brewer's), and 1/2 of a tablespoonful of white sugar reduced to syrup; shake well and allow to stand in refrigerator 2 to 3 days, when it may be used. It will keep there indefinitely if laid on its side. Much waste can be saved by preparing the bottles with ordinary corks wired in position and drawing off the koumiss with a champagne tap.

Wine Whey.—Put 1 quart of new milk in a saucepan, and stir over clear fire until nearly boiling; then add a gill (2 wineglassfuls) of sherry, and simmer a quarter of an hour, skimming off curd as it rises. Add a tablespoonful more sherry, and skim again for a few minutes; strain through coarse muslin. Two tablespoonfuls of lemon-juice instead of wine may be used.

Junket.—Take 1/2 of a pint of fresh milk, heated luke-warm; add 1 teaspoonful of essence of pepsin, and stir just enough to mix; pour into custard cups, let stand until firmly curded; serve plain or with sugar and grated nutmeg. Sherry may be added.

Egg Lemonade.—Beat 1 egg with 1 tablespoonful of sugar until very light; stir in 3 tablespoonfuls of cold water and juice of a small lemon; fill glass with pounded ice and drink through straw.

Egg-nog.—Scald some new milk by putting it, contained in a jug, into a saucepan of boiling water; *but do not allow it to boil.* When cold, beat up fresh egg with a fork in a tumbler with some sugar; beat to a froth, add a dessertspoonful of brandy, and fill up the tumbler with scalded milk.

Nutritious Coffee.—Dissolve a little isinglass or gelatin (Knox) in water, put 1/2 of an ounce of freshly ground coffee into a saucepan with 1 pint of new milk, which should be nearly boiling before the coffee is added; boil together for 3 minutes; clear it by pouring some of it into a cup and dashing it back again; add the isinglass, and leave it to settle on the hob for a few minutes. Beat up an egg in a breakfast cup, and pour the coffee upon it; if preferred, drink without the egg.

Rum Punch.—White sugar, 2 teaspoonfuls; 1 egg, stirred and beaten up; warm milk, large wineglassful; Jamaica rum, 2 to 4 teaspoonfuls; nutmeg.

Champagne Whey.—Boil 1/2 of a pint of milk; strain through cheese-cloth; add a wineglassful of champagne.

Peptonized Oysters.—Mince 6 large or 12 small oysters; add to them, in their own liquor, 5 grains of the extract of pancreas with 15 grains of bicarbonate of sodium (or 1 Fairchild peptonizing tube). The mixture is then brought to blood-heat, and maintained, with occasional stirring, at that temperature 30 minutes, when 1 pint of milk is added and the temperature kept up 10 to 20 minutes. Finally the mass is brought to boiling-point, strained, and served. Gelatin may be added, and the mixture served cold as a jelly. Cooked tomato, onion, celery, or other flavoring suited to individual taste may be added at the beginning of the artificial digestion.

Beef-tea.—Free a pound of lean beef from fat, tendon, cartilage, bone, and vessels; chop up fine, put into a pint of cold water to digest 2 hours. Simmer on range or stove 3 hours, *but do not boil.* Make up for water lost by adding cold water, so that a pint of beef-tea represents 1 pound of beef. Press the beef carefully and strain.

Beef-juice.—Cut a thin, juicy steak into pieces 1 1/2 inches square; brown separately 1 1/2 minutes on each side before a hot fire; squeeze in a hot lemon-squeezer; flavor with salt and pepper. This may be added to milk or poured on toast.

Beef-tea with Acid.—One and a half pounds of beef (ground) cut in small pieces; same quantity of ice, broken small. Let stand in deep vessel 12 hours. Strain thoroughly and forcibly through coarse towel. Boil quickly 10 minutes in porcelain vessel. Let cool. Add 1/2 of a teaspoonful of acid (or acid phosphate) to the pint.

Mutton Broth.—Lean loin of mutton, 1 1/2 pounds, including bone; water, 3 pints. Boil gently until tender, throwing in a little salt and onion, according to taste. Pour out broth into basin; when cold, skim off fat. Warm up as wanted.

Chicken Broth.—Skin and chop up fine a small chicken or half a large fowl; boil it, bones and all, with a blade of mace, a sprig of parsley, 1 tablespoonful of rice, and a crust of bread, in a quart of water, for an hour, skimming it from time to time. Strain through a coarse colander.

Clam Broth.—Wash thoroughly 6 large clams in shell; put in a kettle with 1 cup of water; bring to a boil and keep there 1 minute; the shells open, the water takes up the proper quantity of juice, and the broth is ready to pour off and serve hot.

Cream Soup.—Take 1 quart of good stock (mutton or veal), cut 1 onion into quarters, slice 3 potatoes very thin, and put them into the stock with a small piece of mace; boil gently for an hour; then strain out the onion and mace; the potatoes should, by this time, have dissolved in the stock. Add 1 pint of milk, mixed with a very little corn-flour to make it about as thick as cream. A little butter improves it. This soup may be made with milk instead of stock, if a little cream is used.

Apple Soup.—Two cups of sliced apples; 2 cups of water; 2 teaspoonfuls of corn-starch; 1 1/2 tablespoonfuls of sugar; 1 saltspoonful of cinnamon and a pinch of salt. Stew the apples in the water until very soft, then mix together into a smooth paste the corn-starch, sugar, salt, and cinnamon, with a little cold water; pour this into the apples and boil for 5 minutes; strain it and keep hot until ready to serve. May be served with hot buttered sippets.

Raw-meat Diet.—Scrape pulp from a good steak, season to taste, spread on thin slices of bread; sear bread slightly and serve as sandwich.

Meat Cure.—Procure a slice of steak from top of round—fresh meat without fat; cut meat into strips, removing all fat, gristle, etc., with knife. Put meat through mincer at least twice. The pulp must then be well beaten up in a large saucepan with cold water or skimmed beef-tea to consistency of cream. The right proportion is 1 teaspoonful of liquid to 8 of pulp; add black pepper and salt to taste; stir mince briskly with wooden spoon the whole time it is cooking, over slow fire or on cool part of covered range until thoroughly hot and the red color disappears. This requires about 1/2 hour. When done, it should be a soft, smooth, still purée of the consistency of a thick paste. Serve hot. Add for first few meals the softly poached white of an egg.

DIGALEN.—Liquor Digitoxin Solubilis. A uniform solution of the active principle of digitalis containing no inert or antagonistic principles. Digalen is said to consist of 1 part of soluble digitoxin (Cloetta) in 1000 parts of glycerin, and 1600 parts of distilled water with 7.5 percent of alcohol. Owing to its far greater solubility this amorphous digitoxin is said to have the advantage over the crystalline form of prompt action, and of not producing irritation; and because of its more rapid diffusion and elimination it is said to have no cumulative effect. Dose, 16 minims.

DIGESTANTS.—A name sometimes given to the adjuvants to gastric digestion. The digestion ferments are pepsin, pancreatin, ingluvin, papain, and dilute hydrochloric acid. They are used to

supplement the action of deficient gastric juice, and are fully discussed under their separate headings.

DIGESTION, DISORDERS.—See Gastric Neuroses, Gastritis, Enteritis, etc.

DIGITALIS (Foxglove).—The dried leaves of *D. purpurea* of the second year's growth, growing wild in Europe and cultivated in America, often in private gardens for its beautiful spike of purple flowers. It is one of the most unreliable drugs in respect to its physiologic activity. The active principle is said to be digitalin, an amorphous product of complex composition that, however, does not represent the full properties of digitalis leaves. No alkaloid is contained in the drug. Four other glucosids are obtained from it—digitoxin, digitalein, digitonin, and digitin. The first two are active cardiac stimulants and are highly poisonous. The third is a direct depressant of the heart, antagonizing the stimulant action of the others.

Therapeutics.—The 3 important uses of digitalis are (1) to act as a powerful cardiac stimulant, (2) to slow the heart and regulate its rhythm, and (3) to act as a diuretic. As a cardiac stimulant it is indicated in weak heart, in syncope, collapse, and poisoning by cardiac depressants, especially aconite, and in dilatation of the heart. Dyspnea, dropsy, and feeble pulse are the indications for its use in valvular diseases of the heart. It is not so serviceable as strychnin in fatty degeneration. When the diuretic action of digitalis is desired, the infusion is the most suitable preparation in doses of 1/2 ounce, four times a day, to be reduced one-half when the desired effect is obtained or the pulse rate falls below 50 beats per minute. Nitroglycerin may advantageously be combined with digitalis when the peripheral resistance in the arterioles is very marked. In the second stage of pneumonia, in exhausting fevers, and in congestion of the lungs in typhoid fever, the drug is serviceable. When circulation is sluggish in congestion of the kidneys, digitalis acts as a diuretic. A cumulative action is said to occur in the course of administration when, in ascites or dropsy, paracentesis is performed. Signs of poisoning then ensue. To avoid this toxic action it is advised that the drug be withheld for 24 to 36 hours before paracentesis is performed.

The contraindications to the use of digitalis are marked atheroma of blood-vessels, aneurysm, apoplexy and other states of arterial excitement, arrhythmia when due to depressed conductivity, and gastric irritation. See also under Heart-disease.

In dropsy:

℞. Tincture of digitalis, ʒ j to ij
Tincture of squill, ʒ ij
Compound spirit of juniper, ʒ iv to vj
Acetate of potassium, ʒ iv
White wine, enough to make ʒ vj

A tablespoonful 3 or 4 times daily.

℞. Powdered digitalis, Powdered squill, each, ʒ ss
Potassium nitrate, ʒ j.

Make into a mass and divide into 30 pills. One pill thrice daily.

For cystitis:

℞. Tincture of digitalis, ♏ lxxx
Citrate of potassium ʒ ss
Spirit of chloroform, ʒ ijss
Infusion of buchu, ʒ viij.

Two tablespoonfuls 3 or 4 times daily.

In acute Bright's disease:

℞. Potassium acetate, ʒ ijss
Infusion of digitalis, Infusion of juniper, each, ʒ iij.

A tablespoonful every 2 to 4 hours as a diuretic.

In acute bronchitis when valvular lesions exist:

℞. Tincture of digitalis, ʒ ij
Aromatic spirit of ammonia, ʒ j
Spirit of ether, ʒ iv
Spirit of chloroform, ♏xl.

Give a teaspoonful in a small wineglassful of water every 3 hours.

Poisoning.—The slow, full pulse is followed by a shuttle-like, hobbling, dicrotic pulse, and the heart beats against the chest-wall in angry, tumultuous throbs. Vomiting occurs, with exopthalmos and a peculiar blue pearliness of the sclera. Consciousness is preserved until near death.

The treatment of this condition of poisoning includes the use of the stomach-pump, emetics when the heart is not much affected, the application of external heat, especially about the abdomen, the maintenance of the horizontal position, the administration of tannic acid as the chemic antidote, and of tincture of aconite as the physiologic antidote.

Incompatible with *Digitalis* are: Acids, alkalies, alkaloidal precipitants, cinchona infusion, ferrous sulphate, lead acetate, tannic acid, vegetable astringents, syrupy and aqueous solutions. Physiologically incompatible are: Aconite, chloral hydrate, cocain, glonoin, muscarin, saponin, scoparin, strychnin.

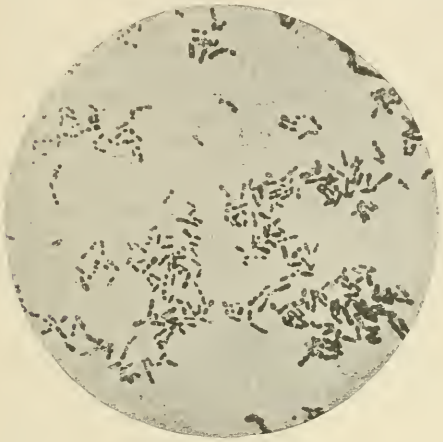
Preparations.—The dose of the leaves is 1/2 to 2 grains. **D., Ext.** Dose, 1/8 to 1/2 of a grain. **D., Flext.** Dose, 1/2 to 3 minims. **D., Infusum,** 1 1/2 percent in strength. Dose, 1 to 3 drams. **D., Tinct.,** 10 percent. Dose, 5 to 20 minims.

DIONIN.—Ethylmorphin hydrochlorid. A derivative of morphin, used as a substitute for other opium alkaloids and as an analgesic. Its indications and dosage are the same as those of Codein (*q. v.*).

DIPHTHERIA.—An acute infectious disease caused by the Klebs-Loeffler bacillus, and characterized primarily by local, and secondarily by constitutional, symptoms—the latter being due to the absorption of toxins produced by the growth of the bacillus upon the mucous membrane.

Diphtheria Bacillus.—This microorganism was first discovered by Klebs in 1883, and was isolated,

cultivated, and described by Loeffler in 1884. It is about the length of the tubercle bacillus and about twice as broad. It is frequently curved, and has rounded ends, one of which is sometimes swollen. It does not grow in chains, but is isolated. In the swab from the throat the streptococcus may slightly resemble this bacillus after being stained. This is due to the fact that the Klebs-Loeffler bacillus is very polymorphous. It is nonmotile and does not contain flagella or spores. It grows well upon artificial culture media, such as gelatin, agar-agar, potato, and milk.



Bacillus of Diphtheria.—(*After Fränkel and Pfeiffer.*)

It can be stained by the following solution:
Saturated alcoholic solution of methylene-blue, 30 parts,
Aqueous solution of caustic potash (1 : 10,000), 100 parts.

An aqueous solution of dahlia may also be used. If searched for in the tissues, Gram's method is preferable.

See Method of Staining, under Pathologic Technic.

The contagium is principally in the secretions of the nose and throat. Diphtheria is a toxinemia and the bacilli are not distributed in the blood or through the body, but are found at the site of, and in the parts adjacent to, the local disease. To the absorption of the toxic substance produced by the bacilli are due the general symptoms of the disease.

This toxalbumin injected into animals causes nephritis and albuminuria and paralysis.

Diphtheria is communicated by direct contact, as by kissing, or by the patient coughing or spitting in the face of another person; and indirectly by eating, utensils, toys, clothing, or anything that may have become infected by contact with the patient. The infection may be communicated during the incubation stage as well as during the attack, and for a considerable period following it—3 weeks at least—and as long as there are any of the bacilli present, and probably as long as there is any discharge from the throat, nose, ears, or other parts.

A lesion of the mucous membrane is necessary for the development of the disease, and any unhealthy condition of the nose or throat predisposes to the infection.

The incubation period is short—from 1 to 4 days; probably never longer than 7 days, although it is possible for the germs to remain in the mouth for an indefinite period, and finally, if the mucous membrane becomes weakened, produce the disease.

Pathology.—The formation of a pseudomembrane is the most constant lesion of diphtheria. This may occur upon any mucous surface, or may affect a freshly wounded surface of the skin, but is most commonly seen on the mucous membrane of the upper air-passages, as the tonsils, pharynx, soft palate, nose, or larynx. It is composed of fibrin, cells, granular matter, and bacteria. While it is usually of a mouse-gray color, it may vary from a white to yellow, green, or almost black color. A false membrane, similar in appearance, may be caused by other bacteria or by irritants. On the other hand, the Klebs-Loeffler bacillus may produce only a catarrhal inflammation, without the formation of the membrane.

There are present, due to the poison of diphtheria, degenerative changes in the cells of certain organs of the body—especially of the liver, nervous system, heart-muscle, spleen, and lymph-glands, and due to the invasion of the system by other organisms, as the streptococcus and pneumococcus—affections of the kidneys and lungs, or possibly a general septicemia.

Symptoms.—The symptoms, both local and constitutional, vary greatly in extent and severity. Locally, there may be only a catarrhal condition of the throat, with the bacilli present, but without the formation of a pseudomembrane; again, there may appear only a small patch upon the mucosa, or, on the other hand, the amount of pseudomembrane may be so great as to cover the tonsils, pharynx, soft palate, and uvula, and also extend to the nose, larynx, trachea, and bronchial tubes. Other mucous membranes, such as the vaginal and intestinal, and the conjunctival, are rarely attacked by diphtheria. Constitutional symptoms may be so slight as to pass almost unnoticed, or may reach the opposite extreme, the patient being prostrated, the fever high, the tongue parched, a fetid discharge from the nose, the throat and neck swollen and painful, food refused or taken with the greatest difficulty, and, when the larynx is involved, added to this picture of suffering is the noisy and difficult breathing of membranous croup.

Diphtheria, especially in young children, may begin abruptly, with chilliness, vomiting, or perhaps a convulsion. Usually, however, the onset is gradual, the child being indisposed, with perhaps a trifling sore throat for a day or two, and but a slightly increased temperature.

These symptoms increase steadily for 4 or 5 days, when the disease reaches its height. From the first the fauces and tonsils are a dull red color, the pseudomembrane appearing from the second to fourth day, usually first on the tonsils, and gradually or rapidly, according to the severity of the case, spreading to the fauces, back of pharynx, and uvula. This exudate is very adherent to the

parts, and when separated, leaves a bleeding surface.

The breath now becomes very offensive, swallowing is painful, the lymphatic glands at the angle of the jaw are swollen, and the pulse becomes rapid and weak, the appetite is lost, and the patient is greatly prostrated. Albumin, sometimes in great quantities, is usually present in the urine during the attack.

In uncomplicated cases the temperature is seldom high, ranging from 100° to 103° F. The symptoms mentioned continue until about the seventh or eighth day, when, if the course of the disease is favorable, there is noticed an improvement in the general condition, the membrane becomes loosened, and may be pulled away in large pieces. The swelling of the neck diminishes, fever declines, and by the end of a week the patient is convalescing, though still weak and usually very anemic. Convalescence is likely to be slow, and the heart's action remains feeble for weeks.

In unfavorable cases death most commonly occurs during the height of the local disease, the symptoms all growing more severe and death ensuing from asthenia, due to the poison of the disease. Another common case of death is heart failure, which comes on suddenly and may occur at any time during the course of the disease.

Death may also occur from extension of the disease to the larynx, or from complications, as bronchopneumonia, septicemia, or nephritis.

It is well to remember that an acute purulent rhinitis, unless caused by a foreign body in the nares (in which case it would be one-sided), is likely to be diphtheritic and therefore infectious. Since the introduction of diphtheria antitoxin the course of the disease, as well as the prognosis, has undergone a marked change; so that in average cases in which antitoxin has been given early, the exudate disappears in 24 to 48 hours after the injection, all alarming symptoms subside, and convalescence is established.

Complications and Sequels.—The most common complication is nephritis. Capillary bronchitis, bronchopneumonia, endocarditis and arthritis are met with. The most important sequel is paralysis. This involves most frequently the palate; next in frequency the muscles of deglutition, sometimes the eye muscles.

Diagnosis.—Diphtheria must be differentiated from other affections accompanied by an inflammation of, and perhaps an exudate on, the mucous membrane, especially from follicular tonsillitis.

In making this diagnosis the history of the case is important. Diphtheria is most common in children under ten years of age, and inquiry would elicit the fact of a probable exposure. The gradual onset and low temperature are characteristic of this disease, and enlargement of the cervical glands is usually present early.

Follicular tonsillitis often follows an overindulgence in rich food or pastry—the onset is sudden, temperature higher, the tonsils usually more acutely congested, and the exudate is *in* the follicles, while in diphtheria it is *on* the surface, is adherent, so that forcible removal is followed by bleeding, and the false membrane spreads to the adjacent structures in a typical manner. The gastric disturbances, coated tongue, and anorexia may be present in either affection.

In many doubtful cases a clinical diagnosis is impossible, and a culture showing the presence or absence of the diphtheria bacillus will alone remove the doubt. This bacteriologic test should be made in all cases in which there is any suspicion as to the origin of the disease, as only by this means is it possible to guard against infection from an apparently benign inflammation that in reality is diphtheritic, and that may, by infecting another, give rise to the most severe form of the disease.

Quite recently the **Schick reaction** has attracted some attention. Schick uses a toxin solution intradermically to determine the susceptibility of a patient to diphtheria; he injects 1 c.c. of toxin solution, and if the patient is *not* immune a reaction occurs somewhat similar to the von Pirquet reaction in tuberculosis. (And see DIPHTHERIA ANTITOXIN.)

Prognosis.—Practically, the prognosis of diphtheria is determined by the interval between the onset and the administration of antitoxin; provided a sufficient dose be injected. It is never safe to give too favorable an opinion as to the outcome of diphtheria, as the mildest cases may prove fatal, the physician often being disappointed in his expectations of an eventual happy issue, and complications causing a fatal result may arise at any time. The rapidity of the spread of the exudate and the degree of toxemia, as shown by the pulse and the nervous symptoms, are, as a rule, a reliable guide to the prognosis. The previous condition of the patient must also be considered, and the age is an important element, as the mortality rate in older children is low, and in adults diphtheria is rarely fatal.

In giving the prognosis it must be remembered that paralysis following diphtheria occurs in a large percentage of even very mild cases. It usually appears from 2 to 4 weeks after the attack, and is first noticed by the nasal tone of the voice, and from the fact that liquids, when swallowed, are regurgitated through the nose, as the palate is usually the first and often the only part affected. The extremities, pharynx, larynx, and muscles of the eye may also be involved. The course of diphtheritic palsy is nearly always to recovery, but it may continue for a period of several months.

Treatment. Prophylactic.—All cases of diphtheria should be isolated, and other members of the family kept from school or other places to which they may carry the infection. The danger is not that they will carry the disease on their clothing, but that they may have become infected, and have the germs of the disease in their mouths or throats. Quarantine, therefore, is necessary for 10 days or 2 weeks following the time when they may have been exposed.

It is important that a child's teeth, mouth, and nose should be kept in a healthy condition at all times, but this is especially true when there is danger of exposure to diphtheria. All the hangings, carpets, and unnecessary furniture should be removed from the sick-room which latter should

be large, well-ventilated, sunny, and kept scrupulously clean.

Any clothing or other articles that may have become infected should be soaked in a solution of carbolic acid (1 : 20) or bichlorid of mercury (1 : 1000), and afterward boiled, to sterilize them.

Other children in the family and the attendant nurse should be given an immunizing dose (1000 units) of antitoxin, and cultures should be taken on alternate days from the throats of all persons exposed to infection, until the patient is convalescent.

Curative.—As soon as the exudate is discovered, antitoxin treatment must be begun (as described in the following article), without waiting for bacteriologic confirmation of the clinical diagnosis.

The attendant or nurse should be careful to avoid infection, and the danger of this is slight if proper precautions are taken. She should take exercise daily in the open air, should gargle the throat frequently with an antiseptic solution, and should be careful that the secretions from the patient do not get into the eyes, nose, or mouth.

The room occupied by the patient including mattresses, pillows, etc., should be disinfected with formaldehyd or with sulphur. The convalescent patient should be isolated until thoroughly disinfected by a bichlorid, carbolic acid or alcohol bath for several successive days and by similar treatment of the hair.

A patient with diphtheria should be kept in bed, and not allowed to get up for any purpose, thus putting as little strain as possible on the heart. The food—preferably milk—should be given at regular intervals, and, if necessary, the patient, should be forced to take it. Water (to which has been added a tablespoonful to the quart of the following solution) should be kept boiling in the room.

℞. Oil of eucalyptus, Carbolic acid, each, ʒ j
Spirit of turpentine, ʒ vj.

Local treatment by sprays, etc., should not be forced upon an intractable child, as the excitement and exhaustion produced by resistance may be very harmful.

Syringing is an efficient method of cleansing the nose and throat. For injecting a liquid into the nose a small glass or rubber syringe with a soft-rubber tip should be used, and when this is done carefully from the beginning of the attack, the child will seldom rebel. Older children, or those more easily managed, should also gargle their throats and wash their mouths every 3 or 4 hours.

Nothing is better for irrigation or gargle than normal salt solution; next in efficiency is hydrogen dioxid diluted with an equal quantity of glycerin and twice the quantity of water. Strong alkaline and other antiseptic solutions are irritating and should not be used. It has been found by careful experiments that normal salt solution will cause disappearances of the bacilli from the throat more promptly than any other agent.

Recently pyocyanase, an enzyme obtained from a culture of the bacillus pyocyaneus, has been advocated as a local application by reason of its marked bacteriolytic properties.

Internally, at the beginning of an attack, give 1/6 of a grain of calomel every hour until the bowels are freely moved, and after that the following mixture:

℞. Mercuric chlorid, gr. j
Chlorate of potassium, ʒ j
Tincture of chlorid of iron, ʒ iij
Glycerin, ʒ jss
Water, q. s. ʒ vj.

To a child 4 or 5 years old a teaspoonful every 4 hours.

After 3 or 4 days it is well to omit the mercuric chlorid in the foregoing formula and add strychnin sulphate in the same quantity.

Alcohol should be given early and throughout the attack if the heart is at all weak. A teaspoonful of brandy or whisky, well diluted with water, may be given every 1 or 2 hours, when there are symptoms of heart failure, and every 3 or 4 hours at other times, to a child 4 or 5 years old.

During convalescence tonics and iron are indicated, which may be given in the following pill or capsule:

℞. Strychnin sulphate, Arsenic trioxid, each, gr. ss
Dried iron sulphate, Quinin sulphate, each, gr. xxiv
Extract of gentian, ʒ j.

Make into 24 pills, giving one 3 times a day.

The most efficient method of combating diphtheria is by treatment with **antitoxin**, though it should be remembered that when this remedy is used the local and general measures mentioned should be none the less vigorously pursued. To secure the best results from antitoxin it should be given early and in large doses, as stated in the following article, which see. Laryngeal obstruction demands special measures. See Intubation and Tracheotomy for the indications and technic of these operations.

DIPHTHERIA ANTITOXIN.—Diphtheria antitoxin is prepared by growing on a culture medium the bacilli of diphtheria, which are later destroyed by adding to the medium a weak antiseptic solution and subsequently removing by filtration the organisms that have thus been killed. The filtrate, which contains only the toxins secreted or generated by the bacilli, is then injected into a horse in very small quantities at first, repeating the injections at intervals, and increasing the dose gradually, until at the end of 2 or 3 months the serum of the horse, being tested, will show that antitoxin of proper strength has been formed.

The antitoxin unit is fixed by law and is under the control, in the United States, of the Hygienic Laboratory of the Public Health Service. The

immunity unit is the quantity of antitoxin which will neutralize 100 minimum lethal doses of toxin for a guinea-pig weighing 250 gms.

"A number of test doses of the toxin are prepared, each containing a hundred times the minimum fatal dose. To each test dose is added a measured quantity of the serum in question. To one dose is added 0.01 c.c. of the serum; to another, 0.05 c.c. of the serum; to another, 0.1 c.c. of the serum; to another, 0.5 c.c.; and to still another 1 c.c., and so on. The mixtures are now injected into guinea-pigs and the results observed. Animals not dying within four days were protected; local infiltration, wasting or death after the fourth day does not enter into the computation. The mixture containing the smallest amount of serum and yielding this result contains 1 immunity unit. If 0.05 c.c. of a serum neutralizes 100 times the minimum lethal dose, each cubic centimeter contains twenty immunity units. Antitoxin as placed upon the market, is labeled as containing a certain number of immunity units, and the measured quantity of serum necessarily varies, as the number of units obtained are rarely exactly the same in two animals" (Coplin).

The antitoxic serum now on the market varies in strength from 100 to 1000 units to the cubic centimeter, the dosage being regulated by the immunizing units represented, and not by the quantity of the serum. The horse is selected in the preparation of diphtheria antitoxin because it is naturally immune to diphtheria, is easily operated upon, and furnishes large quantities of serum.

The treatment does not affect the horses' health, nor are they at any time made to suffer pain, except that of the introduction of a large-sized hypodermic needle, which in them is very slight indeed.

The results of this remedy are shown a few hours after administration, by a decrease in both the local and constitutional symptoms. The swelling of the throat decreases, the membrane ceases to spread, the pulse and temperature are reduced, and, finally, the membrane disintegrates and disappears much sooner than in cases not treated with antitoxin.

Dosage.—Whenever diphtheria is suspected, antitoxin should be given at once. Antitoxin does no harm where the disease is not diphtheria, and delay in a true case may be fatal.

Very much larger doses of antitoxin are given now than formerly. Thus the beginning dose was 1000 *units* for ordinary pharyngeal diphtheria. Now 3000 units are a frequent initial dose, and even more is given in bad cases, 7000 to 10,000. In laryngeal diphtheria at least 5000 units should be given at the first dose. The "concentrated" form is preferred on account of its small bulk. The "standard" is cheaper and just as efficacious, but more painful because of its greater bulk.

If decided improvement is not noticed in 10 or 12 hours, the dose should be repeated, keeping in mind the fact that sufficient antitoxin must be used to neutralize the toxins of the disease, which can only be estimated in a general way by the severity of the local and general symptoms. Given in too small doses, the poison of the disease cannot be neutralized; and as no bad effects are produced by larger quantities, it is safer to give more than is required rather than less.

The *prophylactic dose* for children is 500 to 1000 units, and for adults 1000 to 2000 units. The immunity so conferred is only temporary, its duration depends on the quantity of antitoxin administered, and it gradually decreases as the antitoxin is eliminated.

The prophylactic administration of antitoxin to those who had been exposed to the infection has been universally recommended in spite of the fact that many persons are not susceptible at the time of exposure because of the presence of natural diphtheria antitoxins in the blood. Many persons, no doubt, have been given antitoxin as a prophylactic when nature has supplied sufficiently to protect the individual. The practical difficulty has been the separation of those in which natural antitoxin was present in sufficient amounts to protect the individual from those in which its absence or diminished quantity rendered infection probable. Recently a simple test known as the intracutaneous **reaction of Schick,** has been found of considerable value in estimating the presence of natural immunity. In the performance of the test a dilution of diphtheria toxin is made of such strength that 0.1 mil. contains one-fiftieth of the minimum lethal dose for the guinea-pig. This amount is injected intracutaneously and if a positive reaction results there appears from 24 to 48 hours a circumscribed area of redness and slight infiltration which remains for about a week and then fades, a brownish pigmentic area remaining for a considerable length of time. A positive reaction, according to Schick, indicates that the natural antitoxins are considerably reduced or absent, and such individuals are susceptible to diphtheria. So far this test has been corroborated by Park and other observers.

Method of Administration.—The more concentrated serums (250 to 1000 units to the cubic centimeter) are preferable, as by their use there are noticed none of the possible disagreeable effects caused by injecting a large quantity of fluid subcutaneously.

With a thoroughly sterilized hypodermic syringe, or a special antitoxin syringe, the serum is introduced into a part of the body where there is loose subcutaneous tissue, and where the spot will not be subjected to pressure from the patient's position in bed—the flank or the interscapular region being usually selected. With the concentrated serum small doses may be given with an ordinary hypodermic syringe, and a syringe holding 5 c.c. is large enough for any dose required. (See Serum Therapy and Vaccine Therapy.)

DIPLOPIA.—See Eye-muscles (Anomalies).

DIPSOMANIA.—The uncontrollable desire for spirituous liquors. This is generally regarded as a disease. See Alcoholism (Chronic).

DISARTICULATION.—See Amputation.

DISC, OPTIC.—See Optic Nerve Atrophy.

DISCISSION.—See Cataract.

DISCUTIENTS.—See Sorbefacients.

DISINFECTANTS.—See Antiseptics.

DISINFECTION.—Disinfection constitutes one of the most efficient means of controlling the spread of infectious diseases, and every practising physician should be familiar with its method of employment. The anxious mother in whose family a case of infectious disease, and possibly a death from the same, has occurred, often asks the question, How can I be assured that my other children and those of my neighbors can best be protected?

As infectious diseases differ essentially in their natural history and in the methods of their spread, so they also differ in the use of the disinfectants that are necessary for their prevention. The practical question, therefore, arises in each case of infectious disease, *What is the best disinfectant for use in this particular case, and how shall it be applied?*

If the air of a room is infected, the best method of disinfecting it is to open the windows, and a few moments' time will serve to replace it by fresh uninfected air. And in so doing there need be no fear of endangering the health of the neighborhood, except in the case of small-pox. Infected air is soon dissipated by the enormous dilution of the external atmosphere and by the action of the sunlight, the winds, and the rain, and thus rendered inert.

The actual solid substances that then remain in an infected room, after flushing out its atmospheric contents, are the wall, the ceiling and floor, the beds and bedding, furniture, carpets, clothing, etc.

The principal means of disinfection in use at the present time, and the methods of their use, are as follows:

1. **Actual Destruction by Fire.**—This is unquestionably the most thorough and certain method of destroying infected material, but is only applicable to organic substances, and to such as are worthless or cannot be disinfected by other methods. It may be applied to infected clothing, rags, and bits of infected cloth, such as are contaminated with the infected discharges from the mouth, nose, throat, and other parts of the body in cases of diphtheria, scarlet fever, typhoid fever, and phthisis. Mattresses saturated with infectious material, upholstery, and cheap furniture, which are not deemed worth disinfecting by other methods, may be treated in this manner. Infected school books and library books, especially when worn and of slight value, may be destroyed by fire, in preference to running the risk of using them without disinfection.

In the treatment of cases of small-pox in the milder season of the year, an efficient method would be the selection of an isolated location, remote from inhabited districts, and there treating the patient in a good wall tent that can be burned after the recovery or death of the patient, together with the bed, bedding, and furniture.

2. **The Application of Heat.**—**Dry Heat.**—Exposure of the infected material to a heat of from 150° to 250° F., according to the nature of the disease for which disinfection is required. This mode is not convenient for ordinary use, in consequence of the liability of overheating and of consequent injury of the fabrics or substances to be disinfected.

Moist Heat. *Steam.*—This is only applicable in cities, large towns, public institutions, and quarantine stations, where special apparatus can be provided. It is employed for the disinfection of clothing, bedding, mattresses, carpets, upholstery, metallic surgical instruments, and all other material that is not liable to injury by steam.

Boiling Water.—Boiling water may be employed for the disinfection of bed-linen, clothing, sputum cups, cuspidors and metallic surgical instruments, metal and crockery. These may be placed in a wash-boiler or other convenient receptacle partly filled with water, which may be brought to the boiling point, and boiling maintained for 15 minutes.

3. **Chemical disinfectants** having well-defined powers for the destruction of disease germs, as determined by experiment. Of these, the most efficient and useful in liquid form are solutions of carbolic acid, chlorid of lime, bichlorid of mercury, lime-water, and milk of lime. A good disinfectant for general use should be inexpensive, readily soluble in water, and capable of easy and rapid applications. As a general rule, disinfectants in the crude form and in bulk are both cheaper and more efficient than patented articles.

Crude carbolic acid or **phenol** is soluble in water in the ratio of about 1 part to 30 (about 4 ounces to the gallon). A solution of 1 part in 400 will destroy most bacilli, but not their spores. For disinfectant purposes it is decidedly inferior to the cresols.

Mercuric Chlorid (Corrosive Sublimate).—One part dissolved in 1000 parts of water will suffice to destroy disease germs of all sorts in less than 10 minutes, and ordinary bacilli* in less than 1 minute. The extremely poisonous character of this solution makes it necessary to take special precautions in its use. Its property of forming insoluble compounds with albumin also seriously interferes with its efficiency.

Chlorid of Lime.—This is one of the most efficient disinfectants, and may be used either in powder or in solution, in the latter case in the proportion of 2 parts of chlorid of lime to 100 of water.

Any one of the foregoing may be employed for application to walls, floors, or woodwork.

Milk of Lime (Common Whitewash).—This constitutes a very efficient disinfectant for use in the disinfection of the excreta of typhoid fever or cholera by mixing it thoroughly with the excreta in equal bulk. It may be prepared by sprinkling a quart of water gradually over a quart of quicklime, in broken pieces, in a wooden or metallic vessel. When the lime is reduced to powder, 3 quarts or more of water should be added, and the mixture allowed to stand. This is highly recommended by the German Government in its cholera circular of 1892. It may be used in liberal quantities for the flooding of areas and concrete floors.

Weaker disinfectants are the permanganate of potassium and the sulphates of iron, copper, and

* Ordinary bacilli—*i. e.*, most of the common forms of infectious disease. The spores of anthrax require longer time, but anthrax is a disease of rare occurrence in the United States, and when it does occur as a result of infection from the lower animals, it rarely spreads.

zinc, any one of which may be employed in a 5 percent solution.

The cresols—tricresol, creolin, lysol, etc.—are powerful disinfectants and are extensively used.

Gaseous Disinfectants.—The principal disinfectants in gaseous form are sulphurous acid, chlorin, and formaldehyd. None of these should be used during the occupancy of the room that is to be disinfected. Disinfectants of this character are employed for the disinfection of rooms that have been occupied by the sick. Chlorin gas is but little used, in consequence of its extremely irritating nature. Sulphur is also rapidly falling into disuse, because of its foul odor, the occasional injury caused by it, and the fact that it frequently fails to accomplish its end, as shown by experiment. When used, the sulphur should be broken up and burned in an iron vessel, in such a manner as not to endanger the safety of the woodwork, since fire is not an uncommon occurrence if it is carelessly used. At least 3 pounds should be used for each 1000 feet of air-space, and the disinfection will be much more thorough in the presence of moisture. The dry sulphur dioxid, in itself practically powerless against bacteria takes up the moisture and is converted into *sulphurous acid* which is the disinfecting agent, though the latter has the disadvantage when exposed to the air of taking up oxygen and changing into the destructive sulphuric acid.

Sulphur dioxid, however, is the most efficient *insecticide*. Dry or moist, it destroys vermin and insects, and therefore is invaluable in disinfection against yellow fever, malaria, plague, filariasis.

Formaldehyd is an important gaseous disinfectant for use in apartments after infectious diseases. Its ready application makes it quite desirable for this purpose, and the best authorities show that it can be depended upon for the disinfection of surfaces, but not when penetrating power is required. In this direction too much cannot be expected of any disinfectant. It is also difficult to disinfect the interior of a closed school book or library book, provided the leaves are not loosely opened out. This is mentioned as a practical matter, since books are often exposed to infection when used by sick children.

In the use of formaldehyd the room should be tightly closed, and all cracks, crevices, and openings sealed against the passage of air in or out. Every physician in practice in country districts where there are no efficient health authorities should provide himself at least one good formaldehyd generator, of a sufficient size to disinfect ordinary apartments containing from 1000 to 2500 cubic feet of air. Full directions usually accompany each apparatus. See FORMALIN.

DISLOCATIONS.—A dislocation is a displacement of the articular ends of two or more bones making up a joint, such displacements *persisting* after the displacing force has ceased to act. When the separation of the articular surfaces is *incomplete*, the condition is termed a *subluxation;* and when the separation occurs in the amphiarthroses, it is described as a *diastasis.*

A dislocation is necessarily accompanied by rupture of the joint capsule. Sometimes the bone-end escapes temporarily through the ruptured capsule, but returns spontaneously to its place when the displacing force ceases to act. Such an injury is described as a *distortion.*

Etiology.—As regards causation, dislocations are: (1) *Traumatic,* produced by actual violence; (2) *spontaneous, pathologic,* or *inflammatory,* occurring secondarily in the course of disease, chiefly tubercular disease; (3) *congenital,* due to faults of development or displacements occurring *in utero.* Traumatic dislocations are chiefly considered here.

Dislocations are *recent* or *old,* the term *old* designating the changes that have taken place hindering replacement, rather than the actual lapse of time. Like fractures, these injuries are *simple* when the injury remains subcutaneous, without serious injury to neighboring structures; *compound,* when open communication is established with the skin surface; *complicated,* when accompanied by fractures or by serious injury to adjacent structures, blood-vessels, and nerves. Complicated dislocations are, further, either *closed* or *open* (compound).

Traumatic dislocation is naturally more frequent in men than in women, as the former are more exposed to possibilities of violence, and is relatively rare in childhood and senility; fracture, rather than dislocation, occurring in such because of the fragility of the immature bones and epiphyses of the one, and the brittleness of the bones of the other. The upper extremity, being most exposed to violence, is the seat of the large majority of dislocations, being affected in 92.2 percent of cases, while the lower extremity furnishes 5 percent, and the trunk 2.8 percent (Kroenlein).

Direct violence rarely produces dislocation, and from its nature such dislocation is likely to be complicated by injury of the soft structures about the joint. *Indirect force,* imparted through the long bones, and acting by leverage, is the most common cause. *Muscular contraction,* especially at the shoulder-joint, may cause dislocation; this sometimes follows the general muscular contractions of epilepsy and eclampsia.

Voluntary dislocation of various joints, depending on the laxity of the joint capsule, can be produced by some athletes and by "snake men."

Habitual dislocation is one that, traumatic in its inception, tends constantly to recur, owing to imperfect repair and to permanent lengthening of the joint capsule and ligaments, or owing to the breaking down of the bony "checks."

In simple dislocations if early reduced, complete restitution is the rule. If reduction is not effected, a new joint (nearthrosis) is formed at the site of lodgment of the bone-head. In the case of ball-and-socket joints these nearthroses may become very movable and useful; but in the case of ginglymoid joints they permit little or no motion and use.

Repair after complicated and compound dislocation depends on the nature and course of the complication, function varying from almost com-

plete restoration to entire loss of motion and use. The worst cases may even demand amputation.

The symptoms of uncomplicated dislocation are usually prominent, making the diagnosis easy.

Objectively, they are a change in the contour of the joint; a change in the relative positions of the articular ends of the bones; the absence of the articular end in its normal position and its presence in an abnormal position; a change in the axis of the limb, resulting in most cases in the assumption of a characteristic attitude; an elastic fixation of the limb in its new position; it may be forcibly moved in various directions, but on being released, springs back to its first position—a symptom of great importance in differentiating between dislocation and fracture. In dislocation the limb is generally shortened, but it may be lengthened.

Subjectively, the patient experiences pain and inability to perform normal movements; while passive movements may be possible in some directions, they are impossible in others.

For differentiation between dislocation and fracture, see FRACTURE.

Coincident fracture, especially of the articular end of the bone, renders the diagnosis difficult.

Treatment is directed, first, to the reduction of the dislocation; and, secondly, to preventing its recurrence. While in former times forced reduction was often attempted by means of a powerful traction-apparatus (block and tackle), serious injury often resulted to blood-vessels and nerves, an entire limb even being torn away; nowadays reduction is effected almost entirely by manipulation, without much force, and generally under an anesthetic. In general terms, the displaced bone-end is made to return to its proper position reversely along the route it followed in escaping. Therefore, a proper conception of the anatomy of the dislocation is of supreme importance. After reduction a suitable dressing is applied to maintain reduction and to afford rest and protection during the period of repair. After a week or two careful massage and passive movements should be begun, and continued every day or two unless renewed pain and articular irritation become manifest. With the third week, ordinarily, more extensive movements, with active exercise, should be begun.

Impediments to reduction are, in *recent cases:* Contraction of the muscles surrounding the joint; the small size of the rent in the capsule; the hitching of points of bone on each other; and the interposition of soft parts. In *old cases:* Formation of adhesions; closure of the rent in the capsule; permanent shortening of ligaments and muscles; and alteration in shape of the articular surfaces.

Habitual dislocation calls for a more prolonged immobilization, thereby giving the capsule and ligaments opportunity to shrink and shorten. Irritating injections (tincture of iodin, white-oak bark, alcohol) have been employed for a similar purpose. Refractory cases may eventually demand arthrotomy and retrenchment by partial excision of the capsule.

Some simple and recent dislocations may be **irreducible** because of the small size of the slit in the capsule, but ordinarily because of intervening soft parts. In such cases reduction must be effected early by open incision and by division of such obstructing bands as may be necessary.

When dislocation is **complicated by fracture,** the fracture may first be fixed firmly by splints, and then efforts made to reduce the dislocation. If this fails, or if the fracture occurs close to the articulation, rendering fixation impossible, reduction is attempted by manipulation. This being impossible, control of the bone-end may sometimes be effected by screwing a gimlet or bone-hook into it. If all attempts at reduction fail absolutely, one of two things remains to be done: either the fracture must be set and its repair permitted before further effort is made to reduce the dislocation, or operative procedures must be at once undertaken. The circumstances of the individual case will determine the procedure.

The treatment of compound dislocations, whatever the complications, will be guided by general surgical principles, as in the case of compound fracture. Reduction and fixation, surgical cleanliness in manipulations and dressings, and drainage constitute the basis of the proper treatment. Formerly, such an injury of one of the larger joints was followed by so great a mortality that the condition was considered to demand primary amputation. This is now indicated only in extensive injury of the soft parts and of the blood-vessels.

In **old unreduced dislocations** in which the new joint permits fairly good motion, it is best not to attempt anything beyond improving the range of mobility; but when function is very imperfect, as is practically always the case in hinge-joints, efforts at reduction should first be made, and if unsuccessful, arthrectomy should be performed, with resection of the head of the bone if necessary. Such operations sometimes result in surprisingly good joints. At the hip, malposition can sometimes be corrected by subtrochanteric osteotomy.

For **special dislocations** see ANKLE, ELBOW, HIP-JOINT, JAW, SHOULDER, etc.

DISSEMINATED SCLEROSIS. Synonyms.—Cerebrospinal sclerosis; multiple sclerosis of the brain and cord; cerebral sclerosis; spinal sclerosis.

Definition.—A degenerative disease of the brain and spinal cord, characterized by pains in the back, disorders of sensation, loss of coordination, tremor on motion, scanning speech, and some mental impairment.

Pathology.—The disease consists of the development of patches of grayish, translucent, tough nodules. varying in size from a minute microscopic object up to the size of a walnut, varying in number, and widely distributed in the white matter of the hemispheres, ventricles, optic thalamus, corpus striatum, peduncles, pons, and cerebellum, while in the cord they are found in both the white and gray matter and in the columns. The deposits are also found in the nerve-roots and nerve-trunks. The nodules are composed of the neuroglia, much altered, and of a newly formed connective tissue. The result of the growth of the nodules is pressure upon the nerve structure, ending in its degeneration.

Symptoms.—Charcot divides disseminated sclerosis into 3 varieties, depending upon the chief site of the changes, whether in the brain, the cord, or a combination of the two. The last variety is the more common. Rarely, the malady is ushered in with apoplectiform symptoms, but generally the onset is insidious, with more or less severe pains in the limbs and back, which are attributed by the patient to rheumatism. There are also a fleeing of formication, itching, and burning in the limbs, loss of coordination of the hands in writing, or of the feet in walking, or a jerky coordination, followed after a time by paresis, more or less general, with contracture of the muscles. Voluntary movements of the paretic limbs develop a tremor, with shaking of the head. An early and frequent condition is nystagmus. The loss of coordination, with tremor and with contractures of the muscles of the legs, has given rise to the "waddle" or "hop" gait when walking. There are also present headache, vertigo, mental impairment, with an unnatural indifference to the symptoms and to the surroundings, a scanning or slurring speech, disorders of vision and hearing, sexual disturbances, vesical disorders, gastric and other crises, and often the development of bed-sores. The knee-jerk and muscular reflexes are exaggerated.

The disease is progressive, the symptoms developing as the various nerve-tracts are invaded. It ranges from 1 year to 20 years, an average being from 5 to 10 years.

Diagnosis.—Paralysis agitans may be mistaken for disseminated sclerosis. The chief points in the diagnosis are the continual presence in paralysis agitans of the fine tremor, without shaking of the head, with a peculiar flexion and rigidity of the hand, while in cerebrospinal sclerosis the tremor is produced only on movement of the muscle, and is associated with shaking of the head. Paralysis agitans is a disease of middle life; sclerosis occurs in patients under 40 years of age. Changes in the voice, speech, and vision are present in cerebrospinal sclerosis, but absent in paralysis agitans, Tumor of the pons or crus is accompanied by wild, jerky incoordination, closely resembling disseminated sclerosis, but tremor is also accompanied by headache, optic neuritis, local spasm, and local paralysis. General paralysis of the insane and disseminated sclerosis are frequently confounded, as are locomotor ataxia and primary lateral sclerosis.

Prognosis.—Unfavorable. The disease slowly but steadily progresses; chronic nephritis or tuberculosis frequently develops and causes death.

Treatment.—There is no drug that has the power to cure sclerosis. Syphilis has been the cause of the vast majority of cases, and potassium iodid, in large doses, or the biniodid of mercury is indicated.

DISTOMIASIS.—Infection with the different forms of distomata or fluke worms. Gives rise to symptoms varying according to the location of the worm. The liver fluke, lung fluke, intestinal fluke, and blood fluke (see SCHISTOSOMIASIS) are the chief varieties found in man. Treatment is symptomatic.

DIURETICS.—Agents which promote the secretion of urine, either by raising the local or general blood-pressure, and so increasing the renal circulation, by stimulating the secreting cells or nerves of the kidneys, or by flushing the kidneys with water. Diuretics may be classified according to their physiological action or according to the different purposes for which they are employed. *Refrigerant diuretics*, especially the salines, excite the renal epithelium, induce a hyperemic condition of the kidneys and increase the water of the urine. They possess a sedative action upon the heart and the general circulation, but used to excess they depress the heart and impoverish the blood. Potassium chlorate is a decided renal irritant, and should never be used as a diuretic. *Hydragogue diuretics* increase the water of the urine largely, and in general act by raising arterial pressure, either—(*a*) throughout the body, or (*b*) locally in the kidneys. This they accomplish in various ways, direct and indirect—increasing the action of the heart, contracting the efferent vessels or dilating the afferent vessels, so as to raise the blood-pressure in the glomeruli, etc. The action of the *stimulant diuretics* is directly upon the renal tissue, by which they are largely eliminated from the body. In small or moderate doses they dilate the renal arterioles, increase the renal blood-supply, and so induce diuresis, but in large doses they irritate the renal epithelium, contract the renal arterioles, diminish the renal blood-supply, excite renal inflammation, render the urine albuminous and bloody, and may even induce suppression of the urine. All the members of this division should be used with caution.

Diuretics act: (1) by increasing the action of the heart (alcohol, digitalis, etc.) or by contracting the intestinal and other vessels, thus raising the general blood-pressure; (2) by dilating the afferent renal vessels, thereby increasing the renal blood-supply, raising the pressure in the glomeruli; (3) by contracting the efferent vessels, raising the pressure in the glomeruli and lessening absorption in the tubules, or both; (4) by stimulating the secreting cells or nerves of the kidneys; (5) by flushing the kidneys, as by the ingestion of water in large quantity.

The following list contains the most important agents of this group, which are usually subdivided into the three classes indicated by the subtitles. The numbers refer to the probable modes of action of the drug in the above synopsis:

Refrigerant Diuretics.—Potassium acetate[4], potassium bitartrate[4], potassium citrate[4], potassium chlorate[4], potassium nitrate[4], sodium acetate[4], sodium chlorate[4], sodium chlorid[4], ammonium acetate[4], calcium chlorid[4], lithium carbonate[4], lithium citrate[4], magnesium citrate[4], magnesium sulphate[4], water[5], milk[5], carbonic acid, cold to surface[1]. *Hydragogue diuretics.*—Digitalis[1,2], strophanthus[2], convallaria[1], cimicifuga[1,3], adonis vernalis[1,2] erythrophlœum[1], squill[1,2], broom[3], spartein[3], calomel[4], caffein[1,4], theocin[4], theobromin[4], agurin[4], apocynum[1,2], nitrous ether[2], nitrites[2], strychnin[1], colchicum[4], tobacco[3], sugar of milk[1,4]. *Stimulant Diuretics.*—Alcohol[2], blatta orientalis[4], cantharides[4], turpentine[4], juniper[4], savin[4], copaiba[4], cubeb[4], cannabis[4], capsicum[4],

buchu[4], asparagus[4], guaiac[4], fennel[4], urea[4], uva ursi[4], zea[4].

Diuretics are employed in medicine for certain definite purposes, as follows: To remove fluid from the tissues and cavities of the body in cases of dropsy; to promote the elimination of waste-products and other poisons from the blood; to maintain the action of the kidneys; to dilute the urine, and to alter morbid conditions of that excretion.

In dropsies from cardiac disease, or other dropsies due to venous congestion, the most efficient diuretics are those which act on the general vascular system, as digitalis, strophanthus, squill, etc. Calomel is often very efficient in this form of dropsy, also theobromin sodio-salicylate (diuretin).

In dropsy from renal disease, diuretin, broom-tops, nitrous ether, oil of juniper, digitalis and squill are the most reliable diuretics, in the order named.

In ascites from hepatic cirrhosis, copaiba is the best diuretic when the kidneys are healthy. In this form and the previous ones a little pill of mercury given occasionally will often aid the diuretic action of the other agents.

To eliminate waste-products from the blood, potassium nitrate and bitartrate, turpentine, juniper, caffeine, and water in large quantity.

To dilute the urine, water is the best agent, its most efficient form being distilled water charged with carbonic acid gas.

As adjuvants to diuretics, when pressure on the uriniferous tubules or venous congestion prevents their action—paracentesis abdominis, purgation, cupping over the loins, and even venesection, are often necessary to start the diuretic action.

DIURETIN.—Theobromin sodio-salicylate should contain 46 percent of theobromin. It has been found useful as a diuretic in hepatic cirrhosis, in various diseases of the heart and kidneys accompanied by edema and in cardiac and renal dropsy. Dose, 15 grains every 3 hours.

DIVERTICULITIS.—The papers of Cahier, Brewer, Mayo and others have attracted attention to a condition named acquired diverticulitis. Acquired or false diverticula are simple herniæ of the mucous and submucous tunics through the circular muscular coat of the descending colon and sigmoid at points where the musculosa happens to be weak. Chronic leakage may take place through the diverticular walls and give rise to large inflammatory deposits. The result of the inflammation may be: (1) Abscess. This requires free drainage. (2) Acute local infection *plus* acute obstruction. This requires free drainage *plus* the establishment of an artificial anus. Subsequently, if necessary, the diseased segment of colon may be excised. (3) Chronic obstruction with inflammatory tumor but no abscess. This form is usually mistaken for malignant disease. The treatment is resection of the involved segment of gut.

DIZZINESS.—See VERTIGO.

DOSAGE.—**Conditions that modify** the action of medicines, and therefore affect their dosage, are age, body-weight, temperament and idiosyncrasy, drug habits, intervals between doses, time of administration, condition of the stomach, temperature of the body, cumulative drug action, mode and form of drug administration, disease, climate, race, etc.

The doses given in the following table are for adults; for children the following rule (Young's) will be found the most convenient: Add 12 to the age, and divide by the age, to get the denominator of the fraction, the numerator of which is 1. Thus, for a child 2 years old, $\frac{2+12}{2} = 7$, and the dose is one-seventh of that for an adult. Of powerful narcotics, scarcely more than one-half of this proportion should be used. Of mild cathartics, 2 or even 3 times the proportion may be employed.

In a general way, it may be said that, approximately, the dose for a child of 1 month is one-twentieth that of an adult; for one of 3 months, one-fifteenth; 6 months, one-tenth; 1 year, one-eighth; 2 years, one-sixth; 3 years, one-fifth; 5 years, three-tenths; 8 years, one-half; 10 years, three-fifths; 12 years, two-thirds; 15 years, four-fifths; 20 to 45 years, adult dosage; 50 years, five-sixths; 60 years, four-fifths; 80 years, two-thirds.

For **hypodermic injection** the dose should be one-half of that used by the mouth; by rectum, three-fourths of the same.

Average Adult Doses of Official Preparations (Potter)

Acids (dilute), 30 minims—except hydrochloric and nitro-hydrochloric, 15 minims; and hydrocyanic, 1 1/2 minims.

Alkalies.—Solution of potassium hydroxid (liquor potassæ), 15 minims. Carbonates, 15 grains, except that of magnesium, 45 grains; of lithium, 7 1/2 grains; of ammonium, 4 grains. Potassium bicarbonate, 30 grains; sodium bicarbonate, 15 grains. Sodium borate, 7 1/2 grains.

Alkaloids and their salts form several groups: (1) Aconitin, 1/400 of a grain; (2) those from plants of the *solanaceæ*, including atropin, hyoscin, etc.; also including colchicin, 1/128 of a grain; (3) strychnin and physostigmin, 1/65 of a grain; (4) those from *opium*, 1/4 of a grain, except codein, 1/2 of a grain; narcotin (unofficial), 3 grains; and apomorphin, as an expectorant, 1/30 of a grain, as an emetic, 1/10 of a grain; (5) those from *cinchona*, 4 grains; (6) pelletierin, 4 grains; piperin, 3 grains; caffein, 1 grain; cocain and hydrastinin, 1/2 of a grain; hydrastin, spartein and pilocarpin, 1/5 of a grain; veratrin, 1/30 of a grain, etc.

Extracts vary from 1/8 of a grain to 15 grains, as follows: Physostigma, 1/8 of a grain; belladonna, cannabis indica, digitalis, scopola, stramonium, 1/5 of a grain; nux vomica, 1/4 of a grain; colocynth, opium, 1/2 of a grain; colchicum, hyoscyamus, quassia, 1 grain; aloes, euonymus, 2 grains; cimicifuga, ergot, gentian, leptandra, rhamnus (cascara), rhubarb, sumbul, 4 grains; colocynth compound, krameria, 7 1/2 grains; glycyrrhiza, hematoxylon, taraxacum, 15 grains. Extract of malt, 4 drams.

Fluidextracts vary from 1 minim to 2 drams; 25 have an average dose of 15 minims, and 27 have 30 minims. Of the rest, those of aconite, belladonna root, cannabis indica, capsicum, digitalis, gelsemium, ipecac, nux vomica, scopola, staphisa-

gria, stramonium, have an average dose of 1 minim; phytolacca, sanguinaria, squill, veratrum, 1 1/2 minims; colchicum seed, conium, hyoscyamus, quillaja, 3 minims; convallaria, euonymus, lobelia, lupulin, podophyllum, quassia, 8 minims; matico, pareira, spigelia, 1 dram; taraxacum, triticum, 2 drams; that of mezereum is not given internally.

Glucosids.—Ammoniated glycyrrhizin, 4 grains; salicin, 15 grains; strophanthin, 1/200 of a grain.

Infusions.—Digitalis, 2 drams; wild cherry, 2 ounces; senna, the compound infusion, 4 ounces.

Mixtures.—Chalk, 4 drams; compound iron mixture, 2 drams; rhubarb and soda, 1 dram; compound glycyrrhiza, 2 drams.

Oils, Fixed.—Cotton seed oil, codliver oil, castor oil, 4 drams; expressed oil of almond, linseed oil, olive oil, 1 ounce. Lard oil and oil of theobroma are only used externally.

Oils, volatile, 3 minims—except that of mustard, 1/8 of a minim; bitter almond, 1/2 minim; cinnamon, savin, croton, 1 minim; cajuput, copaiba, cubeb, eucalyptus, 8 minims; betula, erigeron, gaultheria, turpentine, 15 minims. Ethereal oil is not used internally.

Oleoresins.—Ginger, pepper, 1/2 of a grain; lupulin, 3 grains; capsicum, 7 1/2 grains; aspidium, 30 grains.

Pills, 2—except those of opium, phosphorus, and the pills of podophyllum, belladonna and capsicum, 1 pill.

Powders form two classes: (1) Those given in *grains*, acetanilid compound, ipecac and opium, compound morphin, 7 1/2 grains; aromatic powder, 15 grains. (2) Those given in doses of *half a dram* or more, compound chalk, compound jalap, compound rhubarb, 1/2 dram; compound glycyrrhiza, 1 dram.

Resins.—Podophyllum, 1/4 of a grain as a purgative, 1/10 of a grain as a laxative. Jalap, 2 grains; scammony, 3 grains.

Spirits 1/2 dram—except that of nitroglycerin, 1 minim; bitter almond, 8 minims; ammonia, camphor, 15 minims; ether, anise, 1 dram; compound juniper, 2 drams. Spiritus frumenti (whisky) and spiritus vini Gallici (brandy), according to the amount of alcohol desired to be administered.

Syrups, 1 dram or more—except that of ferrous iodid, 15 minims; ipecac as an expectorant, 15 minims, as an emetic, 4 drams; squill and compound syrup of squill, 30 minims; lime, 30 minims.

Tinctures, 1 dram—except that of iodin, 1 1/2 minims; belladonna leaves, cantharides, 5 minims; capsicum, iron chlorid, gelsemium, ipecac and opium, opium, stramonium, strophanthus, 8 minims; aconite, cannabis indica, nux vomica, 10 minims; arnica, asafetida, benzoin, digitalis, hyoscyamus, lobelia (as an expectorant), myrrh, physostigma, sanguinaria, squill, veratrum, 15 minims; aloes, aloes and myrrh, benzoin (compound), cinchona (compound), cinnamon, colchicum seed, guaiac (ammoniated), lactucarium, lavender (compound), quassia, rhubarb (aromatic), tolu, valerian (ammoniated), ginger, 30 minims; camphorated tincture of opium (paregoric), 2 drams. The tinctures of calendula, lemon, pyrethrum, quillaja, and vanilla, are not assigned any dose.

Waters, 1/2 of an ounce—except ammonia, 15 minims; bitter almond, hydrogen dioxid, 1 dram; orange flower (stronger), camphor, creosote, hamamelis, rose (stronger), 2 drams.

Wines, 2 drams—except opium, 8 minims; antimony, ipecac, 15 minims; colchicum seed, 30 minims; coca, 4 drams. White wine and red wine are not assigned any dose, but are prescribed according to the amount of alcohol desired to be given.

Vinegars are only two—that of opium, 8 minims, and that of squill, 15 minims.

See PRESCRIPTION-WRITING.

DOUCHE.—A jet of water propelled against some part of the body or used to flush some body-cavity. The size of the jet, force of its impact, temperature, and composition can be regulated. A simple affusion differs from a douche in that the latter is more local, and is applied with greater force. The extremities and head bear douches better than the chest, the chest better than the abdomen, and the posterior aspect of the body better than the anterior. Warm douches are more easily borne and give less shock. Douches to the head have most general action, those to the spine coming next. Douches for the eye and ear are much used. The Scotch douche is one consisting of alternate cold and hot douches. Ascending douches are used for the rectum and vagina. The shower-bath is a multiplication of fine douches.

The average temperature of the cold douche is 50° F., and the duration is from 4 to 15 minutes.

As a rule, douches are most useful in chronic diseases. Constitutional diseases are best treated by cold douches, and local affections by warm douches, and by alternate hot and cold douches. Nervous diseases are benefited by alternate hot and cold douches. In chlorotic and hysteric conditions, in hysteric paralysis, in oversensibility of the skin with a tendency to catch cold, in special treatment of phthisis, in infantile convulsions, and in maniacal affections, the cold douche is very useful. In congestion of the liver and of the uterus cold douches are effective revulsives. In skin affections and chronic ulcers, in old sprains, in chronic rheumatism, in gouty thickenings of joints, in lumbago, in some paralyses of not too recent origin, douches are beneficial. In threatened tabes dorsalis the Scotch bath has proved more efficacious than any other remedy. See VAGINAL DOUCHE.

DRACONTIASIS.—See GUINEA-WORM DISEASE.

DRAINAGE.—The provision, by means of tubes or strands of fibers, of a channel of exit for the discharge from a wound or cavity.

An aseptic wound in which there is no cavity for blood to collect in requires no drainage. Most superficial wounds, also wounds of the abdominal wall, are completely sutured. An accidental wound, however well disinfected, also an operation wound, which when closed has a cavity in which blood may collect, is better drained for a few days, by inserting a strip of iodoform gauze or a rubber tube perforated by cutting a number of side holes, which can be dispensed with at the first dressing.

A cavity being filled with a long strip of gauze, a little may be withdrawn every day, during which the wall of the cavity is contracting, while discharges are taken up and prevented from being absorbed. The withdrawal of the gauze is facilitated and much pain avoided by soaking it before removal with peroxid of hydrogen; then, seizing the end with clamp forceps, twist up the strip while gently drawing on it. To further facilitate this a strip of gutta percha may be wrapped round the gauze, the "cigarette" drain. Even for draining suppurating wounds and cavities, draining-tubes and counter-openings are not now so much used. Generally, it is better to make a wide opening, and fill the whole with iodoform gauze, which is changed every day or two until the surfaces are lined by healthy granulations, when healing may be expedited by applying secondary sutures, so as to draw the granulating surfaces together. Some wounds are sutured as regards the deeper part, but the skin is partly left open, lest, as in the case of wounds of the bladder, esophagus or larynx, leakage may occur from within, and septic infection spread widely beneath the skin.

Before use, drainage-tubes are kept in carbolic-acid lotion (1 to 20). Lest a tube be lost in a cavity, *e. g.*, an empyema, it should be fixed to the dressings by a strand of silk or by a safety-pin, or have a flange. A counter opening occasionally improves drainage. It is made by pushing sinus forceps through the bottom of the cavity toward the skin avoiding important structures, cutting down upon the forceps, seizing with them the tube and drawing it into the cavity through the counter-opening. A drainage-tube should be removed as soon as possible to avoid the formation of a sinus. (Spencer and Gask.)

Position facilitates or opposes drainage, and gravitation should always be kept in mind in securing drainage (outward and downward). The opening for an abscess should be made in the most dependent position. Pressure, as well as position, may direct fluids outward, and prevent their permeation into the healthy tissues. Drainage-tubes, if necessary, should not be of such size as to act as foreign bodies, preventing contact of surfaces in which union is desired. To prevent a tube from slipping from the wound, its outer end should be of good length and secured by stitches or adhesive strips. It may be passed through a hole in the dressings or between the edges of two pads or folds, the bandage pressing over the tube so as not to close its lumen or shut its orifice. Catgut, horsehair, and iodoform gauze are used as minor drains, but absorbent dressings and gentle pressure may often be substituted.

DRESSINGS.—The two objects of dressings are: first, absorption of secretions; and, second, protection from the infection and injury and prevention of movement. The substances most commonly employed are cotton-wool, loosely woven cotton cloth, gauze, jute, sawdust, moss, etc. They should be in themselves not only aseptic, but also impregnated with antiseptic materials. Proper proportions of corrosive sublimate, the double cyanid of mercury and zinc, carbolic, boric or salicylic acids, or similar antiseptic agents are used for this purpose. Additional security, not only from infection, but also from mechanic violence and against movement, is given by the use of voluminous dressings.

Generally, dressings should be changed as rarely as possible, and to meet distinct indications, such as an elevated temperature, evidences of retention of secretions or of septic absorption, moistened external dressings, hemorrhage, suppuration, or sloughing.

Ordinary cheese-cloth after boiling with soft soap and soda, and being rinsed and dried, may be impregnated with mercuric chlorid, iodoform, or other antiseptic substance.

Dressings are often covered with rubber-dam, which is the thin, pure rubber tissue used by dentists. It should be washed with soap and water, rinsed and dipped in carbolic or bichlorid solution before using. Its purpose is to prevent soiling from secretions that have soaked through the dressings, and to check the access of bacteria to the wound through the dressings. Mackintosh has a cloth finish and is inferior for this purpose. Bandages of unbleached muslin or flannel are most used to hold dressings in place, to make pressure, and to check motion. Absorbent cotton or antiseptic wool is often placed over the dressings and beneath the bandage. For occlusive dressings, dry or moist, gutta-percha tissue is highly recommended.

Permanent Dressings.—The most reliable bandages for permanent dressings are the plaster-of-Paris, silicate of sodium or silicate of potassium, paraffin, and the starch bandage, which is now seldom used.

The plaster-of-Paris bandage is prepared by rubbing dry plaster of the finest quality, and freshly calcined, thoroughly into the meshes of a thick, coarse muslin or crinolin roller, which if not required for immediate use, is loosely rolled and kept in a dry place until it is needed, when it is soaked for a few minutes in cold water. The limb, first carefully enveloped in flannel, wadding, or old linen, is then surrounded by the bandage; 3 or 4 rollers generally answer the purpose. See PLASTER OF PARIS.

The silicate of sodium or of potassium in a saturated solution, applied with a stout brush, is the **"glass dressing"** of surgeons. When well rubbed into the meshes of a wet roller, a firm and immovable apparatus is formed, in no way inferior to the plaster-of-Paris. The glass dressing dries very rapidly, does not irritate the skin, and is easily procured. From 3 to 5 layers of bandage are necessary to insure the requisite amount of stiffness. Sometimes a binder's board will be required to impart sufficient support.

Paraffin is frequently used as a fracture dressing. After being thoroughly melted it is partly cooled to render it more viscid; it is then rubbed thoroughly into the meshes of the bandage with a coarse paint-brush, whereby a neat, light dressing is formed, impermeable to water, pus, and other fluids, and in every way adapted to the treatment of compound fractures.

The glue dressing is prepared by rubbing warm glue into the bandage. Before being used it must be diluted with one-fifth its bulk of alcohol or a small quantity of oxid of zinc, to promote desiccation. When applied in the usual manner, the mixture at once begins to harden, but it does not become thoroughly dry for several hours.

Wadding should be placed next to the skin, and then 2 or 3 layers of bandage must be applied. Should additional strength be needed, fresh strips of linen may be glued on without changing the original dressing.

The starch bandage is also used; it is moistened before application, and is applied, like the glue bandage, by rubbing starch into the interstices of ordinary rollers. Four, and sometimes five, thicknesses are required to insure sufficient support. It may be necessary to place on the sides of the limb strips of pasteboard that have been soaked in starch.

DRIPPING SHEET.—A means of reducing temperature in fever, entirely distinct from the wet pack. The patient is placed erect in a tub containing 12 inches of water at 100° F. A linen sheet (the coarser the better) is dipped in water at 70° F., and the temperature is reduced daily two degrees until 48° F. is reached. This sheet is thrown over the patient from behind, covering the head and body, so that it clings to the person. The attendant now makes rapid passes with both hands, beginning anteriorly and posteriorly, so as to produce friction and afflux of blood to the surface. Occasionally, cold water at from 40° to 70° F. is thrown on from a cup, and friction renewed. The procedure is also said to be useful in anemia.

DROPSY.—See Edema.

DROWNING.—Death due directly to drowning is caused by obstruction to respiration from submersion in a liquid, but death from shock, syncope, apoplexy, etc., may have occurred at the very instant of falling into the water. The evidence of death from drowning is cumulative. Externally, the skin is pale or slightly livid, and the body is bloated if it has been for some time in water. Froth at the mouth or nose, the presence of abrasions or excoriations of the skin, retraction of the penis, the tongue swollen and congested and closely applied to, or clenched between, the teeth, and the muscles of the hair-bulbs rigidly contracted, causing the "cutis anserina," or "goose-skin," are usual symptoms. Internally, the trachea, bronchi, and smaller air-tubes are congested and filled with a mucous froth, more or less tinged with blood. The lungs are edematous and pit on pressure, and pressure causes exudation of a sanguineous fluid. Sand, mud, or small weeds may be drawn deep into the air-passages. Water is often found in the pleural cavity and in the stomach. The right side of the heart gives the symptoms of asphyxia, and the brain is usually congested.

Complete submersion for 2 minutes is often sufficient to cause death.

The treatment of an apparently drowned person consists in removal from the water, freeing the mouth and nostrils from froth, water, and foreign bodies, loosening of clothing that binds the neck, chest, or waist, squeezing water out of the lungs and stomach with the body partly inverted, and clearing the base of the tongue from the larynx, either by pressing forward the angles of the jaw or by drawing the tongue forward out of the mouth. The body may then be laid out flat on the back, with a shawl, folded blanket, coat, or block of wood high under the shoulders so as to cause the front of the neck to be put on the stretch.

Artificial Respiration (*q. v.*) may now be tried, and warm blankets, hot bottles or bricks, and necessary medicines sent for in the meantime. The simplest way to perform artificial respiration is for the operator to place himself on his knees above the head, seize the arms near the elbows, and sweep them around horizontally away from the body and over the head until they meet above it, when a steady, strong pull may be made upon them—say, for 2 seconds. The arms may then be returned to their positions alongside the chest, and strong pressure now made against the lower ribs for several seconds. These movements should be made at a rate of about 16 times a minute, should be maintained for 1/2 to 3/4 hour, and abandoned only when the heart has ceased to beat. Deep pressure just below the end of the breast-bone may reveal pulsations in the aorta when they cannot be found elsewhere. As natural respiration begins, the artificial respiration should be timed to it. Ammonia or smelling salts may stimulate it or hot water may be dashed on the chest. Continued rubbing of the body and limbs toward the heart will aid the circulation and produce warmth. Hot bottles, plates, bricks, stones, or even boards will help to give warmth to the body. Twenty to 30 minims of ether may be given hypodermically. As soon as it can be swallowed, teaspoonful doses of brandy or whisky in a tablespoonful of hot water may be given every minute until danger is passed. Weak tea or coffee, or beef-tea, should be given after consciousness has returned. The reflex sobbing will little by little be replaced by the natural breathing, and must be watched for some time. Removal requires great care, the head being kept low and respiration constantly watched.

DRUG ADDICTION.—The public is gradually being aroused to the enormity of the demand for habit-forming drugs. Exposure has been made of the numerous popular drugged patent medicines —soothing-syrups, tonics, cough cures, so-called cures for drug habits, etc.—of the drug-doped soft drinks and of the illegal sale of these drugs frequently in disguised form. It is estimated that 2 percent of the American people are drug fiends. The use of these drugs undermines insidiously the constitution as well as the moral character of the victim, who is frequently a child, and converts him into a degenerate and often a criminal. See Lambert Treatment, Acetanilid Habit, Opium Habit, Cannabis Indica, Chloral Habit, Cocainism, Ether, Paraldehyd Habit.

DRUG ERUPTIONS.—This class includes eruptions due to the ingestion or absorption of certain medicaments. Drug eruptions are favored by (1) idiosyncrasy, (2) excessive cutaneous elimination,

(3) imperfect renal and intestinal elimination (often due to renal or cardiac disease), (4) large doses, (5) long-continued administration. Individual susceptibility is the most important factor. The eruption may be macular, papular, vesicular, urticarial, bullous, or hemorrhagic.

Aconite, vesicular exanthemata. *Antimony* (locally), papules, vesicles, pustules, similar to the eruption of small-pox. *Antipyrin*, erythema and urticaria, chiefly on thighs and abdomen, with much itching and dyspnea. *Antitoxin* (diphtheritic), erythema, with pain in the joints. *Arsenic*, erythema, eczema, papules, vesicles, pustules. *Atropin*, erythema, like the rash of scarlet fever. *Belladonna*, as atropin. *Borax*, papules, scarlatiniform. *Bromids*, acne, chiefly on the face and back; pustules, deep tubercles with ecchymoses, ulcers, pemphigus. *Castor oil*, urticaria. *Cinchona*, as quinin. *Phenol*, erythema. *Hydrated chloral*, erythema, on face and neck, itching, desquamation, eczema, petechiæ, purpura. *Codein*, as opium. *Copaiba*, also *cubeb*, urticaria, erythema, eczema, pemphigus; the Copaiba rash has a preference for the ankles and wrists. *Cod-liver oil*, acne. *Croton oil* (locally), papules, pustules. *Digitalis*, erythema, after long usage. *Enemata*, of the simplest form, as soap and water, may cause a bright scarlet rash and other symptoms of a mild septic toxemia. *Iodids*, acne, papules, vesicles, pustules, eczema, ecthyma, ecchymoses and purpura; the iodid rash prefers the face and back of neck and shoulders. *Mercury*, erythema, eczema. *Opium and morphin*, erythema, papular eruption with marked desquamation and itching. *Phosphorus*, purpura. *Quinin*, erythema, scarlatina, papular erythema, hemorrhagic purpura, pemphigus and prurigo; the prevailing type of the quinin eruption is erythema, or exceptionally eczema or purpura, and is essentially ephemeral; it is of a bright vivid hue, disappearing on pressure, and resembles the scarlatinal rash, first appearing on face and neck, and thence spreads over the body; in some instances it comes in distinct spots and resembles measles; in others it is an urticaria, with some edema, and distressing burning, tingling, and itching; five cases of purpura are authentically reported. *Rhus toxicodendron* (and other varieties of sumac), vesicles perhaps pustules, with redness, swelling and intolerable itching. *Salicylic acid*, urticaria, purpura, pemphigus, vesicular angina. *Santonin*, pemphigus, vesicles. *Stramonium*, as atropin. *Strychnin*, as quinin. *Sulphur* (locally), erythema, eczema. *Tar*, acne. *Tartar emetic* (locally), as antimony; in some cases of poisoning by tartar emetic a rash of the above description appeared all over the body. *Turpentine*, as copaiba.

DUODENUM, DISEASES.—See Enteritis, Stomach (Ulcer), etc.

DUOTAL.—See Guaiacol (Carbonate).

DUPUYTREN'S CONTRACTION.—See Hand.

DYING DECLARATIONS.—Statements of homicide made by the victim under the solemn belief of impending death. The effect of such belief is regarded as equivalent to the sanctity of an oath. Declarations so made are substitutes for sworn testimony, and they must be such narrative statements as a witness might give on the stand.

It is important for the physician in attendance upon a woman likely to die from the results of a criminal abortion to have clearly in mind his legal position and responsibilities. Dying declarations are accepted in law without being sworn to. It is naturally presumed that all statements made at so solemn a crisis must be sincere, believed to be true by the dying person, even if subsequently shown not to be so. The attending physician, under such circumstances, having expressed the opinion that the patient is dying and in sound mind, a magistrate should be summoned to take the statements that the dying person may wish to make. Should it not be possible to obtain the services of the magistrate, then the attending physician may take the dying declaration. The physician should, however, limit himself to writing down the exact words of the dying person, without offering any interpretation whatever. The statements should be read over to the dying person, and, if possible, the signature obtained.

The declarations must be made not simply *in articulo mortis*, but under the sense of impending death, without expectation or hope of recovery. Such statements are admissible even though others may not have thought the person would die. The declarations may be signs or other appropriate modes of communication. It is not necessary that the examination of the dying person should be made after the manner of interrogating a witness in the case, although any departure from that mode may affect the value and credibility of the declarations. It is no objection to their admissibility that they were made in answer to leading questions, or were obtained by pressing and urgent solicitation, but the declarations must be made under a sense of impending dissolution. It does not matter that death may have occurred a considerable time after such declarations were made.

Declarations of a deceased person are admissible only in reference to those subjects to which he would have been competent to testify if sworn in the case. He must, therefore, in general, speak of facts only and not of mere matters of opinion, and he must be confined to what is relevant to the issue. The circumstances under which the declarations were made are to be shown to the judge, it being his province, and not that of the jury, to determine whether they are admissible.

If the deposition of the deceased has been taken under any of the statutes on that subject, and is inadmissible as such from want of compliance with some of the legal formalities, it seems that it may still be treated as a dying declaration, if made *in extremis*.

DYSENTERY (Bloody Flux).—An acute or chronic inflammatory disease of the large bowel, often leading to ulceration, and characterized by the passage of mucous or bloody stools accompanied by tormina and tenesmus.

Varieties.—Since the discovery of the *bacillus dysenteriae* by Shiga dysentery is classified as: (1) Catarrhal; (2) amebic; (3) bacillary. The term "tropical" is sometimes used incorrectly as a syno-

nym for "amebic;" whereas the commonest form of the disease in the tropics is bacillary dysentery.

Catarrhal Dysentery.

Definition.—Inflammation of the intestine characterized by diarrhea, frequent blood-stained mucous stools, and desquamation of the epithelium lining the large, and to a less extent, the small intestine.

Etiology.—(1) Indigestible food, such as unripe fruits; (2) polluted drinking-water; (3) sudden changes in the weather; (4) secondary to typhoid fever, tuberculosis, the acute infectious exanthemata, diphtheria, etc.

Pathology.—The mucous membrane is congested and swollen, and covered with a thin layer of bloody mucus. The solitary glands are enlarged and may undergo ulceration.

Symptoms and Clinical Course.—The disease is usually ushered in by an attack of diarrhea, accompanied by slight fever, nausea, and vomiting. The pain in the abdominal region is often intense and there is a constant desire to go to stool. The dejections are composed for the most part of glairy mucus, but as the disease progresses, they may become tinged with blood. There may be as many as 20 stools a day, always accompanied by tenesmus, generally worse during afternoon hours or at night. At the onset the temperature may be normal, but as the disease advances it may be slightly elevated (100° F.). Rapid emaciation follows the onset of dysentery, and the strength is early exhausted, causing great debility, restlessness and general nervous disorders. The milder cases may terminate favorably during the course of a week; other cases become protracted if not properly treated, and pass into the chronic condition.

Diagnosis.—It may be distinguished from ordinary diarrhea by the fact that in diarrhea blood is absent from the stools, the course is not so prolonged, and it is not accompanied by the same degree of tenesmus.

Prognosis.—Generally favorable.

Treatment.—Rest in bed and a liquid diet are indicated. The bowels should be thoroughly cleansed by means of salines, such as Epsom salts (4 drams) or Rochelle salts (4 drams). Castor oil (1 ounce) containing laudanum (20 drops) is also highly recommended.

To relieve the pain, opium (1 grain) may be of great advantage. Bismuth subnitrate (10 grains) may be combined with the opium. Naphthalin (7 grains) with bismuth subnitrate (8 grains) is useful.

Suppositories may be beneficial:

℞. Cocain, gr. iij
Extract of belladonna, gr. jss
Extract of opium, gr. iij.
Cacao-butter, enough to make 6 suppositories.

One to be used every 3 or 4 hours.

Hope's camphor mixture, containing nitrous acid (1 dram), camphor mixture (8 ounces), and tincture of opium (40 drops), often acts well in cases disposed to be chronic. The dose is 2 ounces, taken every 3 hours.

Should the symptoms not abate, the colon should be thoroughly irrigated every 2 days by means of the rectal tube and fountain syringe. The fluid may be simply lukewarm water, or starch-water containing laudanum (1/2 of a dram).

Throughout the disease the diet must be bland, nonirritating but nourishing, and leaving little residue. The peptonized foods, beef-juice, beef-peptonoids, together with stimulants, furnish a suitable diet. Well-cooked barley and rice in broths may be added.

Amebic Dysentery (Amebic Enteritis).

Definition.—Ulcerative inflammation of the large intestine, due to *entamœba histolytical* and characterized by ulcers involving the mucous and submucous, rarely the muscular and peritoneal coats of the large intestine.

Etiology.—Its relation to so-called tropical dysentery was first clearly established by Kartulis in Egypt. Councilman and Lafleur in America, and Kruse and Pantini in Italy have also confirmed the etiologic significance of the entameba. The protozoon varies from 25 to 40 microns in diameter and is actively motile. In its resting stage it appears round or oblong, hyaline in color, containing one or more vacuoles, a nucleus, and granular particles. Its movements may be quite active, caused by the constant thrusting out and retraction of pseudopodia. Phagocytosis of the ameba, especially of red blood cells, has been described.

Amebic dysentery occurs sporadically in this country, especially in the Southern States, where it is relatively common. A number of cases are reported annually among soldiers and others returning from the Philippine Islands and other tropical regions.

Pathology.—The mucous membrane is highly congested, containing small spots of extravasated blood, the surface being covered with a whitish or bloody mucus. Ulcers of the large intestine involving the mucosa and submucous tissue form the characteristic lesion; rarely the muscular and peritoneal coats are included in the ulceration, but cellular infiltration occurs throughout the deeper layers. Atrophic cicatrices and a narrowing of the lumen of the bowel may occur.

Symptoms and Clinical Course.—These are the same as in catarrhal dysentery, but more protracted, the stools containing the *entamœba*. Distinct intermissions occur, in which the patient becomes better, but again relapses. The stools are watery and more copious although less frequent than in the catarrhal form. Abscess of the liver is a common complication.

The diagnosis rests upon the history, prolonged course, and the presence of the ameba in the stools.

To examine for the organisms, the stools should be passed into a clean and warm bed-pan; a small mucoid particle is selected, quickly placed upon a warm stage and immediately examined.

Prognosis is guardedly favorable.

Prophylaxis.—Since the mode of infection is the ingestion of water and food containing ameba, it is of signal importance that all possibly contaminated water or food be sterilized. Another

important consideration is a knowledge of the importance of the carrier problem, the stools of all persons preparing food in localities where amebic dysentery is prevalent should therefore be examined for the 4 nucleated cyst of the pathogenic ameba. It must be remembered that while emetin controls the dysenteric manifestations of amebiasis it does not seem to cause the disappearance of the parasite, so that patients who have amebic dysentery tend to become carriers (Stitt). The same precautions recommended for cholera are applicable here.

Treatment.—The patient must be put to bed and given a liquid diet, such as peptonized milk, beef-juice, barley-water, light animal broths.

The **emetin** treatment may now be considered as the specific one for amebic dysentery. In Brazilian ipecac about 72 percent of the total alkaloids is emetin, so that it is better than Carthagena ipecac which contains only about 40 percent of emetin. Emetin was recommended for dysentery as long ago as 1817, but owing to the impossibility of differentiating between bacillary and amebic dysentery, until recently, this method of treatment was little advocated. It is usual to give from 1/3 to 2/3 grain of emetin hydrochlorid, dissolved in sterile saline, by hypodermic injection into the subcutaneous tissues. Some now give as high as 1 grain daily for about 10 days, but Vedder prefers 1/3 grain repeated 3 times daily. In these doses there is practically no nausea (Stitt). The use of this drug has caused the rapid disappearance of the amebæ and of the intestinal symptoms; and so far it seems to be unattended by any bad after-effects.

For internal medication the use of laudanum (30 drops), followed by ipecac (30 grains) within half an hour, has been highly extolled by a few physicians, though decried by others. These remedies may be repeated 2 or 3 times during intervals of 24 hours. During the administration of the ipecac it is important that only milk be given; beef-tea, bread, etc., prevent the favorable action of the drug. On the second day the ipecac is given in reduced quantity supplemented by bismuth salicylate, quinin, naphthol and opium.

Warm injections of quinin (1 : 5000 to 1 : 1000) have been successfully used. The quinin solution has a destructive action on the protoplasm of the ameba.

If diarrhea is excessive, give:

℞.	Codein sulphate,	gr. iv
	Naphthalin,	gr. xl
	Bismuth subnitrate,	ʒ jss.

Divide into 6 powders; 1 powder every 3 hours.

Pain must be relieved by opium (preferably given by the rectum in suppository or small starch-water enemas) or hypodermic injections of morphin (1/6 of a grain) with atropin (1/125 of a grain). The blood should be carefully examined for the plasmodium malariæ, and, if it is found, quinin is indicated in appropriate doses.

For the treatment of hepatic abscess see LIVER (Abscess).

Bacillary Dysentery (Acute Specific Infectious Dysentery).

Definition.—Dysentery due to the *bacillus dysenteriæ*, the form occurring most frequently in temperate and tropical countries, may be (1) *pseudomembranous*, *croupous* or *diphtheritic*, (2) *ulcerative*, or (3) *chronic*. The chronic form may result from catarrhal or amebic dysentery, but in most cases is associated with Shiga's bacillus.

Etiology.—The causal microorganism, *bacillus dysenteriæ*, was discovered by Shiga in 1898, and its pathogenicity confirmed by other observers, prominent among whom are Flexner, Barker and Kruse. The organism belongs to the typhoid-colon group and resembles the typhoid bacillus both morphologically and in certain cultural peculiarities; it is slightly motile when freshly isolated, flagellate, and renders milk alkaline. The bacilli are found in large numbers in acute cases, and in general become more numerous as the attack subsides and the acute inflammatory changes in the bowel disappear. A characteristic agglutination reaction takes place between the bacilli and the blood of dysentery patients.

Pathology.—In cases running an acute and fatal course in from 48 to 72 hours the mucous membrane of the large, and part of the small intestine, is found greatly swollen, infiltrated with blood and serum, and of a pulpy consistency, but no false membrane is formed, death occurring early. The variety usually seen, however, is the *diphtheritic* or *pseudomembranous*, in which a variable portion of the large intestine, sometimes only the rectum and sigmoid, sometimes almost the entire bowel, is involved. The false membrane is grayish-white, granular, deeply injected and covered with blood-stained mucous. Microscopically it is composed of a fibrinous and cellular exudate which penetrates into the depths of the mucosa, invading and causing necrosis of the glands of Lieberkühn. Bacteria in large numbers are present, and the blood-vessels of the mucosa show thrombosis.

The *ulcerative* type is characterized by the formation of a clear line of demarcation between the living and the necrotic tissues. The ulcers may heal or the *chronic* form of dysentery may develop through extension of the ulcerative process into the deeper layers, with the formation of new tissue and thickening of the gut. Secondary infection with pyogenic organisms takes place, and the course of the disease is marked by frequent exacerbations. Polypoid growths and strictures are among the possible results.

Symptoms.—The symptoms are those of the simple catarrhal form greatly intensified. The fever is higher, the pain is greater, the tormina and tenesmus are more severe, the stools more bloody, and the adynamia more profound. Delirium is often present. The abdomen is tender and swollen, and typhoid fever may be simulated. The symptoms in the secondary form are less severe than in the primary.

Complications and Sequels.—The complications

in this form of dysentery are numerous. Fatal *hemorrhage* from the bowel and *perforation* are occasional occurrences. Perforation is followed by peritonitis, the local symptoms of which vary with the seat of the perforation, and which usually proves fatal. *Perityphlitis* and *proctitis* occur in this way. *Peritonitis* may also arise by extension of the inflammation from the mucous coat.

Hepatic or *hepatopulmonary* abscess is the most important complication of this, as well as of the amebic form of dysentery. It is ascribed to thrombotic extension from the seat of inflammation along the vessels of the portal system into the liver, or to emboli carried from the primary focus to the liver. See LIVER, Abscess.

Association with malaria has been observed, and a form of septic arthritis, which may also be of pyemic origin. Paralysis, pleurisy, pericarditis, endocarditis, and Bright's disease are among the sequelæ reported.

Diagnosis.—This is established by demonstrating the *bacillus dysenteriæ* or by the *agglutination test*. In acute cases the bacilli are abundant and can be recovered without much difficulty from the blood-stained mucus in the stools. Plate cultures upon agar-agar are made and incubated for 24 hours. The colonies which have developed at the end of this time are carefully marked with a blue pencil for further study, and the plates returned to the incubator for another 24 hours. The second crop of colonies usually contains a large proportion of Shiga bacilli, which grow more slowly than the colon bacillus in the mixtures of organisms. Transplantations from the second crop of colonies are made into glucose agar tubes, which are incubated for a day, and all gas forming colonies are excluded as being nondysenteric. The tubes which show no gas are then further examined, and among them the specific organisms will be found (Duval).

The *agglutination test* is easily obtained in positive cases in dilutions varying from 1 to 20 to 1 to 1000 in from one-half to one hour, and as early as the third or fourth day of illness. Twenty-four hour cultures on agar-agar are employed, from which suspensions are made in bouillon. The wet method, by which the blood is obtained in capillary tubes, is to be preferred. The test is applicable to the study of all cases of dysentery, as well as the enterocolitides of children.

Prognosis.—The prognosis of this form of dysentery is the most unfavorable of all the varieties. Most patients die, death being preceded by extreme adynamia and other symptoms of the typhoid state, including dry tongue, stupor, emaciation, and the cadaveric countenance. Consciousness is sometimes persistent to the end.

Prophylaxis.—Since the mode of dissemination of the bacillus of dysentery is similar to that obtaining in cholera and typhoid fever through the stools the same prophylaxis is applicable. Food should be screened from flies, stools should be disinfected, drinking water and food should be sterilized. Eating and drinking utensils should be cleaned with boiling water, dried with sterile towels, and handled with clean hands. The ease with which water closet seats may be contaminated should make us pay great attention to their disinfection during an outbreak of bacillary dysentery. The same applies to the bed clothes of such patients sent out for laundering. Great care should be given to the washing of one's hands prior to eating. The greatest care must be taken with rectal tubes when used for treatment. It is better to make an invariable rule to confine the use of a single tube to a single patient, as the rubber tubes are difficult to disinfect other than by boiling and such treatment, especially in the tropics, soon ruins the tube (Stitt).

Treatment.—The first consideration in the treatment of bacillary dysentery is a bland and nonirritating but nourishing diet; one that leaves as little residue as possible.

Opiates are needed to relieve the pain, and their hypodermic injection is sometimes especially useful for this purpose. When the necrotic membrane is removed, an extensive ulcerated surface remains to be healed, and this is favored by the restrained peristalsis that opium produces. The same purpose may be served by the use of ipecacuanha. On the other hand, it is doubtful whether soluble remedies intended for the direct healing of the ulcers ever reach these surfaces in an active state when administered by the mouth. Bismuth, being largely insoluble when administered in large doses, undoubtedly reaches the bowel, and may perhaps produce some healing effect. More promising is the use of iodoform, which may also be expected to reach the lower bowel in a similar manner, and which is not only more healing in its action but is also antiseptic. It may be given in a pill or capsule in doses of 1/2 to 3 grains. For colon irrigation astringent antiseptic solutions are used. After a cleansing enema of normal saline solution nitrate of silver (20 grains to the pint) may be given, followed by an enema of normal salt solution. Hydrogen dioxid solution is useful.

Serum Therapy.—While a very considerable reduction of the mortality of dysentery has appeared to result in Japan and Russia, from 32 to 12, 9 and even 4 percent, the results thus far obtained in this country have not been sufficient to justify any conclusions as to the efficiency of sera, although they show it to be harmless even in the case of little children.

Chronic Dysentery.

Any one of the forms of dysentery described may become chronic. All the lesions occurring in the other varieties of dysentery may be present. The most common is ulceration, varying in extent and exhibiting also efforts at healing.

Treatment.—The patient should be put to bed, and given a diet easy of assimilation and furnishing a minimum of waste. Its quantity should be just what is needed, and no more. Tyson has little confidence in methods of treatment the object of which is to get remedies to the diseased bowel by way of the mouth. Bismuth in large doses and iodoform may be tried for the purpose; 1/2 dram to 1 dram of bismuth should be given at a dose,

so that from 12 to 15 drams are given in the course of a day. Iodoform may be given as directed for diphtheritic dysentery.

The topical treatment of chronic dysentery by way of the rectum is that on which most reliance is placed at the present day. Its object is to get remedies to the diseased part. With this in view they are dissolved and their solutions are introduced into the lower bowel. Nitrate of silver is the favorite remedy, but alum, sulphate of zinc, sulphate of copper, and acetate of lead are also used in the same doses. From 20 to 30 grains are dissolved in 1 pint of water, and from 3 to 6 pints are introduced at one time through a long tube, gently forced well up into the bowel; but at the onset weaker solutions and smaller quantities are injected. The patient should be placed on his back, with the hips elevated by a pillow, so that there may be the cooperation of gravity. This treatment is sometimes painful. Very decided counterirritation to the abdomen by iodin, and even by blisters, is sometimes of decided benefit. Irrigation of the colon through an appendiceal fistula has been advised. (See Appendicostomy.)

DYSIDROSIS.—Excessive activity of the sweat-glands, in association with a retention of their secretion, probably due to some neurotic disorder. It is a rare disease of a vesicular and bullous character, limited to the hands and feet, and thought to be due to a depressed state of the nervous system. It is more common in women and in adult life, and is to be differentiated from eczema and pemphigus.

The treatment keeps in mind the general health, tonic remedies directed to the nervous system, and, locally, soothing and anodyne applications, such as lead-water and laudanum, boric acid lotion, oxid of zinc, boric acid, and diachylon ointment; or—

℞. Powdered salicylic acid, gr. x
Powdered boric acid, } each, ʒ ij
Powdered starch, }
Petrolatum, ʒ iv.

The external treatment is similar to that of acute eczema. See Sweat-glands.

DYSLALIA.—See Speech Defects.

DYSMENORRHEA.—Painful or difficult menstruation.

Etiology.—Dysmenorrhea sometimes occurs independently of any local lesion. These cases are neurotic in origin or they are the result of malnutrition and of bad hygienic surroundings. They are usually associated with scanty menstruation, and sometimes with long periods of amenorrhea.

The local causes of dysmenorrhea are important. They are imperfect development of the uterus and atresia of the cervix; displacements, particularly anteflexion; inflammation of the tubes, ovaries, pelvic connective tissue, and endometrium.

Symptoms.—The pain of dysmenorrhea varies in intensity, position, and character. In women with unstable nervous systems the pain is usually very severe. The situation of the pain depends very largely upon its cause. When the result of inflammation of the pelvic connective tissue, it is usually located in the back; if due to tubal and ovarian disease, in the ovarian region; if due to stenosis of the cervix or anteflexion, in the middle line of the abdomen just above the symphysis pubis. The pain may be most marked before the menstrual flow begins, as in those cases due to anteflexion and stenosis, or it may continue throughout the entire period.

The treatment of dysmenorrhea depends upon the cause. If constitutional in origin, change of surroundings, attention to the diet and general health, and the administration of nerve sedatives will prove of value. Hyoscin, chloral and the bromids, administered just before the menstrual periods, have been followed by good results.

Dysmenorrhea due to anteflexion and stenosis will require dilatation of the cervix. Intrauterine inflammation usually needs curettage; pelvic inflammation will require its appropriate treatment.

Membranous dysmenorrhea is a peculiar and rather rare variety of painful menstruation, attended by the expulsion of membrane from the uterus. The causes of this condition are not known. It occurs most frequently in virginal and unmarried women. It must not be confounded with an early abortion or discharge of deciduæ in an extrauterine pregnancy.

The treatment consists in thorough curettage that may have to be repeated several times before cure is obtained.

DYSPEPSIA.—See Gastric Neuroses, Gastritis, etc.

DYSPHAGIA.—Difficulty in swallowing or inability to swallow. It is a sign of spasm or paralysis or disease of the pharynx or esophagus or of neighboring structures. A foreign body may remain lodged in front of the epiglottis, in the pharynx, or in the loose tissue behind the pharynx, eluding observation, and cause dysphagia.

Spasmodic dysphagia, though usually of central origin, may be due to strychnin poisoning, tetanus, hydrophobia, or inflammation of the cervical cord, and may occur in epilepsy or early insanity. The ordinary spasmodic stricture, very rare among men, is not marked by much pain or craving for food, emaciation, or cough, exhibits no swelling, secondary growths, or hemorrhage, and it vanishes under anesthesia. The immediate violent return of a mouthful of food or milk is an important sign of spasmodic stricture. Electricity often cures, the frictional form being the best. The positive pole of a continuous current may be placed at the back of the neck, and the negative pole over the pharynx or inside the mouth, if it can be borne. Tonics and antispasmodics and an improved mental and moral tone are indicated. In grave cases the cure is tedious and the relapses common.

Dysphagia from disease is usually the result of chronic enlargement of the tonsils (especially in children), acute pharyngitis, pharyngeal erysipelas, retropharyngeal abscess and tumor, spinal disease, nasopharyngeal tumor, and ulceration back of the pharynx and hidden by the uvula. When the

disease is confined to the esophagus, it may be due to erysipelatous and membranous inflammations, pouches, diverticula, valvular obstruction, or benign tumors. Most commonly, however, simple and syphilitic ulceration and malignant disease are responsible. Simple ulceration often follows the swallowing of boiling water, soap-lees, or strong acids. There are no tumors or diseased glands in simple fibrous stricture of the esophagus. The passing of bougies to dilate the stricture is never free from the danger of perforation. A black, olivary catheter is useful, and may pass best after the patient has taken a mouthful of water, or wine, with the head thrown back a little. Malignant disease causing stricture is usually of epithelial type, and is most common in men. The dysphagia is usually gradual. Food may be given through a rubber catheter, or a fine tube may be worked down over a long piece of catgut and tied in.

Disease of the thyroid gland or hyoid bone, mediastinal tumors, advanced spinal curvature, paralysis of the internal or external laryngeal muscles, inflammation of the trachea, acute or chronic edema of the glottis, and ulceration of the esophagus are causes of dysphagia. Dysphagia in combination with cough or dyspnea indicates that the larynx must be examined. Dysphagia may be caused by an aneurysm of the carotid or innominate artery or of the aortic arch. No instrument should be passed down the esophagus in such cases. See Esophagus.

DYSPHASIA.—Imperfect or disconnected speech arising from loss of or faulty arrangement of words, and dependent upon a central lesion. See Aphasia.

DYSPHONIA.—A condition of defective voice; hoarseness. Dysphonia implies imperfect and irregular approximation of the vocal cords in the production of voice, and anything that produces this imperfect approximation may cause it. General or local chronic swelling of the mucous membrane of the larynx, interfering with the closure of the rima; simple, syphilitic, tubercular, and diphtheritic ulceration or exudation; neoplasms, old cicatricial contractions, paralysis of one adductor, or ankylosis of the cricoarytenoid joint, and the general exhaustion seen in phthisis and chorea are among the causes.

The treatment requires removal of the cause as the first object. As simple overstraining is most common, rest should be enjoined. When the voice must be used, the following gargle may tide over an emergency:

℞	Tannic acid,	ʒ j
	Boroglycerin,	ʒ ij
	Tincture of capsicum,	ʒ ss
	Acid infusion of rose, enough to make,	ʒ x.

Use frequently as a gargle.

Local laryngeal disorders interfering with the closure of the rima glottidis may be dealt with surgically. Diphtheria demands serious and prompt treatment adapted to the disease. Hoarseness from central lesions needs for its relief treatment directed to the primary lesion. Remedies suitable for Laryngitis (*q. v.*) are often serviceable.

DYSPNEA.—Difficult or labored breathing. It is due to various causes. It may be either *inspiratory* or *expiratory*, according as it is mainly dependent upon the muscles of inspiration or expiration; or it may be *general*—that is, both inspiratory and expiratory. It may be the result of heart-disease, nephritis, or anemia, or it may occur from conditions preventing or impeding access of air to the air-passages (1) in the nose and nasopharynx; (2) in the pharynx; (3) in the larynx; (4) in the trachea; (5) in the bronchi; (6) in the lungs. In the first instance acute catarrhal or inflammatory tumefaction of the mucous membranes, neoplasms (polypi, adenoids, malignant growths), and deviations of the nasal septum are causative. In the second instance acute tonsillitis, hypertrophy of the tonsils, benign and malignant new formations, foreign bodies, traumatic and edematous pharyngitis, retropharyngeal abscess, and syphilitic contractions may be passed in review. Of conditions in the larynx causing dyspnea, acute laryngitis in infants, edema of the larynx, abscess, erysipelas, diphtheria, large benign growths, syphilis, tuberculosis, perichondritis, ankylosis of cricoarytenoid articulation, lupus, lepra, fractures and dislocations, wounds, foreign bodies, various paralyses, spasm of the glottis, perverse vocal cord action, and compression of the larynx are provocative. In the trachea various stenoses, syphilis, benign and malignant tumors, and compression from goiter, aneurysm, enlarged glands, emphysema, disease of the vertebral column or of the bones of the thorax may be considered.

Capillary bronchitis, diphtheritic deposits, syphilitic cicatrices, foreign bodies, and intrabronchial tumors may cause dyspnea from affections of the bronchi. In the lungs pneumonia and other inflammatory processes, collapse, and atelectasis of the lungs, edema, phthisis, and gangrene, and compression of the lung from tumors or pleuritic effusions, hydrothorax and pneumothorax, may cause dyspnea.

When due to affections of the pharynx or of the trachea, the respiratory movements are prolonged, and there are inspiratory depression of the epigastrium and a tendency to edema of the lung. The degree of dyspnea depends upon the degree of stenosis and upon the quickness of its development. See Asphyxia, Artificial Respiration.

DYSTOCIA.—Difficult labor. It may be *fetal* or *maternal* in origin.

Fetal dystocia may be caused by prolapse of the cord, overgrowth of the fetus, malformations and diseases of the fetus, malpresentations and malpositions, and plural births.

Maternal dystocia may be caused by anomalies in expulsive or resistant power, hemorrhage, or disease. See Fetus, Labor, Pelvis, etc.

DYSURIA.—Difficult or painful urination. It may be due to calculi, cystitis, spasm, or urethral stricture, and is considered under these special headings.

E

EAR, DISEASES.

Diseases of the External Ear,

Anomalous formations of the auricle are sometimes found; they are generally associated with defects in the meatus or the deeper parts of the ear.

Impacted cerumen is due either to increased activity of the glands or to obstacles interfering with the escape of their secretion. The former condition is often associated with disorders of the external and middle ear; the latter may be produced by exostoses or foreign bodies, or by the cerumen being pushed into the meatus during attempts to cleanse the ear.

The symptoms vary according to the size and position of the plug. They are, generally, deafness, often coming on or increasing suddenly, tinnitus, giddiness, and cough; usually there is no pain. The glistening surface of the wax has been mistaken for the membrana tympani.

Treatment.—Syringing with warm water is generally sufficient to clear the meatus if the stream is directed against its floor, but should the plug be hard and near the orifice, it may be gently moved with a spud. If the syringing causes pain, the wax may be softened with the following drops:

℞.	Sodium bicarbonate,	gr. xxx
	Glycerin,	ʒ j
	Water,	ʒ j.

If the ear is tender, a few drops of laudanum may be added. After the wax has been removed, the meatus should be dried with absorbent cotton-wool and a piece kept in the meatus for some hours.

Othematoma, or blood-tumor of the auricle (*hematoma auris*), may occur spontaneously or be due to injury; the former is much more commonly found among insane patients, and more often in men than in women. It appears as a swelling on the outer surface of the auricle, produced by the effusion of blood beneath the perichondrium. The size, outline, and tenseness of the tumor depend upon the amount; its color, on the depth. If the tumor is small and not very tense, it may be left to subside, or the fluid may be evacuated and pressure applied. Traumatic cases are sometimes attended by great disfigurement.

Fungi in the external auditory meatus are usually found when there has previously been disease of the parts, producing an accumulation of epidermic scales. There are usually tinnitus, pain, and impairment of hearing. On examining the meatus the fungus is seen on the walls of the canal, and often also on the tympanic membrane. The ear should be syringed several times a day with a warm solution of perchlorid of mercury (1:1000) or hyposulphite of sodium (5 grains to 1 ounce), and then a few drops of warm alcohol should be put into the ear. This should be continued for several days.

Circumscribed or furuncular inflammation of the external meatus is usually found in the cartilaginous portion and is often associated with deranged health; it may be due, however, to local irritation. If the deeper part is affected, fever, and even delirium, may occur, especially in children. The pain often radiates over the side of the head, and is increased by movement of the jaw and by making pressure over the tragus; it generally increases toward night, and continues, with but slight diminution, until the abscess bursts or is opened. Deafness, when present, is mainly due to the obstruction. Tinnitus may be present. There is often no congestion of the meatus, but one or more extremely tender swellings inside. Recurrence is quite common, especially in debilitated subjects.

Treatment.—Leeches may be applied to the tragus, plugs of gelatin containing 1/6 grain of extract of opium inserted into the meatus, and an incision made into the swollen tissue. Applications of ichthyol and menthol, and dry heat, *i. e.*, hot water bag or hot salt bag, are also advised. After the incision the parts should be painted with carbolized glycerin, solution of boric acid or ointment of yellow oxid of mercury. Hot compresses should not be applied to the auricle. Opium should be given internally to relieve the pain, and much attention should be paid to the general health.

Exostoses are generally multiple and sessile, and they vary in size from slight elevations to large rounded projections. They are often associated with chronic catarrh of the middle ear, and are also said to be caused by gout, syphilis, and sea-bathing. They grow slowly, and should not be interfered with unless they close the meatus. They can be removed with a dental drill. Pedunculated growths are sometimes found in cases of chronic suppuration; they grow quickly, and are, as a rule, easily removed with forceps.

Foreign Bodies in the External Auditory Meatus.—The first and important injunction is to be sure that there is a foreign body in the ear before endeavors are made to extract it. Much damage has been done by groping after a foreign substance said to be in the ear that was not there, and never had been there. In no case should any one not specially trained use any form of surgical instrument to extract a foreign body from the ear. If a living insect has entered the ear, a few drops of sweet oil will smother it, and it may then be syringed out with warm water. If an inanimate substance has been placed in the ear, as is often done in play by children, syringing with warm

water will generally remove it if the ear has not been previously scratched by probes or forceps. If the latter has been done, the child should be etherized, and the foreign body removed by an expert. There is no haste demanded in these cases. The foreign substance had better be left in the ear indefinitely than to apply rough measures for its removal. What a child can slip into the ear in play can be easily removed if the physician first called knows how to do it. Death has resulted from unskilful endeavors to remove a foreign body from the ear of a child. Not the foreign bodies in the ear, but the improper treatment is the cause of death in such cases. The instillation of oil into the ear for the removal of foreign matter from it is futile. If, as sometimes happens in tropical countries, the larvæ of flies are present in the ear, a drop or two of chloroform or ether should be put into it.

Diseases of the Middle Ear.

Otitis media (inflammation of the middle ear, tympanum, or drum-cavity) is divided into 4 clinical forms: viz., acute catarrhal, chronic catarrhal, acute purulent, and chronic purulent otitis media.

Acute catarrhal otitis media is the original form of all the other phases of otitis media. It is caused most frequently by acute coryza, or cold in the head, though it is often caused by the exanthems, typhoid fever, and influenza, the infection entering through the tube, through the meatus, or through the blood. Other factors in its etiology may be traumatism and reflex irritation such as dentition. Its earliest symptoms are a painless, obstructed sensation in one or both ears, with slight hissing or pulsating tinnitus, but without pain, and altered hearing. Sometimes the hearing may be hyperesthetic. Most persons experience this simple stage of catarrhal otitis media with a cold in the head. As a simple coryza passes off all ear symptoms go with it if the local treatment of the nares and nasopharynx has been mild or gentle and purely negative. If we will note conditions in our own nasopharynx and middle ear when we have a cold in our head or an acute nasal catarrh, we shall observe that as secretion increases in the nasopharynx, the Eustachian tube ceases to open at each act of swallowing as it does in a normal state. The ear may feel more or less stuffed, and now and then there may be a dart of slight pain from the posterior nares into the ear. If we are patient, and do not treat locally the nasopharynx, nares, or Eustachian tube in any way, or only with a bland, oleaginous spray at such a time, we shall note that as secretion in the nares and nasopharynx diminishes, in the course of from 3 to 6 days, the Eustachian tube will open spontaneously, and the ear will feel natural once more. This occlusion of the Eustachian tube in the early secretory stages of an acute coryza is beneficent, since it is nature's seal set against the entrance of pathogenic germs from the nasopharynx into the normally aseptic middle ear. If this seal is broken, either by forcible blowing of the nose or by the inflation bag of the surgeon, it is done at the peril of the patient, as pathogenic germs are very likely to be forced by such manipulations from the nasopharynx into the middle ear, and an acute purulent otitis media thus developed. This latter condition constitutes the so-called "earache" of children. Acute catarrhal otitis is almost as common as acute coryza, and as simple, if properly managed; but the transition to acute purulent otitis —a serious malady—will be rapid if the local treatment of acute catarrhal otitis is injudicious.

If the membrana tympani is examined in the early stages of a simple acute catarrhal otitis media, it will be seen to have undergone very slight, if any, change. It may be slightly pink, or even red, along the malleus and periphery. But its general surface undergoes no change in appearance or position in these early stages of acute catarrhal otitis media.

The acute catarrhal otitis media of the exanthems, of typhoid fever, or of influenza, originates also by infection from the nasopharynx but, owing to the more weakened condition of the patient in these maladies than in simple coryza, tends to a more virulent course from the onset. Nevertheless, the simpler the local treatment of the nasopharynx and ear in such cases, the less likelihood there will be of secondary infection, and the more favorable will be the course of the aural disease in the end.

Treatment.—Any infection or irritation in the nasopharynx should receive proper local treatment; in order to get free drainage through the tube 1 to 8000 adrenalin chlorid solution in 4 per-cent cocain solution applied to the mouth of the tube through the nose and mild Politzerization should be employed. If there is a pain in the ear, it can best be allayed with *dry* heat, by means of the hot-water bag, hot-salt bag, or hot stone wrapped in flannel. The application of dry heat about the ear may be combined, in those instances demanding it, with an antifebrile treatment of the general system. Calomel should be given at the outset. Any systemic disease which might act as a predisposing cause should be carefully treated. There will be no harm in instilling into the ear, if it aches, 10 drops, *warmed*, of a solution of carbolic acid (1:40) or one of formalin (1:2000), if these can be borne. But the membrana tympani, when in the slightest degree inflamed, cannot endure the pressure of a column of fluid in the canal. When it can, however, and these drops give relief, it is, in the opinion of many, the heat, and not the drug, that allays the pain, and therefore, hot water may be tried first.

The advantage of instilling an antiseptic into the inflamed ear in the early stages, before the perforation of the drum membrane occurs, is that the auditory canal is thus rendered more or less aseptic—*i. e.*, free from staphylococci—and hence a safer place into which the membrana may rupture or be ruptured, since when the membrana ruptures and pours out the germs causing the acute inflammation into the outer ear freed from staphylococci, there is less danger of the entrance of the last-named germs, the promoters of chronic purulency,

into the drum-cavity, and secondary infection is less likely to occur.

Acute Purulent Otitis Media.—Acute catarrhal otitis media, instead of undergoing resolution, may pass into acute purulent otitis media (especially in exanthems) from the passage of pathogenic germs from the nasopharynx into the middle ear. (And see COLON BACILLUS INFECTION.) The pain will now become more intense, the hearing dull, tinnitus will become louder and distressing, and fever usually sets in, if it is not already present. The membrana tympani will be found injected, and its features lost in the general swelling of its surface as the inflammation within the drum-cavity advances. The patient should be put in bed and kept on restricted diet, his bowels kept open with calomel and salts. Dry heat about the ear will be of benefit in allaying the pain, and sometimes in causing resolution. The ear should be douched every hour or at least 3 times a day, according to the case, with warm carbolic acid solution in water (1 : 40) or saturated boric solution at 99 to 105° F., from a fountain syringe. Judicious local treatment should be given to the nasopharynx in order to obtain tubal drainage. If the pain ceases in a few hours under the foregoing conservative treatment, well and good. If pain continues over 6 hours in a child, or over 12 hours in an adult, without spontaneous rupture of the membrana tympani, paracentesis of the membrana must be performed, because hearing and life are at stake in many cases if the drum-membrane is not opened. As the inflammation advances the membrana tympani will be seen to bulge, especially at its posterior half. Sometimes the most prominent portion, however, is in the membrana flaccida. As the inflammatoin in the drum-cavity increases, of course the pain becomes most intense, children being thrown into convulsions in some instances. After secretion forms in the drum-cavity and the membrana bulges, no relief can be obtained until an escape is offered to the pus by either a spontaneous or an artificial opening in the drum-membrane. In time a spontaneous opening will usually occur, but as the tendency is for secretion inside the drum-cavity to inspissate, the longer perforation is deferred the less likely it is to occur spontaneously, and the retained secretions will burrow toward the meninges, sinuses, and brain-cavity, especially in children. Hence the vital indication is paracentesis in a case of acute otitis media with the membrana still imperforate after a few hours of great pain followed by bulging of any part of the membrane. When the discharge becomes scanty the douching may be stopped and after dry cleansing, boric acid powder may be insufflated. When the active symptoms have subsided mild daily Politzerization should be performed.

In a case of earache with congested and bulging membrane the surgeon must be careful to differentiate between swelling of the outer surface of the membrana and bulging of this structure from its outward pressure by secretions on its inner surface, as it occurs in so-called myringodermatitis. In the latter the prominence is generally more punctate and sharply defined; often being, in fact, a yellowish, brownish, or livid blister. In otitis media the protrusion from retained secretions comprehends more of the surface of the membrana, especially in its lower and posterior portions. In both forms of acute otitis media the condition of the membrana tympani must be watched carefully and constantly throughout the progress of the disease, for only by an intelligent observation of its varying conditions can treatment be properly conducted. In acute otitis media, furthermore, great aid in diagnosis and treatment is derived from observation of the state of the walls of the auditory canal—whether or not they participate in the congestion or inflammation of the drum-cavity. If they do share in this inflammation, the case is always complicated thereby.

Chronic Purulent Otitis Media.—Chronic purulent otitis media is due to the permanent lodgment of staphylococci in the acutely inflamed middle ear by reason of imperfect drainage.

The symptoms of chronic suppuration of the ear are, objectively, a more or less copious and offensive discharge from the ear, with a perforated membrana tympani. The perforation may vary from the size of a pin's head to that of the entire membrana. The membrana loses its luster first, and, sooner or later, becomes thick and red, and, finally, denuded of epithelium, raw and secreting. When the perforation is large, all the ossicles may be visible; or the malleus—the manubrium being partly destroyed by caries—may be the only one visible. The incus is generally the first to go, in part or entirely, as its nutrition is scanty. The stapes is the most resistant of all, especially in its foot-plate, as it is nourished by the vascularity of the inner wall of the tympanic cavity, of which it is practically a part. The head and crura of the stapes may be destroyed by necrosis in some virulent cases. But, as a rule, it persists the longest of the three bonelets, though it may remain invisible through the perforated membrana, because buried in the swollen mucous membrane of the drum-cavity. As this swelling goes down under treatment and the discharge ceases, the stapes comes into view, if still intact.

The subjective symptoms of chronic purulent otitis media are hardness of hearing or deafness, tinnitus of more or less intensity, either constant or interrupted, ear-vertigo at times, in adults, and in children attacks of so-called "gatherings in the ear," and earache, with, of course, impaired hearing, and sometimes tinnitus. Adults, too, will have attacks of earache if they allow cold water or cold air to enter the diseased ear, or if they neglect a cold in the head.

Treatment.—The first endeavor should be to render the external auditory canal and middle ear aseptic. The general health should be attended to and the nasopharynx should receive local treatment in order to get free drainage through the tube. Of course, cotton must never be worn in the chronically running ear. If the discharge is too thick and too copious to mop out, it may be syringed out of the ear by means of warm water, previously boiled. To this may be added a little salt (5 grains to 1

fluidounce) or carbolic acid (1:40). Once or twice in 24 hours is often enough in the worst cases. If the discharge is not copious, it may be removed with an absorbent cotton mop, previously singed, and then 10 drops of an antiseptic solution may be put into the ear, or boric acid powder may be insufflated. A solution of formalin (1:1000, 1:2000) or a solution of carbolic acid (1:40) may be dropped in and allowed to lie there a few minutes, and then turned out into a towel. When there is a tendency to granulations, absolute alcohol may be used instead of the foregoing. This treatment may be repeated once or twice a day in the worst cases, then once a day, and, finally, every second or third day as the discharge lessens. Polypi and cholesteatomata should be removed; tiny cotton pledgets should be passed through the perforation or if necessary an intratympanic syringe with a strong bicarbonate of sodium solution in normal salt solution should be used to remove granulomata and inspissated material. If still some accumulation remains dry suction cups may be valuable.

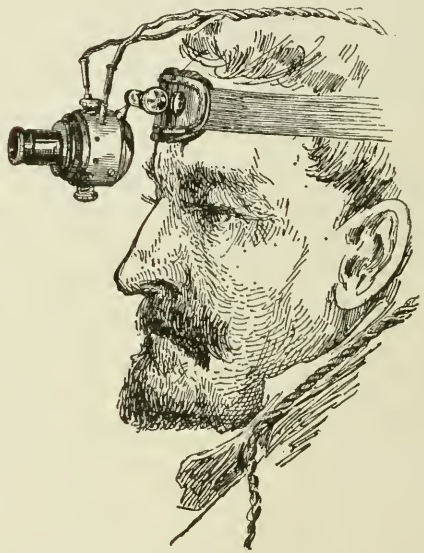
This, or a similar antiseptic treatment, persevered in for many months, will usually lessen the discharge, and in many cases check it, especially if the perforation of the membrana is below the folds and the disease largely or entirely in the lower part of the drum-cavity, or atrium. If the sole perforation is in the membrana flaccida, and the purulency chiefly or entirely in the attic, or recessus epitympanicus, it cannot be cured, as a rule, by local antiseptics. The disease being limited to the atrium and the perforation being generous, local antiseptics will often effect a cure. The surgeon must persevere for months, or even years, if he observes that the tendency of the purulency is to lessen and the condition of the diseased mucous membrane of the drum space improves.

Vaccine therapy has been tried in intractable cases with good results according to recent report and the outlook seems encouraging.

If the purulency ceases under local antiseptics, the hearing may be found to be more impaired after the discharge ceases than while it prevailed. This is due to the fact that in the healing process the partly destroyed ossicles and membrana tympani have been bound together against the promontory and oval window by synechiæ, and sound conduction thus impeded. When the largest ossicles are destroyed by necrosis or removed by the surgeon, healing of the chronic purulency of the drum-cavity ensues, without synechial interference to the oval window, and the hearing is better in such cases than when healing occurs with the ossicles in position. After six months, or sooner, if the tendency of the chronic purulency of the middle ear is not toward improvement under the foregoing local antisepsis, it is because drainage is defective, antisepsis cannot reach the intrenched staphylococci, and caries and necrosis of the ossicles, and sometimes of the neighboring tympanic walls, are advancing. This is especially true in chronic purulency of the attic. Such a patient is threatened now with deeper and most serious lesions in the antrum and mastoid cavities, involving the petrous bone on its inner surfaces, in the middle and posterior cranial fossæ.

Chronic purulent otitis media is in most instances amenable to the antiseptic treatment; but having defied local antiseptic treatment for months, and the ossicles or the petrous bone in their vicinity being carious, ossiculectomy and curettage are indicated. Thus drainage is favored. Some advise immediate resort to a mastoid operation. This is unjustifiable simply for the cure of chronic purulency, because, in the absence of urgent mastoid and cranial symptoms, ossiculectomy and removal of the remnants of the membrana and of polypi, followed by the application of antiseptics, will effect a cure.

Ossiculectomy.—In performing ossiculectomy in chronic purulent otitis media the patient should be etherized, in order to prevent his suffering and to keep him perfectly quiet. Movement of the head defeats the operation. Ossiculectomy is performed under local anesthesia by means of cocain. But anesthesia in the drum-cavity by means of cocain is not total, and the patient flinches

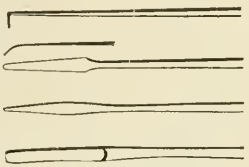


Electric Forehead Lamp.—(*Burnett.*)

and moves more or less; and as a good deal of cocain solution is required, there is some risk of toxic effects. The patient being under ether, the ear must be illuminated by an electric lamp held on the surgeon's head, like a forehead mirror on a band. Then the remnants of the membrana over the region of the incus-stapes joint should be cut away, if not already eroded by disease, and the malleus, in part or in whole, and the incus should be looked for. Sometimes the entire incus will be found in position, with its long process in connection with the stapes head and its body still in articulation with the head of the malleus. But this is the exception in chronic purulent otitis media. Most frequently the incus is entirely destroyed by necrosis. Sometimes the body of the incus, minus its long limb, is found fused with the malleus head,

and is removed with the latter when the malleus is seized with forceps and removed from the drum-cavity after severance of its suspensory ligaments, synechiæ, etc. In other instances the body of the incus is partly destroyed by necrosis, its posterior part being intact and the long limb still attached to the stapes. If the incus is present with the malleus, the former should be removed before the malleus is disturbed. If the malleus is removed first, the incus, unless adherent to it, may fall into the lower, posterior part of the drum-cavity and be lost, or recovered only after considerable, and possibly irritating, grappling. The incus being found and removed, the malleus may then be excised. In no case of chronic purulent otitis should the stapes be removed, or even mobilized, for fear of opening the oval window and inviting the entrance of pus into the internal ear, and thence into the cranial cavity.

Instruments.—The initial incisions in the membrana may be made with a sharp-pointed knife, but further cutting should be made with a blunt-pointed one. The incus is best detached from the stapes by means of the incus hook-knife, and if adherent to the attic, should be turned forward into the front and lower part of the drum-cavity by means of an incus hook-knife larger and blunter than that for detachment of the incus from the stapes. When the incus is entirely freed from its attachments, either normal or pathologic, it may be pulled from the drum-cavity by the blunt incus hook-knife or by means of the foreign-body forceps of Sexton's pattern.



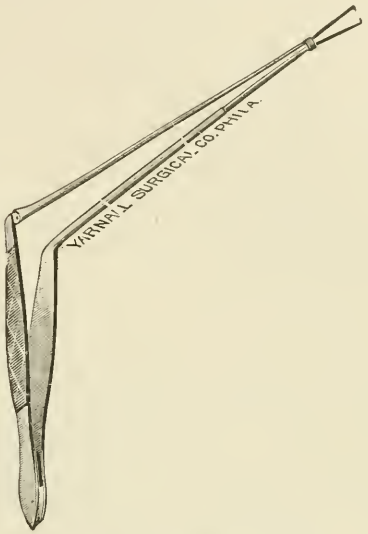
Instruments Used in Ossiculectomy.

After-treatment.—In no case should the drum-cavity be curetted, as such a procedure is very likely to wound the facial canal, irritate the facial nerve, and induce facial palsy. It is, furthermore, unnecessary, as granulations will disappear and denuded bone surfaces heal under proper antisepsis.

After the removal of the diseased remnants of the membrana and ossicles, the ear should be mopped with an antiseptic, like alcohol, or solutions of bichlorid (1 : 1000), or formalin (1 : 1000), and the meatus occluded with a light tampon of sterilized iodoform (5 percent) or carbolated (5 percent) gauze, and the ear let alone for 24 hours. If the gauze in the ear becomes moist with blood or bloody serum, it should be removed and dry dressing placed in the meatus, not far in the canal. In all cases the discharge diminishes at once, and ceases entirely, in the majority of cases, within a period varying from a month to 18 months. The after-treatment should consist in mopping the discharge from the ear and the instillation of a formalin solution (1 : 1000) from once a day to once a week, according to the quantity and frequency of the discharge.

The hearing improves to varying extents, the general health of the patient is rendered better, especially when there have been septicemic symptoms due to the aural purulency, and the patient is freed, by ossiculectomy, from the danger of extension of the suppuration to the mastoid and cranial cavities.

Chronic Catarrhal Otitis Media.—Acute catarrhal otitis media, instead of undergoing resolution or resulting in acute suppuration, may pass into a chronic hypertrophic catarrhal otitis media. In most cases it will be found that the nasopharynx has become the seat of chronic hypertrophic catarrh. The onset of chronic catarrhal otitis media is gradual; hence it has been called chronic progressive hardness of hearing. After an attack



Sexton's Foreign-body Forceps.

of acute catarrhal congestion of the middle ear tending to chronic catarrhal otitis, the ear does not return to its normal state, but remains the seat of more or less tinnitus and of an obstructed feeling. The hearing at first is but little impaired, which leads the patient to disregard his ear-disease, thinking it will pass off, especially if the impediment is confined to one ear. However, with every cold in the head the ear quickly feels worse, and after each cold the noises in the ear and the hardness of hearing increase, and are noticed more and more by the patient and his friends.

As the symptoms of tinnitus and deafness increase, there may be added attacks of ear-vertigo and vomiting, from invasion of the labyrinth, forming a symptom complex, consisting of cochlear and vestibular symptoms, known as Menière's Disease (*q. v.*). These attacks come on suddenly, occurring once or twice a year at first, and are usually not referred to the ear as a cause either by the patient or his physician. In fact, they are commonly considered and treated as attacks of stomachic vertigo. In some instances the attacks of ear-vertigo are preceded by an increase in the tinnitus aurium, and this may arouse in the patient a suspicion that the ear-disease is the cause of his vertigo. If in the later stage of chronic catarrhal deafness chronic ear-vertigo

sets in, the deafness may be profound in one or both ears, if both ears are affected. In every case of chronic catarrhal otitis media there is, very early in the process, contraction of the tensor tympani, retraction of the chain of auditory ossicles, and consequent impaction of the stapes in the oval window. It is this last event that causes compression of the intralabyrinth fluid, irritation of the motor filaments of the auditory nerve and cerebellar peduncles, with reflex phenomena of vertigo.

Treatment.—Since chronic catarrhal otitis media is caused by chronic hypertrophic nasopharyngeal catarrh, and not by throat-disease, the nasopharynx must receive the first attention, and the general health improved, if impaired, as it generally is. In order to improve the circulation and drain the middle ear, forcible Politzerization should be performed, and in the event of no result, catheterization, the frequency depending on the relief obtained without irritation. Gentle pneumomassage of the membrana tympani and of the ossicles will be beneficial. This is best accomplished by the Siegle pneumatic speculum, applied under direct inspection of the membrana by the surgeon. Hot air inflations have proved to be of value.

If, in spite of rational, conservative treatment the ear symptoms grow worse, occasional resort may be had to removal of the incus. The resultant overcoming of the retraction of the chain of ossicles, and consequent liberation of the stapes, will be followed by diminution and final cessation of the tinnitus and vertigo, and in some cases by improved hearing. The instruments and methods of procedure employed in intratympanic ossiculectomy have already been presented. In performing removal of only the incus, an incision must be made in the upper posterior quadrant of the membrana, and the incus-stapes joint exposed. The incus must then be detached from the stapes by means of traction outward and downward with the incus hook-knife. The descending ramus of the incus must then be seized with forceps and gently pulled downward and outward through the perforation in the membrana into the auditory canal, and removed from the ear. The meatus should then be occluded with a loose tampon of sterilized gauze and let alone for 24 hours. Healing by first intention usually occurs, if the ear is protected with dry sterilized gauze and let alone. Removal of the incus is never followed by inflammatory reaction if the foregoing conservative treatment is carried out. If anything is applied to the wound in the drum or to the middle ear, inflammatory reaction will surely occur.

Complications of middle-ear disease are infectious otitis interna, or panotitis (infection of the middle and inner ears), mastoiditis, osteomyelitis, caries and necrosis, phlebitis, meningitis, and brain abscess.

Mastoiditis.—Inflammation of the mastoid cells may be produced by the extension of the disease from the tympanum. Rarely it is due to extension of external inflammation. The symptoms are deep-seated pain (increasing on deep pressure), swelling and tenderness over the mastoid process, accompanied by more or less fever and rapid pulse, coated tongue, anorexia, and malaise. When the periosteum is affected, the tissues behind the ear are swollen and the auricle stands out from the head, the canal is smaller and the posterior superior, inner bony wall of the canal droops. If pus has formed, fluctuation may be detected.

Diagnosis.—In angioneurotic edema the swelling and edema are transient and not stationary. In otitis externa the auditory canal in addition to the extraperiosteal tissue is tender and swollen. In mastoid adenitis there is not often the history of middle-ear disease.

Treatment.—In the early stages rest in bed, paracentesis to secure drainage, saline laxatives, leeching over the mastoid process, douches every hour of saturated boric solution (100° to 110° F.), heat over the mastoid, normal saline solutions by rectum or mouth are indicated. If these measures fail to give relief, operation is necessary.

The Mastoid Operation. Indications.—The **simple mastoid** operation is indicated whenever an acute purulent otitis media involves the mastoid antrum and cells, characterized by the following symptoms:

1. Deep-seated, persistent pain over the mastoid.
2. Swelling (subperiosteal) over the mastoid.
3. Tenderness, probably, over the mastoid.
4. Persistent discharge after paracentesis and 6 weeks of thorough cleansing treatment.
5. Bulging of drum membrane and dropping of the posterior-superior wall, even after paracentesis.
6. Fever, especially in children.
7. Marked leukocytosis and polynucleosis.
8. Symptoms of intracranial involvement or facial paralysis.

A free paracentesis during the first few days of the attack, however, will often obviate the necessity of an operation.

The **modified radical operation** is indicated in a chronic suppurative otitis media unamenable to thorough cleansing treatment, when necrosis is limited to the mastoid antrum and cells (*i. e.*, when the tympanic cavity is not involved in the necrotic process).

The **radical mastoid operation** is indicated:

1. In the presence of cholesteatoma.
2. When there are symptoms of labryinthine involvement—nystagmus, vertigo, loss of bone conduction and caloric reflex, nausea, vomiting.
3. When an acute mastoiditis occurs in the course of a chronic purulent otitis media.
4. When facial paralysis or intracranial complications supervene.
5. When the discharge is intractable in spite of thorough cleansing treatment for at least 6 months, including use of the probe, curet, forceps, and intratympanic syringe and removal of the necrosed ossicles.

The kind of operation—simple, modified radical, or radical—preferable in the given case is best determined in the course of the operation as the exact extent of the diseased area becomes manifest upon thorough exploration.

The Mastoid Operation. Technic.—Rigid aseptic technic is of the greatest importance. The

patient should be prepared as for any other major operation. Preliminary to the operation, paracentesis is performed. The object is to explore the affected region, remove all diseased tissue and open up all the air cells to prevent recurrence and provide permanent drainage. A curved incision is made through the tissues behind the attachment of the pinna. The periosteum is cut and lifted and separated from the exposed mastoid process. The tip of the mastoid process is then removed by a large rongeur. If the disease has extended posteriorly, a posterior cut is made, the periosteum lifted and the diseased tissue removed by large or small rongeur. The bone surfaces should be levelled and smoothed with a Richard's curette. The bony trabeculæ and two-thirds of the posterior meatal wall should be removed. From the inner end of the osseous canal a slit should be made through the posterior wall of the membranous canal to the external meatus.

If the extension of disease calls for a "modified radical operation," the outer wall of the epitympanum may have to be removed down to the ossicles and the posterior wall of the bony canal down to the drum membrane and almost to the facial nerve. The ossicles, however, are undisturbed, therefore hearing is preserved.

If a "radical operation" is demanded because of extensive involvement and necrosis, it is necessary to remove the upper external and posterior meatal wall of the tympanum, avoiding the facial nerve, as well as part of the upper anterior wall. Tympanic structures should be preserved as much as possible in order to obtain better postoperative hearing. Labyrinthine involvement calls for further exposure. Unless the cochlea is diseased it should be left intact for the sake of postoperative hearing. The external wound should be closed at the earliest possible moment. In some cases this can be done at once; in others a very small drain must be inserted. This drainage should be kept up until the tympanum is entirely healed. For further drainage and to prevent adhesions Politzerization should be practised daily, beginning 3 or 4 days after the operation.

The Complete Mastoid Operation through the Diagastric Route.—Wm. S. Byrant's technic is as follows:

An incision is made "close to the posterior fold of the auricle beginning at a point on a level with the upper wall of the meatus. The incision is then carried in a curved line downward and forward to a point level with the tip of the process. The periosteum is next incised at the bottom of the wound on a line corresponding to the skin incision. Then the periosteum is lifted carefully, beginning at the tip of the process nd working upward, extreme caution being taken that the periosteum be removed in even sheets. After the anterior and posterior periosteal flaps have been loosened, the periosteum is lifted from the mastoid process entirely, the operator working around under the tip and up to the bottom of the digastric fossa. Then with a medium sized rongeur the tip is quickly removed, followed by removal of the outer table of the cellular area. The possibility of opening the sinus is thus rendered quite remote even when situated much further forward than is normally the case. If the knee of the sinus encroaches upon the posterior wall of the meatus too closely to allow easy entrance to the antrum by the usual route, the latter can be readily approached from below. The cells in the base of the process are now broken down with the rongeur and cleaned up with the curette, thus fully exposing the antrum."

Bryant considers the advantages of this method to be the following:

1. Elimination of sinus involvement and secondary operation.
2. Less time required.
3. Stylomastoid foramen readily found.
4. Convalescence is sooner and more rapid.

Caries and necrosis may attack the meatus, mastoid process, and tympanum. When this occurs, the granulations constantly return, even after persistent attempts have been made to destroy them, and the discharge frequently remains offensive. Facial paralysis may be present. In children an anesthetic should be administered, and if any caries is found, the diseased surface should be scraped and any sequestra that are present removed.

Phlebitis, when it occurs, generally affects the lateral sinus and the jugular vein, and may produce pyemia.

Meningitis and cerebral abscess may occur during acute or chronic suppurative inflammation of the middle ear, but are more often found in the course of the latter.

Localized meningitis complicating acute otitis media generally demands a simple mastoid operation with removal of every particle of necrotic bone, but complicating chronic purulent otorrhea it calls for a radical operation. The radical operation is indicated, too, in all cases of diffuse otitic meningitis.

EAR, EXAMINATION. Practical Tests for Hearing.—Unfortunately, the watch is commonly regarded as the most simple and ready test, and the voice, with all its varied possibilities, is supposed to be unscientific and haphazard. As a fact, watches vary more than voices. One can claim or imagine, with very little control upon his accuracy, that the known rhythm of the watch-tick is heard, when really inaudible; and its high-pitched, impure tone has very limited value as a test. Each watch must be tried with many normal ears to ascertain how far it should be audible: must be brought up *unseen* from a distance until heard, not withdrawn until it is hardly audible; and should be held half-covered in the hand, so that a turn of the wrist will interpose the hand and largely cut off the sound. In the individual, gain or loss may be thus determined if all conditions are strictly equalized; but imperfect hearing of the watch-tick is common in cases that hear all other sounds perfectly, and is often of no significance, while it may be audible to some who have no hearing. Much the same must be said of the Politzer "acoumeter," which has failed of the universality hoped for it.

The human voice, especially in whisper, is able to test the hearing through many octaves, and

forms the readiest, and often the best, test at our command. Loud, medium, and low voice, stage-whisper and low whisper, are fairly definite terms; while test-words, like the cardinal numbers up to 100, give ample variations and combinations of pitch. The few questions of the primary history taking, asked in a just audible tone, give the careful examiner a fair gage of the patient's defect; and having him repeat the test-words gives good control of the acuity of the hearing. As a standard, it may be stated that a stage-whisper spoken with the "reserve air" after an ordinary tidal expiration should be heard some 5 meters in a fairly quiet place—the high, sibilant sounds of *s* and *x* being generally most audible; while faint, clear whispers should be heard at 1 meter.

More valuable than any such quantitative tests are the qualitative showings of the **tuning-fork.** Various pitches must be used in any attempt at completeness; but much may be accomplished with one or two. Most authorities place first the "tenor C" fork of some 520 vibrations a second, although the "middle C," or the A-fork, of 213 vibrations a second is most sold. A lower fork is useful in revealing the beginning defects of catarrhal deafness, and the high-pitched forks best disclose nerve-lesions. A "continuous tone-series" is needed only by the specialist. With any fork the hearing distance for its tone (which can often be made pure by clamps or short sections of rubber tubing upon the tines, and varied by shifting their position) can be tested as with any other sound; but it is more precise to determine the length of time it can be heard after a certain blow. This is readily attained by letting the fork fall its own height upon a firm but not too hard surface, such as the muscle cushion above the knee or a rubber block upon the table. The A-fork, as generally made, should sound about 100 seconds, and should at first be audible at least 10 inches away in the clinic room—further in a quiet place. This is a test of **air-conduction.**

When the handle of the sounding-fork is rested (the pressure should about equal its weight) upon some part of the head, the vibrations are transmitted through the cranial bones to the auditory apparatus. High-pitched forks should have long handles, or the air-conduction, especially from the mastoid, may confuse this **bone-conduction,** which is normally about half as loud and long as the air-conduction; so the A-fork should be heard some 45 seconds by bone. This constitutes Rinne's or Schwabach's test, and is best indicated by the mathematic proportion, A.c. = 100 : B.c. = 45. Roosa and Emerson have shown the value of simply noting which is *louder* by sounding the fork close before the ear and quickly changing it to rest upon the mastoid. Many patients are confused by tests taking time or demanding precise answers, while any one should be able to correctly report whether it is heard "louder front or back—back or front," suiting the action to the word. This preponderance is best recorded A. c. > B. c., air-conduction is greater than bone-conduction; or A. c. < B. c., when air-conduction is less.

Gardiner Brown has shown that the vibrations should be palpable to the fingers holding the handle just as long as they are normally audible through the bone-conduction of the patient. This gives us a control-test, disproportion of which is a ready indication of abnormality, the patient hearing too short a time if the perceptive apparatus is in any wise impaired. A still older test is Weber's, as to whether the fork vibrating on the vertex is heard louder in one ear than the other. Simple and important as it is, this had better follow the Rinne test or the patient may report falsely, not believing his own ears when the worst ear hears under these conditions better than, and even to the apparent exclusion of, the better ear.

In practice, then, normal ears should hear the A-fork at least 10 inches (25 cm.) away, or for a period of 90 to 100 seconds; should hear it louder by air than by bone, the latter perception being lost in 40 to 45 seconds, just as the examiner ceases to feel it with his fingers; should hear it in front of the ear long after it has become inaudible through the mastoid, but should have increased bone-conduction, equal on the two sides, by stopping the ears tightly with the fingers.

A patient with **affection of the percipient apparatus,** in the labyrinth or beyond, would show reduction, great or small, of the air-conduction with greater or total loss of the bone-conduction—*e. g.*, A. c. 50 : B. c. 10—especially for low tones; the fork vibrating on the vertex or other point in the middle line of the head should be louder in the *better* ear, and probably increased by stopping the canal.

In the more common **affections of the conducting apparatus** (external and middle ear) it should be found that while air-conduction is lessened, perhaps greatly, bone-conduction may be actually, as well as relatively, *increased*—*e. g.*, A. c. 25 : B. c. 50; the fork is heard through the bone after it has become inaudible in front of the ear and is unfelt by the examiner's fingers; stopping the ears may not at all affect the sound, and from the middle line it is louder in the *worst* ear. Low tones are generally heard relatively better than high by bone; but the reverse holds for the air-conduction, and low tones may be inaudible when the shrill sounds are rather unduly distinct.

Another useful test has been devised by Politzer, in which the A-fork is sounded before the nostrils and the patient is told to swallow—it should be heard louder at the moment when the tubes open in deglutition. If either tube fails to open normally, there is less or no increase in the sound on that side; so it forms an index of the physiologic action of the eustachian tubes more instructive than testing their permeability under inflation.

Another serviceable apparatus is the **Galton whistle,** which furnishes very high-pitched sounds, a scale on the outside marking the variable length of the tube employed to form the note. Its piercing sound should be easily heard, while it can readily be concealed in the hand in examining children supposed to be deaf; so if they fail to turn toward the sound, varied through the upper octaves, which are commonly the last to be lost, it may be the sole means of deciding that no hearing remains.

It can take the place, for most purposes, of Koenig's rods or a series of tuning-forks many times as costly and less convenient.

In testing the bone-conduction there is a senile decrease to be taken into account when elderly persons are examined; and one may find that very low tones, if any, are heard through the bone. Coincident thickening of the drumhead and stiffening of the ossicular chain may markedly reduce the upper limits of air-conduction, so some have regarded this **presbycusis** as a nerve impairment or a failure of the hypothetic **aural accommodation.** It is probably to be ascribed to structural changes such as make the bones more brittle in age; but it should be borne in mind as wholly vitiating at times the conclusions that seemed deducible from the tuning-fork tests previously described. In some cases, again, care must be taken to avoid confusion of palpable with audible vibrations. Deaf-mutes will claim to hear a tuning-fork, generally by bone-conduction, when it is certain that it is merely felt. Applied to the knee, they will generally indicate the same perception of it as when it rests upon the head, showing that they have no conception of what hearing is.

Sometimes it is possible to locate lesions of the sound-conducting apparatus at the articulation of the stapes with the oval window, by reason of failure of the consensual action of the stapedius muscles of the two sides. If air-pressure or suction is exercised by the finger-tip or other means upon one drumhead and chain of ossicles, there will be, if the stapes is normally free, impairment of hearing for the tuning-fork or other sound in front of the opposite ear. Unfortunately, only a few patients can give definite and trustworthy answers to this test, called by Gellé, who devised it, "pressions centripetales."

In aural practice defect of hearing is present in 75 percent or more of the cases, in hardly one-tenth of which is the percipient apparatus at fault, and then rarely alone or primarily. Complicated cases or inaccurate responses may confuse or invalidate the tests; but usually those given will serve to locate the seat of the lesion and indicate the lines of treatment to be pursued.

The auscultation tube is a piece of rubber tubing about 30 inches long, having at each end a hollow piece of ivory or vulcanite to fit the meatus. To distinguish the end used for patients, one ear-piece may be made of ivory, the other of vulcanite. By placing one end in the patient's ear and the other in the examiner's, the condition of the eustachian tube can be ascertained while the tympanum is being inflated, by Valsalva's or Politzer's method, or by means of a eustachian catheter. Thus, if there is moist mucus in the tube or tympanum, a bubbling sound is heard, or whistling if the caliber of the tube is narrowed. In cases in which the membrana tympani is perforated the injected air can be felt by the surgeon striking against his own membrane.

Valsalva's method of inflating the tympanum consists in expiring forcibly through the nose while the mouth is closed and the nostrils are compressed by a finger and thumb. In a healthy ear the entrance of air is accompanied by a feeling of fulness and a slight cracking sound.

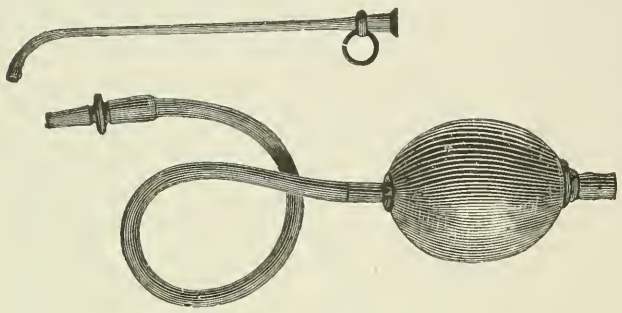
Politzer's method consists in holding a small quantity of water in the mouth, and then, while it is being swallowed, forcing air from an india-rubber bag through one nostril while the other is compressed with a finger or thumb to prevent the air escaping. The sensation produced in the ear is similar to that caused by Valsalva's inflation, but more marked. Instead of swallowing water, the nasopharynx may be shut off by the patient whistling or uttering a guttural sound, such as "huck." In children it is unnecessary, as the eustachian tube is more patent. A similar method is sometimes used: the patient is told to puff out the cheeks with air and when they are sufficiently distended, the bag is compressed.

A eustachian catheter should not be more than 4 1/2 inches long, and it is most convenient to use one with a diameter of small size. While introducing it the surgeon should stand at the patient's right side with the catheter held lightly between the thumb and index-finger of his right hand, the beak or curved end pointing downward, and allow it to slip through the nostril until it touches the posterior wall of the nasopharynx. It should then be withdrawn 1/2 of an inch, and the beak turned outward and sometimes slightly upward, when it will be found to be in the orifice of the eustachian tube.

As the dimensions of the nostrils vary considerably, owing to deviations of the septum, cartilaginous and bony spurs, and other abnormal conditions there is no fixed rule for the position of the catheter during its passage. It often passes best if the beak is directed horizontally outward beneath the inferior turbinated bone as soon as it is well within the nostril, turning it down again a little as it goes through the choana. A catheter should always be passed with the greatest gentleness, and in many instances it is best to allow it to find its own way. Should it be impossible to reach the tube through one nostril, the curve of the instrument must be increased, and an attempt made to do so through the other. If the catheter is drawn backward by muscular contraction when the beak is turned outward in the nasopharynx, it is an indication that it is behind the posterior lip of the eustachian orifice. A special catheter with a distinguishing mark should be kept for syphilitic cases. If a nostril is extremely sensitive, it may be sponged with a 4 percent solution of cocain. As soon as the catheter is in position, the little and the ring-finger of the left hand should be placed one on each side of the patient's nose, the palm of the hand being downward and forward, and the outer end of the instrument grasped between the thumb and index-finger. By this means the catheter is held firmly, and the hand at the same time well supported against the patient's face. The nozzle of the air-bag should now be introduced, and the thumb and index-finger of the left hand slipped forward to hold it in place. Air is then forced into the tympanum by compressing the air-bag. Many aurists prefer a modification of Politzer's bag, having a piece of tubing between the air reservoir

and the nozzle, which prevents the movement of the bag being communicated to the catheter.

For **examining the membrana tympani** many kinds of speculums are used, the simplest consisting of a funnel of metal or vulcanite; another (Brunton's), of a metal funnel with a lens at the opposite end and an aperture at the side for the admission of light. For using the former, daylight may suffice; but for the latter, artificial illumination is necessary. The focus for a Brunton's speculum should be 3/4 of an inch from the end when the center of the cap containing the lens is level with the larger extremity of the speculum. Siegle's



Air-bag with Nozzle to Fit a Catheter.
Suitable also for Politzer's inflation, with a teat slipped into it.

speculum allows the operator to see the movement of the drum under pneumatic pressure.

Before the speculum is introduced, any abnormal condition of the outer part of the ear should be noted, and the auricle raised upward and backward in order to straighten the canal. A healthy membrane is of a bluish-gray color, and is placed obliquely across the canal, its upper and posterior parts being more external than the lower and anterior. Passing downward and backward and a little inward, nearer the anterior than the posterior edge of the membrane, is a whitish ridge—the handle of the malleus; and passing forward and downward from its lower extremity, which is slightly enlarged, and situated just below the center of the membrane, is a triangular glistening surface called the *cone of light*, having its base toward the periphery. At the upper part of the handle of the malleus is a white projection—the short process of the malleus; and stretching backward and forward from the short process to the edge of the membrane are two slight ridges, the anterior and the posterior folds, the latter being the more clearly defined. Above these folds the membrana propria is absent, the part being called Shrapnell's membrane. Not infrequently a whitish line, showing the position of the long process of the incus, is seen behind, internal and parallel to the upper part of the handle of the malleus. Occasionally, the outer part of the stapes can be distinguished. After the position, color, degree of transparency, and any abnormal condition of the membrane that may exist have been carefully noted, the nares, pharynx and nasopharynx should be examined.

ECBOLICS.—See Emmenagogs; Oxytocics.

ECCHYMOSIS.—See Bruise.

ECLAMPSIA, NATURE AND CAUSATION.—At the present day eclampsia may be considered as merely an important detail of the general toxemia of pregnancy, which is expressed by a great variety of symptoms, including convulsive seizures. There is no room here for the discussion of the general autotoxic state upon which eclampsia develops. Moreover the mere subject of gestational convulsions as a general proposition is far from coinciding with that of puerperal eclampsia in the restricted sense.

Literally speaking, puerperal eclampsia should denote convulsive seizures which develop suddenly during the puerperium. As a matter of fact, however, only a minority of cases develop after delivery and these are of a milder type. Delivery, in fact, instead of precipitating convulsions is often the best guarantee of their prevention or mitigation. The great majority of cases develop after labor has begun, while a small percentage appear in advance of labor. When they occur well in advance of labor and cause death of the fetus they are decidedly atypical. Hence for the term puerperal, as used to designate eclampsia, we should substitute some other term, such as parturient or tocogenic.

The toxemia of pregnancy may develop at any period of gestation, and seems much more likely to develop in the earlier or later months than midway between the two. Whether expressed clinically by incoercible vomiting or acute yellow atrophy of the liver or other severe malady, terminal convulsions may appear. These while due to an autotoxic state allied to or identical with that producing tocogenic eclampsia, show wide clinical departures from the latter condition. Epileptic women have seizures during pregnancy, while the latter condition is quite likely to aggravate hysteria, and sometimes major hysterical convulsions are set up. If a woman develops simple acute nephritis in pregnancy, true uremic convulsions may develop, with an inevitably fatal outcome; and it is manifestly impracticable if not impossible to separate such cases from convulsions due to the autotoxic state of pregnancy. Cases of this sort develop with equal readiness at any time during pregnancy. Women already victims of chronic nephritis when they become pregnant seem almost immune from uremic seizures during pregnancy and the puerperium, but often become distinctly worse after the puerperium is past. If we restrict our conception of eclampsia to purely tocogenic cases, it is very evident that those forms of convulsive seizures just alluded to may be left out of consideration almost entirely. Neither true uremia, epilepsy, major hysterical crisis, acute yellow atrophy, incoercible vomiting is likely to develop or become critical during the short interval consumed by labor and the week or so preceding and following it. By thus narrowing our conception we can deal

with a distinct clinical entity having a definite incidence, symptoms, prognosis and indications for treatment and prophylaxis. **Tocogenic eclampsia** may be defined as a series of epileptiform convulsive seizures developing during or near (before or after) labor, often without prodromes, with a tendency to improve after emptying the uterus. In practically all cases oliguria coexists, often complete anuria; and in the great majority of cases there are albuminuria and formed elements from the kidneys. As recovery occurs these urinary abnormalities are rapidly corrected. In fatal cases the great majority show structural changes, but these are neither of a single type nor are they definitely related to the severity of the clinical phenomena. In the few cases subjected to surgical intervention on the kidneys, the latter have been found either pale and anemic or distended and gorged with blood. In the latter type, despite the severity of the symptoms and extreme oliguria, recovery is still possible.

The above brief outline shows us to what extent this clinical type of disease is dependent on the act of labor itself, and shows us why (with full subscription to the belief in a general autotoxic state as the predisposing cause of eclampsia) we should never lose sight of the fact that labor is the great exciting cause. Since we do not yet know just what brings on labor itself we cannot explain why eclampsia may sometimes develop ahead of labor.

In regard to the exact relationship between the autotoxic state of pregnancy and eclamptic seizures, we can only discuss in this connection the so-called preeclamptic state which is often very markedly in evidence for a considerable period before the convulsions develop or in other words before term. Since this condition in rare instances may exist without convulsions, and since the latter frequently develop without evidence of the preeclamptic state, we are unable to state whether the latter is a direct cause or only an accompaniment of the eclampsia. No doubt both are late manifestations of the toxemia of pregnancy, called forth by approaching or actual delivery. In regard to the nature of the toxic substances involved, the latter are evidently manifold in character and may differ notably from those active in early gestation. We naturally accuse either the fetus itself or the decidual structures which have now attained the acme of their development and have become entirely foreign to the maternal organism. But aside from this biologic cause, a more tangible element is present in mere mechanical hindrance to the natural disinteresting action of the intestine and great intestinal glands. From a third point of view we must consider the steady increase of nervous instability under the influence of gestation. If space served, abundant evidence could be cited to show that any one of these three predisposing factors may play a prominent part in eclampsia. That the poison of pregnancy has a neurotoxic action which renders a patient convulsible, well appears from the analogy of uremia, in which convulsions are preceded by marked nervous irritability. Individual cases of eclampsia seem determined by excessive distention of the uterus by pressure upon the ureters with urostasis, by stercoremia from obstipation, etc. The prompt relief which follows emptying of the uterus even in the absence of overdistention and pressure symptoms indicates the possibility of an intrauterine source of the poisoning. In the present state of our knowledge we are forced to conclude that a number of factors are cooperative in determining eclampsia, and that these may differ somewhat in individual cases. In fact, no one can at present disprove the claim that certain fatal cases are examples of pure uremia, however much we may disbelieve such a view. Beginners in medicine and those whose practice has comprised uremic and not eclampsia cases are hard to convince that the latter is not uremia secondary to acute nephritis or an acute exacerbation of chronic nephritis, especially in cases which with inevitably fatal ending present lesions of old or recent nephritis. The most valid answer to this objection is that while nephritis terminating in uremia is essentially a fatal malady, not necessarily during the attack, but within a short interval, eclampsia terminates much oftener in recovery than death, the patient usually making a permanent recovery. When eclampsia ends fatally, it ends thus during the paroxysm. In a uremic crisis the case may for the time being yield to treatment, but another crises should soon develop. In a state of nephritis it is a matter of record that labor does not precipitate a paroxysm of uremic convulsions. Nevertheless with all these reservations there is doubtless a certain number of cases of so-called clinical puerperal eclampsia which are really uremic. It is a problem not as yet much investigated as to whether a hysterical or psychogenic element can be involved in certain cases of eclampsia. Tocogenic eclampsia is a rare affection and analysis of large material shows that about one case occurs in five hundred or less. Nevertheless it occurs at times in groups, and a village physician who has practised for years without having seen a single case may be called on to treat several in close succession. In some localities it seems common enough to be dreaded by pregnant women. The same bunching of cases is sometimes seen in maternity hospitals. Primiparæ are slightly more disposed to it than multiparæ, elderly than young primiparæ, women with narrow pelves than other women, etc. One attack does not predispose to another in the next pregnancy, although attacks are in rare instances thus repeated. It is hardly correct to state unconditionally that eclampsia is peculiar to the calendar end of gestation, but when it occurs ahead of this period it almost always produces or is followed by premature labor, and it is impossible to prove that the labor is solely determined by the eclampsia.

Symptomatology.—In a small proportion of cases the paroxysm occurs without prodromes; without a preeclamptic state. The fact that a patient nearly at term should present edema of the limbs and a trace of albuminuria cannot be brought into any relationship with a prodromal stage, as it is of very common occurrence. Most attacks come on without warning, usually after labor has

begun. The oliguria, often so valuable an aid to warding off an attack, may not be in evidence until the convulsions have appeared. This fact furnishes one of the best proofs that most cases cannot be dependent on a gradual or sudden suppression of urine.

When as usually happens there is a preeclamptic stage, regarded at the present day as a phase of the autotoxemia of pregnancy, the symptoms are as follows: oliguria develops, and this lessening of the twenty-four amount of urine is a far more trustworthy symptom than any mere quantitative alteration in the urea eliminated. If the amount of water excreted is within normal limits, research of the amount of urea may be neglected. Conversely, if with scanty urine there is a fair elimination of urea, too much reliance should not be placed on the latter finding. Oliguria for a single day need not possess great significance, but persistent scantiness of urine is a symptom to be feared. The presence of a slight amount of albumin in the urine is not absolutely a warning of trouble, for this might be accounted for exceptionally by mere passive congestion of the kidneys, pyelitis, cystitis, etc. But the presence of casts naturally possesses much significance. A few words should be devoted to "pregnancy-kidney" so-called, a local condition due to the general toxemia of pregnancy which usually coexists with or precedes eclampsia. The latter may occur at term without pregnancy-kidney, while this lesion is not necessarily followed by eclampsia. But whenever a patient presents oliguria, with a considerable amount of albumin in the urine and formed elements from the kidney we may feel certain that a pregnancy-kidney is present. In the large percentage of eclampsia cases which recover, we may be sure that a pregnancy-kidney has been present, which has undergone rapid resolution. The pathologic condition in pregnancy-kidney has generally been regarded as essentially an acute fatty infiltration or perhaps degeneration of the renal parenchyma. But these findings appear to shade gradually into actual nephritis. Intense congestion is sometimes coexistent, so that the kidneys instead of being pale and flabby are greatly distended (so-called glaucoma of the kidney). Evidences of recent and old nephritis are sometimes found at autopsy, and it is these cases which furnish a presumption that the toxic state is sometimes simple uremia. In the great majority of cases of eclampsia, however, the toxic state of pregnancy precedes the renal lesion, but the latter sets up a vicious circle. The more the parenchyma of the kidney is involved the more likely are we to see marked oliguria with compensatory anasarca. The retinitis which develops at times does not belong to the ordinary syndrome of the toxemia of pregnancy and is very likely due to retention of urinary excreta. But unlike the retinitis of uremia it is not an irrecoverable affection, but usually disappears after delivery. It is usually an indication for quickly terminating pregnancy, for in some cases it may end in total blindness. Detachment of the retina may also occur. When the preeclamptic stage is well marked we see a syndrome not unlike that of uremia. This is present in perhaps a fourth of all cases. Among the leading symptoms are headache, high blood pressure, nausea and vomiting and cortical disturbances, the latter including at times restlessness, vertigo, insomnia, stupor, etc. Epigastric pain is sometimes complained of. Ocular disturbances, such as amblyopia, do not invariably imply acutal retinitis. Generally speaking a condition of restlessness and motor and mental excitation leads naturally up to a convulsive paroxysm. In rare instances there may be either a primary stuporous stage, or one secondary to a stage of cortical irritation, without any convulsive paroxysm. This is the so-called "eclampsia without eclampsia," which also occurs in uremia. In such cases coma is an equivalent of eclampsia and demands precisely the same radical treatment in order to save life. The eclampsia paroxysm usually occurs after labor has begun. It appears that labor itself is often necessary for its genesis, and we know that the most perilous periods for the gravida are the first or second month and at or near term.

The convulsive paroxysm is epileptic in character. Exceptionally an aura may be present. The gravida assumes a staring look and the pupil dilates. A stage of tonic contraction is by no means commonly present. When it does occur it is noted in isolated muscles only, as those of the neck or calves, which may be thrown in a tetanoid spastic state. As a rule, paroxysms begin with clonic twitchings of the face muscles, passing rapidly to the upper extremity, trunk and lower extremity in this order. The contractions of the respiratory muscles arrest respiration and cyanosis develops. The face becomes purple and foam appears at the lips, which is mixed with blood if the tongue is bitten. With the onset of convulsions consciousness is lost. The condition of cyanosis is probably responsible for the cessation of the attack which, however, abates gradually, the convulsions becoming progressively weaker after the acme is reached and as respiration is resumed. The patient passes into a comatose state and the entire musculature relaxes. Consciousness is soon regained and muscular soreness is complained of. In rare cases eclampsia is restricted to a single paroxysm. The duration of the initial attack is seldom long—from a few seconds to a minute.

In the vast majority of cases eclampsia consists of serial attacks, the intermissions varying considerably in length with the case. There is a general tendency for succeeding attacks to become progressively worse, with a shortening of the interval. Serious results due to the repeated convulsions soon become apparent. The patient is no longer able to regain consciousness and lies in a state of protracted coma. The temperature mounts steadily until it reaches 104° F. and upward. Attacks may be repeated until 10 to 20 or more have occurred, but in very many cases, fatal and otherwise, the number is by no means large. Individual attacks are determined in some cases by outside

influences. A labor pain, as might be expected, often provokes an attack; but the latter may be determined even by a digital examination or passage of a catheter, or any experience which acts upon one of the special senses or general sensibility.

The tension of the pulse during serial attacks of eclampsia is a notable phenomenon. During the paroxysms the pulse may be almost imperceptible. Much has been written with a view of proving that high tension is the principal manifestation of the diseased state and that it is an essential prodrome of the condition and the leading indication for prophylaxis and treatment. Like nearly all generalizations set up for this affection, it will not hold water. During the preeclamptic condition, however, the pulse is notably hard and tense.

To come now to the urine: Despite all that has been written of the pregnancy-kidney as a forerunner of eclampsia, along with evidences of metabolic irregularities, it is none the less true that in very many cases the urinary syndrome may be seen only too plainly as a result of the serial attacks of convulsions. With the progress of the convulsions the urine is often seen to be rapidly reduced in quantity, until at times complete anuria results. At the outset the urine may contain a little albumin or perhaps none at all. But as the convulsions increase the quantity of albumin actually increases, at least relative to the bulk of the urine. This seems to denote clearly that a vicious circle is usually present. With the advance of oliguria and albuminuria the formed elements of the urine increase. They comprise hyaline and epithelial casts, renal epithelia in fatty degeneration, and red and white blood-corpuscles. See Phenolsulphonephthalein Test.

It is a noted peculiarity of eclampsia that it has no tendency whatever to arrest labor. In fact, the pains often seem to be increased in frequency and vigor, as if nature were seeking to empty the uterus as rapidly as possible.

If the patient recovers, the convulsions become less frequent and severe, the comatose state clears up, and the amount of urine is increased, perhaps suddenly. Death may occur in several ways. In the majority of cases, the patient being in deep coma, death would be attributed to that cause; but in most of these cases acute pulmonary edema seems to lead to arrest of respiration. Less frequently death occurs during a convulsion from spasmodic arrest of respiration. In a few cases death comes about from central hemorrhage or other accidental cause.

Diagnosis.—If we restrict the notion of eclampsia to tocogenic convulsions only, any question of differential diagnosis can hardly arise. There is no other kind of epileptiform convulsion which is precipitated by labor. An epileptic woman would scarcely have a paroxysm under such circumstances, although it is conceivable, especially in an illegitimate pregnancy that hysterical convulsions could occur at that time. They should be rapidly excluded by the retention of consciousness during the attack and the demonstration of the sensory stigmata of hysteria.

To attempt to exclude uremia, or some form of pregnancy toxemia in which the kidneys function normally, is hardly practicable. A patient with chronic nephritis will almost never develop uremia just as delivery begins; while acute nephritis in pregnancy with suppression of urine and convulsions cannot possibly be differentiated clinically from ordinary eclampsia when seen for the first time. We can only differentiate by following up the case after delivery. An accidental nephritis is not benefited by delivery, but becomes worse. This is also the case with convulsions due to hepatitis and acute yellow atrophy of the liver. In the great majority of cases these patients die long before term. When we see tocogenic convulsions with normal urine we may assume that severe lesions of the liver are present. The entire subject of atypical eclampsia, due to accidentally acquired nephritis, or to destructive lesions of the liver, needs to be studied anew on a clinical and pathologic basis. This is also true of "eclampsia without convulsions."

Prognosis.—It is estimated that 20 percent of mothers who develop eclampsia die during the attack. In individual statistics the mortality may be much higher. It is conceivable that there may be a clinical type with natural tendency to recovery and others with the reverse, but at present we cannot separate the two. While most women make a clean recovery, others are left badly off, hemiplegic, blind or insane as a result of intracranial mischief due directly to the convulsions. In others, organic disease of the kidneys and liver persists and the patients inevitably perish. In cases which do not develop until after delivery the prognosis is much more favorable, but fatal results may ensue. In rare cases which develop well in advance of term, and which technically do not come under tocogenic eclampsia, the immature or premature fetus usually dies *in utero;* and whether or not miscarriage or premature delivery is set up, mere death of the fetus is often conservative for the mother, the convulsions ceasing and albuminuria clearing up. Cases have occurred in which normal expulsion of a dead fetus occurred at term. But these atypical cases need further study. An important point in prognosis is this: If a woman develop convulsions with the onset of a labor of average or prolonged duration, the prognosis is worse than when convulsions appear toward the close of labor; and this is eminently true for the child.

Nearly 50 percent of children die during eclampsia, although under intelligent and active treatment this number may be almost cut in two. Death of the child is due in part to asphyxia from the state of the maternal blood, and may result during the first or any subsequent convulsion. The belief is growing to-day, however, that the infant undergoes the same specific poisoning as the mother. Fetal rigor mortis and convulsions of the newly-born children occur frequently enough to give color to this view. Those who attach the greatest importance to the tension of the blood, and perhaps all clinicians irrespective of theory, regard the pulse as possessing great prognostic value. As long as this continues slow and full

between convulsions there is hope for the patient; if quick and feeble the outlook is bad.

Prophylaxis of eclampsia consists in the recognition and management of the pregnancy-kidney when that condition exists. In the large proportion of cases in which no pregnancy-kidney develops we can proceed as if it were present, although we cannot feel certain that we have headed off eclampsia in a given case. If a high tension pulse is present irrespective of urinary symptoms we can proceed against this condition. But if there are any symptoms pointing to toxemia of pregnancy, as headache, nausea, anorexia, epigastric tenderness, etc., with evidences of intracranial disorder, especially if this syndrome is associated with pregnancy-kidney or urinary anomalies of any sort and high tension pulse, rapid emptying of the uterus is imperative.

Whenever there is constant lessening of the twenty-four hour amount of urine coupled with anasarca and urinary evidences of a renal lesion, and antiuremic regimen should at once be instituted; the quantity of nitrogenous food ingested being reduced to a minimum, and a general depurative treatment being instituted by the use of purgative, diuretics and diaphoretics. The diet should be mild, combining diuresis with the necessary restriction in nitrogen. Some drastic purgative should be given daily at bedtime with a mild saline in the morning. As the bowels are prone to obstipation near term there is a considerable tolerance for purgatives, the patient being able to take one or two compound cathartic pills at night. Another method consists in giving a mixture of calomel, squills and digitalis for its combined diuretic and purgative effect. For the high tension pulse nitroglycerin may be given *pro re nata;* it behaves also as a diuretic. For a more sustained action on the pulse, some of the nitrites may be used. For diaphoresis the warm bath or pack is useful with the emergency use of a hot air cabinet bath. In connection with purgatives high colonic irrigation is often indicated, especially if the urine contains any of the products of intestinal putrefaction as shown by increased amount of indican.

By persisting in this regimen we can at least offset the effects of pregnancy-kidney and intestinal autointoxication. Whether we really prevent eclampsia in a given case cannot be told but doubtless eclampsia very seldom develops when this regimen is employed.

If the woman seems perfectly well as term approaches, to what extent ought we to give her the benefit of an antieclamptic regimen? We doubtless owe it to her to regulate her diet by giving it a low nitrogen value, but not all toxic substances which form in pregnancy are nitrogenous. Some are probably of carbohydrate origin, such as are believed to cause diabetic coma. Such a non-nitrogenous diet might give a false idea of safety and perhaps be overdone. While induction of labor and prompt emptying of the uterus is to a certain extent a prophylactic measure, it is best considered under the head of treatment. In cases in which labor is induced in advance of convulsions, we are not dealing with tocogenic convulsions, but with those forms of the toxemia of pregnancy which develop during gestation, as acute yellow atrophy and incoercible vomiting of pregnancy. It must be admitted that despite its theoretical value this resource is seldom successful unless practised at the earliest possible moment.

Treatment.—A woman in labor having suddenly been seized with convulsions, it is commonly assumed that labor must first be terminated to fulfil the main causal indication of getting rid at once of the source of the poison and the leading peripheral irritation which provokes the convulsions. When the convulsions are sufficiently frequent and violent it will be necessary to suppress them at any price in order to prevent their disastrous secondary effects. To institute a disintoxicating or eliminative treatment is also eminently logical, but there are differences of opinion as to the extent and order of procedure. The older procedure was to leave labor largely to nature, at most hastening the second and third stages by forceps and manual extraction of placenta, while a vigorous antitoxic and anticonvulsive program was being carried out. A more modern view is to empty the uterus by doing away with the delay of the first stage, and to apply other measures subsequently. But since even with the most rapid delivery followed by vigorous eliminative treatment, women succumb from the intoxication who might have been saved by more prompt disintoxication, the most rational course appears to be to institute both measures at the outset. In regard to control of convulsions the question also arises "May these also be prevented?" That is, after the first convulsion can the woman be placed in a state in which these will be reduced in number and frequency without prejudice to other indications? Chloroform given in connection with operative emptying of the uterus also antagonizes the convulsions. If, however, the case is not severe enough for such emergency measures, as when convulsions do not develop until after the first stage, or during the puerperium, veratrum viride may be sufficient to control them. This is especially true of cases with rapid high tension pulse, because veratrum appears to act by reducing the pulse rate. A patient with a pulse of 60 ° seldom has a convulsion. If veratrum fails or if the pulse does not furnish an indication for giving it, then chloral is probably the best antispasmodic and may be given either by the mouth or rectum. Morphin is not looked upon with favor, and in fact with all narcotics, hypnotics and most motor depressants we have to bear in mind that in theory at least they seem to favor the development of the dreaded comatose state, which while apparently due largely to the frequency and violence of the convulsions may sometimes develop after few and mild convulsions, or even after no convulsive stage. We should therefore abandon all idea of stupefying a patient in advance to head off convulsions, and give just enough drugs to diminish their number and severity. Whenever they can be controlled indirectly, therefore, this is a de-

cided advantage. Veratrum does this to a certain extent through correcting the circulation. An ice-bag to the nape of the neck is often useful. Also, whenever this is possible, the patient should be left in a state of passivity, noises and other happenings which affect all the peripheral sensory nerve organs being excluded. These measures are of course indicated when the uterus is empty.

To go back to disintoxicating measures, in a severe case beginning at once after labor, shall we proceed to empty the uterus or shall we first practise rapid eliminative procedures, or may the two be conjoined? Much depends on the surroundings and the experience of the obstetrician. In an institution a woman may be given a hot air bath, hypodermoclysis, and enteroclysis; while an oxygen tank is always at hand. In this way all the emunctories will be started up promptly and at once and the disintoxicating action of the oxygen will be available. In private practice slower and milder measures must be substituted, such as hot packs, hot drinks, etc., with a drop or two of croton oil or a large dose of saline, and dry cupping over the kidneys—all of which measures will of course be useful as adjuncts in institutional cases. The high rectal irrigation may also be used. In private practice nitroglycerin hypodermically is a valuable resource. Pilocarpin, however, is of very questionable value, and is believed to favor pulmonary edema, which is the actual cause of so many deaths. If the pulse, as sometimes happens in the gravest cases, is poor between convulsions, the indications demand in addition to oxygen, hypodermoclysis and nitroglycerin—the use of alcoholics, and even strychnin is not contraindicated if the uterus is empty.

In a certain number of cases the chief indication seems to lie in the state of the kidneys. This results from the operation of the "vicious circle," in which with extensive primary involvement of the organ the latter is entirely unable to exert its function. In these cases the kidneys are gorged with blood, and the complete retention of urotoxic substances greatly aggravates the number and severity of the convulsions. Hence in very recent years a rational procedure has been applied directly to the kidney, either as a substitute for rapid delivery or as a sequence to delivery. This is decapsulation of the organ which relieves the intense engorgement and is followed as a rule by free secretion of urine and diminution of the convulsions with ultimate recovery. Numerous successful cases are upon record. The chief criticism of this operation is that it is impossible to decide in advance whether the kidney is in this engorged state. Upon cutting down it will be found half the time that the organ is pale and flabby, and in these cases the operation has not only failed to save life, but has displaced other possible life-saving measures. Cases of so-called "glaucoma of the kidney" in which the operation succeeds, recover under other measures and even spontaneously, and decapsulation has therefore no sound theoretical foundation. This is the view of Edgar.

There now remains for consideration the method of emptying the uterus. Any consideration which involves saving the child when the mother is attacked early in labor is of minor importance if not altogether negligible as such. But whatever tends to save the mother's life will invariably favor that of the child. After the os is dilated it is a simple matter to extract with forceps. If the os is undilated, we have the alternative of cesarean section in some form and overcoming the resistance of the cervix. The former, once thought to be contraindicated, is now coming more into use especially as vaginal cesarean section. On the other hand, in overcoming the resistance of the cervix, slow forms of mechanical dilatation have given way to rapid manual and instrumental procedures and to deep incisions. The two methods therefore converge, and incisions combined with rapid digital dilatation fill the indication as promptly and with less risk than does typical vaginal cesarean section, and form a method much better adapted to routine use in the hands of the general practitioner. If as often happens convulsions develop before labor sets in, labor pains almost immediately ensue. Should this occur while the fetus is prematurely developed, and the uterus not ready for expulsion the outlook is especially unfavorable. The fetus is more likely to succumb quickly and its death has often a salutary influence on the mother. So far as we know, however, no one would feel justified in destroying the fetus. It is here if at all that an abdominal or vaginal cesarean section would seem indicated on account of the unpreparedness of the uterus for expulsion.

ECSTASY.—By this term is meant a peculiar state of the mind in which a delusion so governs the mental functions that the whole nervous system is held in a condition of subjection or insensibility.

ECTHYMA.—The term ecthyma is applied to an eruption characterized by discrete, flat, deep-seated pustules with broad inflammatory bases. Many dermatologists no longer regard ecthyma as a distinct disease, but rather as a form of dermic pus-infection.

Symptoms.—The lesions, which are usually situated upon the legs, begin as small, pea-sized pustules that rapidly increase until the size of a dime is attained. They are discrete, flat, and surrounded by a markedly reddened and often infiltrated zone. When ruptures take place, an irregular yellowish or brownish crust is formed, beneath which suppuration goes on. Pigmentation or superficial scarring may persist after the disappearance of the lesions.

Etiology and Pathology.—Debility, bad food, and improper hygiene are said to play an important predisposing rôle. The eruption attacks adults rather than children. The exciting cause is, in all probability, the introduction of a micro-organism into the cutaneous follicular openings. It is evident that scratching would greatly facilitate such an inoculation.

Diagnosis.—Ecthyma is to be differentiated from contagious impetigo, pustular eczema, and the large, flat, pustular syphiloderm.

Ecthyma.	Impetigo Contagiosa.
1. Seat of predilection, the legs.	1. Face and hands.
2. Primarily pustular.	2. Primarily vesicular.
3. Pustules deep.	3. Pustules superficial.
4. Marked inflammatory areola.	4. No inflammatory areola.
5. More common in adults.	5. More common in children.
6. Noncontagious.	6. Contagious.

Ecthyma.	Pustular Eczema.
1. Seat of predilection, the legs.	1. Indefinite localization.
2. Pustules discrete.	2. Grouped, often coalescing.
3. Pustules large and flat.	3. Small and rounded or acuminate.
4. Red and infiltrated areola.	4. No inflammatory areola.
5. More common in adults.	5. More common in children.

Ecthyma may be distinguished from the pustular syphiloderm by the more inflammatory character of the lesions, the absence of true ulceration, the distribution of the lesions, and the absence of other signs of syphilis.

Prognosis.—The affection responds promptly to treatment.

Treatment.—Tonics, good food, and improved hygiene are to be advised. The local treatment consists in the removal of the crusts and the application of an ointment such as the following:

℞. Ammoniated mercury,	gr. xxx
Zinc oxid ointment,	℥ j.

ECTOPIC GESTATION.—See Extrauterine Pregnancy.

ECTOPIC KIDNEY.—See Kidney, Movable.

ECTROPION.—See Eyelids.

ECZEMA (Tetter; Salt Rheum). Definition.—Eczema is an acute, subacute, or chronic, noncontagious, inflammatory disease of the skin, characterized primarily by erythema, vesicles, papules, or pustules, and, secondarily, by scales and crusts, and accompanied by itching and burning. The various forms of eczema constitute about 30 percent of all skin-diseases.

Symptoms.—There are 4 elementary types of eczema. *Eczema erythematosum, eczema papulosum, eczema vesiculosum,* and *eczema pustulosum.* These may remain as such throughout their entire course, or may merely represent stages in the development of an *eczema rubrum* or *eczema squamosum.*

Eczema Erythematosum.—This variety of eczema is encountered most frequently upon the face and the genitalia, but may occur upon any portion of the cutaneous surface. It begins as vaguely defined bright or dull red spots, which soon coalesce and form diffuse areas. The skin is roughened and slightly infiltrated. When the region about the eyes is involved, there is marked edema that results in an entire closing of the lids. The eruption is accompanied by considerable heat and itching. Convalescence is indicated by a fading of the color, by a branny desquamation, and by the occurrence of islets of sound skin. This form of eczema usually runs a chronic course. It may remain erythematous or develop into a squamous eczema or into eczema rubrum.

Eczema Papulosum.—Papular eczema involves, with predilection, the arms and legs. It is characterized by pinhead-sized, round or acuminate, reddish elevations, either discrete or closely aggregated. They are often surmounted by minute vesicles. The papules are intensely itchy—a fact which is evidenced by their abraded summits and by the scratch-marks. The eruption tends to relapse, and is often obstinately refractory to treatment.

Eczema Vesiculosum.—The onset of a vesicular eczema is heralded by tingling and a feeling of heat. Soon there develop, upon an erythematous and swollen base, numerous pinhead-sized vesicles, which rapidly become confluent and rupture, permitting the escape of a viscid and sticky serum. The drying of this exudation produces yellow, gummy crusts. The rupture of the vesicles is followed by an abatement of the subjective phenomena. Beneath the crusts the serous exudation continues. The body-linen is stained and stiffened by this constant oozing or weeping.

The course is chronic, with tendency to recurrence. Convalescence begins with a cessation of the serous discharge.

The eruption is common upon the faces of infants, in which locality it has been designated *milk-crust* by the older writers.

Vesicular eczema is very likely to terminate in an eczema rubrum.

Eczema Pustulosum (*Eczema Impetiginosum*).—Pustular eczema may begin as such or may develop from the vesicular variety. It occurs most commonly upon the face and scalp of strumous and poorly nourished children. Rupture of the pustules is followed by the formation of profuse yellowish, brownish, or greenish crusts. The itching is less than in the other forms of eczema.

Eczema Rubrum.—Eczema rubrum represents a later stage of one of the elementary varieties of eczema. It is characterized by redness, swelling, infiltration, and moisture, and is usually attended by much burning. The epithelial covering of the cuticle is lost. Profuse crusting results from the drying of the exudation. When it presents a raw, weeping surface, it is designated *eczema madidans.* It is most frequently situated upon the legs of adults and the faces of infants.

Eczema Squamosum.—This is the terminal stage of the foregoing types of eczema. In it a regeneration of the corneous layer of the epidermis takes place. It is characterized by redness, infiltration, and desquamation. It is often associated with the erythematous variety. In the neighborhood of joints the thickened skin is likely to become fissured. Some writers include under the name of squamous eczema the horny, hard, and infiltrated variety.

Eczema Fissum is characterized by the occurrence of fissures or cracks. Chapping is a mild example of this form.

Eczema Sclerosum is characterized by a leathery infiltration of the skin.

In **Eczema Verrucosum** the papillæ become hypertrophied, giving rise to a warty surface. When the papillary hypertrophy is still greater, a papillomatous condition results—**Eczema Papillomatosum.**

Eczema is also designated as *acute* and *chronic.* These terms refer not only to duration, but also to the intensity of the inflammatory process. An eczema may last a long time and yet be acute in character. Infiltration is the chief characteristic of a chronic eczema.

Etiology.—The causes of eczema are both *internal* and *external. Internal* causes include in their category: Disorders of the alimentary canal (dyspepsia, constipation, intestinal autointoxication, etc.), functional and organic nerve affections, general debility, rheumatism, uric acid diathesis, Bright's disease, diabetes, affections of the uterus and appendages, dentition, and scrofula. These may at times act as predisposing causes, at other times as exciting causes.

The number of *external* causes is legion. They may be classified as follows:

1. Chemic irritants—acids, strong soaps (containing excess of alkali), dye-stuffs, etc.
2. Thermal irritants—solar or artificial heat, cold (particularly when associated with wet), etc.
3. Mechanic irritants—friction of skin surfaces or of clothes, pressure, animal parasites, scratching, etc.

In a predisposed individual the application of any irritant may be sufficient to call forth an eczema.

Diagnosis.—The diagnosis of eczema is, as a rule, easy. The most distinctive features are:

1. Serous exudation.
2. The gradual merging of the patches into the surrounding healthy skin.
3. Polymorphism of the lesions.
4. The symmetry of the eruption.
5. The marked itching and burning.

Vesicular eczema may be confounded with *scabies* and *herpes zoster.*

Scabies.	Vesiculopustular Eczema.
1. Characteristic distribution: webs of fingers, flexor surface of arms, axillary folds, nipples, umbilicus, penis, buttocks, and inside of thighs and legs.	1. No characteristic distribution.
2. Presence of burrows.	2. Absence of burrows.
3. Presence of itch-mite.	3. Absence of itch-mite.
4. Itching much worse at night.	4. Itching variable.
5. Communicable.	5. Not communicable.
6. Except in children, face is exempt.	6. Face frequently involved.
7. Treatment rapidly effective.	7. More refractory to treatment.
8. Other members of family often affected.	8. Not the case.

Herpes Zoster.	Vesicular Eczema.
1. Special distribution—follows lines of nerves.	1. No special distribution.
2. Eruption often preceded by intense neuralgic pain.	2. Itching and burning attend outbreak of eruption.
3. Vesicles arranged in separate groups.	3. No definite arrangement.
4. Vesicles discrete and distinct.	4. Generally confluent.
5. Vesicles large and tense.	5. Vesicles small and flaccid.
6. Vesicles do not rupture spontaneously.	6. Vesicles tend to rupture.
7. Eruption unilateral.	7. Usually symmetrical.
8. Severe shooting pains during course of affection.	8. Variable amount of itching and burning.
9. Tends toward spontaneous recovery.	9. Remains stationary or progresses.

Pustular eczema may be mistaken for impetigo contagiosa and sycosis.

Impetigo Contagiosa.	Pustular Eczema.
1. Contagious; may occur in epidemics.	1. Not contagious.
2. Begins as blebs or vesicles.	2. Begins as pustules or vesicles.
3. Lesions are discrete.	3. Tend to form patches.
4. Lesions very superficial.	4. Lesions deeper.
5. Surrounding skin not inflammatory.	5. Inflammatory areola.
6. Crusts flat and loosely attached—look as if "stuck on."	6. Crusts profuse and firmly attached.
7. Itching slight or absent.	7. Itching more severe.
8. Curable in 1 or 2 weeks.	8. More refractory to treatment.

Sycosis.	Pustular Eczema.
1. Confined to bearded region.	1. Involves other portions of face.
2. Begins in the hair follicles.	2. Begins superficially. Involves hair follicles secondarily.
3. Interfollicular skin free.	3. Skin uniformly involved.
4. Slight itching or burning.	4. Itching more marked.
5. Tendency to recur after cure.	5. No such tendency.

Eczema erythematosum may be mistaken for erysipelas.

Erysipelas.	Eczema Erythematosum.
1. Sudden onset with chill and marked constitutional symptoms.	1. No constitutional symptoms.
2. Eruption sharply marginated.	2. Fades into surrounding skin.

Erysipelas.	Eczema Erythematosum.
3. Glazed, shining surface; great edema.	3. Dull, scaly surface; slight infiltration.
4. Color, violaceous.	4. Bright or dull red.
5. Burning pain.	5. Itching more marked.
6. Occurrence of discrete vesicles or blebs.	6. Vesicles occur in patches, if at all.
7. Progressive peripheral spreading.	7. Spreading irregular.
8. Runs an acute course.	8. Course, chronic.
9. Contagious.	9. Not contagious.

Eczema squamosum may be confounded with psoriasis and ringworm.

Psoriasis.	Eczema Squamosum.
1. Predilection for elbows, knees, and scalp.	1. No seat of predilection.
2. Patches small, round, and sharply marginated.	2. Patches large, irregular, and ill defined.
3. Scales abundant, firmly attached, and mother-of-pearl in color.	3. Scales scanty, loosely attached, and grayish or yellowish in color.
4. Moisture never present.	4. Often history of antecedent moisture.
5. Itching slight, often absent.	5. Itching marked.
6. Often lasts throughout a lifetime.	6. More amenable to treatment.

Tinea Circinata (Ringworm).	Eczema Squamosum.
1. Contagious.	1. Noncontagious.
2. Patches circular.	2. Patches irregular.
3. Patches marginated.	3. Patches ill defined.
4. Patches ring-shaped; clear in center.	4. Patches not clear in center.
5. Eruption proceeds with uniform peripheral extension and central healing.	5. Irregular extension and healing.
6. Trichophyton fungus in scales.	6. Scales free from fungus.

Prognosis.—Eczema very often runs a chronic course. If untreated, it may continue indefinitely. Nearly all cases will yield, however, to judicious and persevering treatment. Factors influencing the prognosis are: (1) Type of the disease; (2) duration and extent of the eruption; (3) history of previous attacks; (4) removability of the cause or causes; (5) ability of the patient to care for himself properly.

Treatment.—The principal point in connection with the treatment of eczema is not only to recognize the disease, but fully to appreciate the stage at the time it is observed. It certainly does not require an expert dermatologist to determine whether it is acute, subacute, or chronic, and yet the general principles of treatment depend, in great part, upon an accurate determination of this question, for it will govern the external or local treatment and the agents that should be employed. In acute conditions soothing applications are demanded; in subacute, stimulating; and in chronic, more stimulating, or even irritating.

In addition to the proper recognition of the stage of the disease, an effort should always be made to discover its cause. It is necessary to fix it either as external, internal, or mixed. Then it is equally necessary to find whether it is parasitic, traumatic, or neurotic, either directly or in a reflex manner. The occupation, the habits, the food, and similar accidents will be found to add much to a proper understanding of a case as well as to a proper and clear appreciation of the functions of the various organs. It is the sum of all these factors that is absolutely necessary to arrive at a proper knowledge of the modes of treatment to apply in a given case and from which a successful result is to be expected. Having obtained this preliminary knowledge of the patient and his disease, treatment may be intelligently applied with almost certain success.

The gastrointestinal tract most frequently needs attention, as functional derangements, with autointoxication as a result, at times, will certainly act in a reflex way. The liver also frequently requires attention, more especially in the way of improving the portal circulation. It must never be forgotten, that rational treatment is always demanded and not mere haphazard. Purgatives should be carefully chosen, as well as those remedies indicated in disturbances of digestion.

Diet.—The diet in all cases of extensive eczema should be carefully regulated. Such articles as salted meats, pork, shell-fish, sugar, pastries, confections, pickles, sauces, condiments, cheese, and excess of starchy foods should be assiduously avoided. Tea and coffee should be reduced to a minimum and alcoholic beverages entirely prohibited.

Laxatives.—Laxatives are frequently necessary to keep the bowels in proper order. This is a matter of great importance.

In acute eczema it is desirable to inaugurate the treatment with free catharsis. This is best done by means of the salines, either alone or preceded by calomel.

A very useful preparation in the treatment of eczema complicated by constipation and anemia is the "acid mixture of iron." It combines the advantages of a tonic and a laxative:

℞.	Iron sulphate,	gr. xxxvj
	Magnesium sulphate,	ʒ jss
	Dilute sulphuric acid,	♏ ij
	Compound tincture of cardamom,	ʒ iij
	Water, q. s.	ʒ vj.

Tablespoonful in a tumbler of water before breakfast.

The saline waters, of which Hunyadi János is the best, are both efficient and convenient of administration.

In infantile eczema the following is efficient:

℞. Powdered rhubarb, Bicarbonate of sodium, each, ʒ j to iij
Peppermint water, ʒ iv.
Teaspoonful in water after meals.]

Or—

℞. Calomel, gr. 1/100
Castor oil, Chalk-mixture, Water, each, ♏ xv.

Stomachic Tonic and Digestives.—Stomachic tonics and digestives are required in many cases of eczema. The following formula is useful in cases suffering from atonic dyspepsia and constipation:

℞. Tincture of nux vomica, Dilute hydrochloric acid, each, ʒ ss
Compound tincture of cardamom, Fluidextract of cascara sagrada, each, ʒ j.
One teaspoonful in water after meals.

Diuretics.—Diuretics are of value both in acute and subacute eczema. The acetate, citrate, and bicarbonate of potassium, in from 10- to 20-grain doses, may be given a half hour before meals, or the alkaline mineral waters may be employed.

Alteratives.—Arsenic has but a limited field of usefulness in the treatment of eczema. It is of most value in the chronic papular and squamous varieties and in the recurrent vesicular eczemas involving the fingers. It is contraindicated in acute eczema and whenever the degree of inflammation is high.

Small doses of mercuric chlorid are sometimes of value in certain chronic thickened eczemas (Duhring).

The wine of antimony is often given with good results in the treatment of acute eczema in plethoric individuals.

Tonics.—In strumous individuals with glandular enlargement cod-liver oil is a remedy of the greatest efficacy. In anemic and chlorotic patients iron, in the form of the tincture of the chlorid, is extremely useful.

Strychnin and quinin are at times employed with great benefit in eczema.

Local Treatment.—The local treatment of eczema is perhaps the more important in the majority of cases. The selection of remedies and their strengths must be governed by the grade of inflammatory reaction present. In an acute eczema the remedies cannot be too soothing. Too strong an application works immediate injury; too weak an application can do no worse than fail to do good.

Water is an irritant in all acute and subacute eczemas, and is to be used as infrequently as is compatible with cleanliness. It may be made less irritant by the addition of bran, starch, or borax. In indolent chronic eczemas soap and water are of therapeutic value. They are useful at times, also, to remove crusts in the acute varieties. It is, however, a better plan to remove crusts by the process of softening. Pieces of flannel soaked in linseed or olive oil kept in contact with crusts for some hours will soften and loosen them; if they are very adherent, a lukewarm starch or flaxseed poultice may be applied. Pastes and salves should likewise be removed from the skin by oily and unguentous substances. Petrolatum (vaselin) or olive oil, and not soap and water, should be employed for this purpose.

Acute Eczema.—At the onset of a vesicular eczema *dusting-powders* may be used with advantage. Many substances have been employed for this purpose: wheat starch, corn-starch, rice flour, bismuth subnitrate, talcum magnesium carbonate (most absorbent), zinc oxid, boric acid, kaolin, etc. The following is a useful combination:

℞. Venetian talcum, Zinc oxid, each, ʒ ss
Starch, ʒ j.

Or, if a more astringent one is desired:

℞. Bismuth subnitrate, Boric acid, each, ʒ ij
Starch, ʒ ss.

Lotions are of paramount value in moist eczemas. They are, as a rule, borne much better than ointments. The simplest is a saturated solution of boric acid. This has been found as soothing to the skin as it is to mucous membranes. Sopped on every hour in acute eczema, it acts admirably in reducing inflammation. The calamin lotion is also a most efficacious application:

℞. Pulverized calamin, Pulverized zinc oxid, each, ʒ j to iij
Glycerin, ʒ ij
Lime-water, q. s. ad ʒ vj.
This leaves a powdery precipitate upon the skin.

A 2 percent aqueous solution of resorcin is a valuable antipruritic and antiphlogistic lotion.

When there is much itching, carbolic acid may be added to any of the above washes:

℞. Carbolic acid, ʒ ss to j
Boric acid, ʒ j
Glycerin, ʒ j
Water, q. s. ad ʒ vj.

A favorite treatment with many dermatologists is the use of the "lotio nigra" (black wash), either pure or diluted one-half with lime-water; this to be followed by the plain zinc-oxid ointment. The "liquor carbonis detergens," in the strength of 1 dram to 4 ounces, is a most useful application in papular eczema.

Its formula is as follows:

℞. Tincture of soap-bark, ʒ ix
Coal-tar, ʒ iv.
Allow to digest for 8 days and filter.

Either of the following formulas may be used with good results:

℞. Boric acid, gr. xxx
Cold cream, ℥ j.

Or—

℞. Salicylic acid, gr. x
Lassar's paste. { Starch, Zinc oxid, Petrolatum, } each, ℥ ij, ℥ ss.

A very old and efficient remedy in acute eczema is the diachylon ointment of Hebra. It must be freshly prepared, and should be applied upon strips of soft linen.

Subacute Eczema.—When the stage of acute inflammation has subsided, more stimulating applications may be used.

Carbolic acid, menthol, and the tar preparations are the most valuable antipruritics. The following formulas containing carbolic acid are useful in the subacute forms of eczema:

℞. Carbolic acid, gr. x
Pulverized starch, Zinc oxid, } each, ℥ ij
Petrolatum, ℥ ss.

Or—

℞. Carbolic acid, gr. x
Calomel, gr. xv to xxx
Zinc oxid ointment or Lassar's paste, ℥ ij.

Or the following may be employed:

℞. Resorcin, gr. xv
Menthol, gr. v to x
Zinc oxid ointment, ℥ j.

The annexed formula is particularly useful in squamous eczema:

℞. Salicylic acid, gr. xx
Lanolin, Petrolatum, } each, ℥ ss.

Chronic Eczema.—In this form of eczema strong applications are required to promote absorption of the infiltrate. Here the tar preparations find their greatest field of usefulness. They are never to be used in acute eczema, and only with caution in the subacute form. Tar is of great value in relieving the itching of obstinate papular eczemas. It may be incorporated in ointments, lotions, or paints:

℞. Oil of cade, ℥ j to ij
Zinc oxid ointment, ℥ j.

The "liquor picis alkalinus" is an excellent remedy in sluggish and thickened eczemas:

℞. Liquid pitch, ℥ ij
Caustic potash, ℥ j
Water, ℥ v.

Dissolve the potash in water and add slowly to the tar in a mortar, with friction. To be diluted 20 times or more.

In recurrent papular eczemas the following is highly recommended:

℞. Oil of cade, ℥ j
Collodion (flexible), ℥ j.

In leathery patches the pure oil of cade may be rubbed in with excellent results.

In pustular eczema the preparations of mercury are particularly valuable:

℞. Ammoniated mercury, gr. x to xxx
Zinc oxid ointment, ℥ j.

In addition to the foregoing local measures used in the treatment of eczema, *baths*, *plaster-mulls*, and *gelatin fixed dressings* are sometimes resorted to. The most frequently employed medicated baths are those containing starch, soda, borax, or bran. X-rays have been found of value in intractable chronic cases.

Staphylococcus vaccine has been injected with success in persistent pustular eczema. Cures are reported in lichenoid eczemas as a result of radium therapy.

Regional Treatment.—In the consideration of the treatment of eczema it is perhaps best to deal with the subject according to the region affected. In other words, the various regions involved and the forms of the disease that present themselves, together with appropriate local treatment, will be considered. The use of water or of soap and water to parts affected with eczema should be strictly prohibited. Exposure of diseased surfaces to the air should also be avoided. Another good rule to follow is to avoid the use of evaporating remedies, as they generally irritate; or, if irritation is intended, they are not of a sufficiently fixed nature to bring about the desired end.

In the treatment of the regional forms of eczema special therapeutic measures are indicated.

Eczema of the Head and Face.—In infants and young children this is generally crustaceous or pustulocrustaceous. Usually, the stools are greenish and frothy, indicating intestinal fermentation. Small doses of calomel and bicarbonate of sodium will readily correct this. The crusts on the scalp and face should be softened with a bland oil and separated, and an ointment applied at least twice daily.

The following is a useful formula:

℞. Carbolic acid, gr. iv
Bismuth subnitrate, ʒ jss
Cold cream, ℥ j.

Apply twice daily.

Should there be excessive or marked itching, the following may be lightly applied immediately before the ointment:

℞. Mercuric chlorid, gr. j
Ammonium chlorid, gr. ij
Carbolic acid, ℥ j
Glycerin, ℥ ij
Rose-water, q. s. ℥ vj.

For external use.

This treatment is also applicable to the erythematous, vesicular, and pustular forms of eczema of the head, face, and ears of infants.

Eczema of the scalp in adults occurs as a pustular, pustulocrustaceous, or squamous eruption, and usually the scalp about the ears and the fold between the ear and scalp are affected. In the scalp affection the hair should be cut in males. In the pustular and pustulocrustaceous forms it is of advantage to use a wash for the itching, which is intense. Of course, the crusts should first be removed. They may be softened with oil, vaselin, or warm water. A good wash for the pruritus is as follows:

℞.	Mercuric chlorid.	gr. jss
	Ammonium chlorid,	gr. iij
	Carbolic acid,	ʒ ij
	Glycerin,	ʒ ij
	Rose-water, q. s.	ʒ vj.

Apply twice a day.

An ointment to be employed after each application of the wash will be found useful in the following form:

℞.	Carbolic acid,	gr. x
	Liquid pitch,	gr. xij
	Ichthyol,	gr. x
	Bismuth subnitrate,	ʒ jss
	Cold cream,	℥ j.

Apply twice a day.

In the squamous form the scales must be removed by the aid of sapo viridis and the foregoing treatment utilized.

In eczema of the face the same treatment may be used, with the exception of the ointment, in which the liquid pitch should be omitted. In the erythematous form of facial eczema, which usually occurs in the old, and in which there is a great thickening of the skin, much difficulty is encountered in the treatment. One of the best methods is the persistent use of Hebra's diachylon ointment, made after the original formula. By combining this with the compound antipruritic solution, a good result will be obtained.

In eczema of the beard the hair of the site of the disease should be pulled out and Lassar's paste with 15 grains to the ounce of salicylic acid should be applied; or, if there is much scaling, 20 drops of oil of cade in 1 dram of olive oil.

Eczema of the eyelids is a distressing condition seen both in children and adults, the cause being either the so-called scrofulous habit, irritation from light, ametropia, or ill-fitting glasses. Proper correction of the cause and the application of benzoated oxid of zinc ointment or yellow oxid of mercury ointment (1 percent) will readily relieve the disease. A bichlorid lotion is of value.

Eczema of the auditory meatus should be treated by checking the discharge and applying diachylon ointment, or if fissures are present, silver nitrate (15 grains to the ounce).

Eczema of the arms and legs occur in all the different forms that have been mentioned, being often accompanied by edema. The treatment already outlined will be found quite efficient. Fissures, however, will occur at the bends of the elbows and knees, and in these localities it is necessary to soften the integument by means of soothing ointments before more energetic measures are employed. The fissures will readily heal, and then the appropriate measures will act. So far as the legs are concerned, it will be found that the presence of varicose ulcers, as well as of varicose veins, will prevent remedies acting, and these conditions must be treated by appropriate measures. Locally, there should then be applied the compound antipruritic solution, followed by a stimulating ointment like the following:

℞.	Carbolic acid,	gr. x
	Salicylic acid,	gr. v
	Liquid pitch,	ʒ ss
	Vaselin,	℥ j.

Apply twice a day.

Methylene-blue in 1 to 3 percent aqueous solution may be applied to the area with advantage, followed by liquid collodion.

The palms and soles offer peculiar forms of eczema, there being but little itching, but, on the other hand, a marked thickening of the skin, with the formation of deep fissures or cracks that bleed upon the slightest contact and are exceedingly painful. Washerwomen, bricklayers, bakers, and those in similar occupations are prone to this form, so far as the hands are concerned. The first step that is absolutely necessary is to abandon the occupation causing the trouble. Next, avoid all contact with water. Then procure a softening of the skin by an ointment made as follows, the strength being graded in accordance with the amount of thickening present:

℞.	Salicylic acid,	gr. xx
	Green soap,	gr. x
	Benzoated lard, Cold cream, each,	℥ j.

Apply well twice daily.

This will soon bring about a desquamation, and then a mild ointment can be profitably employed. It may be necessary to repeat these measures once or twice, but final success will follow their use.

Eczema of the nails frequently occurs in connection with eczema of the hands or feet. A thickening occurs, often accompanied by brittleness, fissuring, or ridges on the nail. The nails are rugous and are very often deformed. While the assiduous application of a soothing ointment will do some good, the internal administration of a phosphorus pill (1/50 of a grain) *during* each meal will greatly aid the local treatment. The fissures, which occur at the ends of the fingers and toes, will also be greatly aided by this treatment. The thickening of the skin at the extremities of the digits must receive the same local treatment as that of the palms and soles.

Eczema of the trunk is very likely to be of the so-called "weeping" form, in which a serous discharge

occurs that stiffens the linen. Or it may be vesicular, or papular, or small pustular, leading to the formation of crusts. In all these forms, with the exception of the first, the general methods that have been described will be found sufficient. For the "weeping" form there is, perhaps, nothing superior to dusting-powders, which should be liberally applied. A powder after the following formula will be found advantageous:

℞. Powdered camphor, ʒ j
Powdered Venetian talcum, gr. xx
Magnesium carbonate, } each, ʒ ss.
Sodium bicarbonate, }
Apply liberally.

This is especially serviceable in eczema of the mammæ between the mammary and pectoral surfaces. In eczema of the axillæ it will serve an equally good purpose. Should it be found necessary to wash the surfaces upon which the powder has been employed, a 5 percent carbolic acid solution will be found to be the best. This, however, is rendered more efficient in allaying the pruritus by placing the acid in a 1 : 1000 bichlorid solution containing some glycerin and a little menthol, the latter not to exceed 2 scruples to 6 ounces of the mixture.

Eczema of the genitoanal region is among the most stubborn forms of the disease. It usually involves the region about the anus, the perineum, and the scrotum in the male, it is erythematous in character, with crusts and excoriations due to scratching, and sometimes crusts. The skin becomes very much thickened, especially that of the scrotum. It begins as an intense itching, and it is always proper to locate any rectal disease, such as fissure or hemorrhoids, and correct it previous to other local treatment. For the rectal involvement an ointment of 10 grains of hydrochlorid of cocain to the ounce of lanolin is excellent. For the scrotum and perineum an ointment like the following is of advantage:

℞. Boric acid, ʒ j
Carbolic acid, gr. x
Bismuth subnitrate, ʒ jss
Cold cream, ʒ j.
Apply twice daily.

If there is exudation, the powder may be applied over the ointment.

Universal eczema, fortunately, is not a common condition, for it is one difficult to combat successfully. The best method is, no doubt, by means of baths, followed by inunctions. The condition presented is erythematous and squamous, a very great thickening of the skin being present. These conditions make a recovery very slow, and the intense itching present renders internal treatment highly necessary. In the old, tincture of gelsemium in 10-drop doses thrice daily seems to act well; and in earlier adult life chlorid of calcium in doses of 20 to 30 grains in milk after meals is also good. A bath containing mucilage of flaxseed, borax, and bicarbonate of sodium twice daily, and followed immediately by inunctions of the diachylon ointment of Hebra, will be followed by diminution of the thickening of the skin and increased softness, if accompanied by a certain amount of massage.

General Hints.—It should always be borne in mind that internal treatment is often indicated in eczema.

The portal circulation should always be looked after in eczema of the legs and in varicose eczema. Solid rubber bandages should be carefully eschewed, as they are a positive detriment.

Ordinary roller bandages should not be employed for eczema dressings. For the arms and legs, white cotton stockings are the best dressings. For the buttocks and thighs, thin, knit white drawers should be used. For the hands, white cotton gloves are the best.

Contiguous affected parts should be kept separated by means of pieces of old thin linen. Opposing surfaces of the axillæ, mammæ, nates, scrotum, and thighs should receive particular attention in this regard.

Insistence should be made that patients implicitly follow directions. This is important in order to obtain good results.

ECZEMA SEBORRHŒICUM.—Dermatitis seborrhœica; pityriasis capitis. A mild eczematous inflammation combined with seborrhea occurring primarily on the scalp and frequently extending to other regions, differing from ordinary eczema by the absence of decided inflammation and the absence of infiltration and by the fact that the primary site is the scalp. It is thought to be of parasitic origin, impaired health being an important predisposing factor. Contrary to ordinary eczema it frequently is readily amenable to treatment. It is important to improve the general condition, paying attention to digestion and the bowels; the best drugs to apply locally are salicylic acid, resorcin and sulphur.

EDEMA.—Swelling due to the effusion of serous fluid into the areolar tissues. Venous obstruction, cardiac feebleness, pressure in the lymphatics, the state of nutrition of the capillaries, peculiar composition of the blood, and a general predisposition are the most general factors in the production of edema. The two varieties are (1) simple or serous, and (2) inflammatory or plastic edema. The former occurs in renal and cardiac disease, and in local obstruction to the circulation. Tissues infiltrated with serum are paler than natural, pit deeply on pressure, and look glistening and jelly-like, and on section or puncture, the fluid rapidly escapes. The looser the texture of the tissue, the more marked is the swelling.

Edema developing suddenly is instanced in *edema of the larynx* and in *chemosis of the conjunctiva*. Edema follows fracture of the bones, and may be increased by injudicious bandages and splints. Edema may last for a few minutes or be long abiding, as from (1) long continuation of the cause, (2) permanent occlusion of blood-vessels, and (3) coagulation and organization of the inflammatory effusion.

Hysterical edema does not pit on pressure.

Angioneurotic edema is a localized but transient,

firm swelling closely allied to urticaria and erythema nodosum, not ordinarily pitting on pressure, found in various regions of the body. It may be periodic, but is more often irregularly recurrent. It is usually associated with gastrointestinal symptoms. See ANGIONEUROSIS.

Treatment.—The chief indication for treatment is the removal of the causes impeding the circulation. Pressure, evenly and continuously applied, as by elastic bandages, is the best method. Elevation of the limb is of material benefit. In cases due to thrombosis, massage, systematically carried out, together with after-pressure, will help in absorption. In acute inflammatory edema free incisions will prevent sloughing. The serous edema from renal or cardiac disease may be overcome by posture and drugs, and fine punctures made in the skin with a darning or other needle will benefit, or Southey's tubes may be inserted. Scarification may be practised, as in the sudden edema of the throat. An emetic may be given at the onset of edema of the larynx, and leeches, ice, or, if preferred, hot sponges, applied over the thyroid cartilage. The laryngeal lancet may be used to scarify the edematous part, or laryngotomy or tracheotomy may be performed as a last resort. Bleeding after scarification may be encouraged by the inhalation of steam. See LARYNGITIS (Edematous).

EHRLICH'S DIAZO-REACTION.—See TYPHOID FEVER.

EHRLICH'S SIDE-CHAIN THEORY.—According to this explanation of the phenomena of immunity, each living cell possesses a central molecular mass and a number of other groups attached as side-chains (*receptors*), the latter capable of combining with materials, *i. e.*, foods or toxins, which come in contact with them. In order to combine with these *receptors* the food or toxin must be homologous, that is, it must possess certain groups called *haptophores*. The toxic part of the toxin is called the *toxophore*. This can act on the cell only when its haptophore group finds an affinity for receptors. If this combination takes place, the cell endeavors to produce a fresh and more abundant supply of receptors to supplant those lost in the combination. These receptors (haptines) are liberated and pass into the circulation forming *antitoxin*. If they come in contact with the homologous toxin material they combine with it and render it inert. See IMMUNITY.

ELATERIN.—The active principle of elaterium. It is irritant to mucous membranes, and causes profuse watery stools with little pain. It is the most powerful hydragogic cathartic; and in toxic doses it causes emesis, spasmodic respiration, great prostration, and death. It is useful in cardiac, pleural, and local serous effusions, in dropsy and ascites, in cerebral effusions, and in congestion of the brain. It should not be used when marked exhaustion is present. The dose of elaterin is 1/20 to 1/12 of a grain.

The triturate of elaterin (10) with sugar of milk (90) is given in the dose of 1/4 to 1 grain.

ELBOW, DISEASE.—Tubercular disease is very common in children, and is usually assigned to accident. As a rule, it begins in the synovial membrane; the epiphyses are not so frequently involved as in other bones. The early symptoms are obscure and ill defined. There is a little fulness on each side of the tendon of the triceps, the muscles of the upper arm are wasted, complete extension cannot be carried out, though the other movements may appear fairly free, and the joint is held rigidly flexed at an angle of about 135°. After a little time the fulness makes its appearance over the head of the radius on the outer side of the joint as well; the swelling becomes more distinct; rotation at the shoulder-joint replaces pronation and supination; the temperature of the skin is distinctly raised, and the diagnosis is beyond dispute. As time passes the swelling, if the case is neglected, grows larger and larger until the joint is completely involved in a spindle-shaped mass the size of which is exaggerated by the wasting of the muscles; caseation sets in, and is followed by liquefaction; the skin becomes thin and undermined; and at length the abscesses break externally, leaving sinuses filled with a mass of soft, pulpy granulation tissue. Finally, suppuration occurs, and the pus makes its way into the synovial cavity, destroying utterly the cartilages and bones, which are already in great measure eroded and replaced by the tubercular deposit.

Treatment.—If the treatment is commenced at once, recovery may be expected, with a fair range of movement. The joint must be enveloped in cotton-wool and fixed with plaster-of-Paris or gum and chalk, so that not the slightest movement is possible. Scott's dressing may be applied underneath for a week or two, but care must be taken, especially in children, that it does not irritate the skin too much. If this treatment is maintained for some months, the splints being changed as often as necessary, the inflammatory exudation disappears, and though the muscles waste considerably, the joint is rarely much stiffened or seriously reduced in strength. When the case is not seen until the disease is further advanced, the same treatment should be tried, but the hope of success is not nearly so good; at the best, a large amount of the exudation must become organized, leaving the joint more or less rigid; and for this reason it is essential to maintain the flexed position. When abscesses make their appearance, they must be opened and drained, or if they are limited in size, and the tissues around them are fairly firm, they may be thoroughly scraped out and filled with iodoform. Finally, EXCISION (*q. v.*) may be performed, either with the view of removing the whole tubercular mass, and therefore during the course of the disease, or afterward, for ankylosis in a faulty position, especially as the results of this operation are exceedingly good, even in the case of children.

ELBOW, DISLOCATIONS.—Dislocations of the elbow-joint are chiefly recognized through the relationship of the olecranon process to the condyles of the humerus, which is necessarily modified in every such dislocation. Comparison with the opposite side is of the utmost importance.

Posterior dislocation of the forearm is frequent,

and results generally from force that produces hyperextension and a backward push. The coronoid process of the ulna drops into the olecranon fossa of the humerus, and the head of the radius occupies the posterior surface of the external condyle. The arm is flexed; the olecranon projects markedly; the lower end of the humerus can be indistinctly felt at the bend of the elbow; the distance between the olecranon and the condyles is increased; the forearm is shortened, while the humerus is not; there is rigidity of the elbow (elastic fixation). The diagnosis of a recent dislocation of this nature is not very difficult unless

Dislocation of the Radius and Ulna Backward (Cooper's Dislocation).

complicated by fracture of the coronoid process or by supracondylar fracture.

Reduction is effected by first hyperextending the forearm, to free the coronoid process of the olecranon fossa; downward traction is made, and followed by flexion, which now meets with no resistance, the dislocation having disappeared. The arm is now fixed in an anterior, angular splint for 2 weeks, with frequent change of dressings and massage, and then passive and active movements practised.

Lateral dislocation of the forearm is also not infrequent, the outward variety occurring oftener than the inward. Both are often associated with fracture of a condyle—the inner condyle in outward luxation, and the outer condyle in inward luxation. While the displacement may be complete, it is usually incomplete, the forearm remaining partly in contact with the humerus, this contact being, however, abnormal. Generally, the forearm is displaced backward at the same time. The lateral ligaments are usually extensively torn, or a condyle is fractured, as already mentioned.

The symptoms of complete lateral dislocation are clear; incomplete luxation may be more difficult to determine. If partially displaced outward, the head of the radius will be unmistakably prominent, with a corresponding projection of the inner condyle, while the olecranon will be further removed from the inner condyle and more closely apposed to the outer. In partial inward dislocation these relations are, of course, reversed.

Reduction is effected by the very careful employment, under anesthesia, of hyperextension, with lateral pressure with the hand, followed by traction and flexion. When irreducible, arthrotomy is indicated, from which a good joint frequently results. A well-applied bandage, with a sling, may suffice for dressing, or 2 lateral angular splints may be necessary (best made of cardboard or leather).

Anterior dislocation of both bones of the forearm without fracture of the olecranon is very rare, and results from a blow on the olecranon with the forearm flexed. The condyles of the humerus are felt behind, from which position the olecranon has disappeared, while the olecranon and radius are felt anteriorly. Reduction is effected by direct pressure, assisted by moderate extension. In some cases forced flexion will be necessary.

Divergent dislocation—the ulna backward, the radius forward, the end of the humerus between the two—is very rare, and permits of direct palpation of the luxated bones. Reduction of the ulna is effected by hyperextension and traction, and then the radius is reduced by direct pressure, with traction and flexion.

Dislocation of the ulna, isolated, is very rare, always backward, and results from a fall on the hand with forearm pronated and hyperextended. The forearm is in a varus position and its ulnar side is shortened; otherwise the symptoms are like those of backward dislocation of both bones, except that the head of the radius remains in its normal position. Reduction may be accomplished by traction and hyperextension.

Dislocation of the radius, isolated, occurs more frequently, and in several directions—forward, backward, and outward.

Forward dislocation is most frequent; in this the forearm is slightly flexed, pronated, supination being impossible; the forearm cannot be further flexed because the radial head strikes against

Dislocation of the Radius Forward.—(*From Walsham.*)

the humerus, sometimes with a distinct blow. Reduction is effected by vigorous traction with the elbow bent, the radial head being helped back to its position by direct pressure of the thumb.

Backward dislocation is very rare; the forearm is slightly flexed, pronated; flexion and extension are impaired; the radial head is felt behind the condyle. Reduction by traction with the forearm in the varus position, and by direct pressure over the head.

Outward dislocation rarely occurs except in conjunction with fracture of the upper third of the ulna. In intractable and old cases replacement by incision (along the radial aspect of the joint) may be necessary.

Subluxation of the radial head occurs in children from 2 to 4 years old, as a result of traction on the forearm (lifting a child violently by one hand)

The arm hangs at the side, the elbow slightly flexed, and the forearm between pronation and supination. Complete flexion and extension are painful, and are resisted. There is no deformity at the elbow. The symptoms disappear with supination and traction followed by flexion.

ELBOW, EXCISION OF.—See EXCISION OF JOINTS.

ELBOW, FRACTURE INVOLVING.—See ARM, FORE-ARM, FRACTURE.

ELECTRICITY.—One of the forces of nature developed or generated by chemical action, magnetism or friction, and probably a mode of ethereal vibration, closely analogous to and convertible into heat and light. It has been largely employed in its various forms for therapeutic purposes. Most animal and vegetable fibers (living) contract when an electric current is passed through them, and, in fact, no substance is known that does not offer some resistance to the passage of an electric current. By the *conducting power* of a substance is meant the ability of a given length and area of a cross-section of that substance to conduct electricity, as compared with an equal length and area of a cross-section of some other substance, such as pure silver or copper. This power may, in various substances, be pronounced partial or absent. *Good conductors* are silver, copper, other metals, charcoal; *partial conductors* are water, the human body, cotton, wood, marble, paper; *nonconductors*, oils, porcelain, dry wood, silk, resins, dry air, shellac, gutta-percha, ebonite, paraffin, glass.

The electric current is a term in electricity applied to the transference of electric force, which is arbitrarily likened to the flow of a liquid in a confined passage. The galvanic and the faradic or induced currents are those most used in medicine.

The galvanic current is generated by the decomposition of acidulated water by means of metallic plates, is continuously evolved, flows always from the anode, or positive pole, to the kathode, or negative pole, which is in connection with the zinc or generating plate of the battery; it always gives well-marked and thermal and electrolytic effects. The cell known as "Leclanché" is commonly used by medical men. See BATTERY.

The induced current is momentary in duration; its direction is constantly changing; it has no chemic, thermal, or electrolytic effect; its tension is greater than that of the galvanic current—that is, it overcomes the resistance of the body with far greater ease, and hence it causes the contraction of the healthy muscle far more readily than the galvanic current. "An induced current acts only during the indefinitely short time of its passage. It is a series of slight excitements. With constant currents real excitement is determined only at the times of making and breaking. It is during the silent period, however, that the principal action of the continuous current makes itself felt."

To apply electric currents a conducting wire and rheophore, or current carrier, terminal, or electrode, are necessary. Rheophores should have insulated handles, made of metal and not of carbon, and are made in the form of discs, balls, or points for reaching particular organs, as the ear, larynx, bladder, etc. They are usually covered with wash-leather. A sponge-holder is a most generally useful rheophore. A wire brush is useful for application to the skin.

High Frequency Currents.—These are alternating currents produced primarily by the continuous charging and discharging of a pair of Leyden jars or condensers. The jars are charged by means of large induction coils or influence machines (static machines). The charge is applied to the inner coating of the jars. This charging current is allowed to spark between two metallic balls connected to the inner coating of the two jars. This produces an extremely rapid oscillation estimated to be about one million per second, from which this current derives its name.

From the outer coatings of the jars the current is usually passed to an Oudin resonator or a Tesla coil, which increases the voltage to the extent of from hundreds of thousands to over a million. From the Oudin resonator or Tesla coil the current is passed to the patient. As long as the jars are not punctured the patient cannot at any time receive the primary current.

There are four methods of applying this current for therapeutic purposes:

1. Derivation (closed circuit).
2. Auto-conduction (large solenoid).
3. Auto-condensation (mattress with tin under the patient forming a dielectric).
4. Unipolar or bipolar local applications.

The first three are used chiefly for their constitutional effects. Of these auto-condensation is most efficient. By this current no direct sensation is felt, except that there is a general feeling of warmth, and if the area of contact of one of the poles is not perfect there will be felt some local heat. As a result metabolism is increased, blood-pressure is restored more nearly to normal, there is often an increased perspiration and an increase of the waste products in the urine. The *blood-pressure can be lowered* rather uniformly (where abnormally high) about ten points in ten minutes. It remains lower about two days, and usually does not rise quite to its original point. In this way a permanently lower blood-pressure is obtained. This treatment is therefore indicated in all the groups of symptoms which result from abnormally high blood-pressure. This form of application is also indicated in those diseases or symptoms resulting from inactivity and improper habits of life, associated with which the secretions have become inactive, as in rheumatism and gouty affections.

Local applications of these currents are of two kinds, the effleuve and the spark (fulguration). The electrodes consist of metal or glass vacuum tubes. The glass vacuum tubes are used when one wishes to produce a local hyperemia, or dilatation of the blood-vessels, or for a local sedative effect, and are used in the treatment of pruritus, prurigo, eczema, acne, etc. The metal electrodes are used especially to produce a localized spark, which is used for the destructive effect. It is certainly one of the very best methods of destroying warts, moles, epitheliomata, nævi, lupus

nodules, boils, carbuncles, etc. The resulting scars are nearly or quite invisible, and resemble very closely those obtained by means of the Roentgen rays. The result is obtained more rapidly than from the X-rays, but the applications are somewhat painful. The pain can be avoided by producing a preliminary local anesthesia by means of cataphoric cocainization.

Local applications by means of vacuum electrodes or the effleuve are used in the treatment of chronic rheumatism and rheumatoid arthritis with some excellent results.

Static currents are obtained from frictional or influence machines. They are high potential currents.

The currents obtained from the static machine are:

1. The static wave current.
2. The static induced current.
3. Convective discharges or effleuve.

The static wave current is produced by grounding one of the prime conductors; the other is connected with an electrode applied to the patient, who is on an insulated stand. The current received by the patient is due to the spark discharge between the knobs of the prime conductors. The patient forms one coating of a Leyden jar condenser, the other coating of which is the earth and surrounding objects, and walls connected electrically therewith.

By means of this current strong localized contractions of tissue are obtained, followed by relaxation. In this way by their own contractility the tissues force out their fluid contents (lymph and blood) and during relaxation are again refilled. Thus chronic congestion is dissipated, induration is relieved, stagnant blood and lymph is replaced by fresh blood. The tissues regain their normal tone. Spasmodic conditions of muscles are relieved, as well as the pain resulting therefrom.

Based upon the above physiologic action, the following diseases have been treated with success: Old inflammatory lesions, lumbago, sciatica, chronic rheumatism, enlarged prostate, constipation, etc.

The static induced current is obtained by connecting the rods to the inner coating of the Leyden jars. The patient is connected to the outer coating of the Leyden jars. The rods are brought close together so that short sparks pass. The local effects of this current are somewhat similar to those from the wave current, but less powerful. It is used chiefly on damp days when the long sparks cannot be obtained for a satisfactory wave current.

The convective discharge or effleuve is obtained from the static machine and consists of the *spray* (from a point); the *brush* from a metal or wooden terminal is passed through or over a wooden electrode. The brush is much the same, but less irritating than when obtained from a metal point. The brush discharge has a distinctly disruptive characteristic, as if multitudes of little sparks were passing in rapid succession, producing a feeling when projected against the surface as if sharp particles of sand were thrown against the skin. This modality is administered with the patient seated upon the insulated platform. The discharging rods should be widely separated and the patient hold the shepherd's crook in the hands or having the feet bare upon a metal plate, connected with the negative side of the machine, and the positive side should be grounded. The effects are rubefacient, antiseptic. It relieves local stasis, softening the underlying tissues, by removing the induration that is present and thereby restoring normal circulation to the parts and instituting an active local metabolism. This form of current is used successfully in the treatment of superficial skin diseases, lupus vulgaris, lupus erythematosus, eczema, psoriasis, herpes, sycosis, favus, ulcerations, etc. It should not be used in acne and furunculosis. In these latter conditions the Roentgen rays are indicated.

Static Sparks.—These are best administered by connecting the patient upon the insulated platform to the positive side of the machine. The negative side is grounded and a second ground is connected to the ball electrode which is used in drawing sparks from the patient at the affected areas.

The effects are counterirritation, without damage to the skin, thus relieving pain; strong local contractions of the tissues, thus relieving congestion, spasm and induration; increasing the local blood supply and local metabolism, thereby removing exudates. These sparks are indicated and successfully used in the treatment of chronic joint affections, lumbago, sciatica, chronic neuritis, and at times for stimulating effects upon the spine.

As a whole the results in electrotherapy depend more upon the skill and careful technic of the operator than anything else.

The two methods for applying electric currents are general and local. In the former the current is passed through the entire or greater part of the body. Its utility is doubtful. The latter method influences special nerves, muscles, or organs. The method is a direct one, since it may influence a muscle itself, or an indirect one by stimulating the nerve supplying the muscle.

No one should use electricity without first acquiring a knowledge of the **electric units.** They are as follows: **Ampere,** the unit of measurement of an electric current. It is the electromotive force of 1 volt produced in a circuit having 1 ohm of resistance, equal to 1/10 C.G.S. electromagnetic unit. It is sufficient to deposit 0.3 grain of copper a minute on the plate of a copper voltameter, or to decompose sufficient acidulated water to generate 10.32 c.c. of mixed hydrogen and oxygen a minute. For convenience, the one-thousandth part is used in medicine: namely, the *milliampere.* This equals 1 volt divided by 1000. **Ampere-hour,** a unit of electric quantity equal to 1 ampere flowing for 1 hour; it is the equivalent of 3600 coulombs. **C.G.S. System:** centimeter gram second units; the system of fundamental units in which a centimeter is adopted as the unit of length, a gram as the unit of mass, and a second as the unit of time. **Coulomb,** the unit of measurement of electric quantity; the quantity of electricity that passes during 1 second through a conductor

having a resistance of 1 ohm, with 1 volt of electromotive force. The *microcoulomb* is the millionth part of this amount. **Unit of Current,** a conductor 1 cm. long, which, if bent into an arc of 1 cm. radius, will act with the force of 1 degree on a unit magnet pole at the center. **Dyne,** the unit of force; *i. e.*, the force that, if it acted for 1 second on a mass of 1 gram, would, if the mass was previously at rest, give it a velocity of 1 centimeter a second; or if it was previously in motion in the direction of the force, would in that time alter its velocity by that amount. **Erg.** See UNIT OF WORK. **Ergten,** 10,000,000,000 ergs. **Farad,** the unit of electric capacity. Practically, a capacity sufficient to hold 1 coulomb of current having a potential of 1 volt. The *microfarad,* one-millionth part of the theoretic farad is commonly used. A practical form of condenser of 1 farad capacity consists of 300 leaves of tin-foil, each 16 centimeters in diameter, separated by leaves of mica. The entire surface has an area of about 1.1 square meters. **Joule,** the unit of electric energy or work. The volt coulomb. It equals 10,000,000 ergs. **Unit Magnet Pole,** a magnet having a strength of pole sufficient to repel a similar pole at a distance with a force of 1 degree. **Megalerg,** 1,000,000 ergs. **Megavolt,** 1,000,000 volts. **Microcoulomb.** See COULOMB. **Microfarad.** See FARAD. **Microvolt,** one-millionth part of a volt. **Milliampere.** See AMPERE. **Ohm,** the unit of resistance. Practically, it is the resistance of a pure silver wire 1 meter in length and 1 millimeter in diameter. The theoretic or absolute unit is one-millionth part of the unit practically used. **Volt,** the unit of electromotive force, or the force sufficient to cause a current of 1 ampere to flow against a resistance of 1 ohm. The following is the voltage of several popular cells: Smee 0.65; Bunsen, 1.90; Daniell, 1.05; Callaud, 1.60; Leclanché, 1.50. **Volt-ampere,** the unit of electric work. It is the amount of pressure developed by a current of 1 ampere having an electromotive force of 1 volt. Its mechanic equivalent is about 44.2 foot-pounds a minute. It is sometimes called a *watt.* **Voltcoulomb,** the unit of electric work. **Watt.** See VOLT-AMPERE. **Weber,** an ampere or coulomb; not much used. **Unit of work,** the erg; it is equal to the work required to move a body through 1 centimeter against a force of 1 dyne. The reciprocal relations of these electric units may be expressed thus:

1 volt × 1 coulomb	= .....1 joule
1 volt × 1 ampere	= .....1 watt
1 volt × 1 ohm	= .....1 ampere
1 ampere × 1 ohm	= .....1 volt
1 volt × 1 ampere × 1 ohm	= .....1 watt
1 volt × 1 ampere × 1 ohm × 1 second	= .....1 joule
1 ampere × 1 second	= ...1 coulomb

Electrotherapeutics.—Electricity is used in medicine as a stimulant, to excite muscular and nervous tissue, normal or diseased. It is used as a sedative to allay pain. It is employed to promote absorption, coagulation, and dissolution of the fluids and tissues of the body. It is used as a cautery and as an illuminant.

Electricity is of undoubted service to distinguish between paralyses of central and peripheral lesions. The electric current may remove the cause of paralysis by influencing the nutrition of the parts, by stimulating absorption of a blood-clot in the brain, or by acting upon the chronic degenerative changes in the cord or brain.

The following rules should be heeded in the use of electricity for the treatment of paralyses: (1) The aim should be to preserve the muscular part of the locomotive apparatus in a state of health and readiness; (2) that form of current should be employed to which the muscles most readily respond; (3) the weakest currents which will cause muscular contraction are to be used, and the risk of exhausting a muscle by causing a too prolonged contraction is not to be taken; (4) if the paralysis remains absolute to the will, and the contractility of the muscle is perfect, perseverance with electric treatment is of no avail; (5) if the paralysis to the will remains absolute, and if the irritability to the muscle is diminished, electricity is useful in so far as it improves the nutrition of the muscles and helps to restore their normal degree of irritability; (6) if irritability to both forms of current has completely disappeared, perseverance is not justified, and false hopes must not be held out to the patient. A trial, nevertheless, is advised.

The power of electricity to relieve pain is usually temporary, sometimes permanent. The anode, or positive pole, is applied to the painful spot. It may divert the mind from troubles, real or fancied, or act as a counterirritant. It may give relief when every known remedy has failed. All three forms of electricity relieve pain, but the galvanic current is most practical. In neuralgia, the pains of which muscular movements increase, in headaches of all kinds, in lumbago, sciatica, and tinnitus aurium, the galvanic current often benefits when other remedies fail. Writer's cramp has yielded to the electric treatment, and tonic spasms of the bladder and bowel have been benefited by the galvanic current. In the paroxysms of angina pectoris, the burning pains of herpes zoster, obstinate skin-diseases, such as dilated acne rosacea, diabetes, exophthalmic goiter, postpartum hemorrhage, ovarian pain and tenderness, and amenorrhea the electric current has been used with benefit; also in gouty arthritis, myalgia, enuresis, nocturnal incontinence of urine, constipation, inflammatory exudations, ascites, suspended animation, and as a test for death. Its absorbent action has been utilized in nearly every form of inflammation. When it is used as a cautery the advantages are obvious. The method of galvanopuncture has the advantage of the hemostatic action of the heated knife or needle.

The practice of electrotherapeutics is in the hands of skilled specialists, who follow prescribed rules and use exact quantities measured by milliamperemeters, etc.

ELECTRICITY, ANESTHESIA.—Professor Leduc, in 1902, announced the possibility of passing electric currents through the unopened skull, the brain, and higher nerve centers, producing a form of anesthesia which he called "*electric sleep.*" For

the most part the experiments have been performed upon animals. The results have not been uniformly satisfactory. At times, however, surgical operations can be performed without any evidence of pain, and the animal regains consciousness immediately after the current is cut off. It is clearly in an experimental stage, and is not without danger.

ELECTRICITY, INJURIES.—The alternating and direct currents are the forms most often employed for commercial purposes. The former supplies incandescent-lighting systems, requiring voltage from 1600 to 2000; the latter is used in arc-lighting systems and as motive power in railways, factories, etc., requiring voltage ranging from 500 to 3000. The lethal force of electricity is almost entirely dependent upon voltage, or electromotive force, being actually the result of the current in amperes that is caused to flow through the body, against its resistance, by the electromotive force. There are cases on record in which a pressure of 500 volts has proved lethal, but by far the greater number of fatalities have been produced by pressure exceeding 1000 volts. From 1500 to 2500 volts have been employed in electrocution, the skin resistance brought to the minimum by contact sponges of large surface wet with saline solution.

Of the various human tissues, the skin presents the highest resistance to electric penetration; different thicknesses produce resistance of varying degree. When not removed, destruction is markedly intensified. Skin resistance is increased by dryness; when moistened, especially by saline solution, it is decidedly diminished. Experience tends to show that a current of 1 or 2 amperes is fatal to the majority of individuals. The fact that comparatively low voltages have proved fatal in some cases, and that victims of shock from relatively high voltages have recovered, does not necessarily show that some systems can withstand more current than others, but rather that the skin resistance was greater, or the area of contact smaller or drier, in the more fortunate cases (according to Ohm's law).

Any current sent through the body being dependent upon resistance offered (the skin remaining the chief factor), it follows that the larger the area of contact, the less resistance and a proportionally greater amount of current is received. It has been proved that a 2 percent or 3 percent saline solution offers a resistance equal to about one-twentieth of that of pure water, and that sea-water offers about one-fortieth. It is also known that a resistance of 80 ohms—60°—is offered to an alternating current by a cubic foot of pure water at 60° F., while a cubic foot of pure water plus 0.15 of a pound of rock-salt produces but 7 ohms' resistance to the same current. If these waters are elevated to 212° F., it will be seen that pure water resists to the extent of 24 ohms, the saline solution to but 4.2 ohms. From these and other data it is justifiable to deduce that (1) the salinity of the sweat, (2) temperature, (3) atmospheric humidity, and (4) season of the year are all important determinant factors in the intensity and gravity of trauma and shock due to electricity. Of the two more important and ordinarily utilized currents, the direct has the greater electrolytic intensity, while from the alternating permanent chemic change does not occur. In cases of fatal exposure to either current, sudden and profound shocking of the sympathetic system is, without doubt, the lethal agency.

Electricity produces injuries, ranging from insignificant burns to death, of which an overwhelming percentage consists of burns. They occur, as do all other injuries, upon the most exposed portions of the body, and differ from ordinary burns or scalds in (1) appearance, (2) accompanying pain, (3) concomitant shock, (4) prognosis, (5) subsequent manifestations, (6) reaction to treatment, and, frequently, (7) the result (Sharpe).

1. *Appearance.*—The majority of electric burns, seen early, present a dry, crisped aspect, excavated and bloodless, with a surrounding zone characterized by pallor. This condition changes within 36 hours; serous oozing exists, the tissues soften, and hyperemia replaces the pallor.

2. *Pain* is, as a rule, very moderate, in some cases practically absent; from 24 to 48 hours after contact it is usually present.

3. *Shock.*—The systemic shock is from the contact—there is none from the burn itself.

4. *Prognosis.*—In regard to time, electric burns average from 1 1/2 to 3 times as long in recovery as do other burns. In severe cases, dependent upon locality, such as proximity to bones and joints, the ratio is as 5 or more to 1. Prognosis of result is as uncertain as time-prognosis; severe cases may progress relatively rapidly; mild cases are often persistently rebellious to recovery; usually, both mild and severe cases are tedious and prolonged.

5. *Subsequent Manifestations.*—The rule of the electric burn is that it changes within 36 hours from contact to a serum-saturated area, with disintegrating walls and floor, progressing to profuse purulent secretion, with continued tissue degeneration. This degeneration will frequently involve nerve, muscle, tendon, joint capsule, ligaments, articular surfaces, periosteum, and bone itself; exuberant granulations springing up, the entire surface is bathed in pus.

6. *Reaction to treatment* is very unsatisfactory, it being an apparent impossibility to check the disorganizing process, especially in severe cases, with most scrupulous antisepsis or asepsis. After a varying period of from 15 to 50 or 60 days, and often much longer, firm granulation will slowly proceed; and—

7. *The result* will be as good as is ordinarily secured in other burns. In some cases, however, owing to the disintegrating process involving bones and joints and producing necrotic masses, amputation is necessary.

Sloughing is almost invariably present.

General Rules for Guidance in Electric Accidents.—(1) Break the circuit at once, if there is an interrupter close at hand. If not, lose no time, but proceed to rule 2. (2) Do not touch the body with the bare hands, but if india-rubber gloves are not at hand, pull the body off the cable by

the coat tail, or fold a coat or some dry article into two or three thicknesses, and, using this as a pad to take hold of the body, pull it away from the circuit, and resort to rule 5. (3) If unable to get the body off, raise, with covered hand, that part of the body that touches the earth, or one of the poles of the circuit. This will break the circuit, and it will usually be thus possible to get the body easily away, and, if so, proceed to rule 5. (4) If still unsuccessful, make another pad, and, placing it between the ground and that part of the body in contact with the ground, continue the efforts to detach the body. (5) Having pulled the body away from the cable, free the neck of clothing, and treat the case as one of drowning. If the teeth are clenched and cannot be separated with the fingers, gently insert the handle of a pocket-knife or a small piece of wood, cork, etc.

The treatment of profound shock from an electric current should be instituted upon lines analogous to those pursued in shock from other agents. The patient will be found pulseless, or nearly so; respiration of the most feeble character, or absent; a warm skin, which rapidly cools, with pallor, immobile pupils, and absolute muscular relaxation. Laborde's method of tongue traction in the horizontal position, or with the head upon a lower plane than the body, is advised. Friction, heat to the trunk and extremities, hypodermic injections of brandy, digitalis, etc., are valuable. In cases in which respiration is not absolutely suspended, inhalations of amyl nitrite, until the face flushes, followed by a large dose of strychnin hypodermically, will bring the vital forces together. This effect should be followed by nitroglycerin. Electric applications are *not* advised.

Dissatisfied with the poor results of classic aseptic treatment of these cases of burns, among other agents the following are utilized by Sharpe: Bichlorid solutions, carbolic solutions, pyrozone solutions, zinc chlorid solutions, in varying strength; hydrogen dioxid; sterilized water, hot and cold; iodoform, dry, in emulsion, and in glycerin; salicylic and boric acids; sodium bicarbonate, loretin, aristol, iron and potassium tartrate in solution; and for digestion of the sloughs, pepsin, trypsin, and pancreatic extract in appropriate media. Both moist and dry dressings are employed.

Conclusions (Sharpe).—

1. The skin is the chief factor of resistance in an individual sustaining an electric shock.

2. Moisture of the skin, and especially marked salinity of sweat, favors access of the current.

3. Humidity and temperature of the atmosphere and season of the year, are important factors in determining individual resistance.

4. Electric trauma differs from ordinary burns or scalds in duration.

5. Electric trauma differs from ordinary burns or scalds in results (noticeable in severe cases).

6. Prognosis in all cases should be guarded.

7. Rigid asepsis should be followed in the manipulation of all cases.

8. Sloughs are best removed by solution of pepsin, thus:

℞. Scale pepsin, ʒ j
Hydrochloric acid (U. S. P.), ʒ ss
Distilled water, ʒ viij.

This should be washed off in 2 hours with hydrogen dioxid, pyrozone, or hydrozone; the application should be repeated as may be necessary.

9. Deep disintegration demands especial watchfulness for the detection of bone invasion or joint invasion.

10. Necrosis of bone should be combated by injecting a 3 percent solution of hydrochloric acid, in distilled water, repeated not more frequently than every 2 hours. Every second day the acid pepsin solution described should be used, until the necrotic masses are cleared away, when gauze packing should follow. When a case is complicated by tuberculosis, a 10 percent solution of iodoform in ether should be subsequently employed.

11. Persistent bone invasion or joint invasion, with necrosis, requires amputation, or, in some cases, resection.

12. Degenerative division of important nerves should be subsequently repaired by Levering's method; degenerative division of important arteries and veins should be repaired by Murphy's method, whenever this is possible.

13. Granulating areas, after sterilization, should, when feasible, be covered by large skin flaps.

14. When the healing process has started, peripheral skin-growth is hastened by the use of a layer of sterile gauze, saturated with an iodoform glycerin mixture, covered by rubber tissue.

15. For the treatment of profound shock Laborde's method of tongue traction, application of heat and frictions, inhalations of amyl nitrite, hypodermic injections of large doses of strychnin, together with nitroglycerin internally, are recommended.

ELECTROLYSIS.—The dissolution of a chemic compound by an electric current; the dissolution of any morbid growth by means of an electrochemic current. Most forms of electricity cause electrolysis, and the amount of decomposition is proportional to the intensity of the current, which intensity is determined by the amount of electricity generated and the resistance offered to its passage. Electrolysis has been used in the treatment of aneurysm, for the destruction of morbid products, the disintegration of urinary calculi, and in hydrocele. In aneurysm the aim is to coagulate the blood in the sac. The constant current should be used. Both poles, when inserted, are more effective, accurate, and painless, but the needles should be insulated when in contact with the tissues, to prevent pain, inflammation, and the risk of hemorrhage. Steel needles are sometimes used, but a platinum or gold-pointed needle will not be affected by acids. A duration of from 1/2 of an hour to 1 1/2 hours is usually necessary for an application. When properly performed, electrolysis is free from risk. Embolism has never occurred, and the hemorrhage from the puncture is easily checked by gentle pressure. The operation cannot be preferred to compression or ligation in surgical aneurysm.

In blood tumors it brings about cure, by, first, cauterizing the tissues, and, secondly, by coagulating the blood. It is the best treatment for cirsoid aneurysms. For the cure of subcutaneous nevus without scar electrolysis is safe, and often certain; several operations are required, extending over a space of about 6 weeks. Vascular goiter is amenable to electrolysis, but this is not true of the cystic and fibrous varieties. For solid tumors electrolysis presents no advantages over the knife, cautery, or caustic, and it is less certain, more tedious, and not more safe than the knife. In some chronic hypertrophies and inflammations it may be useful. Enlarged lymphatic glands may be treated by electrolysis. Electrolysis is frequently used to remove superfluous and aberrant hairs. It is also employed in the treatment of urethral, lacrimal, esophageal, and rectal stricture.

The *negative* electrode or pole of the battery is that used for destructive purposes (electrolysis), while the *positive* electrode or pole is sedative in character. The galvanic battery is the one used. While not absolutely essential, the best and most satisfactory results are obtained by the use of a milliamperemeter—an instrument to measure the exact strength of current. Any make of galvanic battery may be used. The current is made or broken by the patient grasping the positive electrode with either hand and releasing it as indicated by the operator.

Superfluous hairs must be removed one at a time. Insert the needle carefully into the hair channel until it pierces the bulb or bottom of the hair follicle. This is indicated by a peculiar resistance at first, followed by a slight sensation of freedom of the needle-point that is so characteristic that it must be practised to be appreciated. Always introduce the needle with an open or unclosed current. When the hair follicle is pierced, the current is closed, and in from 2 to 6 seconds a small bubble or two is seen about the needle. This usually suffices to destroy the hair-root. Always break the current before withdrawing the needle, otherwise the patient will experience an unpleasant shock or stinging pain. If successful, the hair will come out readily without pain to the patient. If it is necessary to use traction, the hair follicle is not destroyed and the hair will return. The strength of current used should be from 3 to 6 milliamperes, or about the strength obtained from one or two of the small bichromate battery cells. Never remove at one sitting 2 hairs that are closely approximated, but select them at least 1/4 to 1/2 of an inch apart to prevent too much local irritation. From 10 to 75 hairs may be removed at a sitting. Bathe the face afterward with hot water and apply a soothing unguent. A current of 10 to 20 milliamperes will destroy surrounding tissue and leave white scars, while the lighter current will leave none. Moles are removed by piercing the base on several sides and using a current of from 10 to 15 milliamperes; but weaker currents will often suffice. The change of color will indicate success or failure. Too strong currents will leave scars. Warts and small tumors are removed in the same way as moles. Birth-marks are dependent upon enlarged capillary vessels, and, if not too large, can be readily removed by introducing the negative electrode needle into the layer of tissue containing these vessels. If from 4 to 6 milliamperes of current are used, the vessels surrounding the needle are contracted and destroyed, and, with the following contraction of the scar tissue formed, will be permanently effaced. Small areas must be treated at each sitting until the result is accomplished. Enlarged veins of the face, nose, or ears may be removed by introducing the needle into the caliber of the vein as far as it can be seen; with a current of from 4 to 6 milliamperes gradually withdraw the needle, and a small white line is left, without the loss of any blood. In a day or two this line will disappear, and no trace of the vein be left. The so-called "whisky nose" can be treated by this method (Stewart).

The olive-tipped metallic bougie is probably best for electrolysis in urethral stricture, and the stem should be covered with hard rubber. Test the caliber of the stricture first, and use an electrode slightly larger than will ordinarily pass. If it is impermeable, use the smallest electrode. Remember that mechanic force must not be used. Introduce the aseptic electrode, anointed with glycerin as an emollient, until the olive tip is in contact with the stricture. Place the positive pole over the pubes or on the perineum. With a rheostat or current controller gradually turn on the current until 5 or 6 to 8 milliamperes are registered. Another guide is the feelings of the patient. If there is too much pain or burning, the current is too strong. Use only the mildest pressure on the bougie electrode, and in almost every case it will slip past the stricture in from 2 to 8 minutes. When the current is broken and the instrument withdrawn, the back of the olive tip will be covered with a frothy substance, which is part of the disintegrated scar tissue and the fluids present in the urethra. Never continue a treatment over 10 or 12 minutes. Give treatments every third or fourth day, and use a larger electrode each time until the urethral caliber is normal, which will require from 6 to 10 treatments. Contrary to some recent reports published, from 10 to 15 milliamperes will cause severe pain, will destroy too much tissue at one time, will be liable to produce more scar tissue in healing, and can be likened only to division with large bougies. With weak currents the patient should experience no discomfort, and should be able at once to resume his business pursuits.

ELECTROTONUS.—The change of condition in a nerve during the application of a current of electricity. A decrease in the electromotive force of a nerve effected by sending a current through the nerve in the opposite direction to that of the nerve-current is termed the *negative phase* of electrotonus, while an increase in the electromotive force of a nerve effected by sending a current through a nerve in the same direction as the nerve-current is termed the *positive phase* of electrotonus.

ELEPHANTIASIS (Elephantiasis arabum; Barbados Leg; Pachydermia).—A chronic hypertrophic disease of the skin and subcutaneous tissue, due to obstruction of the lymphatic channels, and resulting in enormous enlargement and thickening of the part, with papillary outgrowth.

Symptoms.—The most frequent seats of elephantiasis are the leg and foot, although the penis, scrotum, clitoris, and other parts are at times involved. The affection usually begins as an erysipelatous inflammation, accompanied by fever, lymphangitis, pain, swelling, and heat, and followed by more or less permanent enlargement of the part. Such attacks recur at intervals of a few months, the affected area each time becoming larger. Finally, a state of chronic hypertrophy is reached, the limb is greatly enlarged, the skin and subcutaneous tissue are enormously thickened, and the surface is pigmented and covered with papillomatous growths and fissures. The maceration of the epidermis and the collection of decomposing sweat, sebum, and effete products give rise to an offensive odor.

There is, as a rule, no pain, although during the acute exacerbations it may be severe. The enormous weight of the hypertrophied part may make locomotion difficult or even impossible. The course of the affection is chronic.

Etiology.—The disease is most common in tropical countries, where it occurs chiefly in those inhabitants who are subject to bad hygiene and improper food. It is due to inflammation and obstruction of the lymphatic vessels by the filaria sanguinis hominis. Sporadic cases may be due to obstruction of the lymphatics from other causes, such as recurrent erysipelas, ulcers, cicatrices, tumors, etc.

Pathology.—There is a hyperplasia, participated in by the subcutaneous tissue and by all the layers of the skin. The chief change is in the subcutaneous tissue, which is enormously hypertrophied and is traversed by irregular bundles of connective tissue. When the surface of the skin is warty, the papillæ are greatly elongated. Both blood-vessels and lymphatics are enormously distended, the latter leading to dilated lymph spaces. The neighboring lymphatic glands are enlarged. In advanced cases the muscles undergo fatty degeneration and the bones become enlarged.

Diagnosis.—The history of recurrent erysipelatous inflammation, with slowly progressing hypertrophy, is peculiar to elephantiasis. In advanced cases the appearance is unmistakable.

Prognosis.—In the beginning the process may at times be arrested. When the growth is far advanced, treatment accomplishes but little.

Treatment.—The erysipelatous attacks are best treated by rest, hot or cold applications, and the internal administration of salines and quinin. Good food and hygiene, tonics, and change of climate are important matters in endemic cases. Elastic compression by means of a well-applied rubber bandage is the most efficient therapeutic measure. Green soap and the mercurial ointments may be rubbed into the skin.

In advanced elephantiasis of the leg resort may be had to stretching or partial exsection of the sciatic nerve, or to digital or instrumental compression, or even ligation, of the femoral artery. Elephantiasis of the Scrotum (*q. v.*) is best treated by amputation.

ELIXIR.—A sweetened, aromatic, spirituous preparation, which is practically a flavored syrup, designed as an excipient for extracts and tinctures. There are three official elixirs:

Elixir Adjuvans (adjuvant elixir). Fluidextract of glycyrrhiza, 120 c.c.; Aromatic elixir, 880 c.c.

Elixir Aromaticum (aromatic elixir). Compound spirits of orange, 12 c.c.; syrup, 375 c.c. (Purified talc, 30 grams, for filtering); alcohol, 238 c.c.; distilled water, q. s. to make 1000 c.c.

Elixir Ferri, Quininæ et Strychninæ Phosphatum.—Soluble ferric phosphate, 17.5 grams; quinin, 8.75 grams; strychnin, 0.275 grams; phosphoric acid, 2 grams; ammonium carbonate, 9 grams; alcohol, 60 c.c.; acetic acid, 28.65 c.c.; ammonia water, to neutralize distilled water; aromatic elixir q. s. to make 1000 c.c. Average dose, 4 c.c. (1 fluidram).

McMunn's elixir is a preparation of the deodorized tincture of opium of 10 percent strength, the dose of which is 5 to 30 minims.

Yvon's hypnotic elixir is made thus:

℞.	Paraldehyd,	♏ ijss
	Alcohol (99 percent),	♏ jss
	Tincture of vanilla,	♏ ss
	Water,	♏ j
	Simple syrup, enough for	♏ iv.

A teaspoonful or two every hour until sleep results.

The substances generally used in elixir form are arsenic, bismuth, ammonium bromid, lithium bromid, potassium bromid, calisaya bark, hydrated chloral, coca, gentian, guarana, ferric chlorid, ferric phosphate, ferric pyrophosphate, pepsin, quinin phosphate, strychnin phosphate, taraxacum, ammonium valerate.

Many of these agents are often combined with one another, as the elixir of bismuth and strychnin; elixir of calisaya, iron, and strychnin; elixir of gentian and tincture of iron chlorid; elixir of iron, quinin, and strychnin phosphates.

EMACIATION (Leanness).—Loss of the fat and flesh of the body. In chronic wasting diseases calcium phosphate is serviceable. Arsenic is used to fatten oxen and cattle quickly. Arsenic, iodin and the salts of iron improve the digestion and appetite. Cinchona, in small doses, also improves the appetite and the general tone. Inunctions of olive oil are useful in many wasting diseases, and cod-liver oil may be given internally and externally, with friction. It is especially useful in marasmus in children, and is effective in malnutrition. Pepsin directly promotes the digestion of food.

EMBEDDING.—The fixation, in order to preserve it intact, of a tissue specimen in a firmer medium before freezing, or otherwise hardening, and section. See Pathologic Technic.

EMBOLISM.—The sudden plugging of a blood-vessel by a foreign body (embolus) transported in the blood stream. Emboli are usually detached portions of thrombi, but they may be vegetations from the valves of the heart, detached atheromatous plates, fat globules, air bubbles, portions of tumors, cells from some of the normal structures of the body, masses of bacteria, or parasites.

EMBROCATION.—A preparation similar to a liniment, but of thinner consistence. The term is not much used now. See Liniments.

EMBRYO.—See Fetus, Abortion, etc.

EMBRYOCARDIA.—See Heart disease, functional.

EMBRYOTOMY.—Some form of mutilating operation upon the fetus to reduce its size and thus render possible its extraction through the birth canal.

The important varieties of embryotomy are *craniotomy, decapitation, evisceration, cleidotomy* (division of the clavicles), *rachidotomy* (perforation of the spine), and *amputation of extremities.*

Craniotomy consists in perforating the skull and evacuating its contents, thus securing sufficient reduction in size to accomplish delivery. Crushing should rarely be resorted to.

The indications for craniotomy are: (1) If the child is dead, and by the operation the mother can be saved risk or injury; (2) in faulty cephalic presentations, as face or brow with chin persistently posterior; (3) when there is great disproportion between the fetal head and maternal pelvis.

Craniotomy is contraindicated when the true conjugate measures less than 6.5 cm., since the amount of traumatism necessarily inflicted upon the lower birth canal by the forcible extraction of the crushed head and trunk would be so great as to render cesarean section preferable. Craniotomy

upon the living fetus is rarely indicated when the true conjugate measures more than 8 cm. The size and compressibility of the child's head are always important factors in determining an obstetric operation.

The instruments ordinarily required for craniotomy are a large volsella forceps, a perforator (Blot's), and a cranioclast (Hirst's). Rarely a cephalotribe (Braun's) will be necessary.

The steps of the operation are as follows:

(1) Anesthetize the patient. (2) Sterilize hands, instruments, vulva, and vagina. (3) If the head is loose above the superior strait, grasp the scalp with volsella forceps to steady it. (4) Introduce two fingers of the left hand into the vagina; locate a fontanel or suture and perforate the skull. Enlarge the opening in the skull and break up the skull contents by moving the perforator freely about in all directions. (5) Apply the cranioclast—one blade being introduced into the opening in the skull, the other being applied to the outer part of skull and locked over it—and extract as with forceps. Rarely it may be necessary to crush the skull with a cephalotribe before extraction—(cephalotripsy).

In case of necessity craniotomy may be performed by perforating the skull with sharp-pointed scissors and extracting with forceps.

Decapitation consists in division of the child's neck when delivery and version are both impossible.

The indications for decapitation are: (1) An impacted shoulder presentation; (2) twin presentations with locking of the chins; (3) monstrosities.

The best instrument for the purpose is Braun's blunt hook. A piece of strong twine or thin wire may act as a substitute.

The steps of the operation are as follows: (1) Anesthetize the patient; (2) sterilize hands, instruments, vulva, and vagina; (3) locate the neck with two fingers of the left hand; (4) pass the hook, guarded by the fingers, back of the symphysis and turn it so that it lies over the neck; (5) break the neck with a sharp twist or two of the hook, and, finally, tear through the soft structures; (6) extract the trunk by making traction on the arms; (7) extract the head with forceps, cranioclast, or cephalotribe.

Evisceration and amputation of extremities may be indicated in certain forms of monsters.

Cleidotomy (division of both clavicles after perforation and extraction of the fetal head) is sometimes of vital importance when additional shock must be reduced to a minimum.

EMESIS.—See Vomiting, Antiemetics.

EMETICS.—Agents that produce vomiting. They may be subdivided into 2 groups: (1) *local emetics*, or those that act by irritating the end-organs of the gastric, pharyngeal, or esophageal nerves, such as alum, mustard, salt, ammonium carbonate, zinc sulphate, copper sulphate, subsulphate of mercury, tepid water in quantity, and vegetable bitters, as quassia, in strong infusions; (2) *general* or *systemic emetics*, which act through the medium of the circulation. Both these classes produce the emetic action by irritation of the vomiting center in the medulla—the first by reflex, the second by direct stimulation. The principal systemic emetics are the following: ipecacuanha, emetin, ouabain, apomorphin, tartar emetic, veratrin, senega, and squill. Ipecacuanha, tartar emetic, and probably apomorphin act locally as well as systemically, irritating the gastric nerves as well as the vomiting center. Pilocarpin is a local emetic, and digitalis and muscarin are systemic emetics, but no one of them is used medicinally for that purpose. Opium, morphin, and codein produce emesis as an after-effect. Emetics are employed to remove food causing irritation or not properly digesting; in poisoning; to expel bile from the gall-bladder or from the body; and to expel false membranes from the air-passages. For removing irritating food, large drafts of lukewarm water, of mustard (1/2 of an ounce) and water, of salt (1 ounce) and water, or an infusion of camomile are usually beneficial. In poisoning, mustard (1/2 of an ounce), sulphate of zinc (30 grains), sulphate of copper (5 to 10 grains), or ammonium carbonate (30 grains), are used. For croup or diphtheria, ipecacuanha is most generally used (30 grains of the powder or 1 dram of the wine). A teaspoonful of powdered alum and honey is often useful. Three grains of tartar emetic or 1 dram of the wine may be given. Apomorphin (1/6 of a grain) may be used hypodermically. See Antiemetics, Vomiting.

EMETIN.—See Ipecac.

EMISSIONS.—See Nocturnal Emissions.

EMMENAGOGS.—Remedies that restore the menstrual function, either directly by stimulation of the uterine muscular fiber, or indirectly by improving the blood and toning up the nervous system. Menstruation can only be restored by removing conditions that prevent it. Tonics, like cod-liver oil, quinin, and fresh air, exercise, sea-air and sea-bathing, may reestablish suspended menstruation; iron may act by removing anemia. Menstruation arrested by cold or shock may be restored by means promoting dilatation of vessels of the pelvic region and favoring a free circulation over this vascular area. Warm hip-baths and sitz-baths and hot poultices to the lower part of the abdomen are such means. Hot mustard foot-baths, with a small quantity of hot, dilute alcohol at bedtime, are domestic remedies.

The direct emmenagogs are ecbolic in large doses. The principal members of this class are enumerated in the following lists, viz.:

Direct emmenagogs.—Ergot, savin, tansy, digitalis, cantharis, pulsatilla, asafetida, alcohol, indigo, biniodid of mercury, caulophyllum, rue, apiol, borax, myrrh, guaiacum, polygonum hydropiperoides, potassium permanganate, cimicifuga, oxalic acid, hedeoma, origanum, viscum flavescens.

Indirect emmenagogs.—Iron, manganese, cinnamon, quinin, strychnin, aloetic purgatives, cod-liver oil, hot hip-baths, leeching the genitals, rubefacients to thighs, tonic remedies.

In simple atonic amenorrhea:

℞.	Dried iron sulphate,	gr. xlviij
	Powdered aloes,	gr. xij
	Oleoresin of turpentine,	gr. xxvij
	Oil of turpentine,	♏ x.

Divide into 30 pills. Give 2 pills 3 times daily.

℞. Tincture of iron chlorid, ℥ iij
Tincture of cantharides, ℥ j
Ammoniated tincture of guaiac, ℥ jss
Tincture of aloes, ℥ ss
Syrup, enough to make ℥ vj.
Give a tablespoonful thrice daily.

℞. Extract of aloes, ℥ j
Dried sulphate of iron, ℥ ij
Asafetida, ℥ iv.
Make into 100 pills. Give 1 after each meal, gradually increasing to 3.

EMMETROPIA.—Normal or perfect vision. The condition of an eye whose shape and refractive media are such that, with suspended accommodation, parallel rays of light are brought to a focus upon the retina. For practical tests, rays of light from a point 20 feet away are considered as parallel.

EMOLLIENTS.—Substances that soften and relax the tissues to which they are applied. They relieve tension, dilate vessels, diminish pressure on the nerves, and protect inflamed surfaces from the air and from friction.

The principal emollients are: Hot fomentations, poultices, glycerin, lard, linseed oil, olive oil, spermaceti, almond oil, petrolatum, soap liniment, starch, cacao butter. See DEMULCENTS.

EMPHYSEMA, CUTANEOUS, OR SUBCUTANEOUS.—The presence of air or other gas in the subcutaneous tissues. The swelling begins at some point near the upper air passages, and may extend to the entire body. A characteristic crackling sensation, like that of brown paper, is imparted to the palpating fingers, and there is no pitting on pressure. The causes are: ulcerations of the upper air passages or of the esophagus; ulceration or rupture of tuberculous cavities; rupture of the lungs from hard coughing (whooping cough), crying, severe exertion, traumatism. It is frequently associated with fractured ribs.

EMPHYSEMA, GANGRENOUS.—Malignant cutaneous emphysema of microbic origin.

EMPHYSEMA, PULMONARY.—An abnormal condition of the lungs, in which excess of air is the feature. The bulk of the lungs is increased, while elasticity is lowered and the total respiratory surface is diminished.

Varieties.—(1) Vesicular or hypertrophic emphysema; (2) interstitial or interlobular emphysema; (3) atrophic emphysema; (4) compensatory emphysema.

Vesicular (Hypertrophic) Emphysema.—A disease of the lungs in which the alveoli and smaller bronchial tubes become overdistended with air; this is manifested clinically by enlargement of the chest, dyspnea, and hyperresonance of the percussion-note and prolonged expiration.

Etiology.—(1) Congenital weakness of alveoli and bronchial tubes; (2) high pressure in air-cells, caused by increased resistance on expiration, as in glass-blowers and those who blow wind-instruments; (3) the sequel of spasmodic asthma or chronic bronchitis (common).

Pathology.—The emphysematous chest is characterized by an increase of the antero-posterior and proportionately lesser increase of the transverse diameter of the thorax. The respiratory excursions are diminished, the thoracic cage being elevated instead of expanded during inspiration. The lungs are soft, like cotton, greatly enlarged, and do not collapse after being removed. The alveoli are greatly overdistended with air, giving rise to a thinning of the elastic coat. Frequently, the elastic tissue between two alveoli ruptures, and the two become converted into one sac. The epithelium of the bronchial tubes often shows a degree of fatty degeneration. The pleura is pale and frequently edematous. This pathologic condition gives rise to increased pressure in the blood-vessels, causing hypertrophy of the right ventricle.

Interstitial (Interlobular) Emphysema.—In this variety the air vesicles rupture from overdistention, and the air escapes into the surrounding interlobular tissue, forming small beads or bullæ. If the lungs collapse, a condition of atelectasis is produced. The lungs are soft and on pressure the air escapes with a creaking sound. According to the site and degree of extension of this escape of air, the emphysema may be even subcutaneous, or pneumothorax may be found. Interstitial emphysema occurs around wounds in which the tissues become gangrenous.

Atrophic Emphysema.—Occurs principally in the old. The lungs are greatly diminished in size and are filled with large air vesicles, the walls of which contain the remnants of air-cells.

Compensatory Emphysema.—Increase in size and function of one lung or part of a lung to compensate for loss of function due to disease in other portions.

Symptoms and Clinical Course of Emphysema.—The onset is gradual, marked by a distressing cough, with expectoration of whitish and very tenacious mucus. Respiration is labored and there is a great effort to get rid of residual air in the lungs, and forced respiration gives no relief. Slight exertion causes dyspnea and early exhaustion is the rule. The pulse is soft and accelerated and cyanosis about the lips may be observed.

Physical Signs. Inspection.—The emphysematous chest (barrel-shaped) with the anteroposterior diameter increased. During respiration the chest moves up and down as if in one solid piece. There is absence of the apex-beat.

Palpation shows diminished vocal fremitus and a feeble or entirely absent impulse over the precordia.

Percussion.—The percussion-note is hyperresonant. Cyanosis of the lips, ears, and hands is present; in long standing cases the fingers are club-shaped. Owing to the increase in the size of the left lobe, the upper border of the cardiac dulness is depressed and the excess of air in the lung may make it difficult to outline accurately the upper border of the liver.

Auscultation.—Inspiration is short; expiration is prolonged, low pitched and soft. The slight

amount of mucus nearly always present in the bronchial tubes gives rise to rales such as are found in bronchitis (sonorous and sibilant), to which the condition is often due. The heart-sounds are distant; usually there is accentuation of the pulmonary second sound of the heart.

Complications.—Bronchopneumonia, lobar pneumonia, dilatation of the right ventricle, tricuspid regurgitation, and dropsy.

Diagnosis.—

Emphysema.	Chronic Bronchitis.	Pneumothorax.
1. Frequently sequel of chronic bronchitis; disease bilateral.	1. Sequel of acute bronchitis; disease bilateral.	1. Sequel of tuberculosis; empyema may result from traumatism; disease unilateral, as a rule.
2. Great expiratory dyspnea; prolonged expiration.	2. Dyspnea slight or absent; expiration normal.	2. Dyspnea; expiration prolonged, more feeble than in emphysema.
3. Emphysematous chest.	3. Chest normal, except in later stages.	3. Phthisical chest or normal.
4. Diminished vocal fremitus.	4. Vocal fremitus normal.	4. If due to phthisis, vocal fremitus is increased.
5. Percussion-note hyperresonant.	5. Percussion-note normal.	5. Percussion-note hyperresonant.
6. Succussion produces no abnormal sound.	6. Succussion produces no abnormal sound.	6. Succussion produces a splashing sound; metallic tinkling may be heard.
7. Heart seldom displaced; upper border of heart dulness depressed.	7. Heart seldom displaced.	7. Heart generally displaced.

Prognosis is, on the whole, unfavorable, and is influenced by the complications.

Treatment.—The patient should avoid overexertion or excitement in every form. Short periods of absolute rest in bed may, therefore, be indicated. Systematic sponging with cold water, or cold douching if patient is strong enough, assists in toning up the tissues. Breathing exercises maintain the functional power of the unaffected portions of the lungs. That diet should be selected that is most nourishing, and that produces the least amount of flatulence. Sufferers from emphysema should spend their winter in a mild, equable region of low altitude where the air is dry.

As a rule, the great desire to get rid of the retained air in the lung is one of the troublesome symptoms, which a rest in bed may partially relieve. Frequently, there is an excess of mucus in the bronchial tubes, giving rise to a distressing cough. Prescriptions similar to the following may be indicated:

℞.	Tincture of digitalis,	ʒ ij
	Aromatic spirit of ammonia,	ʒ iv
	Simple elixir,	ʒ iv
	Water enough to make,	ʒ iij.

Two tablespoonfuls every 4 hours.

℞.	Strychnin sulphate,	gr. 1/4
	Tincture of belladonna,	ʒ j
	Elixir of curacoa,	ʒ iij
	Water, enough to make	ʒ iij.

Two teaspoonfuls every 3 or 4 hours.

For anemia:

℞.	Strychnin sulphate,	gr. 3/4
	Reduced iron,	ʒ j.

Divide into 30 capsules; 1 after each meal.

Or—

℞.	Strychnin sulphate,	gr. 3/4
	Mass of ferrous carbonate,	ʒ j.

Divide into 30 capsules; 1 after each meal.

For further treatment see Bronchitis (Chronic).

EMPLASTRUM.—See Plaster.

EMPROSTHOTONUS.—See Opisthotonus.

EMPYEMA.—Pus in the pleural cavity or in the chest. It may be *primary*, which is rare, or *secondary*. There is associated a hectic type of fever, with chills and sweating. Rarely empyema may rupture spontaneously through the lung or chest wall. Empyema is most frequently encountered in children, but may arise from pleurisy, tuberculosis, septic conditions, and infectious fevers in any individual. See Pleurisy, Tuberculosis. For **Empyema of the Antrum, or of Frontal Sinus.** See Nose.

EMULSIONS.—Aqueous, liquid preparations containing some insoluble medicinal substance in a state of minute subdivision, suspended by the aid of some viscid excipient, such as gum, that may be contained in the medicinal ingredient itself, or may be added by the pharmacist.

The chief emulsifying agents are: Acacia, tragacanth, yolk of egg, Irish moss, quillaja bark, extract of malt, casein, pancreatin, and gelatin. There are six official emulsions:

Emulsum Amygdalæ (emulsion of almond). Sweet almond, 60 grams; acacia, 10 grams; sugar, 30 grams; water, to make 1000 c.c. Demulcent. Average dose, 4 ounces.

Emulsum Asafetidæ (emulsion of asafetida). Asafetida, 40 grams; water to 1000 c.c. Antispasmodic. Average dose, 4 drams.

Emulsum Chloroformi (emulsion of chloroform). Chloroform, 40 c.c.; expressed oil of almond, 60 c.c.; powdered tragacanth, 10 grams; water to make 1000 c.c. Anodyne. Average dose, 4 drams.

Emulsum Olei Morrhuæ (emulsion of cod liver oil). Cod liver oil, 500 c.c.; acacia, 125 grams; syrup, 100 c.c.; oil of gaultheria, 4 c.c.; water to make 1000 c.c. Average dose, 4 drams.

Emulsum Olei Morrhuæ cum Hypophosphitibus (emulsion of cod liver oil with hypophosphites). Cod liver oil, 500 c.c.; acacia, 125 grams; calcium hypophosphite, 10 grams; potassium hypophosphite, 5 grams; sodium hypophosphite, 5 grams; syrup, 100 c.c.; oil of gaultheria, 4 c.c.; water enough to make 1000 c.c. Other appropriate flavors may be used. Average dose, 4 drams.

Emulsum Olei Terebinthinæ (Emulsion of oil of

turpentine). Rectified oil of turpentine, 15 c.c.; expressed oil of almond, 5 c.c.; syrup, 25 c.c.; acacia, 15 grams; water enough to make 100 c.c. Average dose, 1 dram.

Natural emulsions comprise two classes of substances: (1) Those emulsions that exist ready formed in nature, as milk, yolk of egg, the milky juices of plants, etc.; and (2) the mixtures formed by rubbing up gum-resins (as ammoniacum, myrrh, asafetida) with water. Each of the latter substances contains, together with its resin, enough gum to make a perfect emulsion when triturated with water. The manufactured emulsions are simply imitations of the natural ones, sufficient gum being added, in case of a resinous substance, to cause its suspension in the aqueous diluent.

Emulsification consists in the division of the oily or resinous substance into very minute globules, and the surrounding of each globule with a thin envelope of the excipient. If properly done, the globules will remain mechanically suspended in the water, without any tendency toward recombination. Milk is the best illustration of a natural emulsion, its butter existing in the aqueous portion as very minute globules, each surrounded by a thin film of casein. Yolk of egg is a dense emulsion, consisting of oil suspended in water by means of albumin.

A cod-liver oil emulsion:

℞. Cod-liver oil, ℥ ij
White wine, ℥ jss
Dilute phosphoric acid, ℥ iij
Syrup, ℥ v
Yolk of 1 egg,
Almond water, q. s. ad ℥ viij.

Mix and make an emulsion. Tablespoonful doses.

An alkaline emulsion of copaiba:

℞. Copaiba, Liquor potassæ, each, ℥ ij.

Mix and add—

Pulverized acacia, Pulverized sugar, each, ℥ ij
Peppermint water, q. s. ad ℥ iv.

Mix and make an emulsion. Tablespoonful doses.

ENCEPHALITIS.—See BRAIN (Inflammation).

ENCEPHALOCELE.—A congenital protrusion, containing in its sac some extracerebral fluid and a portion of the brain with its membranes. It is small, does not fluctuate, has a broad base, pulsates, becomes tense on forced expiration, is opaque, and when reduction is attempted, symptoms of brain-pressure are caused.

The treatment consists in the use of electrolysis. The following injection (Morton's fluid) is used:

℞. Iodin, gr. x
Potassium iodid, gr. xxx
Glycerin, ℥ j.

Mix thoroughly.

Pressure and excision are also employed.

ENCHONDROMA.—A tumor arising from or resembling cartilage in texture, etc.; chondroma. See TUMORS.

ENDARTERITIS.—Inflammation of the intima, or innermost coat of an artery. The *acute form* is rare, and occurs only in the aorta and the larger arteries. Ulceration is very rarely present. The *chronic form*, also named *atheroma*, and *arteritis deformans*, is a peculiar change or degeneration occurring in the arterial coats of the aged, and is preceded by a fatty degeneration of the tissues of the arteries. Syphilis is supposed to play an important part in the production of this condition. The immediate cause, however, is mechanic irritation due to the force of the circulation. The fatty débris and the cholesterin that are formed during the degenerative process accumulate in spaces beneath the intima, and constitute the so-called *atheromatous abscesses*. The so-called *atheromatous ulcer* is formed by one of these abscesses breaking through the intima. The sequels of *atheromatous degeneration* are very grave. Aneurysm, thrombosis, embolism, and apoplexy frequently result, and hence the ultimate prognosis is bad. **Arteriocapillary fibrosis, or arteriosclerosis,** is a peculiar change occurring in the small vessels throughout the body, and consists in a thickening of the adventitia and intima by a deposit of a hyaline-fibroid material that diminishes the caliber of the vessels, increases the arterial tension, and thus gives rise to the hypertrophy of the heart that is present in this condition. See ARTERIOSCLEROSIS.

ENDOCARDITIS.—Inflammation of the endocardium or lining membrane of the heart. Acute rheumatism and tonsillitis are frequent causes, though pneumonia, gout, or any infectious disease may precede. The valves are nearly always the parts affected, and usually those of the left heart. The disease is prone to terminate fatally or to result in permanent injury to the valves. Fibrinous deposits or vegetations project into the cavity of the heart; the thickened endocardium is liable to become atheromatous, with chronic ulceration. Acute endocarditis may be divided into *simple* and *malignant*. *Acute endocarditis* includes chronic disease of the valves of the heart. There is a fibrous or cirrhotic thickening of the latter, associated with contraction and calcification. Usually this chronic disease, like the acute, is confined to the left heart, and it is generally rheumatic in origin. *Malignant* or *ulcerative endocarditis* is also called *diphtheritic*, *infectious*, and *septic endocarditis*. It is a rapidly fatal type, due to septic infection. It is marked by high fever, chills and profound prostration. This is followed by the development of a murmur, purpuric skin eruptions, hematuria, delirium, convulsions, hemiplegia, enlargement of the spleen, the typhoid state, and death. Frequently no cause can be found. Ulcerations are found around and in the valves, and in these ulcers microorganisms are present in large quantities. See HEART-DISEASE (Organic).

ENDOCERVICITIS.—See CERVIX UTERI, UTERUS.

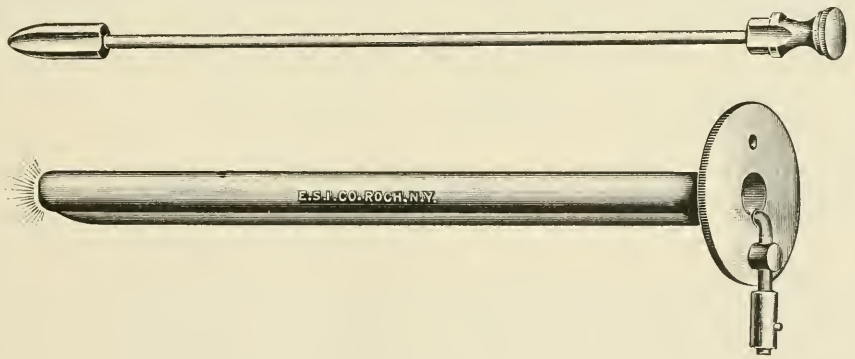
ENDOMETRITIS.—Inflammation of the lining membrane of the uterus. Endometritis may attack the cervix or the body of the uterus. See Uterus.

ENDOSCOPE.—An instrument designed for the direct exploration by sight of internal organs and cavities. It is not for general use, but intended as a means of *diagnosis* and *treatment* in exceptionally obscure cases. The urethral tube is the most generally used, but special tubes are employed for examination of the rectum, nasal fossæ, stomach, and other cavities and organs.

In Diagnosis.—A tube or speculum is first introduced, at one extremity of which is placed a mirror of polished silver, perforated in the center, and placed at an angle of 45 degrees. This mirror reflects the light, placed laterally into the tube so as to illuminate its end. A most brilliant light is required, since the caliber of the tube is small. To obtain the best effects, the light should slightly converge upon the mirror, which may be effected by placing a planoconvex lens of suitable focal length between the light and mirror.

Sunlight, daylight, and magnesium and electric lights are used. For electric illumination a power of from 8 to 12 volts is needed, while from 20 to 30 volts is useful for cautery. Carbolized oil or glycerin is needed for lubricating the tube. Direct illumination of the urethra may be obtained with the instruments of Nitze, Oberländer and Valentine. In Koch's urethroscope which also affords direct illumination, a small auxiliary tube for the light carrier and lamp is placed alongside the tube proper. As the lamp is thus outside the latter, it does not obstruct the view nor cast shadows. Applications can be made directly to the urethra; otherwise its walls are blanched and pain results.

In a number of cases examination with the endoscope has demonstrated that the inflammatory process does not extend deeper than to the mucous membrane, even after long duration; in such instances the urethra will not lose its elasticity nor suffer impairment of its extensibility, even after years. When the process advances deeper, the infiltration and the subsequent shrinkage will produce more intense thickening, and, later on, shrinkage, with loss of elasticity and narrowing of the lumen of the urethra itself, conditions usually called stricture. Endoscopy enables one to determine with a high degree of exactness how far inflammation has advanced in every single case and on every single spot, and thereby suggests the proper means for treatment. When the final stage is reached, and a true organic stricture has been found, the endoscope may still be of great value for diagnosis, in clearing up the configuration of the entrance of the stricture and sometimes to locate the spot through which an entrance by a bougie may be gained. The endoscope has confirmed beyond doubt the existence of the so-called spasmodic stricture, which had always formed a weak spot in the defenses of those who claimed perfection or superiority for the examination with bougies, etc. This spasm usually yields by the aid of the endoscope, and proves the absence of all pathologic conditions that might account for the obstruction to the progress of the instruments. Of great importance also have been the conclusions obtained by urethroscopy in regard to the participation of the different portions of the urethra in the continuation of chronic inflammation; it has



Koch's Urethroscope.

diseased parts under the guidance of the eye without having the applicator catch on the lamp when it is withdrawn. Instruments for illuminating the posterior urethra have been devised by Swinburne and Wossidlo. These urethroscopes have a curve conforming to the shape of the posterior urethra.

In examinations of the urethra a sound or bougie larger in its caliber than the tube of the endoscope, should be passed before using the tube, to encounter constrictions and to accustom the urethra to the presence of instruments. The caliber of the tube should not be large enough to stretch the

been demonstrated that every part from the meatus to the bladder may be the seat of pathologic conditions, and that therefore for a thorough diagnosis it is necessary to subject the full length of the channel to examination before decision as to diagnosis and appropriate treatment can be given.

In Treatment.—The endoscope is of practical value in three different ways: (1) The determination of the nature and of the location of pathologic conditions supplies, in the most exact manner, information, by means of which those therapeutic measures that promise the best and quickest

results may be selected and applied to the proper spot; (2) by freely exposing the diseased portions to the eye and bringing them within easy reach, endoscopy naturally renders possible and invites the application of suitable drugs with great exactness to those parts, and to them only, thereby allowing of the use of much stronger and more effective remedies, which would injure any but the affected portions; (3) the surgeon is enabled by the endoscope to control the effects of any treatment, applied through the endoscope or otherwise, so that he is enabled to tell whether the adopted treatment is successful or not. The field for the endoscopic treatment proper is, perhaps, a limited one, but not so limited as some believe. It is principally indicated in those superficial inflammations in which circumscribed patches of the mucous membrane, wherever located, have undergone certain changes, which cannot be affected any more by the usual injections of astringents or parasiticides, because those remedies are powerless in the solutions that may be syringed into the urethra without injury to the healthy or less seriously affected portions. By using as a brush the simple cotton tampon twisted around a wooden stick or a wire, much stronger solutions or powders, or even caustics, may be applied to the diseased spot. Surgical instruments and the cautery may be used.

ENEMA.—A liquid injected by means of a suitable instrument into or through the rectum. Enemata are demulcent, laxative, nutritive, stimulant, or vermifuge in character. Warm or tepid water, with medicaments incorporated therein, is chiefly used, but plain water may be used as a wash for the bowel.

A simple domestic enema consists of soapsuds with a little common salt, or a pint of cold water. Warm water or gruel is sometimes used; or to one or the other of these is added soap, turpentine, or castor oil, with soap or gruel, to suspend the two latter. Very cold water may be used without inconvenience. Starch, boiled or raw, of cream consistence, temperature 100° F., with a few drops of laudanum may be used in extreme cases of choleraic diarrhea, or that of phthisis or typhoid fever.

The instruments used for administering enemata are (1) An elastic bottle with ivory or gum-elastic pipe; (2) an india-rubber bottle with flexible tube at either end and double action; (3) an ordinary piston syringe, worked by the hand, which is either simple or provided with a double action so as to supply a continuous stream; (4) a French instrument, known as the irrigator, worked by a spring; (5) the hydraulic enema (fountain syringe, consisting of a piece of rubber tubing about 6 feet long). The tube, filled with the injection, has one end placed in the containing reservoir, while the other end is connected with the bowel. When the vessel supplying the injection is elevated, the liquid gravitates into the bowel, filling the large intestine. The patient should lie first on the left side, when a large quantity is to be injected into the bowel, then on the back, and finally on the right side, to promote the filling of the intestine. Care should be exercised that the nozzle of the injecting pipe is not in contact with the sphincter nor thrust against the sacrum nor into feces. The injection must be carried on slowly, with occasional pauses, otherwise expulsion of the enema will result.

Anthelmintic Enemata.—Injections of salt and water or of lime-water, or 2 to 4 drams of spirit of turpentine, held in suspension by the yolk of an egg in 4 ounces of water, are used to expel thread-worms. An enema of aloes, quassia, or asafetida may likewise be employed.

A vermifuge enema:

℞. Fluidextract of quassia, ʒ jss
Water, ʒ ijss.

A tablespoonful with an equal quantity of warm water as an enema, to be retained as long as possible.

Antispasmodic Enemata.—Chloral hydrate (1/2 of a dram or more) is injected in puerperal convulsions. Injections of asafetida or of rue are also useful. Sulphuric ether (2 or 3 drams) in warm water may relieve spasmodic invagination of the bowel. Enemata of turpentine or of asafetida will act as stimulants and carminatives.

Astringent Enemata.—An enema of opium is useful to check diarrhea. Ice-cold water used as an enema will arrest intestinal hemorrhage. Enemata of silver nitrate (5 grains to the pint of distilled water), of zinc sulphate or alum (1 or 2 grains to the ounce of water), or copper sulphate (1 grain to the ounce), are especially useful in ulcerative conditions with mucous discharges.

Emollient Enemata.—Decoctions of starch, linseed, or barley, or of pure linseed oil, will soothe irritable mucous membranes. From 4 to 6 pints of warm water, or of milk and water, will make an internal fomentation.

A demulcent enema:

℞. Tincture of opium, ♏ xx
Decoction of starch, ʒ iv to vj.

Nutritive Enemata.—Peptonized milk, beef-tea, and eggs beaten up together make a good nutritive enema. From 4 to 6 ounces are to be used at once. If there is rectal irritability, a few drops of laudanum may be added to each enema. Preparations of pancreatin and pepsin facilitate assimilation of nutrient enemata. Brandy and water, or beef-tea and brandy, are of benefit in prostration from uterine hemorrhage or other causes.

Nutrient enema:

℞. Beef-tea, ʒ iv
Hydrochloric acid, ♏ x
Glycerite of pepsin, ʒ ij.

If the rectum is irritable, add 10 to 20 drops of laudanum.

Sedative Enema.—The enema of opium is very useful.

Purgative Enemata.—As many as 4 or 5 pints

can be forced into the bowel, when the process is gradual, with occasional intervals and pressure on the anus. As a rule, a pint is enough for an adult, 4 to 6 ounces for a child of 4 years, and 1 ounce for an infant. Glycerin is now used commonly for injection into the rectum, 1 or 2 drams being employed. There is always more or less straining and expulsion of flatus. Glycerin suppositories are more practical, and are taking the place of enemata. Injections of large volumes of soap and water—sometimes with oil added—are used in intestinal obstruction; in combination with massage of the abdomen, obstruction due to impacted feces is speedily overcome.

Frequent use of large injections is undesirable, while the habitual use of injections washes away the mucus designed to lubricate the bowel.

ENOPHTHALMOS.—A term applied to retraction of the eye within the orbit. It depends upon the absorption of the orbital fat, decrease in the contents of the orbital vessels, or great loss of fluid from the body after intense purging. Traumatism involving the walls of the orbit may produce enophthalmos on the side affected. Senile enophthalmos is bilateral, and is due to the gradual absorption of orbital fat in old persons.

ENTERALGIA.—Pain in the bowels. See Colic, Dysentery, Enteritis, etc.

ENTERECTOMY.—See Intestines (Surgery).

ENTERIC FEVER.—See Typhoid Fever.

ENTERITIS.—A catarrhal inflammation, usually affecting the small intestine, but occasionally involving the large bowel as well.

Varieties.—(1) Acute catarrhal enteritis; (2) chronic catarrhal enteritis; (3) croupous (or diphtheritic) enteritis.

Synonyms of Acute Catarrhal Enteritis.—Acute diarrhea; acute intestinal catarrh; acute ileocolitis.

Synonyms of Chronic Catarrhal Enteritis.—Chronic enterocolitis; chronic diarrhea.

Etiology.—(1) Improper food or overeating; (2) organic or mineral poisons; (3) spring or summer season, with sudden change in the weather; (4) nervous conditions; (5) certain diseases, as tuberculosis, typhoid fever, dysentery, septicemia.

Pathology of Catarrhal Enteritis.—The mucous membrane is hyperemic and swollen. The surface is covered with a serous or purulent material, containing a large number of leukocytes and desquamated epithelial cells. Peyer's patches are usually swollen and are distinctly outlined, and in their centers may be seen slight erosions. In chronic enteritis, usually, there is an overgrowth of the connective tissue. In membranous enteritis shreds of membrane, of a yellowish or grayish color, are detached from the lumen of the bowel.

Symptoms and Clinical Course. Acute Catarrhal Enteritis.—Diarrhea is the most common symptom of acute catarrhal enteritis. The stools are generally thin or watery in character, brownish or yellowish in color, and often stained with bile. The odor, which at first may be very offensive, later becomes less so. The stools may contain particles of undigested food (lienteric diarrhea), and the evacuations are accompanied by a great deal of flatus. Pain is mainly abdominal and of a colicky character. Fever is generally absent. The duration of the disease is from 2 to 3 days.

Chronic Catarrhal Enteritis.—This may follow the acute form. Diarrhea is present, but pain is not so severe as in the acute form. If the upper portion of the small intestine is affected, large quantities of undigested food may be passed in the stools. The mucus is excessive, whitish in color, and often semisolid in character.

Croupous (or Diphtheritic) Enteritis.—This is generally a sequel of typhoid fever, nephritis, cirrhosis of the liver, or carcinoma. In one variety the membrane may be yellowish or grayish, and firmly adherent to the mucous coat of the bowel. It may be detached and passed off with the feces. In another group it may be flaky or appear in crusts, and at times no membrane is formed, but the process attacks the lymphoid follicles, giving rise to necrosis and ulceration.

Diagnosis.—

Acute Catarrhal Enteritis.	Dysentery.	Enterocolitis.
1. Stools thin and brownish in color, often containing mucus and sometimes particles of undigested food.	1. Stools variable; generally contain a large quantity of mucus tinged with blood; bright red blood may be passed from bowel.	1. Stools yellowish in color or variable in the beginning, later become greenish, and finally whitish mucus may be passed; chiefly occurs in children.
2. Pain located in abdomen, of a colicky character.	2. Tenesmus often extreme.	2. Tenderness exists over area of colon.
3. Fever slight or absent.	3. Moderate fever (100°–102° F.).	3. At first fever high, attended by convulsions; later, collapse ensues and temperature may be subnormal.

Prognosis.—In the acute form the prognosis is good; in chronic enteritis and membranous enteritis it is unfavorable.

Treatment of Acute Catarrhal Enteritis.—Absolute rest and a liquid diet, principally composed of milk, soups, and beef-broth, are indicated. In the beginning it is always well to give a purgative, such as magnesium sulphate (4 drams), Rochelle salts (4 drams), or castor oil (4 drams), to remove all products of putrefaction and irritating particles that might otherwise give rise to autointoxication.

Subsequently, if the bowels should move too frequently and the pain increase, tincture of opium (10 minims) may be given every 3 hours. If the pain is severe, morphin (1/4 of a grain) should be given hypodermically.

Intestinal antisepsis should be secured so far as possible, and naphthalin or salol may be given:

℞. Codein sulphate, gr. iij
Bismuth subnitrate, ʒ ss
Naphthalin, ʒ ss.
Divide into 6 powders; 1 powder every 2 hours.

Salol (3 grains) may be substituted for the naphthalin in the foregoing prescription.

The "sun cholera mixture" may also be given. See CHOLERA.

Treatment of Chronic Catarrhal and Croupous Enteritis.—The patient should be put upon the strictest regimen possible, and in order to do this successfully, rest in bed is best. The diet should be mainly composed of pure, fresh milk, and if the digestive powers are good, the milk may be boiled. No article of diet should be allowed that can in any way irritate the congested bowel, and those foods should be chosen that have the least residue, such as carbohydrates, soups, beef-juice, sweet milk, cooked fruits, and vegetables. Beef-juice is very nourishing, and may be obtained in the following manner: Take a piece of tender-loin or porterhouse steak cut an inch thick; after sprinkling with a small quantity of pepper and salt, and spreading over it a sufficient amount of butter, the steak is placed in a pan upon a hot stove and allowed to brown on one side; it is then quickly turned, and after a moment or two is removed and cut in small pieces, which may be chewed by the patient, permitting only the juice to be swallowed. Soft-boiled eggs may also be given. The white portion of the eggs may be prevented from hardening by placing them in hot water in a tin bucket (covered and surrounded by a blanket), and letting them stand 10 minutes.

Hot biscuits and hot bread are to be forbidden. Bread a day or two old is best. Crackers may be substituted for bread.

In beginning the treatment the bowels should first be cleansed by means of a saline purge: *e. g.*, by magnesium sulphate (4 drams), or calomel in fractional doses (1/4 grain), combined with bismuth subnitrate (4 grains). Subsequently, it is well to prevent putrefaction in the digestive tract by administering intestinal antiseptics, such as naphthalin (5 grains), salol (5 grains), and iodoform (3 grains). Bismuth salicylate or bismuth subnitrate may be combined with any one of these substances. It should be remembered that salol contains over 30 percent of carbolic acid, and should not be given continuously for periods longer than 5 days, on account of its irritating effect on the kidneys. Silver nitrate (1/4 grain) is valuable when taken before meals in half a glass of water. It may also be given by high enema once every day or two in doses of 5 grains. Argyrol is a suitable form of silver for this purpose; ten grains in three ounces of water may be injected twice a day, or a colonic irrigation with 1 to 4 pints of a 1 to 1000 solution may be substituted. The high injection can best be given by means of a rectal tube and a fountain syringe. Lavage may be of great benefit in combination with other measures.

ENTEROCLYSIS.—Injection of salt solution or nutrient material into the intestine in cholera, collapse, etc.; more generally, any rectal enema or clyster. See ENEMA, TRANSFUSION.

ENTEROCOLITIS, ACUTE.—An acute catarrhal inflammation of the intestinal tract due to bacterial infection and characterized by fever, diarrhea, rapid loss of flesh and a strong tendency to a fatal termination.

Synonyms.—Acute ileocolitis; follicular enteritis; follicular dysentery; summer diarrhea; milk-infection; food-infection.

Etiology.—The direct cause is infection by bacteria introduced in most cases with the milk; the most important are the bacillus coli communis and others of the same group, staphylococcus and streptococcus, colon bacillus and bacillus pyocyaneus. Tyrotoxicon, a poisonous ptomain contained in stale milk is an occasional cause. Among predisposing and exciting causes are: prolonged summer heat with excessive humidity; sudden changes of weather; the presence of simple indigestion; general want of cleanliness and faulty hygiene. Bottlefed babies show less resistance than infants reared on breast milk who are comparatively rarely attacked. The great majority of cases are caused by infected milk.

Symptoms.—During the initial stage the symptoms are those of acute indigestion—vomiting, diarrhea, moderate fever, thirst, anorexia, and abdominal pain. The fever soon rises to 103° or 104°, the diarrhea increases in severity, and tenesmus is added to the abdominal pain. The urine is scanty and of high specific gravity; albumen and casts are usually present. The stools number from 4 to 12, or even more, in the 24 hours and occur immediately or soon after taking food. The most conspicuous change in the stools is the green color due to the presence of chromogenic bacilli; the consistence is watery; particles of mucus, curds and occasionally blood, are present. The odor is sour and the discharges may be frothy from the presence of yeast. The disease may abate here and convalescence be established, though recovery is protracted; or the symptoms may increase in severity, the fever persist, the stools be painful and small, consisting mainly of mucus and blood. The child wastes away to a skeleton, the skin becomes loose and flabby, and the senile appearance is assumed. Absolute inability to take food is soon followed by the gravid symptoms of intoxication, convulsions, head-rocking, stiffness of the neck, strabismus and other signs suggesting meningitis. Coma and death may occur at any time even, during the first week, or the case may last 5 or 6 weeks, terminating fatally, or in recovery. Relapses after convalescence are not uncommon, and should be guarded against.

Diagnosis.—The diagnosis presents no difficulties. Acute enterocolitis is characterized by greater severity than simple *acute indigestion* or dyspeptic diarrhea—high fever, a large amount of mucus in the stools, greater pain, suffering, and more rapid decline. From *cholera infantum* it differs in its lower hyperpyrexia, the infrequency and milder character of the vomiting, of the colliquative diarrhea, and of collapse.

The stools alone are characteristic, showing a change from normal yellow color to green. Prostration shows itself early and removes any remaining doubt. The acute infections, pneumonia, typhoid fever, may begin with symptoms pointing to the intestinal tract, and pneumonia is a not uncommon late complication in summer diarrhea. In *typhoid fever* there is as a rule less vomiting, the temperature is higher, splenic enlargement is usually present in children; the stools do not exhibit the characteristic green color. A positive serum reaction and the appearance of rose spots will clear up the diagnosis after the first five days. Severe cases of enterocolitis may suggest *intussusception*, in which, however, the paroxysmal pain, prostration, and evacuation of mucoid, bloody stools precede the fever, and a tumor is present in the left iliac region.

Prognosis.—This is very much influenced by early, appropriate treatment and by *social conditions*—the possibility of improving the hygiene enforcing cleanliness, suitable food, ventilation and, if necessary, a change to country or seashore. *Age* is an important factor, babies in their second summer, when teething is most active, being proverbially a source of anxiety. "Being a baby must be classified as an extra-hazardous occupation." *Previous vigor*, which is dependent upon previous methods of feeding and the care or neglect of digestive disturbances during the winter, is an important factor; the prognosis in bottle-fed infants and in those who have had repeated attacks of diarrhea is distinctly more grave. The average *duration* is from 3 to 4 weeks, but with careful management recovery is not impossible even after a long and severe attack. The violent, dysenteric forms, with early prostration and bloody stools from the outset, usually end fatally in a week or earlier.

Treatment.—*Prophylactic* measures are obviously directed toward maintaining a favorable hygienic environment. The first departure from health must receive immediate attention.

The *indications* are: (1) removal of the cause, which is an infected food supply; (2) prevention of reinfection; (3) maintenance of the patient's strength. The first is met by immediate *withdrawal of milk* and all other foods except barley or rice-water, albumen water, beef-juice or peptone preparations, until the diarrhea is under control. The strictest attention to *hygiene* is imperative; the room must be well ventilated or, if possible, the baby kept out of doors most of the time. If the heat is excessive, the air must be cooled by means of electric fans, ice, etc., and in grave cases immediate removal to the seashore is to be urgently advised. The discharges must be disinfected, clothing treated with antiseptic solutions, such as 1 to 1000 bichlorid of mercury, the drinking-water boiled, and fly-pollution combated in order to *prevent reinfection*. When feeding with milk is resumed, all the rules of infant-feeding must be observed until complete recovery, and the advent of cool weather removes the danger of reinfection.

Medicinal and Local Treatment.—The intestinal tract must be emptied at the outset by administering *castor oil* in 1- or 2-dram doses, or fractional doses of *calomel* (1 to 1 1/2 grains in 1/4-grain doses at intervals of 1/4 hour), and this treatment repeated according to indications every 3 or 4 days. *Bismuth subnitrate* or *subcarbonate* is usually recommended; it must be given in large doses, frequently repeated (10 grains for a child of one year to eighteen months every hour or every 2 hours) in order to have any effect. The addition of 3 drops of castor oil to each powder adds to the astringent effect. *Salol, salicylic acid*, and other so-called intestinal antiseptics have their adherents; sulphocarbolate should not be given to infants on account of the danger of intoxication. More effective than any medicinal treatment is thorough and systematic irrigation of the intestinal tract. An initial *enteroclysis* should never be omitted and, if necessary, may be repeated 2 or 3 times in the twenty-four hours, according to indications. Simple salt solution, boric acid or a mild solution of bicarbonate of sodium may be used, and the quantity may vary from 2 to 4 pints for each enteroclysis. Besides cleansing the intestines, this treatment restores the fluid that has been drained from the tissues and neutralizes the acidity of the body-juices. If prostration is extreme, *hypodermoclysis* may be substituted for the colonic irrigations, from 1 to 2 ounces of salt solution being injected 2 or 3 times in the twenty-four hours. *Fever* is controlled by hydrotherapy. *Convulsions* sometimes occur and sedatives are required; sodium bromid, 5 to 10 grains, and 2 to 5 grains of chloral hydrate, administered by the rectum, make a suitable prescription. A hot mustard bath or mustard compresses to the extremities are sometimes needed if the child goes into *collapse*, with cold hands and feet. If alcohol is given as a stimulant, *brandy* should be given the preference, administered by the rectum or, if necessary, subcutaneously. Finally, to check an excessive diarrhea that threatens to kill the patient by exhaustion, opium may be demanded. The drug should not be given, however, unless the indication is imperative. Diarrhea is to a certain extent a necessary eliminative act and must not be interfered with too soon; the character of the stools is more significant than the daily number of evacuations.

ENTEROPTOSIS.—See Visceroptosis.

ENTEROTOMY.—See Intestines (Surgery).

ENTROPION.—Inversion of the eyelid so that the lashes rub against the globe of the eye, producing inflammation, pannus, etc. It may be cicatricial, organic, or spastic in origin. See Eyelids.

ENURESIS.—Incontinence of urine. A frequent affection of early childhood, due to a variety of pathologic conditions, including the presence of ascarides, phimosis, and vulvitis. See Urine (Incontinence).

ENZYMOL.—A glycerin aqueous acid extract derived from the fresh animal gastric mucous membrane. It is said to be efficient when applied to suppurative and necrotic surfaces for the removal of pathologic material.

EOSINOPHILIA.—See Blood (Examination).

EPHELIS.—See FRECKLES.

EPICARIN.—A combination of betanaphthol and creosotic acid. It is a nonpoisonous parasiticide, which has been used as a 5 to 10 percent ointment with lanolin as a base, for scabies and prurigo with most satisfactory results.

EPIDIDYMITIS.—See TESTICLE (Inflammation).

EPIGASTRIUM.—The region at the upper and central part of the abdomen, just below the ensiform cartilage, between the sloping margins of the thorax down to the level of the ninth cartilage, corresponding to the "pit of the stomach." The structures occupying the epigastrium are the greater part of the stomach, a small portion of the liver, a part of the pancreas, the aorta giving off the celiac axis and superior mesenteric branch, the vena cava inferior, the veins forming the commencement of the portal vein, the receptaculum chyli, and the solar plexus. See ABDOMEN.

The abnormal sensations referred to the epigastrium are generally associated with the stomach. Sensations of throbbing or sinking at the pit of the stomach are usually of a nervous character, and generally occur in women. The sensation of hunger is referred mainly to the epigastrium, and the pain felt here is usually relieved by the taking of food. Vomiting or retching causes pain or aching in this region, and heartburn is referred to the epigastrium. Pain deeply situated and shooting toward the back is usually due to disease of the posterior part of the stomach or pancreas or to aneurysm. Extreme emphysema, and collections of air or fluids in the pleura, or extensive pericardial effusions, give pain just below the ensiform cartilage. In Addison's disease and in pernicious anemia a deep pain is referred to the epigastrium, probably connected with the sympathetic plexuses.

Physical examination of the epigastrium shows:

1. The rate of respiration.

2. Morbid conditions of the abdominal wall. The recti muscles are often hard and rigid on examination, and serious lesion may be suspected.

3. Growths connected with the peritoneum, especially the great omentum, may be felt.

4. Abnormal states of the stomach, such as dilatation, carcinomatous infiltration or thickening, localized tumor, etc.

5. Disease of the liver, in which the abnormal physical signs are noticed especially in this part. The gall-bladder may be displaced.

6. Pulsation, which may be due to displacement of the heart, enlargement of its cavities, pulsating aorta, enlarged pancreas, or abscess of the liver, etc. A murmur may sometimes be heard here, usually a conducted cardiac murmur, occasionally an aneurysm.

See ABDOMEN (Examination, General Physical Diagnosis).

EPIGLOTTIS.—A thin fibrocartilaginous valve that aids in preventing food and drink from passing into the larynx. See NECK (Injuries), LARYNX (Examination).

EPILEPSY. Synonyms.—Sacred disease; morbus comitialis; great disease; falling sickness; grand mal.

Definition.—Epilepsy is a disease manifested or characterized by a periodic disorder of consciousness and by muscular convulsions, either of which may be absent in exceptional cases. There are all possible gradations of disorders of consciousness, from complete loss to that of a perfect retention of it. A complete loss of consciousness for a longer or shorter period of time is the general rule. The muscular phenomena in epilepsy are similarly subject to variation, but are less frequently absent than a loss of consciousness.

The epileptic population in the United States is estimated as 1 in 500. In France the percentage is still higher, while in many European countries no accurate estimate can be made, through lack of reliable data. The existence of epilepsy in ancient times is well established.

The muscular convulsions of epilepsy may be tonic (continuous rigidity) or clonic (muscular contraction alternating with more or less complete relaxation). Usually a tonic stage begins the convulsion, being a severe form of spasm. There is no fixed and constant rule for the order of occurrence of tonic and clonic spasm. Severe convulsions rarely consist of prolonged tonic contraction throughout; a continuous clonic spasm is much more common.

Classification.—The existing classifications are not satisfactory. The simplest and most universally recognized is the division into *organic*, based upon a definite brain-lesion or condition, and *idiopathic*, a name implying ignorance of the cause of the disease.

The etiology of epilepsy is conveniently divided into the *immediate* and the *remote* cause. The *remote* cause consists mainly of hereditary factors favoring a predisposition in the individual epileptic. An inherited tendency, indicated in epilepsy or insanity or other nervous and mental diseases in some immediate or collateral branch of the patient's family, is found in over three-fourths of all cases. Low physical and mental types with criminal or delinquent tendencies are very frequently found in the family history. Inebriety and syphilitic conditions play a very important rôle, as well as many other unhygienic vices. Degenerative bodily diseases, such as neoplasmic growths and tuberculosis, are of very frequent occurrence in the neurotic family types.

Women suffer from epilepsy a little more frequently than men—about in the ratio of 7 to 6. Seventy-five percent of all cases begin in childhood, under the age of 16. It is especially frequent in early infancy. It is not limited to any particular period of life, although it seems to occur most about the physiologic epochs. So-called retarded epilepsies may be seen in advanced life, even after 80 years of age. Much doubt rests upon the nature of seizures occurring for the first time in extreme old age. Frequently senile convulsions are mistaken for true epilepsy. The two conditions are probably analogous in many respects.

Of the *immediate* cause, a poor physique, with a handicap of neurotic hereditary factors, is most often found. Abnormal and difficult labor plays no small part in the causation in many cases,

and prolonged labor is doubly as injurious as the possible injury of instrumental delivery. Almost all cases having convulsions at birth are due in greater part to prolonged labor. The presence of unilateral convulsions of series in infancy, with history of after-palsy, however slight or transient, of one side, should always lead one to suspect a palsy lesion of the brain. This fact was mentioned by Bravais half a century ago, and Sachs and Freud, of our day, have urged the point anew.

In many cases eyestrain has been found to be the reflexly exciting cause of epilepsy, the wearing of the correct lenses required effecting a cure.

Rachitis and malnutrition aggravate many epileptic predispositions into a distinct disease. The infectious diseases cause about 1 percent of epilepsies, and more cases of epilepsy owe their origin to scarlet fever than to all other infectious diseases combined. Intestinal worms may cause convulsions in infancy, which may persist later as true epilepsy. Masturbation is no longer looked upon as causing epilepsy so much as aggravating the disease when it once becomes established. This last statement is also true in regard to sexual excesses.

Trauma of the cranium, although it may not cause a distinct fracture or immediate pressure-symptoms of the brain, may still disarrange the component molecules of the cerebrum in such a manner as to provoke epileptic symptoms with a predisposition to the disease.

Disorders of menstruation sometimes favor the onset of epilepsy, especially at the age of puberty. Puerperal women with eclampsia without a very marked predisposition rarely become epileptic from the bearing of children.

There are many cases provoked by seemingly slight and altogether insignificant causes. This phenomenon can only be explained by supposing that the patient was strongly predisposed to the disease; as to what chemicobiologic change or state lies back of this is not clear.

Pathology.—The etiologic pathology of epilepsy is still unknown.

Symptoms and Diagnosis.—In considering symptoms manifest in attacks, the **premonitory signs** are the first encountered. They may be present for hours, days, or weeks before the paroxysm actually occurs. They may even become constant, and these form the epileptic disposition. They may consist either of a motion, sensation, or, more commonly, a peculiar irritable, disagreeable, depressed, or exalted mental state in various combination.

The aura is found in about 75 percent of all epileptics, although but one-half of this number have the aura for a sufficient length of time before the seizure to make it of practical value in avoiding the disagreeable consequence of an epileptic paroxysm or in preventing accidents from falls in attacks. The aura of epilepsy is always a subjective symptom, and signifies that the pathologic physiology of an epileptic fit has already begun in the cerebral cortex. Sometimes seizures are aborted at the aura, and then attacks consist only of this symptom in the varied sensory, motor, and psychic manifestations.

Auras are divided into sensory, psychic, and motor. In the order of their frequency, *sensory auras* comprise three-fourths of the whole phenomena. All known possible physiologic sensations of the body may serve for the aura, and it may manifest itself in any part of the body.

The psychic auras generally consist of emotions of fear, joy, hate, anger, pleasure, or pain. *The motor auras* consist of muscular twitchings in the extremities or face, or about the mouth and eyes. Just before the spasm becomes general, and as the patient is about to fall, is heard the epileptic cry, or, better, groan.

It is very necessary to observe the order of *muscular invasion.* The new era of cerebral localization has really made this study of paramount importance. All possible variations of the invasion are fairly constant in the same cases. The spasm generally begins at the free end in one extremity, and quickly involves all muscles of that side, finally crossing to involve the opposite side in like manner. In a severe seizure the muscular spasm generally begins by the body becoming fixed in severe tonic spasm for a few seconds, and then the condition gradually gives way to a fine, general tremor, which grows coarser until the typical clonic condition is present. In a few seconds the clonic spasm becomes less marked until it finally ceases altogether in one or two general jerking movements, which toss the head and extremities about with more or less violence, and the patient once more breathes deep and loudly, snoring like one in narcosis of chloroform or ether. This last stage is the stertor period.

In the majority of all cases there is an initial pallor during the convulsion, best noticed in the face, which is quickly followed by a deep suffusion and congestion, ending in extreme cyanosis, which, in turn, may persist in a more or less marked degree for hours. In the clonic period the tongue is usually bitten at one side or the other, which side is, for the most part, constant in the individual patient. Frothing at the mouth or nose occurs in the clonic period. Vomiting may occur in many patients at any time throughout the paroxysm. Care must be exercised to prevent vomited matter from entering the trachea. Frequently, accompanying the depression of seizures there is marked constipation for days. The contents of the rectum may be expelled, and urine frequently voided, sometimes during the attack.

Undue sudden physical or mental strain may cause an attack to appear at any time. The emotional element is often markedly prominent. Attacks are often prevented or postponed, when naturally presenting themselves, by applying some slight mental or physical shock to the patient, thus increasing the inhibitory control of the nervous centers.

Minor attacks of epilepsy consist of a lessening of all the exaggerated symptoms seen in major epilepsy, or *grand mal* attacks. They may consist entirely of a disorder or loss of consciousness.

Epileptiform seizures, or epilepsy following gross brain-lesions, are often mild, and localized to the side partially paralyzed. The paralytic symptoms are almost always increased after epileptic fits, from exhaustion of the previously weakened center. Palsy is often very difficult of detection. Too much attention cannot be given to the search for it. In the mild cases it frequently appears to be idiopathic epilepsy.

The very temporary character of the exhaustion —paralysis after certain kinds of epilepsy—is sufficient to differentiate it from a chronic palsy, however slight.

The mental disturbance following one attack, or oftener a series of fits, may vary all the way from mild mental automatism into delirium or stupor and persistent coma, delirious mania, mania, and systematized epileptic insanity. There are frequently fury and violence in the automatic state after fits. Occasionally, this condition precedes seizures.

The occurrence of one epileptic fit presupposes that another will follow in a more or less short period of time. Thus the disease quickly establishes itself, and soon becomes chronic in its course.

Epilepsy may be stimulated by hysteria, but the main differences are shown in the following table:

Epilepsy.	Hysteria.
1. No apparent cause.	1. Cause, emotional.
2. Sudden and rapid onset.	2. Onset gradual, usually after some mental excitement.
3. Aura generally present.	3. Globus hystericus or palpitation.
4. Consciousnesss lost.	4. Consciousness generally preserved.
5. Pupils generally dilated.	5. Pupils normal.
6. Tongue often bitten.	6. Tongue never bitten.
7. Patient very liable to hurt himself.	7. Patient not liable to hurt himself; may injure others.
8. May be involuntary bladder and bowel discharges.	8. Never.
9. Of short duration.	9. Duration longer.

The prognosis of epilepsy as to recovery is poor; only about 2 percent of patients recover. The absence of attacks for a few months is not unusual in epilepsy; if a period of 2 years elapses, the patient will probably not have any more seizures. The prognosis as to life is variable. Epilepsy may last a few years or throughout a long life. It not infrequently persists for over half a century. Patients most frequently die of some intercurrent disease; death during a convulsion is very rare. The mental sequels of epilepsy are by far the most to be dreaded. Progressive mental enfeeblement is the rule, but this cannot be charged to any particular kind of epilepsy in origin or course. Most mental failure occurs in those epileptics having the most frequent *grand mal* attacks. Patients having psychic attacks are not predisposed to mental failure more than other epileptics with *grand mal* or *petit mal* attacks.

Epileptics are particularly susceptible to valvular lesions of the heart, mitral insufficiency being most frequent. Of lung affections, epileptics die most frequently of tuberculosis and congestive disorders, such as lobar and lobular pneumonia.

By far the greater danger to the epileptic lies in the disease itself—that is, in the repeated occurrence of seizures one after the other in rapid succession until exhaustion and death occur. The condition is called *status epilepticus*. It is the necessary climax or acme of the disease. There are many grades of the condition and many varieties in different cases, but the essential symptoms of the status are as follows: Repeated attacks, followed by increasing stupor until coma is reached; an increasing rise in temperature, pulse-rate, and respiratory frequency; the temperature may rise to 107° or even higher; the pulse-rate may reach 180 or 200, the respiration 60, or even higher as death approaches.

A scheme for case-examination in epilepsy is as follows:

Number, name, age, religion, social status, address of nearest relative.

Family History.—Phthisis, rheumatism, inebriety, consanguinity, feeble-mindedness, rachitis, insanity, epilepsy or other convulsive diseases.

Number of brothers and sisters, which child in order of birth, number of deaths in family and their cause, habits of parents and relatives.

Habits of Patient.—Diet, appetite, digestion, sleep, alcohol, tobacco, narcotics.

Personal History.—Prenatal causes, if any; injury at birth; convulsions at birth; convulsions at dentition; diseases of childhood—scarlet fever, measles, typhoid fever; bottle- or breast-fed; laryngismus stridulus; croup.

Cause of Epilepsy.—Syphilis, masturbation, sexual excesses, headaches, epistaxis, trauma.

Disorders of sleep in family or patient, night-terrors, paralysis in infancy.

Kind and quality of work while at school, degree of education, occupation and regularity of work.

First Seizure.—Character of disorder in consciousness, aura, subsequent stupor, subsequent mental state, subsequent paresis or aphasia, character and duration of subsequent seizures, time of day when attacks occur most frequently.

Primary Movements.—Order of invasion and side most affected, sphincters, conditions that cause or arrest attacks, mental state in interim, memory, disposition, frequency of attacks at present, date of last attack.

Manifestations of Hysteria.—Automatism, hallucinations, pallor, flushing.

Heart, pulse, circulation, lungs, respiration, bodily condition, hearing, sight, pupils, speech, skin, bowels, tongue, superficial reflexes, deep reflexes, motion and coordination, dynamometer (right, left), stigmata of degeneration.

Menstruation.—First occurrence, character, length of time present, regularity, relationship

of seizures to menstruation or pregnancy, anomalies of menstruation at present, if any.

Treatment.—Surgical operation upon the cranium is no longer practised except when distinct evidences are obvious that the brain has been injured. Operations can be of but little value unless done within a few months of the injury, while the seizures are distinctly localized, of the character of Jacksonian spasm or monospasm affecting a single extremity. Even then the previous neurotic family history and inherited predisposition to epilepsy may render useless any operative interference. Simply because an idiopathic epilepsy has a slow and distinct order of invasion is no good reason why it should be included in operative cases.

The surgeon who, without great cause, as of depressed fractures or the like, operates upon the cranium of epileptics does so without the best scientific sanction. Various other surgical procedures upon special organs of the body have been practised, but are no longer fully justifiable. We have no right to look beyond the nervous mechanism of the brain for the explanation of the epileptic paroxysm.

The general management of a case of epilepsy demands close attention. The proper regulation of the diet, exercise, and sleep of the epileptic is absolutely essential. Many of the wonderful results obtained from the *colonization* of epileptics, both abroad and in this country, notably in Ohio, Pennsylvania, Massachusetts, and New York, are directly credited to the careful regulation of the patient's life. At the Craig Colony, Sonyea, N. Y., by the establishment of small homes, the industrial form of education, and occupation suitable for epileptics, great success has been attained. Too much cannot be said for this rational plan of caring for epileptics and for properly treating the disease.

A scientific **dietary** is given for regulating the patient's meals:

Breakfast.—Oranges; apples—raw, baked; peaches—raw or with milk; oatmeal, cracked wheat, hominy, to be thoroughly cooked and eaten with milk or small portion of cream; eggs—soft-boiled, scrambled, poached; toast—dry or lightly buttered; baker's bread, Graham bread, corn muffins; coffee—moderate strength; milk—hot or cold.

Dinner.—Oysters—raw; soup—bouillon, tomato, vegetable, oyster; chicken or mutton broth, meats—roast beef (rare or well done, as taste demands), roast lamb, roast chicken or turkey, baked white- or blue-fish, or shad; vegetables—potatoes (white or sweet), spinach, carrots, turnips, tomatoes (raw sliced), onions, stringbeans, lima-beans, peas, squash, asparagus (all vegetables well cooked); relishes—onions, celery, lettuce; dessert—puddings; bread, farina, rice, tapioca; cup custard; cheese—Edam, American, cream; crackers.

Supper.—Toast—dry, buttered, milk; crackers, corn bread; eggs—soft-boiled, poached, scrambled; stewed prunes, baked apples, apple sauce; milk, tea (made weak), coffee.

Articles Prohibited.—Pastry of any kind, rich puddings, cake of any kind, pork, veal, ham, anything fried in grease, high seasoning, alcoholic beverages of all kinds.

Tea should be drunk sparingly, and should be weak; coffee may be allowed for breakfast, but not for supper if it causes wakefulness.

The epileptic should eat slowly, masticate thoroughly, and not overeat.

The medicinal treatment forms a very desirable adjunct to the foregoing treatment of epilepsy. Chief among all medicines are the bromin salts, singly or given in various combinations. One salt is as effective as another; change from one form to another is advisable. The bromids should be systematically employed only when other drugs have been found ineffective, as they frequently do no more than postpone the fits for a longer or shorter period of time.

A modified combination of the Brown-Séquard remedy has proved one of the best bromid mixtures:

℞.	Potassium iodid,	ʒ ij
	Potassium bromid,	ʒ j
	Ammonium bromid,	ʒ ijss
	Potassium bicarbonate,	ʒ j
	Tincture of calumba,	ʒ j
	Fowler's solution,	ʒ ij
	Water, q. s.	ʒ v.

One to 4 drams night and morning, as the case demands.

Solution of ammonium bromid (containing 5 grains of bromid to the dram) is a pleasant and efficacious remedy.

The treatment of the status period, the climax of the disease, is of paramount importance. It is arranged under 2 heads—dietetic and medicinal.

Food must be given early, and in the most highly nutritious form, before the interparoxysmal stage of coma is continuous. Subsequently, enemata may be required. It must always be remembered that the secretory and nutritional activity of the brain is at a minimum; therefore nutrition and medicine must be given early. A good plan is to give the following prescription to the patient's relatives, with instructions that it is to be administered under certain specific directions when the seizures are frequent and prolonged (8 to 12 in 4 to 5 hours).

℞.	Deodorized tincture of opium,	♏ v
	Potassium bromid,	gr. xxv
	Chloral hydrate,	gr. xx
	Solution of morphin sulphate (containing 1 grain to the ounce),	ʒ jss.

One dose; repeat in 2 hours if necessary.

The temperature, pulse, and respiration must be taken hourly, to measure the progressing exhaustion, which is the one great danger above all others in serial or status periods. Chloral, given alone in large doses, always depresses the heart-action, which is the organ bearing the brunt of status, and which should not be hindered more than is absolutely necessary. Finally, when all else fails, hypodermic injections of bromids

must be given, and strychnin and whisky in the same manner for stimulation.

Sedative medication in status for the convulsion is contraindicated for the stupor and coma following; therefore all sedatives should be administered with great caution, and the behavior of the vascular system toward these depressants closely observed.

EPINEPHRIN.—See Adrenalin.

EPIPHORA.—See Lacrimal Disease.

EPISCLERITIS.—See Scleritis.

EPISIOTOMY.—Incision through the vulva during childbirth for the purpose of preventing rupture of the perineum. It consists of two lateral incisions upon the mucous membrane just within the vulvar opening. They should be from 3/4 to 1 inch in length, and from 1/4 to 3/8 of an inch in depth. This is supposed to relieve vulvar and perineal tension and thus to facilitate the birth of the head. The incisions should be closed immediately after labor.

Episiotomy cannot be recommended, since injury to the perineum presents fewer disadvantages than incision of the vulva.

EPISPADIAS.—See Penis.

EPISTAXIS.—Bleeding from the nose, occurring spontaneously or from injury.

Causes. General.—1. Disease of the vascular system and the blood, such as is found in scurvy, purpura, hemophilia, etc.

2. Fragility of the blood-vessels following acute infectious diseases (acute exanthems, typhoid, diphtheria); also subacute and chronic infectious diseases (malaria, pyemia, septicemia).

3. Those diseases that lead to obstruction of the circulation (valvular disease of the heart, diseases of the lungs, tumors of the mediastinum, cirrhosis of the liver, Bright's disease, amyloid degeneration of the kidneys and liver, and, lastly, also the physiologic process of pregnancy).

4. Vicarious menstruation.

Local.—1. Erosions and superficial ulcerations of the mucous membrane.

2. Varicose dilatation of the veins on the anterior portion of the nasal septum.

3. Perforating nasal ulcer.

4. Ulceration of the mucous membrane and of the bones in the course of syphilis, tuberculosis, lupus, and other destructive processes.

5. New growths—especially sarcoma and soft carcinoma.

6. A certain fragility of the mucous membrane, for which, microscopically, no cause can be assigned.

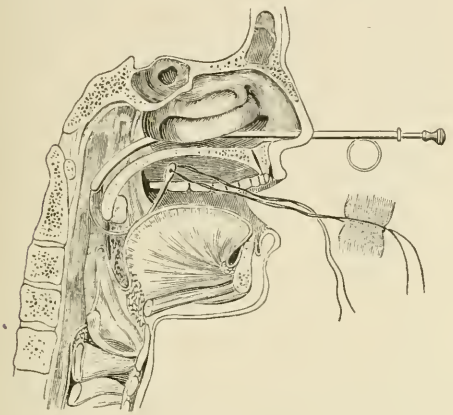
7. Trauma.

Treatment.—Usually, the bleeding will cease without the interference of the physician, if the patient will lie quiet—better with the head hanging, so the blood will flow from the nostril instead of running back—and apply cold to the spine, or douche the nose with cold or very hot water, with a little salt or vinegar, lime- or lemon-juice in it, or plugging the nostril with some cotton or linen. A method strongly advised by Hutchinson is to soak the patient's hands and feet in water as hot as can possibly be borne. If the physician is summoned, occasionally his presence will be all that is necessary, as the bleeding often ceases when fears are quieted; but if this is not the case, it will be necessary to resort to measures for relief.

Cleanse the nostrils by douching with very hot water, and let the patient blow gently, yet forcibly enough to expel the plugs and foreign substances; contract the tissues, using a few drops of 2 to 4 percent cocain applied with the spray, medicine dropper, or on cotton (sometimes this will control the bleeding), so that the place of bleeding may be seen, and a styptic applied directly to it. Hydrogen dioxid applied in the same manner will sometimes control the bleeding entirely; it surely cleanses the nares and makes them aseptic. When the hydrogen dioxid comes in contact with the blood it foams, and afterward becomes more solid, often hanging in long pieces from the nostril; this portion should be cut away with scissors, leaving the plug in place. Adrenalin chlorid sometimes proves successful. Lapat, of Savannah, Ga., says that if epinephrin chlorid is applied by a cotton-tipped applicator to the side of the septum from which the hemorrhage occurs, the whole mucous membrane, except in those spots in which the bleeding takes place, becomes blanched. If it is a vessel that has caused the bleeding, it will stand out strongly in contrast to the rest of the mucous membrane. If it has been due to capillaries, a red circular spot about the size of half a ten cent piece stands out prominently. This procedure makes it a simple matter to find the bleeding spot and cauterize it with 90 percent trichloracetic acid. The acid obliterates the vessel or capillaries, and in a few days it heals over, removing with very little trouble the source of bleeding. If these measures do not prove effective, cleanse the nostril and apply lime-juice or lemon-juice pure, a strong solution of tannic, acetic, or gallic acid, persulphate of iron, antipyrin, or a saturated solution of ammonio-ferric-alum. If these measures fail, then it will be necessary to resort to posterior and anterior plugging.

Remembering the size of the posterior nares, it will be necessary to make a plug of absorbent cotton or fine linen, about the size of the end of the thumb, when tied firmly in the middle, with a strong, preferably twisted, string, doubled, extending about 18 inches from the plug in both directions. Then, having cleansed the nostril again, pass a Bellocq's cannula, a soft-rubber catheter or tubing, or any suitable instrument, or a wadded string, through the bleeding nostril into the pharynx and below the soft palate; grasp it with the fingers or forceps and draw through far enough to tie the string of the plug to it; then, placing the finger above the string and at the base of the soft palate, draw the plug in; when it reaches the end of the finger, pass the latter behind the soft palate, drawing it toward the front, and pull the plug above it into position in the naris. If the plug is in the proper position, it will be impossible for the patient to breathe through it. Sometimes it is necessary, after the plug has passed the soft palate, to push it into the proper place with the finger; then, by a quick, firm pull, set it tightly. Having accomplished the

posterior plugging, it will be necessary to plug anteriorly with absorbent cotton, fine linen, or a small piece of handkerchief, made umbrella shape, filled with any material that may be convenient. The absorbent cotton is loosely rolled to about the size of the little finger, on a cotton carrier, probe, knitting-needle, or smooth wire, dipped into the desired styptic, and pressed firmly into the nostril below the posterior plug string, which latter is then divided and firmly tied over it, that neither may become loosened.



Application of Bellocq's Cannula.

The posterior plug should never be left in place over 40 hours, and, on account of the odor, seldom over 24 to 30, as there is danger of septicemia. The removal of the plug is quite as difficult as its insertion. The string over the anterior plug should be severed and the dressing softened with hot water, so that it may be removed without disturbing the mucous membrane or the clot. After the anterior plug has been removed, flush the nostril with hot water until some of it passes into the throat, when the plug is soft enough to remove by gentle traction on the other end of the string tied to the plug when it was introduced, placing the finger between the string and soft palate that the latter may not be injured, and that the plug may be pulled *downward* into the oropharynx and out of the mouth. Occasionally there will be some slight bleeding immediately after the removal of the plug, but this generally ceases in a moment.

EPITHELIOMA. **Synonyms.**—Epithelial cancer; carcinoma epitheliale; rodent ulcer.

Symptoms.—Three varieties of epithelioma are recognized—the superficial, deep, and papillary.

Superficial Epithelioma (Flat or Discoid Variety).—This form of the disease makes its appearance as one or more grouped yellowish or reddish papules, or as flat infiltrations, warty outgrowths, or degenerative seborrheic patches. These show a tendency to become excoriated and covered with brownish or yellowish crusts. In the course of several months or years the deposit increases, or new lesions appear, which undergo degeneration, with the formation of superficial ulcers. The ulcer is usually roundish, with sharply defined, flat or raised, indurated, rounded, pearly edges. The base is hard, reddish, uneven, easily disposed to bleed, and secretes a scanty, yellowish fluid. The general health is unimpaired, pain slight, and lymphatic involvement absent.

Rodent ulcer (Jacob's ulcer), a peculiar form of superficial epithelioma, almost invariably limited to the upper two-thirds of the face, occurs in old age, and begins as a little nodule, at first covered by normal skin, which eventually ulcerates. It contains cells similar to those of sebaceous glands presenting a picture resembling that of a squamous-celled carcinoma with the exception that a cell-nest is but rarely present. Ulceration and extension continue without involvement of lymphatic glands or other organs. The disease progresses very slowly, sometimes lasting thirty or forty years, and occasionally cicatrizes in spots, the scars later breaking down.

Deep-seated Epithelioma (Infiltrating Variety).—This form develops from the superficial variety or from a nodule having its seat in the corium and subcutaneous tissue. The nodule varies in size from that of a pea to a walnut, firm, indurated, rounded or flat, shining, and of a reddish or purplish color. After a lapse of some months ulceration takes place. The ulcer is deep, rounded, or irregular in shape, with an uneven, reddened, easily bleeding base, and hard, everted, purplish edges. An areola of redness and infiltration indicates the spreading infiltration. The lymphatic glands become involved, the pain is severe and of a lancinating character, and the patient slowly succumbs through marasmus, hemorrhage, or exhaustion.

Papillary Epithelioma.—This form may develop from the superficial or deep variety or from an ordinary wart. It appears either as a small verrucous elevation, or as a larger, coin-sized, lobulated, spongy, papillary growth. The surface may be dry and covered with horny yellow scales, or moist and covered with uneven, exuberant granulations, secreting a sanguineous or translucent fluid. Disintegration occurs, with the production first of fissures and later of ulcers. The course is progressive and malignant.

Epithelioma involves with predilection the face, particularly the lower lips, eyelids, and nose. The penis, labia, and other parts of the body are not infrequently affected.

Etiology.—Obscure. It occurs after middle life, and more frequently in men than in women.

Pathology.—The process consists of an abnormal downgrowth into the corium of the interpapillary projections of the rete mucosum, a proliferation of the rete cells, their isolation in the corium in the form of nests, the occurrence of "pearly bodies," and certain secondary inflammatory changes.

Diagnosis.—Epithelioma may be confounded with warts, the ulcerating syphiloderm, and lupus vulgaris.

The age of the patient, the occurrence of ulceration, the general appearance of the growth, the history, and the course will usually distinguish an epithelioma from a wart.

Epithelioma may be differentiated from syphiloderm as follows:

Epithelioma.	Tubercular Ulcerating Syphiloderm.
1. Occurs late in life.	1. Occurs in early and middle life.
2. No history or concomitant signs.	2. History and concomitant signs of syphilis.
3. Evolution slow.	3. Evolution rapid.
4. Ulceration single.	4. Ulceration usually multiple.
5. Edges of ulcer hard and indurated. Discharge scanty, bloody and stringy.	5. Edges of ulcer not indurated. Discharge abundant, yellowish, and creamy.
6. Lancinating pain.	6. No pain.
7. Yields only to destruction.	7. Heals under the use of iodids and mercury.

The differential diagnosis from lupus vulgaris will be found under that disease.

Prognosis.—The superficial form resulting from seborrheic degeneration may be permanently cured by early and thorough destruction. In the other forms the prognosis is more grave, and will depend upon the age of the patient, the extent of the disease, the rapidity of the process, etc.

Treatment.—The treatment consists of thorough destruction of the diseased tissues. One of the best methods of accomplishing this end is erasion by means of the dermal curette, followed by cauterization of the part; or, if in a convenient situation, the growth may be excised. In some cases such caustics as caustic potash, pyrogallic acid, arsenic trioxid (*i.e.*, arsenous acid), acid nitrate of mercury, and zinc chlorid may be employed. Arsenic trioxid seems to possess some selective action in the destruction of epithelioma; for this destruction 9 to 24 hours is required—the paste applied consisting of 50 to 75 percent arsenic trioxid, 50 to 25 percent powdered acacia and water. Methods that are intensely destructive are dangerous, because they merely promote additional growth.

Carbon dioxid snow has been used with excellent results especially in the rodent ulcer type. It is in this form of cancer that X-ray treatment has proved particularly successful. Rodent ulcers have also been treated successfully by means of the Finsen light, radium and the electrolytic introduction of zinc ions from the positive pole. The light-treatment, however, in a true chronic epithelioma causes a more rapid growth.

See Tumors.

EPULIS.—See Jaws (Diseases).

ERGOT.—The sclerotium (compact mycelium or spawn, intermediate fibrous stage) of *Claviceps purpurea*, replacing the grain of rye. It occurs in fusiform, curved, grain-like bodies, of purplish-black color, peculiar, heavy odor, and oily, disagreeable taste. When more than one year old it is unfit for use. Dose, 10 to 60 grains.

The composition of ergot and the nomenclature of its supposed constituents are subjects upon which there exists a great diversity of opinions, and about which there is nothing settled. According to Kobert, it contains three active principles, viz.—*ergotinic acid*, a nitrogenous glucosid, which has no ecbolic action but affects the nervous system, the heart and the respiration; *sphacelinic acid*, a nonnitrogenous resin, which stimulates the vasomotor center and causes uterine contraction; and *cornutin*, an alkaloid, found in very small quantity, and believed to be the ingredient which causes the convulsions. Ergot also contains *trimethylamin*, tannic acid, and a fixed oil.

Ergot is a powerful vasoconstrictor, a cardiac sedative, a motor excitant, and a stimulant of involuntary muscular tissue. It is hemostatic, ecbolic, anhidrotic, and convulsant. The most familiar use of ergot is to promote uterine contraction in protracted labor due to inertia of the womb, but as it produces continuous (tetanic) contractions instead of the intermittent natural ones, it is dangerous when there is much resistance in front of the child, the probable results being rupture of the uterus or severe laceration of the perineum, and stoppage of the placental respiration of the fetus. Toward the end of the second stage, when the head is beginning to emerge at the vulva, is the proper time for its administration, if used at all, in order to promote firm uterine contraction, thereby preventing postpartum hemorrhage, promoting the expulsion of the placenta, and guarding against puerperal infection by closing the uterine lymph-spaces and thus opposing a barrier to the entrance of infectious material. It is used in many uterine affections, as chronic metritis, subinvolution, congestive dysmenorrhea, hemorrhages, fibroids, and polypi, to produce firm contraction and promote the absorption of inflammatory products. It is efficient in many cases of amenorrhea in plethoric subjects, and in the atonic type of spermatorrhea.

Ergot is extensively employed in all forms of hemorrhage in which no direct styptic application can be made, and even when such is possible it is a useful hemostatic adjuvant. It is particularly efficient in uterine hemorrhages, purpura hemorrhagica, and in venous, capillary, and atonic arterial bleeding; but may be injurious in active arterial hemorrhage. Hemorrhoids are well treated by its local application, but in this affection it should not be used internally as it promotes venous congestion. In aneurysm it aids coagulation by slowing the blood-current, and in cardiac hypertrophy without valvular lesion it acts well by slowing the heart. In diabetes insipidus full doses of ergot are often curative, and it has been used with benefit in diabetes mellitus. In epilepsy it increases the efficiency of the bromids, and often gives good results. It is very efficient in enlargement of the spleen, and is said to have even cured leukemia. In conjunctivitis, gonorrhea, and inflammations of mucous membranes generally, it is of striking benefit, if used both locally and internally. It is an excellent remedy in acute and chronic dysentery, chronic diarrhea, mania due to cerebral hyperemia, headache and migrain of congestive form, myelitis, spinal congestion, cerebrospinal meningitis, lax sphinc-

ters of the rectum and bladder, and incontinence of urine from paralysis of the sphincter vesicæ.

Incompatible with *ergot* preparations are: Tannic acid and other alkaloidal precipitants; also caustic alkalies, metallic salts. Physiologically incompatible with its action on the circulation are: aconite, amyl nitrite, lobelia, tobacco, veratrum.

Preparations —Extractum ergotæ. Dose, 2 to 10 grains. **Fluidextractum E.** Dose, 10 to 60 minims. **Vinum E.,** has of the fluidextract 20 percent. Dose, 1 to 4 drams. **Ergotinin citrate** is said to be an efficient substitute for ergot. Dose, 1/200 to 1/100 grain hypodermically.

ERGOTISM.—A disease due to the action of ergot taken in food made from contaminated rye-meal. The appearance and severity of the disease vary with the amount of ergot consumed. Children at the breast are never attacked. The symptoms are of an irritant character, including vomiting, purging, and colic, giddiness, headache, formication, and itching of the skin. Hematuria and jaundice often occur. The severe cramps—affecting chiefly the legs, and leading to tonic contractions of the affected muscles—persist after the previous symptoms subside. Gangrenous forms affect the fingers, nose, and ears. The removal of the cause is the first requisite to treatment, and vomiting should be encouraged or induced. Spasm must be combated by opiates or potassium bromid. Gangrene is best treated according to the rules of surgery. Spasmodic ergotism may last for 2 weeks or for as many months. The gangrenous variety is very protracted and variable.

ERICHSEN'S DISEASE.—Railway spine; railway brain. A train of symptoms following accidents, which may assume the form of traumatic hysteria, neurasthenia, hypochondriasis, or melancholia. See Spinal Cord (injuries).

ERIODICTYON.—Yerba santa, or mountain-balm. The leaves of *E. glutinosum*, a shrub of California; an excellent expectorant, and valuable as an excipient for quinin, the taste of which it largely conceals. It is useful in bronchial affections. Dose, 5 to 30 grains. There is one official preparation, the fluidextract, dose, 5 to 30 minims.

ERRHINES AND STERNUTATORIES.—Agents which produce increased nasal secretion and sneezing, when locally applied to the mucous membrane of the nose. The first term is usually applied to substances which cause increase of the mucus without sneezing, the latter to those which invariably produce sneezing. The drugs should be applied in powder. The stimulus produced by these agents is transmitted by the nasal branches of the fifth nerve to the respiratory center, exciting the sudden and forcible expiratory effort called sneezing; also to the vasomotor center, contracting the smaller vessels throughout the body and producing a general rise in the blood-pressure. The principal are—

Tobacco (as snuff),	Euphorbium,	Capsicum,
Ipecacuanha,	Sassy bark,	Hellebore,
Sanguinaria,	Saponin,	Ammonia,
Veratrum album,	Ginger,	Cubebs.

The last two named may be used as simple errhines, as the vapor of dilute ammonia-water, and the smoke of burning cubebs, do not excite sneezing generally.

ERUCTATIONS.—The sudden escape or expulsion of gas from the stomach through the mouth, with or without admixture of portions of liquid or solid foods, of gastric juice or other liquids. It occurs in all gastric diseases attended by an undue formation of gas. It is constantly complained of in atonic dyspepsia, more especially in elderly persons.

The indications are to prevent the decomposition of food and the formation of gases and other products, to restore tone to the stomach, and to treat any morbid condition of this organ. Of drugs, nux vomica, charcoal, bismuth, chloroform, carbolic acid, turpentine, strontium bromid, asafetida, valerian, sodium sulphocarbolate, dilute phosphoric acid, oil of anise, and ether, are all of service.

A diet free from sugar, starchy food, and tea, with slow eating, in small quantities and regularly, and general abstention from alcoholic drinks and from vegetables, especially cabbage, is recommended. Pepsin or ingluvin after meals will promote digestion.

℞. Tincture of nux vomica,
Tincture of physostigma,
Tincture of belladonna, } each, ʒ j.

Fifteen drops twice daily in a little water.

℞. Gum camphor,
Powdered ginger,
Powdered pepper, } each, gr. j.

Make into 6 pills. Give 1 as required for gastric and intestinal flatulence.

See Flatulence.

ERUPTION.—Applied especially to the chief symptom of certain skin-diseases, consisting in pimples, vesicles, rash, etc.; the breaking forth of a tooth from the gum. See Exanthems, Drug Eruptions, Skin-diseases.

ERYSIPELAS (St. Anthony's Fire).—An acute infectious and contagious dermatitis, characterized by severe local inflammation of the skin with a tendency to spread, and accompanied by fever and constitutional disturbance.

Etiology.—The affection is due to the introduction into the skin of the streptococcus erysipelatis, identical with the streptococcus pyogenes. The disease is transmitted by direct contact, through a third person or through the air. Depression of the vital forces, as in chronic diseases and alcoholism, and the existence of wounds or abrasions act as predisposing causes. Women during or after labor are readily inoculated. The disease may be engrafted on leech-bites, or vaccination punctures. Certain individuals seem prone to acquire it. After one attack a person seems rather predisposed to another. In the recurrent variety, due to nasal infection, catarrhal conditions of that organ predispose.

Streptococcus of Erysipelas.—(*Coplin and Bevan.*) × 800 diameters.

Symptoms.—The disease is usually ushered in with a chill, malaise, anorexia, headache, and elevation of temperature (102° to 105° F.). The erysipelatous eruption is highly characteristic. The affected area is sharply defined, of a shining crimson or violaceous hue, elevated above the surrounding skin, and firm, hot, and tender to the touch. In addition, vesicles or blebs are prone to develop. The patient complains of pain, burning, or itching. The eruption tends to spread by peripheral extension, the older parts first undergoing involution, the maximum of inflammation being found at the periphery. In any one locality it runs its course in 4 or 5 days, ending in desquamation. The disease, however, may last for weeks, owing to constant extension. Albuminuria may be present. There is marked leukocytosis.

The form commonly met with is the so-called *idiopathic erysipelas* in which the abrasion through which the infection enters is not discovered. The face is by far the most frequently affected region. In this location the eruption is extremely likely to spread over the forehead and scalp to the nape of the neck.

Erysipelas ambulans or migrans is a variety that tends to subside rapidly in one region, reappearing in another, the whole process continuing for several weeks.

There is a mild recurrent form of erysipelas that is prone to attack the cheeks and the alæ of the nose. The constitutional disturbance is mild or entirely absent. The eruption does not tend to spread beyond the face, and disappears in 3 or 4 days. It is due to microorganismal infection through the mucous membranes of the adjacent cavities, particularly the nose.

Prognosis.—Favorable in the vast majority of cases. In rare cases abscesses or gangrene may develop. In severe cases death may result. See Suppuration.

Treatment.—Internally, tincture of the chlorid of iron, 10 minims every 2 or 3 hours; quinin, 2 grains 4 times a day; and stimulants. Locally, carbolized petrolatum; 25 percent ichthyol ointment; or an ointment of phenol 1 part, ichthyol 10 parts, lanolin 20 parts, or moist compresses of a dram to the ounce aqueous solution of hyposulphite of sodium, 1 percent phenol, 1 to 1000 potassium permanganate, or 1 to 1000 mercury bichlorid. When the extremities are involved, extension may sometimes be checked by the use of tincture of iodin or the stick of nitrate of silver applied to the spreading periphery.

In the recurrent form the nose and mouth should receive careful treatment, detergent washes, such as Dobell's solution, being employed.

The patient should be isolated, with a special nurse in attendance. Surgeons and obstetricians should not attend erysipelas cases. The inflamed part should always be kept warm and raised, air being excluded from the surface. Warm fomentations are the best. Subcutaneous injections of a solution of phenol, and nitrate of silver in solution, say from 20 to 30 grains to the ounce of water, applied directly over the affected parts, are highly recommended.

Constitutional treatment should be eliminative and supporting. Pilocarpin hypodermically, has been advocated for its effect on the skin.

Judd advocates a single application of 95 percent solution of carbolic acid to blanch the tissue, followed by an application of pure alcohol till the area becomes pink again, only a small section of the diseased tissue being treated at a time, followed by dressings of bichlorid or salt solution, but not of carbolic acid.

In the *cellulocutaneous* forms of the disease (*phlegmonous erysipelas*), as soon as tension of the integument appears, incisions must be made deep enough to allow the escape of the serum from the cellular tissue beneath and to relieve the tension. Some surgeons recommend that the incisions be free, so as to extend the whole length of the affected parts; others prefer a greater number of limited incisions; preference is given to the latter method. The long incisions are attended by copious hemorrhage and great risk of life, while the hemorrhage from the limited incisions can generally be controlled by elevation of the part and pressure. The part should be frequently dressed and irrigated.

Serum Therapy.—Injections of antistreptococcic serum seem to ameliorate the symptoms.

Diphtheria antitoxin is reported to have been used with success.

Vaccine Therapy.—Specific vaccine has proved of value in shortening the attack.

ERYSIPELOID.—An infection caused by the bites of crabs, punctures with fish fins and contact with putrid fish or other decomposing animal matter. Jopson thus describes a case in which the finger was affected: "It appears as a swelling, with elevated, sharply defined edges, which soon affects the entire circumference of the finger; and is commonly described as of a dark red color, with purplish or even livid edges. The finger is tense and only moderately painful, but itching and burning are prominent symptoms. It has a characteristic tendency to spread toward the palm, the primarily affected area fading from red to yellow, and thence to normal. There are no constitutional disturbances. It commonly lasts from ten days to three weeks." Jopson paints the affected parts with tincture of iodin.

ERYTHEMA INTERTRIGO (Chafing).—A form of traumatic erythema, occurring chiefly in those regions where skin surfaces are in apposition, such as the genitals, flexures of joints, neck, etc. It is common in children and in stout individuals. Moist diapers and the contact of intestinal discharges are often causative. The condition may remain as an erythema, or may develop into a dermatitis or an eczema. It is then characterized by redness, excoriation, and a mucoid discharge. There is usually a feeling of heat and soreness.

Treatment.—When the condition remains as a true erythema, dusting-powders suffice. The following is a useful combination:

℞. Magnesium carbonate,
Venetian talcum,
Zinc oxid, } each, ʒ ij.

If an eczema or a dermatitis supervene, the condition should be treated according to the principles laid down in the treatment of those affections.

ERYTHEMA MULTIFORME.—An inflammatory disease, characterized by variously sized and shaped patches or erythema, papules, vesicles, and blebs, running an acute course, and accompanied, as a rule, by constitutional disturbance.

Symptoms.—The disease is usually preceded or accompanied by febrile disturbance, malaise, rheumatoid pains, etc. The eruption, which comes out more or less suddenly, may consist of macules, maculopapules, vesicles, and blebs, one type of lesion, as a rule, predominating. After remaining stationary for some days the eruption gradually disappears. Any part of the body may be involved, although the disease exhibits a marked predilection for the backs of the hands and feet, and not infrequently for the face and neck. Itching and burning, when present, are usually mild. The lesions are at first bright or dusky red, later becoming purplish or bluish.

When the patch is circular, with peripheral spreading and central clearing up, it is called **erythema circinatum,** or **erythema annulare.** Concentric rings of variegated colors are termed **erythema iris,** and when the rings are made up of vesicles, **herpes iris.** The fusion of circular patches often produces gyrate or festooned configurations, **erythema gyratum et figuratum. Erythema papulosum,** characterized by discrete or aggregated, reddish or violaceous maculopapules or papules, is the commonest expression of the disease. **Erythema vesiculosum** and **erythema bullosum** are characterized respectively by vesicles and blebs.

The eruption comes out in crops, and lasts from 1 to 4 weeks. In some cases there is a distinct tendency to recurrence.

Etiology.—The disease occurs most frequently in youth and adolescence. Meteorologic conditions, particularly humidity, are looked upon as causative. Most cases are observed in spring and autumn. Duhring looks upon erythema multiforme as a general disease of infectious or nervous origin, and considers the skin manifestations merely conspicuous symptoms. Upon this point there is considerable divergence of opinion.

Pathology.—There is dilatation of the papillary and subpapillary blood-vessels, with serous and sometimes moderate cellular exudation into the tissues. The affection is an angioneurosis.

Diagnosis.—The distinguishing features of this disease are the distribution, peculiar coloration, and multiformity of the lesions, the acute course, the spontaneous involution of the eruption, and the associated general symptoms.

Prognosis is favorable. The tendency of some cases to recur should be remembered.

Treatment.—Quinin is recommended in idiopathic cases. Symptomatic eruptions must be treated according to the individual indications. The salines are to be employed when constipation exists.

Locally, soothing lotions, such as the following may be used:

℞.	Carbolic acid,	♏ xxx
	Boric acid,	ʒ j
	Glycerin,	ʒ ij
	Water,	ʒ vj.

ERYTHEMA NODOSUM (**Dermatitis contusiformis**).—An acute inflammatory disease of the skin, characterized by the formation of roundish or oval node-like swellings.

Symptoms.—The disease is usually ushered in with fever, articular pains, malaise, and coated tongue. Soon roundish or oval node-like swellings, varying in size from a hazelnut to an egg, develop over the region of the tibia. In some cases the forearms, trunk, and face are involved. The nodes are rosy-red in color, tense and shining like erysipelas, and exquisitely tender to the touch. At first hard, they later soften, but never suppurate. Their duration is from a week to 10 days, during which time they undergo all the color gradations observed in common contusions. In number they vary from about 5 to 20. Erythema nodosum is frequently associated with other forms of erythema multiforme.

Etiology.—The affection is one of childhood and adolescence. It is distinctly rare after the age of 20. It occurs twice as frequently in girls as in boys. Rheumatism, gastrointestinal disorders, and general nutritive disturbances are not infrequently associated with it. The disease is probably closely allied to, and perhaps a form of, erythema multiforme.

Pathology.—The nodes show serous exudation throughout the entire cutis and even the subcutaneous tissue. There are dilatation of the lymph-spaces and some cell-infiltration. Blood-stains from hemorrhages are present.

Diagnosis.—The distribution, tenderness, symmetry, course, and color changes of the lesions enable one to differentiate the affection from bruise, abscess, gumma, and erythema induratum.

Prognosis.—Favorable, recovery ensuing in from 1 to 3 weeks.

Treatment.—Regulation of the bowels by salines. Internally, quinin or salicylate of sodium. Locally, hot lead-water and laudanum, rest, and elevation of the limbs.

ERYTHEMA SIMPLEX (**Stomach Rash**).—A congestive disorder of the skin, characterized by nonelevated, variously sized and shaped patches of redness.

Redness is the essential characteristic of the disease. It may be a bright or a dull red, but always disappears upon pressure. Infiltration and elevation are absent. Mild burning and itching are usually present.

Erythema may be due to external or local causes and to internal causes. When not arising from local causes, it is due to toxemia. Local causes are heat, cold, traumatism, poisons, etc.

Erythema caloricum is due to exposure to extremely high or low temperatures.

Erythema solare (sunburn) is due to exposure to the solar rays.

Erythema traumaticum is due to injury.

Erythema venenatum is due to exposure to poisonous plants.

The internal, or *toxemic*, erythemata are exemplified in the stomach rashes of children, in intestinal autointoxication, after the use of the various antitoxins, drugs, etc.

Treatment.—If the erythema is due to a toxemia it is evident that treatment must be directed toward this condition.

A saline purge will immediately relieve an erythema due to the absorption of ptomains from the intestinal tract.

Stomach rashes in children will nearly always succumb to fractional doses of calomel.

The local treatment consists of the use of dusting-powders and cooling lotions. The following may be employed:

℞. Carbolic acid,		♏ xxx
Boric acid,		ʒ j
Glycerin,		ʒ ij
Water,	q. s.	ʒ vj.

ERYTHRASMA.—A rare disease of the skin, always attacking the axillæ or inguinal regions, or the nates. It forms reddish or brownish, sharply defined, slightly raised, desquamating patches, that cause no itching or inconvenience. It is due to the microorganism, microsporon minutissimum, and is readily curable.

ERYTHREMIA.—A rare disease characterized by an increase in the number of red blood corpuscles, enlargement of the spleen and cyanosis.

Synonyms.—Vaquez's disease; Osler's disease.

Etiology.—The cause is unknown; probably it is due to hyperactivity of the erythroblastic tissue of the bone marrow.

Symptoms.—There is an enormous increase in the number of red blood corpuscles, as many as 10 or 12 millions to the cubic millimeter being observed; the hemoglobin is increased, and the leukocytes moderately increased. The spleen is much enlarged; and cyanosis, particularly of the hands and face, is frequently observed. Other symptoms are headache, vertigo, constipation, albuminuria and hemorrhages.

Diagnosis.—This is made by the presence of the polycythemia, enlarged spleen, and cyanosis, and the absence of congenital heart disease.

Prognosis is unfavorable.

Treatment is symptomatic, and uncertain; splenectomy is not advised.

ERYTHROCYTOSIS MEGALOSPLENICA.—A condition or syndrome characterized by polycythemia, cyanosis, splenic enlargement, generally albuminuria, hyperviscosity and rapid coagulation of the blood, and often hepatic enlargement.

ERYTHROL TETRANITRATE.—Tetranitrol. A vasodilator and antispasmodic similar in action to nitroglycerin, but slower and more prolonged. It is claimed to be especially valuable in preventing attacks of angina pectoris. Dose, 1/2 to 2 grains.

ERYTHROMELALGIA (Red Neuralgia; Terminal Neuritis).—A variety of chronic dermatalgia characterized by burning and then aching pain of a part, usually of one or more extremities, intensified by warmth and by the dependent position, and accompanied by flushing and local fever.

ERYTHROXYLON (Coca; Cuca).—The leaves of *E. coca*, a shrub indigenous to the Andes. (Not to be confounded with *cocoa*.) It contains an alkaloid, Cocain (*q. v.*), to which its properties are mainly due. It is an aromatic tonic and cerebral stimulant, its use developing a remarkable power of enduring hunger and fatigue. Large doses cause hallucinations. Its effects are similar to those of coffee, but are more intense. It is used by the Indians of South America for sustenance during long journeys. The leaves, smoked, are beneficial in hay-fever. **Fluidextractum C.**, dose 10 to 60 minims. **Vinum C.**, dose 1 to 8 drams. Elixirs, wines, pastes, etc., of coca are numerous.

ESCHAROTICS.—See Caustics.

ESERIN.—A poisonous alkaloid derived from Physostigma (*q. v.*). It occurs as colorless, slightly pink crystals. It is sparingly soluble in water, but readily so in alcohol and in dilute acids. Dose, 1/100 to 1/50 of a grain. Eserin is used locally in many affections of the eye, such as glaucoma, failure of accommodation, ciliary paralysis, and suppurative keratitis without iritis. It is recommended in abdominal distention and tympanites in typhoid fever and after operations, but its action is uncertain. The sulphate is generally employed.

Eserin causes contraction of the pupil and spasm of the ciliary muscle by its property of stimulating unstriped muscular fibers. It temporarily diminishes the mydriasis resulting from pathologic or experimental paralysis of the third nerve, and increases the miosis due to paralysis of the sympathetic. Its effects are more temporary than those of the stronger mydriatics, and when the latter are overcome by its use, they subsequently reassert themselves. In *complete* ciliary paralysis by atropin, and in the mydriasis induced by hyoscin, eserin has no effect. Eserin begins to contract the pupil and to cause accommodative spasm in about 5 minutes, and reaches its maximum effect in from 20 to 45 minutes. Its effect on the accommodation lasts only a few hours; in the pupil rather longer—sometimes several days. In strong solutions it causes pain in the eye and head, ciliary congestion, twitching of the orbicularis muscle, and occasionally spasm of the external muscles; if constitutional effects have been induced, giddiness and faintness are added to these symptoms. The sulphate is the form most in use. Its solution becomes red after standing for a time and loses some of its efficacy. The salicylate is said to be more permanent. It is usually prescribed in solutions of from 1/10 of a grain to 1 grain to the ounce. For continued use even weaker solutions are sometimes preferred, but when a rapid and decided effect is sought, 2 to 4 grains may be needed. The susceptibility to its unpleasant effects varies greatly in different individuals.

Pflüger states that eserin increases the intraocular tension of a normal eye; but that it diminishes tension in the early stages of glaucoma is universally admitted. It is not to be compared in this respect to iridectomy or sclerotomy, and has little

effect in advanced stages of the disease when the paralyzed muscular fibers of the iris fail to respond to it; but will sometimes check the commencement of an acute attack, and should always be used when, for any reason, an operation must be avoided or postponed. When it fails to contract the pupil, it may do harm by increasing the flow of blood to the iris and inducing irritating spasm of the ciliary muscles. Some authors have advised against its use in the hemorrhagic form of glaucoma. It is often used after cataract extraction, particularly without iridectomy, to withdraw the iris from the wound, and for the same purpose is indicated in peripheral perforation of the cornea from ulceration or puncture.

ESOPHAGOTOMY.—Esophagotomy has been successfully performed for the removal of foreign bodies lodged in the esophagus and for morbid growths attached to this organ, to establish a passage for food below a malignant growth obstructing the tube, and for the relief of stricture of the esophagus.

The operation is indicated especially for the removal of impacted foreign bodies that cannot be removed with esophageal forceps, hook, snare, or bristle probang; and in about 80 percent of suitable cases it will prove successful; whereas, without such interference most of these cases would result fatally by sepsis or ulceration of adjoining parts.

Among the foreign bodies that often become lodged in the esophagus are tooth-plates, coins, tin whistles, fish bones, buttons, and pins, the tooth-plate being most frequent. They usually lodge where the lumen of the esophagus is smallest, at about the level of the cricoid cartilage, but they may become fixed at any point along the canal. The diagnosis of foreign bodies in this organ, though frequently easy, is often only made with great difficulty and after a long and harmful delay. The foreign body can sometimes be reached by the examining finger, especially in children. If not discovered in this way, a long curved probe or, better, an esophageal bougie, may be employed to locate it. The laryngoscope should be employed in the examination when possible, for it may furnish a view of the object, and thus avoid severer measures. Esophagoscopes have been devised, but have not come into general use; indeed, they have not yielded results of much value. Kerstein's modified autoscope promises to be especially useful in young children when laryngoscopy is impracticable. The X-ray apparatus has on several occasions been serviceable in locating the foreign body.

The symptoms indicating the need of operation depend chiefly upon the size and shape of the foreign body. A large object may cause speedy death from its pressure upon the larynx or from spasm of the glottis. An angular and irregular object may usually be felt externally, and bodies of any considerable size may produce dysphagia or complete obstruction. Tenderness in the side of the neck, soreness behind the sternum, dyspnea, cough, and a constant discharge of mucus and saliva are common symptoms. Later, if the obstruction continue, infection is likely to take place, leading to ulceration, with loosening and expulsion of the foreign body, or more frequently, to extensive inflammation of the surrounding tissues. Abscesses thus formed may extend along the deep fascia to the pleura or pericardium, or ulceration of the adjacent blood-vessels may lead to speedy death. The foreign body may work its way by ulcerative process into the trachea, from which it may be expelled by cough or through which it may reach the glottis and cause clonic spasm and death. In many cases, especially of fish bones and pins, the sensation of the presence of the foreign body remains a long time after its dislodgement. When a positive diagnosis has been made and simpler means have failed to dislodge the object, esophagotomy should be performed; for although foreign bodies have been successfully removed by this operation as long as two years after their impaction, the danger attending their prolonged retention is very great.

Anatomy.—The esophagus is in relation in front with the trachea, the thoracic duct, the thyroid gland, and the recurrent laryngeal nerve, the latter running in a groove between the esophagus and trachea. Behind, it rests on the vertebral column and the longus colli muscle. On each side —especially on the left, as it inclines to that side— it is in close relation with the sheath of the great vessels and part of the lateral lobes of the thyroid gland.

Operation.—Unless there is some special contraindication—as, for instance, the projection of a foreign body plainly upon the right side—the incision is to be made on the left side of the neck, along the anterior border of the sternomastoid muscle, from a point opposite the thyroid cartilage to within an inch of the sternoclavicular articulation. The larynx and trachea are thus upon the inner side of the incision, and the great vessels on the outer. The superficial structures are divided, the deep fascia is slit up on a director, and the sternomastoid is retracted, so as to expose to view the sheath of the great vessels, which should be protected by blunt retractors. With blunt-pointed instruments the dissection is carried between this sheath and the trachea, the thyroid gland being crowded aside and great care being taken to avoid injuring the arteries and veins and the recurrent laryngeal nerve, running in its groove between the esophagus and trachea.

The upper two inches of the esophagus is thus exposed. If the omohyoid muscle cannot be retracted, it may be divided. If on retracting the trachea from the carotid sheath a good view of the esophagus is not obtained, the sternohyoid and sternothyroid muscles may be divided. The foreign body may make the esophagus prominent, but if not, a sound, an olive-tipped bougie, or the esophageal forceps may be passed through the mouth, and made to project in the wound. A longitudinal incision is now to be made over the point thus indicated, keeping as much to the side as possible, so as to avoid the position of the recurrent laryngeal nerve. If the exact position of the foreign body cannot be determined at once, small, curved needles, armed with silk, may be passed through the edges of the esophageal wound. An assistant can hold the wound open by drawing on

these threads, and thus expose the esophagus to free inspection and instrumentation. The location and size of the foreign body having been ascertained, the incision may be enlarged to the required size, and the offending body extracted with suitable forceps.

It is now necessary to decide whether to close the wound or allow it to heal by granulation. If the impaction is recent, the tissues not being bruised or inflamed, the esophageal wound may be closed with catgut, the sutures being placed in the muscular coats only. The external wound may be closed in the usual way. When conditions obtain that are likely to prevent union by primary intention, it is best to leave the whole wound open, save for a few stitches in the integument. Suitable drainage should be established and a large antiseptic dressing applied.

Some operators feed the patient through a stomach-tube for the first few days; but greater success has attended those cases in which the only food given consisted of nutrient enemata. These should be relied upon for at least 72 hours. After this, liquids may be taken by the mouth. The wound is usually completely closed in from 2 to 4 weeks. A fistulous opening sometimes persists for a long time, but in most cases it finally closes without further operation.

Esophagotomy for the cure of membranous stricture of the tube has been successfully performed by Dr. Christian Fenger. An oblique membranous diaphragm having a small perforation was found and excised. The mucosa of the lower part was stitched to that of the upper part, and the wound in the esophagus closed by a double row of sutures over a flexible tube passed through the right nostril. The external wound was drained.

Esophagotomy in cases of malignant growths may be justifiable for the purpose of prolonging life, but it yields no more brilliant results than do operations for malignant tumors elsewhere, and for nourishing the patient gastrotomy is preferable. See Neck (Injuries).

ESOPHAGUS, DIVERTICULA.—Diverticula occasionally are present in the neck and communicate with the esophagus or pharynx. When these are large, food passes into them and serious symptoms, even death, may result. The condition is often unrecognized by the physician. In serious cases operation is demanded. Sometimes good results are obtained by having the patient swallow a whip cord and, using this as a guide, passing bougies in a manner analogous to the passage of Gouley's tunnelled sounds over a whalebone filiform in urethral stricture (Mixter).

Operation.—The first steps are those of an esophagotomy. The trachea is retracted toward the right, the sternomastoid and the sheath containing the carotid, internal jugular, and vagus to the left. An esophageal bougie is passed if possible, through the mouth into the diverticulum, in order that the diverticulum and its relations to surrounding structures may be appreciated. Then the bougie is removed. The diverticulum is separated from its surroundings by blunt dissection. Where the diverticulum joins the esophagus its neck may be as thick as a man's thumb. At this junction it is divided layer by layer. The wound of the mucous membrane is sutured with catgut. The wound of the outer tunics of the neck of the diverticulum is closed by an invaginating suture like Lembert's intestinal stitch. The external wound is partially closed, free drainage being provided by means of iodoform gauze. The after-treatment is that of esophagotomy. When the diverticulum is comparatively small, the skin-incision need not be longer than that for esophagotomy. It is, however, better to make an incision longer than necessary than to be cramped, while operating, through lack of room.

ESOPHAGUS, INJURIES.—The esophagus may be wounded from the outside in cases of cut-throat, or from the inside by corrosive fluids or sharp-pointed foreign bodies. In rare instances rupture has taken place during vomiting, but probably only when the walls have been weakened beforehand by inflammation or fatty degeneration.

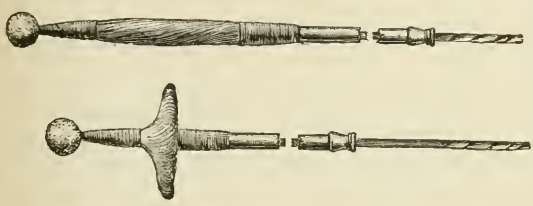
Swallowing corrosive fluids is nearly always done with suicidal intent, the liquid (usually a mineral acid or a very strong alkali) being thrown quite to the back of the pharynx, so that the lips, mouth, and tongue are often not touched. The immediate effect is profound collapse, with intense burning pain, followed by vomiting of mucus, blood, and sloughing shreds of epithelium, mixed with the contents of the stomach. If the result is not immediately fatal from perforation or collapse, the severity of the symptoms gradually subsides; there is less blood and more mucus and pus in the fluid that is brought up; the pain becomes less severe; the swelling and thickening around the esophagus diminish, and the febrile symptoms abate. Swallowing, however, causes very great pain, and if more than the epithelial surface has been destroyed, it rapidly becomes more and more difficult, until at length a traumatic stricture is established. The wall of the esophagus contracts spasmodically on the irritant before it is vomited back, and thus it may happen that the whole of the tube, from the cricoid almost down to the cardiac orifice, will be more or less eaten away. In cases of long standing the walls become enormously thickened from inflammatory deposit and fused with the structures around. The interior is rough and irregular, marked by sloughs and cicatrices in all directions, and here and there the cavity may be completely obliterated. Great emaciation follows.

Foreign Bodies in the Pharynx and Esophagus.—False teeth, pieces of unmasticated food, coins, fish bones, pins, and the like, are not uncommonly impacted in the esophagus, generally where it is narrowest—at the level of the cricoid cartilage—but sometimes immediately behind the arch of the aorta or the left bronchus.

The symptoms depend chiefly upon the size and shape of the foreign body. If it is large and smooth instant death may occur from pressure upon the aperture of the larynx, or from the spasm of the glottis; if pointed and irregular, there may be dysphagia or complete obstruction. Tenderness

in the side of the neck, soreness behind the sternum, dyspnea, and a constant discharge of saliva and mucus are often present. Later, if the case remains untreated, inflammation sets in. Sometimes this leads to spontaneous expulsion, as the foreign body becomes loosened; more frequently it makes matters worse by extending into the tissue around. Abscesses may form under the deep cervical fascia and spread into the pleura or pericardium. The walls of the carotid, and even of the aorta itself, may give way. The foreign body may ulcerate through into the trachea and be coughed up, or it may be driven into the pericardium and even into the substance of the heart. When the foreign body is a large one, there is seldom any difficulty in the diagnosis. The finger can explore the whole of the upper part of the pharynx, from the level of the soft palate down to the back of the arytenoid cartilages, and in children even lower, and the mucous membrane may be thoroughly inspected by means of a laryngoscopic mirror; but when the foreign body is situated below this, and is of small size—a fish bone, for example—its presence is often only a matter of inference. In many cases the sensation and soreness persist only after the offending substance has been dislodged.

Treatment.—A foreign body must, if possible, be extracted through the mouth; if this cannot be done, it may be pushed on into the stomach, removed through a side opening, or left to itself,



Horsehair Probang, Expanded and Unexpanded.

according to its nature and situation. Sometimes it is ejected during the retching and vomiting that accompany exploration of the fauces, but emetics should never be given for the purpose. The esophagus has been ruptured by violent vomiting. Long-handled, curved forceps, such as are used for extracting foreign bodies from the larynx, are the most useful, especially if such are small and rough. Pins and fish bones may be caught by an expanding or umbrella probang, but care must be taken not to drive them further in; they may easily be forced into the carotid or pericardium. If smooth and firm and low down, the obstructing body may sometimes be pushed onward, especially as, after a few hours, it becomes coated over with mucus; and in the case of meat it has been proposed to soften the surface by means of dilute acids. Irregular structures, such as false teeth, may be seized by what is known as a coin-catcher—a blunt, flat hook attached to a probang by a thin strip of steel, so that it may glide past an obstacle, and then catch against it as it is withdrawn—and considerable force may be used. If this fails, and if the foreign body is impacted in an accessible part of the esophagus, it must be removed by Esophagotomy (*q. v.*).

For other **wounds of the esophagus** see Neck (injuries).

ESOPHAGUS, STRICTURE.—Organic stricture may be congenital or acquired. The former is exceedingly rare; the latter, which is common, may be simple or malignant. Simple stricture nearly always arises from the swallowing of corrosive fluids. The mucous membrane sloughs, and cicatricial contraction follows. Sometimes almost the whole length is obliterated in this way, but the effect is always greatest at the commencement. In very rare instances it may arise from some form of specific inflammation, such as tubercle or syphilis. Malignant stricture is always the result of squamous epithelioma, and is usually annular, the muscular coat above being considerably hypertrophied.

Symptoms and Diagnosis.—Pain and difficulty in swallowing are the prominent symptoms. The diagnosis can only be made certain by the passage of a bougie; but as dysphagia occurs in other affections in which a proceeding of this kind is not unattended by danger, an attempt must always be made to exclude them first.

Muscular spasm or **paralysis** may simulate true stricture. There may even be a history of some foreign body swallowed; but it is never the kind that causes traumatic stricture. Nor is there really any likelihood of mistaking spasmodic contraction for malignant disease, for while the latter rarely occurs except in men, and never under the age of forty, the former is almost confined to young women, and is always marked by the peculiar incongruity of its symptoms. In diphtheritic paralysis, which is very rare, the food usually passes slowly down for some time before it stops, and solids are swallowed more easily than liquids.

Compression of the Esophagus.—Dysphagia arising from this condition is exceedingly common, and although the cause is usually sufficiently evident, this is not always the case. Aneurysms of the aorta; tumors of all kinds growing from the vertebræ, lymphatic glands, cellular tissue, or other structures near the esophagus; enlarged or accessory thyroids; gummata (especially retropharyngeal); abscesses, connected with the vertebræ or not, and other conditions, may give rise to it. Aneurysms have been ruptured by the passage of a bougie, and without an excessive amount of force having been used.

In a few cases **dysphagia** has been traced to the presence of a pharyngocele dragging the orifice of the esophagus out of its true axis.

Practically, unless there is a very clear history of a gumma or of tuberculous disease, a stricture that develops after the age of 40 without injury is malignant.

If the presence of an external tumor pressing upon the esophagus is negatived, a bougie must be passed, not only to verify the existence of a stricture, but to ascertain its locality, and, perhaps, its diameter. The patient should be seated on a straight-backed chair and the head supported by an assistant—forward rather than upward, in order

to straighten the cervical spine; if it is thrown back, the bougie strikes against the bodies of the vertebræ. A medium-sized gum-elastic instrument (equal to No. 24 or No. 27 catheter on the French scale) should be chosen to begin with, warmed by dipping in hot water, and well lubricated with glycerin. The point should be bent a little downward. The operator then, standing in front of the patient, runs the forefinger of the left hand over the tongue, and guides the bougie, which is held in the right, over the base to the back of the throat. If protected in this way, it cannot pass up into the nasopharynx or enter the larynx. A certain amount of spasm nearly always follows contact with the mucous membrane, and when it comes near the cricoid, it is not infrequently gripped tightly, and then forcibly ejected by retching, or suddenly pulled out by the patient. To some extent this can be prevented by a cocain spray, or by brushing the surface of the mucous membrane with a 2 percent solution, but it can nearly always be overcome by patience. No force must be used under any circumstances. If the end is definitely arrested, but not gripped, the bougie must be withdrawn and a smaller one selected; in some cases only a catgut will pass. Measured on a bougie, the cricoid cartilage is approximately 7 inches from the teeth, the left bronchus 11, and the opening in the diaphragm 15 (Moullin).

Other methods of examining the esophagus are of very little value. Auscultation (the stethoscope being placed by the side of the spine while the patient drinks some water) may be tried, but it rarely gives any indication that can be interpreted. The condition of the lungs, especially the amount of bronchial irritation caused by the passage of a bougie, and the state of the cervical glands, whether enlarged or not, are very important factors in the prognosis.

The treatment of stricture of the esophagus depends upon the cause, whether it is traumatic or malignant. In the former case the walls are usually very much thickened (although it may be a long time before the sloughing in the interior ceases), the patient is often young, and there is no danger but that of starvation; but, if the patient lives sufficiently long, ulceration always gains the upper hand and causes perforation, and even if starvation and pneumonia are successfully prevented, the result must inevitably prove fatal within a few months from the malignant cachexia.

Traumatic Stricture.—In any case in which the interior of the esophagus has been seriously injured, contraction must be prevented by the use of bougies. At first they must be passed every day; then, if the tendency to contract is not very marked, at gradually increasing intervals; but, as it may be necessary to make use of them for the rest of his life, the patient should learn as soon as possible how to pass them himself. The food must, of course, be always suitably prepared.

In old cases in which the stricture has been allowed to contract, the difficulty is very much greater. Gradual dilatation is the most successful method, using slightly conic instruments. It may be necessary to begin with catgut, if the constriction is very narrow, leaving it in place for 24 hours, or making use of it as a guide on which a fine rubber tube can be slipped down; the patient can always swallow liquids by the side of it. Internal Esophagotomy (*q. v.*) (division of the stricture from within) is a very dangerous operation, and, as the stricture must be a permeable one to allow of its being done, can very seldom be advised. In exceptional instances an artificial opening has been made in the neck below the stricture (esophagostomy), and the stomach has been opened and the stricture dilated through the cardiac orifice. Practically, if dilatation fails, **gastrostomy** (see Stomach (Surgery) must be performed. The results, compared with those of the same operation for malignant disease, show a far higher percentage of success, but it is not probable that all the unsuccessful cases have been published.

Malignant Stricture.—Excision of the growth has been practised with success, an artificial opening into the esophagus being left at the root of the neck; but cases in which such a proceeding is possible are infrequent. As a rule, all that can be done is to make an artificial opening below the stricture, either in the esophagus or stomach, or to maintain the patency of the canal by means of tubes or bougies.

ESSENCES.—See Spirits.

ESSENTIAL OILS.—The essential or volatile oils (*attars*) are found extensively distributed throughout the vegetable kingdom. They occur in almost all parts of the plants except the cotyledons of the seeds. They impart the peculiar and characteristic odors to the plants, furnish the perfumes, spices, and aromatics, and many of them possess valuable medicinal properties. Chemically, essential oils are subdivided into the following classes:

(1) *Hydrocarbon oils* (or *terpenes*), consist of C and H, most of them having the formula $C_{10}H_{16}$ and are therefore isomeric with rectified oil of turpentine, which is the type of this class. (2) *Oxygenated oils*, contain C, H and O, are highly aromatic and usually consist of a terpene mixed with an oxygenated principle (an acid, an aldehyde, etc.). The oils of cinnamon and peppermint are examples of this class. (3) *Sulphuretted oils* contain sulphur in addition to their other elementary constituents, and are pungent and disagreeable in odor and taste; as the oils of garlic and mustard. In the latter case the oil is formed by the reaction of the constituent principles in the presence of water and does not preëxist in the plant. (4) *Nitrogenous oils*, contain N, as the compound cyanogen, CN, in the form of hydrocyanic acid, which is formed only after maceration with water. Examples are the oils of bitter almond, peach-kernels, etc.

ESTHIOMENE.—Lupus exedens; lupus of the vulva. A very rare and chronic disease, commencing during the menstrual period. It is a form of ulceration accompanied by fibrous overgrowths of the surrounding and adjacent tissues. It produces hard, cicatricial tissue on healing. There is a process of imperceptible disintegration of the tissues, but no sloughing. Death may result from hemorrhage or perforation into the peritoneal cavity or bladder.

ETHER.—A thin, colorless, volatile, and highly inflammable liquid; in composition a diethylic oxid

$(C_2H_5)_2O$, known also as ethylic ether. It is obtained by the action of sulphuric acid on alcohol, and is of strong characteristic odor. It is freely soluble in alcohol, water and chloroform. Official preparations contain about 4 percent of alcohol. It is used mainly as a solvent for fats and oils, and as an anesthetic. Internally it is anodyne, antispasmodic, diaphoretic, and narcotic. Inhaled it is an anesthetic and a cardiac stimulant; in toxic doses, it paralyzes the respiratory centers and depresses the circulation. Used habitually it produces effects similar to those of chronic alcoholism.

Therapeutics.—Its anesthetic use is discussed under ANESTHESIA and ANESTHETICS (General) (*q. v.*).

When used internally, ether is best given in capsules or in ice-cold water. If cold water is not used, the evaporation as it passes the fauces will cause such irritation as to prevent deglutition. It may be given in 20-drop doses with cod-liver oil, taken at the time discomfort usually appears. It is of service in hiccup, colic and flatulence, especially that of children, and is best given in the form of compound spirit of ether (**Hoffmann's anodyne**). It produces local anesthesia by evaporation, and is used in paracentesis or thoracentesis, in opening abscesses, etc. The local effect is also used to ease the pains of neuralgia. The contraction caused by the local application of ether is utilized in reducing hernia.

The sweet spirit of niter, or spirit of nitrous ether, is an alcoholic solution of ethyl nitrite containing 4 percent of crude ether. It should not be kept long, as it turns acid with age. It is an ingredient of the compound mixture of glycyrrhiza. The dose for an adult is from 20 drops to 1 dram, and for a child of 1 year, 5 to 10 drops. As inferior preparations are usually sold in shops, a ready means of detection is given in the addition of a grain or two of antipyrin to 1/2 of an ounce or less of the spirit. If ethyl nitrite is present, a purple color will appear, immediately followed by a green precipitate, which is not at all poisonous.

Sweet spirit of niter is very extensively used by the laity. It is a sedative to the circulation and to the nervous system, and, according to the mode of administration, it is a diaphoretic or diuretic. The diuretic action is best obtained by using the drug in cold water, and by keeping the patient lightly covered and cool. The diaphoretic action is best obtained by giving warm drinks, such as hot lemonade, with the niter, and keeping the patient well wrapped. It is very useful as a diaphoretic in the treatment of acute colds in adults and in children. In incontinence of urine in children it is of service when followed by belladonna or combined with potassium citrate. It is beneficial in the nervous excitement of fevers and in states of irritation in infancy, when it is a distinct antispasmodic. It is a valuable vasodilator.

In incontinence of urine the following is useful:

℞.	Potassium citrate,	ʒ j to ij
	Spirit of nitrous ether,	ʒ ss
	Water, enough to make	ʒ iv.

Give a dessertspoonful every 5 hours until urine becomes clear.

Preparations.—**E., Commercial,** contains 94 percent of ether. It is unfit for use except as a solvent. **Oleum Æthereum,** ethereal oil, contains equal parts of ether and heavy oil of wine. **E., Spt. of,** ether 32.5 and alcohol 67.5. **E., Comp. Spt. of,** Hoffmann's anodyne. Ether 32.5, alcohol 65, ethereal oil 2.5 percent. Dose, 5 minims to 2 drams. **E., Spirit of Nitrous,** *sweet spirit of niter,* a solution of ethyl nitrite in alcohol. Dose, 10 minims to 2 drams.

ETHMOIDAL SINUS, DISEASE OF.—See NOSE (Accessory Sinuses).

ETHYL ACETATE.—Acetic ether. Combined with other carminatives, it is used as an antispasmodic and stimulant. Dose, 10 to 30 minims.

ETHYL BROMID.—Ethyl bromid had a short period of popularity as an anesthetic, but fell into disrepute after a few cases of death under its influence, which were probably not due to the agent used. Its action is less prolonged than that of ether, but it has many advantages, being noninflammable, acting rapidly in small quantity, and being comparatively free from ill effects. It may be used as a primary inhalation before the use of ether, a method of inducing anesthesia which has given good results in many cases, being free from bronchial irritation, requiring less ether to maintain the effect than when ether is given alone, having less intoxication and muscular excitement, less tendency to vomiting, and a more rapid return to consciousness. It is considered an excellent anesthetic in obstetrics and gynecology; its inhalation has proved useful in hysteria, epilepsy, chorea and other spasmodic disorders; and it has been employed subcutaneously in place of ether in the treatment of spasmodic affections such as whooping-cough and chorea.

ETHYL CARBAMATE.—See URETHANE.

ETHYL CHLORID.—Monochlor-ethane, kelene. A colorless, highly volatile fluid, of strong ethereal odor. It is usually kept in glass tubes drawn to a point, which is broken off and the chlorid expelled as a spray by the heat of the hand. The evaporation from the spray produces intense cold, the part becoming first red, and finally white, when complete anesthesia is present. It is a safe local anesthetic for minor operations, and used as a preliminary inhalation to ether or chloroform prevents the stage of excitement of the latter.

ETHYL IODID.—Hydriodic ether. It is used to relieve the dyspnea of bronchitic asthma and edematous laryngitis. The dose is 5 to 20 minims, to be inhaled 3 or 4 times daily. It is of service in chronic bronchitis, complicated with emphysema, and in catarrhal affections of the bronchi; it is an alterative.

EUCAIN.—A local anesthetic, the salt of which is Beta-eucain hydrochlorid; it is soluble in water and not decomposed when boiled. The solution does not precipitate, and phenol or salicylic acid need not be added to preserve it. It is painted on mucous membranes or injected into the area to be operated upon. Its area of anesthesia is more extensive than that of cocain, it lasts longer, and the heart is not influenced by it; 30 grains may be injected without risk. Solutions of 15 percent

strength are permanent, and do not become flocculent. Solutions of from 2 to 5 percent, instilled into the eye, will anesthetize in from 1 to 3 minutes. Eucain causes no ischemia, and anesthesia in the eye lasts from 8 to 12 minutes. A 2 percent solution is usually employed, but 2 drams of a 5 percent solution have given no symptoms of poisoning. Anesthesia is usually complete in from 3 to 5 minutes, and the duration has varied from 20 to 60 minutes. Hemorrhage is more abundant when eucain is employed than when cocain is used, and the injection is more painful than that of cocain. Eucain should not be used in the urethra more than once daily. Eucain has been used with the best results in the nose and throat. **Beta-eucain lactate** has the same action and is more soluble. See also Intraspinal Anesthesia.

EUCALYPTOL.—$C_{10}H_{18}O$. An antiseptic camphor prepared from the essential oil derived from the distillation of the leaves of *Eucalyptus globulus* and other species of the genus. The dose is from 3 to 10 minims in capsule. Eucalyptol is used for the same purposes as the oil of eucalyptus, and is the refined product of the latter. In malarial fever, when quinin cannot be borne, in bronchitis and in subacute forms of gonorrhea, in emulsion or in capsule, it is serviceable.

℞. Eucalyptol,
Oil of sweet orange, } each 5 j.

Place in 20 capsules. Give 1 three times daily, after meals.

The drug is largely used by rhinologists in lotions and in nasal applications. It is insoluble in water, but soluble in alcohol and ether, and is used in solutions of the fatty oils.

EUCALYPTUS.—The leaves (lanceolate, after 3 years' growth) of *E. globulus*, or blue-gum, native to Australia, but now cultivated in California. It contains a volatile oil that yields *eucalyptol*, a camphor, by distillation. It is an aromatic bitter, promoting digestion. It is highly antiseptic and antimalarial, and is valuable in atonic dyspepsia and in intermittent fevers. **E., Fluidextract.** Dose, 10 minims to 1 dram. **E., Ol.**, the volatile oil. Dose, 5 to 20 minims, in capsules or emulsion.

EUCHININ (Euquinin).—An antimalarial, antispasmodic and antineuralgic, used as a substitute for quinin; it is produced by the action of ethyl-chlorocarbonate on quinin. It is said to cause no gastric disturbance, to produce cinchonism less often and less intensely than quinin sulphate, though it is equally efficient. Dose, 5 to 20 grains. Recent observers claim better effects from small doses (1 to 3 grains) than from the large doses recommended by von Noorden. See Quinin.

EUDOXIN.—Bismuth tetraiodophenol phthalein. It is an insoluble, odorless, tasteless powder, reddish brown in color, containing 52.9 percent of iodin and 14.5 percent of bismuth. It has been used in intestinal inflammations. Dose, 3 to 8 grains, t. i. d.

EUGALLOL.—An active substitute for pyrogallol. It is said to be useful in lupus and psoriasis. If irritation result, the treatment should be discontinued for a few days. Dose, one application daily, the painted part being then covered with powdered zinc oxid.

EUGENOL.—See Cloves.

EUMYDRIN.—Methylatropin nitrate. A mydriatic intermediate between atropin and homatropin in its effects; and an antihydrotic. It is recommended in night sweats, enuresis and whooping-cough. Dose, 1/60 to 1/24 grain; as mydriatic, a solution 1/10 stronger than the usual atropin solution.

EUONYMUS.—Wahoo. The bark of *E. atropurpurea* is an astringent tonic and purgative, resembling rhubarb, jalap, aloes, etc., but rather milder. It is beneficially employed in dropsy and hepatic affections. **E., Ext.** Dose, 1 to 5 grains. **E., Fluidextract.** Dose, 5 to 15 minims. **Euonymin** is tonic, laxative, and expectorant. Dose, 1/2 to 5 grains.

EUPATORIUM.—The leaves and flowering-tops of *E. perfoliatum*, thoroughwort, or boneset. It is a bitter tonic, diaphoretic, aperient, and emetic, of value in remittent and typhoid fevers, and believed, also, to be a teniafuge. **E., Fluidextract.** Dose, 10 minims to 1 dram. *E. purpureum*, trumpet-weed, another American species has similar qualities, but is more markedly diuretic.

EUPHORIN.—Phenylurethane, derived from anilin. A white, crystalline powder, nearly insoluble in water, soluble in weak alcohol. It is an antipyretic in doses of from 2 to 8 grains. It may be used as an antiseptic dusting powder for ulcers and skin diseases.

EUPHTHALMIN.—The hydrochlorid of the mandelic acid derivative of Eucaine-B, is a brief and efficient mydriatic, but not an anesthetic. Two drops of a 5 percent solution cause maximal dilatation of the pupil in 35 minutes, without any raise of tension or appreciable effect on accommodation, the patient being able to read as usual. The effect passes off in 2 to 4 hours. It is the most satisfactory mydriatic for ophthalmoscopy, being safe in glaucomatous cases, and of rapid and short action.

EUPYRIN.—A compound of para-phenetidin with vanillin ethyl-carbonate. The toxic action of phenetidin is said to be counteracted in eupyrin by the vanillin. It is claimed to be a stimulant antipyretic. Dose, 20 grains once or twice daily.

EUQUININ.—See Euchinin.

EURESOL.—Resorcin monacetate. Its action is similar to that of resorcinol, but milder and more lasting because of the gradual liberation of the phenol. Euresol is recommended in acne, sycosis, seborrhea, and particularly in the treatment of chilblains. It is applied in 5 to 20 percent ointments and in acetone solution.

EUROPHEN.—A preparation of iodin recommended as a substitute for iodoform. It occurs as a fine, amorphous, yellow powder, with an odor like that of saffron. It contains about 27 percent of iodin. It is insoluble in water and in glycerin, but soluble in alcohol, ether, chloroform, and fatty oils. Heat and starch readily decompose it and light does so slowly. It is 5 times more bulky than iodoform. It is a valuable antiseptic, antisyphilitic, and antituberculotic. It is used freely as a powder or combined with lanolin as a base to make an ointment of 5 to 10 percent strength. It must not be combined with metallic oxids or mercurials or with zinc starch paste. In skin-

diseases a 5 to 10 percent ointment is employed. A 3 to 10 percent solution in olive oil is employed hypodermically.

EUSTACHIAN CATHETER.—See EAR (Examination).

EUSTACHIAN TUBE.—See EAR (Diseases).

EVIDENCE, EXPERT.—See EXPERT TESTIMONY.

EVISCERATION.—1. The removal of the abdominal viscera. See ABDOMEN, INTESTINES, etc. 2. The removal of the viscera of a fetus. See EMBRYOTOMY. 3. Removal of the contents of the eyeball. See EYEBALL (Removal).

EXALGIN.—Methylacetanilid. A crystalline compound allied to acetanilid. It is a valuable analgesic. It is readily soluble in dilute alcohol, less so in warm water, and with difficulty in cold water. Dose, 1 to 5 grains, in wine or other dilute alcoholic mixture. Exalgin, 16 grains, alcohol 1/2 of a dram, and water, 1 ounce, form a permanent solution. Exalgin should never be employed as an antipyretic. In severe neuralgia, headache, migraine, chorea and in locomotor ataxia it is very efficient.

℞. Exalgin, gr. xxiv
Brandy, ʒ iij.
Dissolve in a solution and add:
Syrup of orange, } each, ʒ jss.
Water, }

Give a teaspoonful to a dessertspoonful every hour until 4 or 5 doses have been taken.

EXANTHEMS.—The eruptive fevers. They are separately considered under their individual headings.

THE DIFFERENTIAL DIAGNOSIS OF THE EXANTHEMS.

NAME.	PERIOD OF INCUBATION.	STAGE OF INVASION.	TIME OF APPEARANCE OF ERUPTION.	CHARACTER OF ERUPTION.	DURATION OF ERUPTION.	LOCATION.	DESQUAMATION.	DURATION OF DISEASE.	CONVALESCENCE.
Cerebrospinal Meningitis.	Unknown.	Sudden.	2nd to 4th day.	Herpes labialis, purpuric spots, dusky erythema.	.....	Herpes on lips; purpuric spots over entire body.	.....	Variable; many sequels.	Lysis.
Erysipelas....	Few hours to 3 or 4 days.	1 to 3 days.	Within 24 hours.	Efflorescence; bright red: polished; with well-defined, raised margin.	4 to 8 days.	Face.....	Branny or in large flakes.	1 to 3 weeks.	Crisis.
Measles.....	10 to 12 days.	4 days.	4th day.	Papules; small, dark-red, with crescentic borders. Complete in 24 hours.	4 to 5 days.	Face; then downward over body.	Branny; 8 to 11 days.	2 weeks.	Crisis.
Rötheln.....	8 to 17 days.	24 to 48 hours.	Within 48 hours.	Macules; rose-colored; rounded discrete.	3 days.	Face and scalp; then downward over body.	Slightly branny.	4 to 7 weeks.	Crisis.
Scarlatina....	1 to 21 days.	1 to 2 days.	Within 24 hours.	Diffuse; scarlet; punctate.	7 to 10 days.	Neck, chest, face; then over body.	Scales or large flakes. About one week.	2 to 3 weeks.	Lysis.
Typhoid Fever.	5 to 35 days.	6 to 8 days.	7th day.	In crops. Rose-colored, lenticular spots.	Each crop 3 to 5 days. Last 10 to 20 days or throughout course of the fever.	Abdomen, chest, and back.	Slightly branny or none.	3 to 4 weeks.	Lysis.
Typhus Fever.	4 to 12 days.	5 days.	Usually 5th day: may be on 3d or not until 7th day.	Measly spots petechiæ: streaks: color, mulberry-red.	Few days, or may last throughout the course of the disease.	Sides of chest and abdomen; arms; back.	Slightly branny.	2 to 4 weeks.	Crisis.
Varicella.....	4 to 14 days.	1 to 2 days.	Within 12 to 24 hours.	In crops. Vesicles.	5 to 8 days.	Back, chest, arms.	Crusts; 5 to 8 days.	2 weeks.	Lysis.
Variola.....	8 to 14 days.	3 days.	4th day.	Umbilicated pustules.	21 to 25 days.	Face, and over body.	Crusts; 12 to 22 days.	4 to 5 weeks.	Lysis.

EXCISION OF BONES.—In the excision of diseased bones care must be taken that the wound is so situated that no injury will be done to arteries, nerves, muscles, or tendons. In choosing interstices between muscles and tendons only those should be selected that correspond to the borders of nerve distribution. If the preservation of the function of a muscle is desired, its motor nerve must be preserved.

The Upper Extremity

Excision of the Clavicle.—An incision is made along the whole course of the bone, which, being subcutaneous, can be easily reached. In this incision the platysma and supraclavicular nerves are divided. The periosteum should be separated from the bone. The clavicle may then be sawed through in the middle, as this facilitates the removal of each half separately. The parts to be detached from the bone are: *above*, the clavicular attachment of the sternomastoid muscle and the trapezius; *below*, the clavicular portion of the pectoralis major and deltoid; *behind*, the subclavius muscle and the costoclavicular ligament.

Excision of the Scapula.—An incision is to be made from the point at which the acromion must be severed, along the spine of the scapula to its posterior margin, then downward to the angle of the scapula, preserving as much of the acromion as possible, as important muscles—the trapezius and deltoid— are attached to it. If no part of the acromion can be saved, the incision is to be carried into the joint and the triangular flaps, formed by the incisions previously named, dissected back.

The posterior margin of the deltoid should be raised and separated from the spine at the acromion as far as the acromioclavicular articulation, or to the point at which the acromion is divided, and the acromion cut with a chisel. If the articular surface of the scapula can be saved, the muscles should be cut one by one, first raising them on the finger or on an elevator, and then sawing off the articular part of the scapula. If the articular surface cannot be saved, the muscles that are attached to the head of the humerus—viz., the supraspinatus, infraspinatus, and teres minor, from the greater tuberosity, the subscapularis from the lesser tuberosity, as also the latissimus dorsi and teres major—are to be dissected off, preserving the axillary nerves and the posterior circumflex artery at the lower margin of the teres minor, and, further backward the dorsalis scapulæ, which must be ligated. Beginning at the acromion, the trapezius is to be divided on the finger and its separation continued backward along the spine of the scapula, drawing the scapula downward and separating the muscles attached to its upper margin—viz., the omohyoid (here the terminal branch of the transverse scapular artery must be tied), and the levator scapulæ at the posterior superior angle of the bone, where some branches of the dorsalis scapulæ artery may require ligation. The posterior margin of the scapula should next be dealt with, separating the attachment of the serratus magnus. The scapula is now turned over, the rhomboids are divided, and the dorsalis scapulæ artery ligated as it passes along the edge of the bone.

The Ulna.—The ulna lies so near the skin throughout its entire length that its excision requires no special description.

The Radius.—The part of the radius most easily exposed is the middle third of the shaft along its posterior surface between the long and short extensors and the extensors of the fingers. There are no vessels of any importance at this part, and the nerves may be disregarded, as the muscles receive their nerve supply higher up. The head of the radius may be felt posteriorly just below the external condyle of the humerus, and is readily exposed by an incision along the course of the bone.

Metacarpal Bones and Phalanges.—For the metacarpal bones dorsal incisions are required, care being taken to preserve the extensor tendons and the radial and ulnar nerves. For the phalanges bilateral incisions should be employed, otherwise cicatricial contraction may cause deformity.

The Lower Extremity

The Shaft of the Femur.—Along the outer aspect of the bone an incision may be made from the base of the great trochanter to the outer condyle of the femur without fear of dividing vessels, nerves, or muscles of any consequence. If the incision is made above the base of the great trochanter, the terminal branch of the external circumflex artery, as it passes under the vastus externus muscle, will be divided. If the incision is carried beyond the condyle of the femur, another artery will be endangered—viz., the external superior artery of the knee, as it runs transversely around the bone between the posterior margin of the vastus externus and the biceps.

The Patella.—A longitudinal incision over the patella exposes the bone. The periosteum and fascia of the quadriceps are separated by a periosteal elevator, and the bone enucleated from the anterior wall of the capsule. This operation is indicated when the patella alone is diseased, and its early performance will prevent a general inflammation of the knee-joint.

The Tibia is so near the skin that no special directions for its excision are necessary.

The Fibula.—Two structures must be avoided in excision of the fibula—viz., the peroneal nerve, which winds around the neck at the upper extremity of the bone, and the peroneal artery, which passes behind the lower half of the fibula. Avoiding these, the whole bone can be excised by an incision behind the peroneal muscles in their entire length.

EXCISION OF JOINTS.—When joints are hopelessly diseased, or so extensively injured as to threaten the life of the individual and render repair impossible, cutting out the portion of diseased or injured bone is resorted to instead of amputation. It is now well established that in many joints excision is better and safer than amputation; less violence is done to the body; fewer great arteries, nerves, and veins are divided, and the patient retains a limb that, although imperfect, is in most cases highly useful.

Excision is usually attended with the best success in the elbow, and here it may be done at a later period of life than would be advisable elsewhere. In the shoulder, elbow, and wrist, fibrous ankylosis is aimed at in order to secure a movable joint; in the hip and knee, firm bony union is sought in the most useful position of the limb, which is that of extension.

Contraindications.—Excision should *not* be undertaken—(1) when the disease is acute; (2) when there is much destruction of the bones or riddling of the soft parts with sinuses; (3) when there is much atrophy of the bones and muscles; (4) when the bones are in a state of osteomyelitis; (5) when the patient is either young or old, as in the former instance, the epiphyses are liable to be removed and the growth arrested in consequence, and in the latter, the powers of repair are usually insufficient to ensure sound healing and a subsequently useful limb; (6) when there is lardaceous disease or signs of phthisis, or other organic mischief; and (7) when the patient's powers of repair are exhausted by long-continued suppuration. Under most of the above circumstances amputation is generally indicated.

Excision of the Shoulder-joint.—Surgeons differ as to which is the best incision to make in commencing this operation; many authorities recommend an anterior, in front of the deltoid; Nélaton used the transverse, and other surgeons, the deltoid, flap. Bryant advocates a vertical incision from the acromion process, through the thickness of the deltoid down to its insertion. A vertical incision should be made down to the bone, rotating the head of the humerus successively outward and then inward; a transverse cut is next made across the tuberosities, to divide the insertions of the scapular muscles; the capsule is divided, turning the head out of the wound, and resecting through the tuberosities. Should the glenoid cavity be diseased, the dead bone must be removed. When the vertical incision is employed, and opening must be made posteriorly through the soft parts, at a point corresponding to the upper end of the humerus, for the purpose of drainage; it must be kept open by means of a drainage-tube. After the operation the arm should be abducted and placed on a pillow, and the edges of the wound carefully brought together and dressed antiseptically. From 3 to 4 months are required to secure a useful arm.

Excision of the Elbow-joint.—The patient is placed on his back, and the arm, with the hand in a prone posture, held by two assistants, one of whom holds the arm and the other the forearm. A straight vertical incision 4 inches long through the skin and subcutaneous tissues is then made, a little to the ulnar side of the hinder surface of the joint; its center about the level of the olecranon and to the outer side of the groove in which the ulnar nerve lies. Deeper cuts are then made around the upper border and sides of the olecranon, laying bare the condyles of the humerus, separating the origins of the muscles of the forearm, and cutting into the joint transversely, severing the triceps from the olecranon. The ulnar nerve is drawn inward, off the inner condyle, by a double blunt hook, and protected from the saw, the lateral ligament severed, the elbow forcibly bent, so as to turn out the ends of the bones. The olecranon may now be cut off with the saw or forceps, when the other diseased portions of bone will be visible. The end of the humerus, as well as the head of the radius, may now be removed. Enough bone must be removed to prevent ankylosis. As much of the brachialis anticus must be removed from the coronoid process as may be necessary; the triceps tendon must be left as long as possible. When the bleeding has ceased, the wound is to be brought together by sutures, dressed antiseptically, and the arm, in a half-bent posture, laid upon a well padded angular splint and secured by bandages.

When the reparative stage has fairly set in, the arm is to be moved from time to time, so as to form a *false joint*. There are many varieties in the plan and shape of the incisions; the most practical is to make the incisions connect and fall into the tract of any sinuses that may exist. In short and muscular men the **H** incision is the best, especially if there is much enlargement of the joint.

Excision of the Wrist-joint.—The incision and modes of procedure in this operation vary in each case according to the situation and extent of the disease; no precise rules can therefore be laid down. The form of the incision must be guided by the presence of the sinuses on the surface; by following these a sufficient opening may usually be made between the extensor tendons and the bones. One of the most usual modes of operating consists of longitudinal incisions on both sides of the wrist-joint, or incisions on the dorsal and internal lateral aspects, directed so as to go between the tendons without dividing them. An incision to the ulnar side of and parallel to the tendon of the extensor secundi internodii pollicis, and another incision vertical on the inner side of the joint, between it and the flexor carpi ulnaris, will allow sufficient room to remove the diseased carpal and bases of the metacarpal bones.

Excision of the Hip-joint.—To perform this operation a long, straight incision is made down the outer side of the limb, beginning below and behind the anterior superior spine of the ilium, and passing over the great trochanter. The attachment of the muscles having been severed from the trochanter, the bone is turned out of the wound by raising and adducting it at the knee; the neck and head of the bone, if necessary, are to be dissected out of the acetabulum.

Another method of performing this operation is to make a semicircular incision, beginning just above the edge of the tensor vaginæ femoris, and curving downward and outward, so as to cross the bone an inch below the trochanter, whence it should turn a little upward. This flap, including skin, fascia lata, tensor vaginæ femoris, and part of the gluteus maximus should be turned up, the muscles attached to the injured parts divided, and the remaining steps of the operation completed in the manner described.

Excision of the hip-joint should be performed with antiseptic precautions. If foul sinuses exist, they may be scraped with a sharp spoon and

cleaned well with a sponge dipped in a solution of sulphate of zinc. Antiseptic dressings may then be applied and the limb fixed in a long splint or in plaster.

Excision of the Knee-joint.—A semicircular incision is to be made, with convexity downward, commencing at the side of one condyle of the femur and passing immediately above the tubercle of the tibia to a corresponding point on the opposite condyle. This incision divides the patellar ligament, and the patella is turned up in the flap; the crucial ligaments should then be cut across, and any remaining lateral attachments divided. The limb must now be forcibly flexed and the knife carefully applied to the posterior part of the head of the tibia; a blunt-pointed resection knife is best for this purpose. The articular surfaces are to be sawed off. The lower end of the thigh bone should first be removed; the division must be made accurately at right angles to the shaft of the femur, in the anteroposterior direction. A thin slice is next taken off the tibia; the section must be accurately at right angles to the shaft of the tibia. Care must be taken not to remove more of the bones than is absolutely necessary, especially in young subjects. If the patella is much diseased, it should be removed; if it is only slightly carious, it may be scraped or gouged out; if healthy, it should be left to consolidate and strengthen the joint. But the articular surface should be destroyed to favor firm union with the femur. To keep the bones in position they should be drilled obliquely at the anterior part, and secured by two strong sutures of catgut. If the wound is septic, wire sutures are the best. Before the wound is closed all hemorrhage must be thoroughly arrested. Ligatures must be applied to the articular arteries, if necessary. The patellar tendon should be stitched in place with catgut and the wound drained for 1 or 2 days by tubes or numerous strands of silkworm-gut. The limb must be kept at perfect rest for the first few weeks; a narrow, properly padded splint, extending from the hip to the heel, will meet all indications. It should be fixed in position by a flannel bandage above and below the knee, over which a firm plaster-of-Paris bandage must be applied. An interrupted plaster splint with connecting side irons allows free access to the joint for dressing and prevents soiling of the splint. The first dressings should be changed after 24 hours. After that the dry, antiseptic wool dressings should be used, which can be left untouched for 2 or 3 weeks.

Excision of the Ankle-joint.—The foot is placed on its inner side, and an incision made along the posterior face of the fibula, beginning 3 inches above its lower extremity; after reaching the end of the malleolus its direction changes, and it terminates about 1/2 of an inch short of the metatarsal bone of the little toe. The flap is raised and reflected forward, exposing the surface of the fibula, taking care not to injure the tendons of the long and short peroneal muscles, which lie against the posterior and outer surface of the bone. The fibula is now to be cut through with strong bone-pliers, and its lower extremity dissected out. If the disease is very limited and easily accessible, the one incision here recommended will suffice; if the disease is more extended, the foot must be placed on its outer surface, and a second incision must be made along the inner angle of the tibia and terminating at the internal cuneiform bone. The flap is dissected back, keeping close to the bone, so that the tendons of the tibialis posticus and of the flexor longus digitorum, and the posterior tibia artery, veins, and nerves may be raised without injury. These parts should be held aside, the internal malleolus cut away with the bone-pliers, and the internal lateral ligament divided. The bone is cleared in front and behind with the periosteal elevator, and the foot strongly everted, when the tibia and upper surface of the astragalus will be exposed at the internal wound. The bone should now be divided from behind forward by a narrow-bladed saw passed through the internal wound, behind the tibia, and made to appear at the external opening. The upper surface of the astragalus may now be sawed off. The wound must be thoroughly washed out with bichlorid solution, a drainage-tube passed through from one side of the joint to the other, the sides of the incision closed by interrupted sutures, and the whole dressed antiseptically. The foot and leg must be covered with a bandage and plaster rollers applied, care being taken to give the foot a proper angle with the leg, the foot being held by the hand of an assistant until the plaster has hardened. Traps are to be cut on the sides of the splint opposite the wounds.

EXCORIATION.—The superficial destruction of a portion of skin or mucous membrane. The surface of the skin is usually denuded only so far as the stratum mucosum. Healing takes place without a scar. Excoriation occurs chiefly in pruritic diseases. Acetanilid and boric acid in equal parts may be dusted over the surface. The nitrate and carbonate of bismuth also make good dusting-powders. Camphor added to these powders will allay heat and itching. Calamin, (zinc carbonate), and zinc oxid are useful. Lime-water will allay the irritation resulting from the presence of urine. Soap may be used when acid secretions are causative, followed by oily applications. Boric acid in ointment, glycerin with tragacanth, and the glycerite of tannin are serviceable.

EXCRETA.—See Feces.

EXENCEPHALUS.—1. A species of single autositic monsters, characterized by a malformed brain, situated, at least in part, outside the cranial cavity, the bony walls of which are themselves imperfect. The specimens of this nature are divided into two main classes—those with and those without a spinal fissure. 2. A variety of autositic monsters of the foregoing species in which there is an arrested development of the cranial bones, with protrusion of the brain, associated with an extensive spina bifida.

EXENTERATION.—1. Removal of the intestines or thoracic viscera in Embryotomy (*q. v.*). 2. In ophthalmology the operation of evisceration of the contents of the eyeball, leaving the globe as a stump in the orbit, or the removal of the contents of the orbital cavity. See Eyeball (Removal).

EXERCISE.—Broadly, the setting in motion of the body, or the functional activity of the organs, whether muscular, nervous, nutritive, secretory, or reproductive. Popularly, the term is applied only to the muscles and to the parts called into play through the same—especially the circulatory and respiratory systems. Exercise is essential to the preservation of health; the want of it is frequently associated with the causes of disease; it is often a rational and successful means of treatment; and it is often abused. General muscular exercise increases the number of respirations and the quantity of air inspired. When walking at the rate of 2 miles an hour, the amount of inspired air is doubled; at 4 miles trebled. General muscular exercise also increases the force and frequency of the heart's action. The excretion of water from the skin is increased, and the loss of chlorids and fatty acids is considerable. The amount of water and chlorids in the urinary excretions is decreased, and the eventual result is a small increase in the amount of nitrogenous loss by exercise. Regular constant exercise increases the density and the bulk of muscle; there is actual storage of nitrogenous tissue; while excessive exertion leads to muscular exhaustion, diminished irritability, and, finally, to degeneration. Exercise increases the appetite, especially for fats and meats; digestion becomes more rapid and the hepatic circulation is better; the total weight of feces is decreased, the amount of water ingested increased, and nutrition is markedly improved.

Deficient exercise lessens oxidation, diminishes the efficiency of the circulation, and lowers metabolism. The muscular system wastes, while fat and water increase; the muscles become smaller, more flabby, paler, and the heart shares in the changes, so that subsequent exertion favors dilatation. Deficient exercise lowers pulmonary nutrition and favors the onset of tuberculosis; appetite is lessened, digestive power enfeebled, and chronic constipation favored.

Exercise is excessive when it produces a distinct sense of fatigue. A laborer's daily work amounts to 900 foot-tons. A 9-mile walk equals 150 foot-tons. Excessive exercise produces laborious respiration, with occasional sighing; if it is persevered in, hemoptysis may result. Palpitation or intermittence of the heart may occur after exercise too long continued. Overexertion, often repeated, produces cardiac hypertrophy, valvular disease, atheroma of vessels, and even rupture of the heart.

A pulse of 120 to 140 in rapidity from exercise is excessive in amount or velocity, disturbing rhythm; and exercise causing it should be abandoned. The more rapidly work is done, the more exhausting it is. Both tea and alcohol are to be avoided when the sense of fatigue is pronounced.

Exercise in the treatment of chronic heat-disease has been reduced to a system. Fatty hearts, from general obesity, and enlarged hearts, from gout and chronic mitral disease, especially when dropsy, renal disturbance, bronchial congestion, or catarrh are present, are the conditions to be improved. Specified distances, under certain elevations, are made use of. These are daily increased as the restoration of compensation is secured. In climbing the arteries are fuller, although the walls are more relaxed. Exercise is of the utmost service in chronic bronchitis phthisis in a quiescent state, atonic dyspepsia, dyspepsia with plethora, hepatic tenderness, constipation, and cachectic conditions, especially in scrofula, the "tubercular diathesis," rickets, and anemia.

In local paralyses or pareses from disease, injury, or disuse exercise is indicated (1) when the patient retains voluntary power over the muscles and can bring them into action, and (2) when the muscles may be involuntarily moved by electric stimulation.

It is most important that in manhood no violent exercise should be undertaken that throws a strain upon the thoracic organs until their powers have been brought into play by careful preliminary training. See HEART-DISEASE (Organic), LOCOMOTOR ATAXIA, SCHOTT TREATMENT.

EXHAUSTION.—A phenomenon that consists in a failure to respond to stimulation, and that occurs in all irritable tissues. Excessive, continuous, or quickly repeated stimulation will bring about exhaustion of muscle and nerve. Previous insufficient exercise of function, exposure to the extremes of temperature, and an insufficient supply of oxygen, an excessive supply of carbon dioxide exposure to certain toxic agents, and alteration in the quantity of blood supply favor exhaustion. Overwork, physical or mental, will cause exhaustion, especially when unremitting and monotonous. In a healthy man, however, great permanent harm from physical work seldom results; but excessive mental labor, especially if continuous, will permanently damage the nervous tissues. Exhaustion quickly results when, in addition to hard, voluntary mental labor, some constant stimulus unceasingly works upon the brain, as in a person harassed by poverty or affected by the sudden death of a relative or by a severe money loss. Anemia, faulty nutrition, prolonged pyrexia, inadequate diet, persistent morbid discharges, or venereal excesses favor general exhaustion. A previous condition of excessive slothfulness, exposure to extremes of temperature, retention of morbid products, etc., also predispose. Severe injury or psychic causes—such as fright—occasionally induce general exhaustion.

Local exhaustion is the result of excessive local stimulation, and is particularly liable to occur in those suffering from general exhaustion. Loss of power in the rectum results from the excessive use of purgatives. Failure of the uterus in protracted labor and failure of the voluntary muscles in "writer's cramp" are instances of exhaustion from overstimulation.

The chief indications for the treatment of general exhaustion are to lighten the labor and obtain rest. Narcotics, such as chloral, opium, sulphonal, and potassium bromid, are sometimes advisable. Phosphorus is given for physical and mental exhaustion and in depression from overwork. Grain doses of calcium phosphate, calcium carbonate, and ferric phosphate may be given. Potassium bromid allays bad dreams, insomnia, and irritability. One drop of laudanum with 2 or 3 drops

of tincture of nux vomica, 3 or 4 times daily, is of value in exhaustion with headaches, flushing, and dyspepsia. Musk benefits all forms of nerve exhaustion. Cimicifuga is advised for headache from overstudy or excessive fatigue. Coca lessens the sense of fatigue, and is suitable for convalescents. Cocain has been used in exhaustion from sunstroke from loss of blood, and in diarrhea. A cold wet sheet may be used as restorative. Seabathing is valuable. Change of occupation is better than absolute rest. Fresh air and good diet are most necessary. Stimulants are to be used with caution. The brain-worker should seek recreation in outdoor exercise, by music or painting, or by practising some handicraft. See COLLAPSE, SHOCK, NEURASTHENIA.

EXOPHTHALMIC GOITER (Basedow's Disease; Graves' Disease).—A disease characterized by tachycardia with palpitation, goiter, exophthalmos and tremor, palpitation usually being the initial symptom. The pulse ranges from 90 to 120 or higher. Occasionally the exophthalmos is so extreme as to produce spontaneous dislocation of one or both eyes.

There are present *Graefe's lid-sign*—namely, inability of the upper lid to follow perfectly the downward movement of the eye—and, usually, *Stellwag's sign:* viz., apparent widening of the palpebral aperture, due to retraction of the upper lid. The disease is usually encountered in women; its course is chronic, and the ultimate outcome is recovery. Death, however, occasionally results.

The etiology is obscure, but the disease occurs frequently in those of the neurotic habit. The theories propounded for the explanation of exophthalmic goiter may be placed in 3 divisions: (1) The *cardiovascular theories*, which locate the seat of the disease in the heart itself, in the vessels, and in the blood; (2) the *mechanic theories*, which connect the symptoms with compression of vessels or nerves in the neck by a primarily hypertrophied thyroid; (3) the *nervous theories*, which attribute the disease to disturbance in the vagus nerve, in the sympathetic nerve itself, or in the central nervous system proper.

Treatment.—Rest and protection from excitement are essential conditions of a successful treatment. After this the treatment is mainly directed to the symptoms. The remedies most used are the bromids and digitalis: digitalis to slow and steady the pulse, the bromids for two reasons—(1) as nervous sedatives and (2) for their reputed action in producing anemia of the nerve-centers. Quinin hydrobromid has been used in doses of five grains, thrice daily.

In some cases, when there is no cardiac lesion and the pulse is good and strong, aconite with the bromids is of service. Ergot, for its power of contracting the caliber of blood-vessels, is also a rational remedy. There is a difference of opinion as to the propriety of administering iron. Tyson believes the decision should be based on the condition of the patient and on the presence or absence of anemia. Galvanism of the sympathetic is said by German writers to be of service. Theoretically, it should be. A constant current of from 5 to 8 cells is used; the negative pole is placed on the fifth cervical vertebra, the positive pole along the sternum. Special efficiency has been claimed for the tincture of nux vomica. Thyroid extract (see THYROID TREATMENT) has not proved very useful.

Section of the cervical sympathetic is advocated by some. Ligation of the carotid has been practised in pulsating exophthalmos.

Reports from the clinics of Kocher, Halsted and the Mayos show improvement in cases of goiter treated surgically, and they are uniform in the stated changes occurring in the thyroid, especially as to the apparent cell activity essential to excessive secretion. There has been a great reduction in the mortality of operations for hyperthyroidism. In cases hardly severe enough for thyroidectomy ligation of the vessels will often effect a cure in a few weeks. Ligation is also indicated in acute, severe exophthalmic goiter and in the chronic, very sick cases with secondary affections of the heart, liver, spleen, kidneys. The operation is of particular value in cases with marked pulsation and thrill in the superior thyroid arteries. Ligation is also a valuable step to reduce excessive secretion before thyroidectomy.

Five hundred and eighty patients suffering from hyperthyroidism or exophthalmic goiter have been operated on at St. Mary's Hospital. Of these, 225 were ligations of the superior thyroid arteries and veins. A number of these ligations have been too recent to base observations on except as to the immediate risk of operation, which is about 2 percent in deaths occurring within a few days. Ten of these patients were operated on too late, dying in from eight to ten months later of their disease. In these deaths is included a case of pernicious anemia. The Mayos now have full records of 138 cases which were ligated sufficiently long ago to make the report of value.

There were 12 cases of ligations of the remaining superior thyroid artery and vein following thyroidectomy of the larger lobe and isthmus, the primary operation being followed by relapse after one or several years with growth of the remaining lobe. Twenty-eight cases of thyroidectomy followed the ligation of both superior thyroid vessels. Although all of them were very severe cases at the time of ligation, there was no mortality from the second operation.

In cases of ligation without thyroidectomy the results were as follows: Slight improvement, 9; great improvement, 44; very marked improvement, 11; absolutely well, 4; cases of questionable exophthalmic goiter, no improvement, 9.

In one hundred and ten cases in which partial thyroidectomy was performed there were nine deaths. Of the rest 50 percent made an early recovery, 25 percent improved as regards the main symptoms during several months, and 25 percent, while greatly improved, had occasional temporary relapses of the tachycardia and tremor. Mayo's rules for operation in exophthalmic goiter are as follows: If the condition is fair, operate; if the pulse is 130 to 160, or if it suddenly fluctuates in tension and rapidity, if there is anemia with

swelling of the feet, the patients are placed upon belladonna treatment for some days. The more severe types are also given X-ray exposures, from two to six weeks.

EXOPHTHALMOS.—Protrusion of the eye from the orbit; it may be due to increase in the bulk of the eye by disease, orbital cellulitis, an orbital tumor, a foreign body or hemorrhage in the orbit, myopia, or exophthalmic goiter. It may be present in a slight degree after tenotomy. If one eyeball alone bulges forward, there is likely to be a local cause, such as abscess, injury, aneurysm, or other tumor, and it should be treated accordingly. Protrusion of both eye-balls is probably the result of some circulatory disturbance, such as **exophthalmic goiter** (**Basedow's** or **Graves' disease**); injury of the internal carotid within the cavernous sinus (**pulsating exophthalmos**); or of some condition causing thrombosis of the ophthalmic vein. In such cases local treatment is of no avail. See Exophthalmic Goiter.

EXOSTOSIS.—See Bones (Diseases); Nails (Diseases).

EXPECTATION, TABLES.—See Life Assurance Examination.

EXPECTORANTS.—Remedies that modify the secretion of the bronchopulmonary mucous membrane and promote its expulsion.

Nauseating Expectorants.—In large doses these act mechanically by expelling the mucus in the act of vomiting; in small doses, by increasing osmosis from the inflamed mucous membrane. The members of this subdivision generally increase secretion and tend to lower blood-pressure. The principal are:

Antimony, tartar emetic, ipecacuanha, emetin, pilocarpus (jaborandi), apomorphin, quebracho, alkalies, potassium iodid, lobelia, lobelin.

Stimulant Expectorants.—These are largely eliminated by the bronchial mucous membrane, which they stimulate, altering the secretion and facilitating expectoration. These remedies generally diminish secretion and increase blood-pressure. They are:

Ammonium chlorid, ammonium carbonate, benzoin and benzoic acid, balsams of Peru and tolu, wood-tar and tar, acids, squill, garlic, onion, turpentine, sulphur, nux vomica, strychnin, senega, saponin, licorice, saccharine substances.

EXPECTORATION.—See Sputum.

EXPERT TESTIMONY.—Under the present judicial system, in matters involving scientific or technical knowledge for their decision, information must be given to the 12 men who constitute the jury, as well as to the judge himself, by persons whose special education has given them the knowledge required. Such a person is known as an expert witness; when medical subjects are involved, a medical expert witness.

It is not uncommon for the laity to abuse medical experts, and, indeed, the whole medical profession, on account of the medical testimony given in the courts. There is undoubtedly good reason for complaint, but this complaint should rest against the legalized judicial system and the scheme or plan of expert testimony that it involves; not against the medical profession, which neither in its solidarity nor its individuality has borne a prominent part in the legislation upon which the procedures in courts are based. The medical profession, as a profession, has no control over its membership; the whole tendency of medical education and the stimulating force of professional *esprit de corps* are toward the elevation of the character of the individual, so that the average personnel of the profession is superior to the average of the educated classes of the community. Nevertheless, the medical profession does, and probably must always, contain within its ranks many men of feeble intellectual powers and not a few who are lacking in moral character.

According to the present custom, the lawyer who wishes to use medical testimony for his purpose goes from doctor to doctor, getting opinion after opinion, until he finds what he is after or relinquishes the quest. By the acceptance of the fee for the opinion, the mouth of the physician concerned is sealed, so that it is not known that the lawyer has approached, it may be, a dozen doctors, and received a dozen adverse opinions, before he has found one opinion that is suited to his purpose.

It is evident that in this way the legal profession is able to avail itself of whatever of crankism, incompetency, or dishonesty is to be found in the medical profession. Under these circumstances the question arises to every self-respecting member of the medical profession, "Shall I or shall I not allow myself to be called into court?" It is evident that the expert is an absolute necessity to the doing of justice. Thus, how can a conviction of poisoning be reached until death from poisoning has been established by the expert. As, therefore, the expert is an absolute necessity, and as the refusal of the honest and capable would leave the field even more open that it is at present to the dishonest and incapable, it would seem that members of the profession are not justified in refusing to testify on matters concerning subjects within their immediate knowledge.

When approached by the lawyer, the physician should receive as far as possible a definite statement as to the facts involved, and should give upon these facts the best opinion that he is capable of, receiving for this work a suitable fee. In order that no misunderstanding should arise, both the allegation as to facts and the opinion given should be in writing.

In giving direct testimony upon the stand the bearing of the medical witness should be quiet, dignified, as far as possible free from any evidence of nervousness, and the statements made should be in plain, nontechnical language, direct, without equivocation. There should be no apparent voluntary offering of opinion, but simple replies to direct questions. Garrulousness and attempts at oratory or at the methods and manner of the lecture-room are out of place.

As **cross-examinations** are now conducted they are often very trying to the physician, and more usually adapted to obscure than to bring out the truth. In a large proportion of cases their obvious intent is to throw discredit upon the witness, so that the latter is usually at once forced

into the position of personal defense. It is, however, most essential for the witness to avoid the exhibition of partizanship or of personal irritation. As technical language is more accurate than non-technical, but at the same time less readily understood by the cross-examiner and jury, a witness upon his defense should avoid the use of such language. He should use as few words as possible, and give no more information than is required by the question asked. At the same time the answers should be straightforward, direct, and promptly given, so that there shall be no appearance of insincerity or uncertainty. All questions that are allowed by the court should be answered, but whenever there is reason for doubting the propriety of a question, the expert should pause for a moment before answering, so as to give opportunity to the counsel by whom he has been employed to make objection to the question. When the questions are personally very offensive, the expert has the right to appeal to the court, though such appeal is very rarely advantageous; but the court has been known to intervene.

The various pitfalls arranged by legal skill are too numerous to be discussed in detail, but some of the most common may be pointed out. Words or sentences having two meanings, one technical and the other popular, or ambiguities of other form, are often used; the expert has the right to insist that the question be clear. Assertions are made that the expert has said something that he has not said; the expert has the right to appeal to the stenographic record. There is a strong tendency to repeat words that have just been used or to accept a statement that is hurriedly put, even though it is not accurate or correct; the expert should guard against this. Impugning the sincerity or the honesty of the expert witness should be met with a quiet, good-humored denial; at such point it is the duty of the court to interfere, and this duty is sometimes fulfilled. Categoric questions, requiring an answer "yes" or "no," should usually be answered without reserve. Sometimes the answer may be given "yes and no;" in all cases in which explanation is necessary, the expert witness should insist upon his right to make such explanation.

In many cases, especially in those involving questions of sanity, there is room for such honest differences of opinion that there will be discordance in the statements of experts. Leaving aside these cases, vital differences in expert testimony are much less frequent than is generally believed. Failure of justice has been more often by disregard of concordant statements than through the disagreements of experts. Not rarely contradictions arise through members of the profession giving opinions concerning matters upon which they are not thoroughly informed. The intellectually honest expert will confine his testimony to what is strictly within his own province.

The question whether the court has the power to compel a person having special knowledge to give expert testimony without any pecuniary compensation save that of the ordinary witness as to facts is sometimes raised, and has received various answers at the hands of the courts. Practically, in civilized communities the question has very little importance; the injustice of the procedure is so apparent that the judge who attempts to enforce it demonstrates thereby his unfitness for judgeship. Furthermore, few lawyers would be willing to trust the interests of their clients to expert opinions given under such circumstances. He must be a remarkably good or a very dull-witted man whose service as an unwilling, unpaid expert would be valuable.

The basis upon which the expert testimony is given of course varies with the case. In many suits a personal examination of the subject is made by the expert, and the results, with the deductions therefrom, given in the court-room. In making and reporting such examinations it is usual for the expert to distinguish between subjective and objective symptoms: that is, between those symptoms the knowledge of which by the doctor depends upon the statement of the patient, and those symptoms that are directly perceived by the doctor. Pain is an example of the subjective symptoms; the shortening of a limb or an exaggeration of the knee-jerks is an objective symptom. Objective symptoms usually have much more weight in the consideration of the court than have subjective manifestations, but very many objective symptoms are capable of being feigned, so that it is essential to distinguish carefully, even in regard to objective symptoms, between the real and the feigned.

The examinations made by the expert should always be very thorough, with exposure of the person as free as is at all necessary, and usually more prolonged than is necessary. Thus, the doctor may be perfectly able to reach a positive conclusion in a certain case in 5 minutes, but his opinion formed in that short time would very probably be impugned by opposing counsel, and perhaps disregarded by the injury.

Very frequently the expert opinion is not based upon personal observation, but upon statements made in the court-room. In such cases there are several methods of procedure adopted by different courts. One is for the expert to have heard all the testimony given or to have studied the stenographic report of the testimony. Under these circumstances the statements of the witness must be based upon the testimony of one side of the case. When, as is usual, there is more or less conflict of testimony, if the expert bases his testimony upon the whole case, he must take upon himself the function of the jury, because he must assume as the basis of his opinion that one set of alleged facts is true, the other false.

The question to the expert by the counsel should always, in the case under consideration, be formed somewhat as follows: "Assuming that the testimony for the defense [or prosecution] is correct, what is your opinion," and so on. As ruled by some courts, under any circumstances—and certainly whenever there are antagonistic assertions and denials of alleged facts—the opinion of the expert should be based upon a supposititious case, or upon the so-called hypothetic question. Us-

ually, it is necessary to have at least two hypothetic questions, in one of which is embodied the case of the prosecution, in the other the case of the defense; one question being in accord with one set of alleged facts, the other with the other set of alleged facts. Which of the contradictory statements as to facts is proved by the testimony to be true it is the province of the jury, not of the expert, to determine; and the application to the case in hand of the opinion of the expert should stand or fall as the jury finds the hypothetic question he has answered is or is not in accord with what it believes to be the facts of the case. The opinion of the expert should always be correct, but may or may not be applicable to the case in hand, as viewed by the jury.

The expert should never prepare the hypothetic question, although, if necessary, after the question has been framed by the counsel the expert may point out defects, so that irrelevant matters may be omitted and the question thereby gain in brevity and simplicity; or relevant matters that may have been omitted may be inserted, so as to make the question more positive and definite. If the expert takes an active part in the preparation of the question, it will almost certainly be discovered by the opposing counsel, who will then, perhaps successfully, discredit the whole proceeding by asserting to the jury that this partizan expert came and made out a question for himself to answer in order to help his side of the case.

Whenever the testimony of an expert is as to the facts of a case, all possible direct proof of corroboration of these alleged facts should be produced in court. Thus, in a case of fracture or dislocation, skiagraphs should confirm the statements of the witness; and the chemist should always produce in court the poison that he has obtained from the body. In poisoning cases the chemist must see that the parts that have been given to him for investigation have been so kept that it is not possible for them to be tampered with, and should, by his own testing, have positive knowledge of the chemic purity of his reagents. He should make clear, definite notes in writing at every step of his various procedures, and when on the stand, should be prepared to show these notes, if requested to do so by the opposing counsel.

EXPLOSIVE COMPOUNDS.—See INCOMPATIBILITY.

EXTRACTS.—Solid or semisolid preparations obtained by evaporating solutions of vegetable principles. There are 28 official extracts, as follows: Extractum Aloes; Ext. Belladonnæ Foliorum; Ext. Cannabis Indicæ; Ext. Cimicifugæ; Ext. Colchici Cormi; Ext. Colocynthidis; Ext. Colocynthidis Compositum; Ext. Digitalis; Ext. Ergotæ; Ext. Euonymi; Ext. Gentianæ; Ext. Glycyrrhizæ; Ext. Glycyrrhizæ Purum; Ext. Hæmatoxyli; Ext. Hyoscyami; Ext. Krameriæ; Ext. Leptandræ; Ext. Malti; Ext. Nucis Vomicæ; Ext. Opii; Ext. Physostigmatis; Ext. Quassiæ; Ext. Rhamni Purshianæ; Ext. Rhei; Ext. Scopolæ; Ext. Stramonii; Ext. Sumbul; Ext. Taraxaci.

EXTRAUTERINE PREGNANCY.—The development of the ovum outside of the uterine cavity.

Its **frequency** is very difficult to determine, one for every 500 cases of normal pregnancy being about the proportion.

Etiology.—The cause of extrauterine pregnancy may be stated as any condition that interferes with the passage of the ovum from the ovary to the uterine cavity. Such are salpingitis, twisting or contortion of the tube, polypi growing from the tubal mucosa, and congenital malformations of the tube.

Varieties.—Primary extrauterine pregnancy is probably always tubal in character. Depending upon the part of the tube in which the ovum develops, it is called *ampullar*, or tubal proper; *infundibular*, or tuboovarian, and *interstitial*, or tubouterine. Primary *ovarian* and *abdominal* pregnancies have been described, but their existence is doubtful. Secondary abdominal pregnancies are not infrequent, and are due to rupture of the tube with extrusion of the ovum into the abdominal cavity.

Terminations.—Four terminations of extrauterine pregnancy have been described:

1. Rupture of the tube with extrusion of the ovum into the peritoneal cavity or between the layers of the broad ligament. This is by far the most frequent termination. It occurs usually between the eighth and twelfth weeks. If of the intraperitoneal variety, unlimited hemorrhage and death will usually result; if of the extraperitoneal variety, a hematoma will form between the layers of the board ligament, which will be absorbed, or which will form an abscess or cyst, or which will finally rupture through the broad ligament, causing unlimited intraperitoneal hemorrhage.

2. Death of the ovum without rupture of the tube. This is usually followed by atrophy and disappearance of the entire gestation sac. Hematosalpinx or other form of salpingitis may result.

3. Extrusion of the ovum into the uterine cavity or through the fimbriated extremity into the peritoneal cavity (*tubal abortion*) may occur. The former takes place, rarely, in the interstitial variety of extrauterine pregnancy, and is usually looked upon as an ordinary abortion. The latter occurs not infrequently in the ampullar and infundibular varieties. The hemorrhage is most frequently slight and is absorbed; if great, death may result.

4. The ovum may proceed to full term without rupture of the tube. This is an exceedingly rare occurrence. More frequently gradual rupture will take place without destruction of the ovum, which may then proceed to full term as a secondary abdominal pregnancy.

After any of these terminations, unless maternal death speedily occurs, mummification, formation of adipocere, or lithopedion formation may take place in the fetus.

Symptoms.—The symptoms of extrauterine pregnancy are of two classes: those *before rupture*, and those *after rupture*.

Before Rupture.—For the first few weeks the symptoms of extrauterine pregnancy are exactly similar to those of normal pregnancy. There are cessation of menstruation and, perhaps, nausea

and changes in the breasts. Later, there will develop *pain*, which is the most characteristic symptom of this condition. It is extremely sharp and cramp-like, occurs periodically, and is usually reflected down one thigh. After having missed one or two menstrual periods, the patient will have *return of menstruation*. The bleeding is usually profuse and attended by some pain. In the discharge will be found flesh-like masses (decidua). In other words, the common symptoms of an ordinary abortion are present.

Vesical irritability and *constipation* are commonly present, since the gestation sac is likely to cause pressure on the bladder and rectum. Slight *rise of temperature* may occasionally be noticed. If the ovum continues to develop, *abdominal enlargement*, *fetal heart-sounds*, and *fetal movements* will be present.

The physical signs are important. The cervix will be softened, the uterus enlarged and somewhat displaced—usually forward or to one side. The enlargement will not be so great as in a normal pregnancy, and will be most noticeable in the long axis of the uterus. Behind or to one side of the uterus will be felt a small cystic tumor, slightly adherent and exquisitely sensitive.

After Rupture.—Rupture is almost invariably attended by *intense pain*. So great is this pain that *syncope* is a common accompaniment. The subsequent symptoms will depend upon the character of the rupture. If intraperitoneal and extensive, hemorrhage will be unlimited and death will result, usually in a few hours, attended by symptoms of profound shock; rapid, weak pulse; blanched, cold skin; sighing respirations, and fall of temperature. If the rupture is extraperitoneal —between the layers of the broad ligament—a limited hemorrhage will occur, and the symptoms of shock and bleeding will be slight. Pressure of the resulting hematoma on the bladder or rectum may cause vesical irritability or constipation.

The physical signs are not so clearly marked as before rupture. If of the intraperitoneal variety, fluid will be felt in the pelvic and abdominal cavities. This is best determined sometimes after rupture, when clotting has occurred. If of the extraperitoneal variety, the broad ligament will be felt distended and bulging into the vagina, and the uterus will not be pushed to one side.

Diagnosis.—Although the diagnosis of extrauterine pregnancy is difficult, it should be determined, in the majority of instances, by a careful study of the patient's menstrual history and of the physical signs, and particularly by characteristic pain. After rupture the history of early pregnancy, intense pain, syncope, and collapse will inevitably determine the diagnosis. Among the conditions that most closely simulate extrauterine pregnancy are: abortion complicated by a tumor near the uterus; pyosalpinx with an indistinct history of pregnancy; normal pregnancy with a rapidly growing fibroid on one side of the uterus; and pregnancy in a bicornuate uterus. In all of these conditions celiotomy is indicated, so that the differential diagnosis is not of vital importance.

Prognosis.—If treated by operation, the mortality should be less than 5 percent. When operative treatment is not instituted, fully 66 2/3 percent will die, and of the remaining 33 1/3 percent, a large proportion will remain invalids from some pelvic complication.

Treatment.—If the case is diagnosed before rupture, immediate operation is indicated. This consists in the removal of the tube and ovary of the affected side, and differs in nowise from an ordinary salpingooophorectomy.

Seen just after rupture, immediate operation is again indicated; the bleeding should be controlled by a double ligature, securing the ovarian artery, and the blood-clot, fetus, and gestation sac removed. Some surgeons advise waiting for reaction, but this is unwise, as reaction will not take place until the hemorrhage has been arrested.

If a developing extrauterine pregnancy is first seen after the fourth month, the difficulties of removal are much increased. Uncontrollable hemorrhage is likely to occur when the placenta is removed. To avoid this it is best to open the sac, remove the fetus, ligate the cord, and suture the sac-wall to the lower angle of the abdominal incision. The cord is allowed to protrude through the opening and the sac is packed with sterile gauze. This is removed at the end of from 4 to 6 days, and the placenta may then be taken away without much risk of hemorrhage. Some operators allow the placenta to come away spontaneously.

EYE, EXAMINATION.—Notice if the **eyelids** are swollen, hypertrophied, or faulty in form, shape, position, or movements. Normally, the lids follow the movements of the eyeball. In exophthalmic goiter this harmony does not exist. This symptom was first noticed by von Graefe, and has been named after him. It has since been shown by Gowers and others that this sign is present in some central cerebral lesions.

The cilia should be inspected, and their form, size, and position carefully noted, as many unpleasant conditions may arise from misplaced cilia.

The position of the **lacrimal puncta** should be noted, and whether or not they are patulous. In the normal state the **lacrimal sac** is empty, while if it is distended with mucus or pus, pressure with the finger will usually cause escape of the contents, either from the nose or from the punctum. Further examination is effected by lacrimal probes.

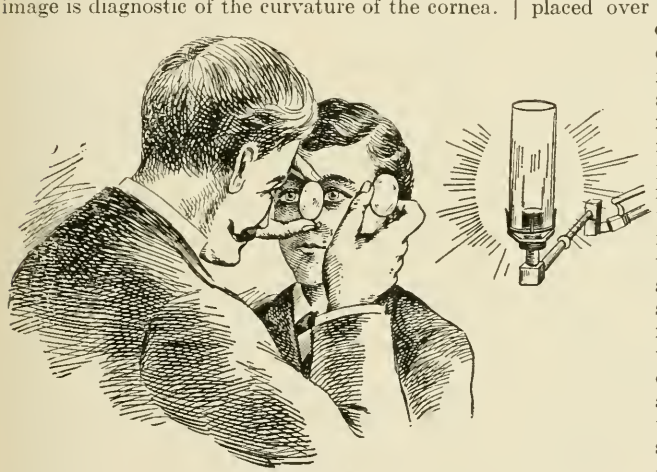
The conjunctiva is normally so translucent as to allow the bluish-white sclera to show through; it contains only a few minute blood-vessels. In old age there may be a deposition of fat in the subconjunctival tissue, giving a yellowish tinge to the membrane, and its translucency is additionally affected by an increase in the size and number of blood-vessels. In inflammatory conditions of the conjunctiva it should be thoroughly examined for the presence of a foreign body or an inverted cilium. The surface of the bulbar conjunctiva is first inspected, and then the lower sulcus, which is easily brought into view by simple tension downward with one finger. Eversion of the upper lid is readily effected without the use of a probe or

other instrument by telling the patient to look down, seizing the edge of the lid and cilia with the thumb and forefinger of the right hand, and drawing the lid first forward and downward away from the globe, and then upward over the point of the thumb or forefinger of the left hand, which is held stationary on the lid and acts as a fulcrum.

Conjunctival injection is recognized by its brick-red color; by the great irregularity, tortuosity, and intimate anastomosis of the blood-vessels; by the mobility of the vessels on the sclerotic; by the fact that pressure applied through the lid to the globe produces a distinctly anemic spot; by the injection being more intense on the lids and in the culdesac and diminishing toward the cornea; by the accompanying mucous or muco-purulent secretion.

Ciliary injection is distinguished by its pink appearance; by the vessels running in a straight parallel course, radiating from the cornea; by the immobility of the vessels when the conjunctiva is moved; by the fact that gentle pressure on the margin of the lower lids produces an anemic spot, which gradually becomes pink when the pressure is removed; by the congestion being most intense nearest the cornea, and fading away toward the equator of the globe.

The cornea is perfectly transparent and glistening in health, and returns diminished erect images of all objects held before it. The shape of the image is diagnostic of the curvature of the cornea.



Oblique Illumination.

The iris and the pupil are readily seen through the cornea. A foreign body, abrasion, opacity, ulcer, scar, or vascular formation is usually readily detected by simple inspection in a bright light, or with the opthalmoscope and a high convex lens; but it is always best to use what is called **focal** or **oblique illumination.** This method is effected by placing the patient in the line of the source of illumination—to the right side if the left eye is to be examined—and focusing the rays of light obliquely on the cornea with a convex lens held in that hand of the surgeon nearest the light. The illuminated point is viewed either directly or through a magnifying lens held at the focal distance from the patient's eye. Diffuse keratitis, corneal abscess, leukoma, and other similar corneal affections should be examined by oblique illumination.

The exact extent of the corneal abrasion of an ulcer may be ascertained by the application of a drop of a solution **of fluorescin** in the lower culdesac and rubbed over the eyeball. A few drops of boric acid solution are then instilled to wash away the superfluous stain, and the denuded area is stained a bright yellowish-green color. If the epithelium is changed and roughened, but not denuded, as in keratitis and glaucoma, then the defective spot does not stain.

The aqueous humor is so transparent in health as to be invisible, but may be rendered turbid by inflammatory and hemorrhagic deposits, or may contain pus, which gravitates to the bottom of the anterior chamber, forming the condition known as **hypopyon.**

The iris is ordinarily bright, and presents a polished surface. The pigmentation and fibrillation are distinctly visible, and the pupil is perfectly round, and surrounded by a ring of dark pigment. The size of the **pupil** in its usual state varies with each individual. A general average is 4 mm. The pupil should be equal, and should at all times respond to light. The patient should be placed before a window or light, the surgeon standing before him, and one eye perfectly occluded either with a hand or bandage; then one hand should be placed over the exposed eye and quickly withdrawn. Under the shadow the pupil dilates, and when the hand is removed, it quickly contracts. This is a direct reflex by means of the optic nerve. To study the **consensual reflex,** the patient is placed near a point of light in a room and the rays focused gradually on the cornea of the proximal eye, the eye furthest removed from the light still being in the shade. In health a simultaneous and sympathetic contraction of the shaded pupil is also seen. The pupil normally contracts in the act of convergence, and the patient should be directed to look at some distant object and then at an object near the tip of the nose, and the variations in the size of the pupil noticed. There are certain conditions, such as locomotor ataxia, in which the eye contracts as usual in accommodation but has lost its contractility to light. This condition is commonly known as the **Argyll Robertson pupil,** and is a significant diagnostic sign. If the eyes do not react at all to light and accommodation, there is probably disease of both optic nerves. Permanent dilatation (mydriasis) and contraction (miosis) are discussed under Pupil (*q. v.*). Further inspection of the iris should determine whether it is steady or tremulous, and whether it is in its normal vertical position, or is convex and displaced forward toward the cornea, or concave and depressed toward the vitreous, thus forming a shallow and deep **anterior chamber.** Instead of being circular, the pupil may be oval, with its greatest diameter

horizontal, as is often seen in glaucoma. Adhesions of the iris to the anterior capsule of the lens or to the posterior surface of the cornea, called **synechiæ**, also distort the pupil. Focal illumination and examination with a high convex lens by the ophthalmoscope render iritic adhesions more conspicuous.

Measurement of the Tension of the Eyeball.—The surgeon stands in front of the patient, who is directed to look downward. All but the index-fingers of the surgeon's hands rest over the eyebrow of the patient, and the tips of the index-fingers alternately and slightly indent the eyeball through the closed lid. The educated sense of pressure (*tactus eruditus*) measures the elasticity and resistance. It is well to immediately compare one eye with the other, as there is often quite a noticeable difference between the two. As a standard, the student has the tension of his own eye as a guide, from which any abnormal tension can be calculated. In glaucoma the eyeball is often hard, and there is none of the normal sense of elasticity left. In certain extensive destructions of the choroid and liquefaction of the vitreous the eyeball is soft and mushy. The eyes of the young are generally softer than those of the old. The degree of tension is expressed by the capital letter T., preceded by a plus sign (+) if there is increase; or preceded by a minus sign (−) if there is decrease. The amount of deviation from normal is expressed by numerals; thus, +T. 1, expresses distinct hardening; +T. 2, decided hardening; and +T. 3, extreme hardening, resisting all efforts to produce dimpling. See also OPHTHALMOSCOPY, RETINOSCOPY, REFRACTION, FIELD OF VISION, COLOR-BLINDNESS, etc.

EYEBALL, INJURIES.—**Punctured and incised wounds** about the sclerocorneal margin are especially dangerous on account of involvement of the ciliary body; chronic cyclitis and even sympathetic inflammation of the other eye resulting. Wounds of the sclera are accompanied by prolapse of the choroid and retina and loss of vitreous. Detachment of the retina is a serious sequel. Injury to the lens or its capsule results in traumatic cataract. Corneal opacity is liable to follow a corneal wound, and the opacity will be greater if the iris prolapses.

One of the chief sources of danger in penetrating wounds of the eyeball is the liability to infection, which is augmented by the impossibility of disinfection, on account of the depth and narrowness of the traumatic canal.

Treatment consists in thorough disinfection of the eyeball and appendages with a 1:5000 mercuric chlorid solution, closure of the wound with a conjunctival suture, sprinkling with finely powdered iodoform or one of its substitutes, and an antiseptic bandage. Prolapse of the iris should be combated by restitution, abscission, atropin, or eserin. If the lens is injured, atropin and iced compresses are indicated and the ordinary treatment of traumatic cataract instituted. Injury of the lens through the pupil offers the best prognosis. In case the retina is completely prolapsed and much vitreous is lost, causing blindness, immediate enucleation may be necessary.

Contused wounds of the eyeball are the result of blows from the fists or from a blunt instrument. "Black eye" usually results. There may occur hemorrhage into the anterior chamber, and sometimes when this clears up vision is lost by a coincident retinal hemorrhage. The iris may be torn from its attachment (iridodialysis) or the lens may be dislocated. In severe cases the globe is ruptured at the weakest point in the sclera, opposite the point of impact, about 2 to 5 mm. from the cornea. In such cases the vitreous escapes and the iris may be prolapsed in the rent. The ciliary body and the retina are very susceptible to serious injury. A curious result of rupture of the eyeball is seen in those cases in which, by an accidental blow, a cataractous lens has been removed and vision thereby restored. The prognosis of ruptured eyeball is always serious, and many injured eyes become atrophied.

Treatment consists in careful disinfection, the application of ice, eserin or atropin, a bandage, and rest in bed. A bruised iris must be carefully excised. The various complications should be treated as they arise. If there is an extensive rupture of the sclera, conjunctival and scleral sutures may be necessary to prevent complete prolapse of the vitreous. Nothing can be done for the iridodialysis except iridectomy. A dislocated lens must sooner or later be removed. Hemorrhage into the anterior chamber and subconjunctival hemorrhages will usually absorb without treatment.

Foreign Bodies in the Eyeball.—After injury to the eyeball it is always important to determine whether or not a foreign body remains within the eye. If it can be seen by the naked eye, focal illumination, or the ophthalmoscope, the diagnosis is easy. In other cases in which the media become quickly opaque, or the body lies concealed in the sclerocorneal covering, or is near the ciliary body, it may escape detection. In these cases the patient's general and local condition and the nature of the injury must be carefully considered. If there is no point of exit, and there is absolute history of entrance of a foreign body, it must be assumed that it is in the eye. The surest way of locating a foreign body is by the Roentgen rays.

Prognosis depends on the location of the foreign body, its chemic nature, and whether or not it was aseptic. Aseptic and chemically unirritating substances, however, have produced alarming inflammations in the ciliary region. Infection from a foreign body in the eye may result in panophthalmitis and speedy destruction of the globe. However, there have been cases in which small aseptic foreign bodies have remained for years in different parts of the interior of the eye, even in the sensitive ciliary body. According to reliable statistics, the loss of the eye from foreign bodies in the anterior chamber is virtually nil; in the lens, 30 percent; and in the vitreous, 71 percent.

It must be remembered that a foreign body remaining absolutely quiet within the eye is at all times dangerous, both to the affected eye and to its fellow.

Treatment.—Foreign bodies should always be

removed from the anterior chamber. A lens with a foreign body in it will sooner or later have to be extracted. If the foreign body is in the vitreous, the treatment depends on its nature. In such case, if the foreign body is of iron and can be located, it should be removed through a scleral incision by the electromagnet. Aseptic substances, such as copper, wood, stone, or glass, may be permitted to lie quiescent and be treated expectantly. At the first sign of inflammation they should be removed by a pair of fine forceps through a scleral incision. If the symptoms are indicative of much ciliary involvement, enucleation should be performed or active sympathetic inflammation may soon set up and destroy the uninjured eye. Of all operations, removal of a foreign body from the eye should be performed under the strictest antiseptic precautions.

A good rule in those cases of foreign body in the eye seen soon after the accident is to secure the patient's assent to the application of the magnet, under anesthesia; and in case of failure of extraction, to submit to immediate enucleation. However, if there is evidence of intense ciliary inflammation in the injured eye or signs of sympathetic inflammation in its fellow, it is not safe to lose time in attempting extraction; the injured eye should be removed at once. See SYMPATHETIC OPHTHALMIA.

Parasites in the eye are usually the cysticercus, the larva of the tape-worm, which may also be found in any part of the body. Liebreich gives a good ophthalmoscopic image of a living cysticercus in the vitreous. Thread-worms have been found in an opaque lens and in the virteous. It is possible that remnants of the persistent hyaloid artery have been mistaken for worms in the vitreous.

EYEBALL, REMOVAL.—Evisceration of the eyeball is performed as follows: The cornea is removed by making incision with a Graefe knife, so as to include one-half of the corneoscleral margin, and completing the circumcision with scissors. The contents of the globe are then evacuated by means of a special scoop, care being taken to remove the choroid unbroken, by carefully peeling it from the sclerotic backward until it is only attached at the lamina cribrosa. The interior of the eyeball is washed out, and after all hemorrhage has ceased, the edges of the sclerotic are stitched together and the conjunctiva united over it.

In **Mule's operation** the opening is enlarged vertically to admit of the introduction of a hollow glass or silver or aluminium sphere. The margins of the sclerotic are now united vertically by interrupted silk sutures; the conjunctiva is then sutured at right angles to the scleral closure. Two points of importance are strict antisepsis and the checking of all bleeding in the cavity before the glass ball is inserted. The advantages claimed for this operation are that it leaves muscular attachments adhering to the stump and offers a movable ball on which to insert an artificial shell; that it keeps the orbit filled out; and that it lessens the danger of meningeal infection, sometimes following enucleation. The cosmetic improvement is by far the greatest point in its favor. The operation is of particular value in staphyloma of the cornea and in disfiguring leukoma. The disadvantages are the uncertainty of result, possible infection, and sympathetic involvement, though the occurrence of the latter is rare.

Some operators practise **insertion of the glass sphere in the capsule of Tenon** instead of the scleral cavity. The operation is similar to an enucleation except that the recti muscles are secured with sutures before dividing them. The glass sphere is placed in the cavity previously occupied by the eyeball, and the sutures holding the four recti are tied tightly together over it; care must be exercised to secure adaptation of the sutures, so that the tendons assume the same position they occupied in the living eye. This operation eliminates all the dangers and disadvantages of evisceration or Mule's operation, and leaves as useful a stump.

Total combined keratectomy is the name given to an operation that Panas has most successfully used for several years in all cases in which enucleation is ordinarily indicated. A half-curved Reverdin needle is introduced through the sclerocorneal junction, passed back of the iris and lens, coming out at a point opposite. The needle is then armed with a thread and allowed to remain in place. The cornea is detached as in evisceration. The iris is removed by forcibly tearing with a pair of forceps. The speculum is gently raised away from the globe by an assistant. The lens is next removed with a scoop, care being taken not to lose any vitreous. The Reverdin needle, armed with its thread, is now withdrawn, and the suture made is tied. Two sutures, one on each side of the middle one, are made and tied. The projecting angles of the wound are trimmed with scissors, and the wound is dressed antiseptically.

Enucleation.—The patient is placed on an operating table and, preferably, anesthetized with ether or chloroform, although sometimes local anesthesia with cocain alone is used. After thorough disinfection of the eyeball and neighboring parts a speculum is introduced, the arms of which are widely separated. A fold of conjunctiva is seized by a fixation forceps in the left hand, opened with a pair of enucleation scissors curved on the flat, and cut close entirely around the circumference of the cornea. The separated conjunctiva and capsule of Tenon are pushed back with the closed scissors. The tendon of the internal or external rectus muscle is seized by the fixation forceps close to the insertion and divided back of the forceps. One blade of the scissors is passed under the tendon of the superior rectus, which, with the tissues surrounding it, is divided close to the globe. The inferior rectus is then severed with one cut; the globe is then rotated forward and toward the nose, the scissors passed backward, and the optic nerve and the adjoining tissue divided. The globe is then seized with the fingers and forced from the socket, and the remaining tendons and attached tissues separated from it. Instead of crowding wet antiseptic sponges into the orbit to check the hemorrhage, it is better simply to irrigate the cavity with sterile cold water, and thus avoid crushing and lacerating the remaining muscles. These muscular remnants are then puckered to a point with a "purse-string"

suture, and afford a more or less movable stump. When the bleeding has subsided, the cavity is washed out with a sublimate solution and an absorbent sponge or wad of cotton is placed over the orbit, leaving free drainage, and a bandage applied without exerting undue pressure. The old custom of immediately applying a pressure-bandage after enucleation to check hemorrhage is not advisable. It is better to delay permanent bandaging until the hemorrhage has subsided. The dressing may be changed in 24 hours, and the parts cleansed with a sublimate solution and a new dressing applied. After the fourth day the bandage may be discarded, and the patient given a mild antiseptic wash to use in the eye 2 or 3 times daily until the wound has completely healed.

An **artificial eye** may be worn after a lapse of 2 or 3 weeks, if all inflammation has subsided. Early insertion of the artificial eye is advisable to prevent absorption of the orbital fat. It must be remembered that the orbit is very tolerant of foreign bodies; however, to thoroughly accustom the orbit, the artificial eye should not be worn over a few hours at a time for the first few days. To insert an artificial eye, it is lubricated and the broad outer end slipped under the upper lid, which is slightly raised. The lower lid is then drawn downward, the patient directed to look down, and the eye is gently manipulated into place. Irritation of the stump by an artificial eye has led to sympathetic inflammation of the other eye, and must be guarded against. An artificial eye should be taken out at night and placed in water.

Exenteration of the orbital contents, usually for malignant growth, is performed by splitting the external canthus and separating the entire periosteum, with all its contents, from the bony wall, except at the apex of the orbit. Enucleation scissors are introduced, and the stump is cut off close to the bone. Profuse hemorrhage is best checked by actual cautery. If the neighboring skin or the lids are involved, the incision must be made into healthy tissue, and the diseased parts removed with the orbital contents.

EYE-DISEASES, DIAGNOSIS.—It is well to become thoroughly familiar with the table on the following page, as it embodies the most important points in the diagnosis of inflammatory conditions of the eye.

See too, Choroiditis, Conjunctivitis, Cornea, Glaucoma, Iritis, Optic Nerve, Tuberculosis, (Ocular), etc.

EYE-DISEASES, LOCAL TREATMENT.—Local applications to the eye are detergent, soothing, astringent, stimulating, caustic, antiseptic, mydriatic, or miotic; and are made by means of solutions, ointments, oils, or powders.

Collyria are ordinarily applied by means of the pipet with small rubber bulb, but, if this is not at hand, a simple glass tube or quill will answer the purpose nearly as well. While the patient's head is thrown backward, the lower lid is gently drawn down and the solution dropped into the lower culdesac of the conjunctiva. It should be remembered that the strength of the application cannot be regulated by the amount of fluid used, as not more than 1 or 2 drops will be retained in the conjunctival sac. Usually, an excess does no harm; but when the mydriatics are used, not more than 2 or 3 drops at most should be applied. As an additional precaution against the constitutional effects of the drug, it has been recommended to press the end of the finger over the lacrimal canals for a few minutes, to prevent the passage of the fluid into the nose and throat. When it is desired to act upon the lacrimal passages, they should first be emptied by pressure upon the sac, and the solution should then be applied freely to the inner canthus. When it is desired to flush the conjunctival sac for cleansing and antiseptic purposes, as before, during, and after an operation, and in purulent cases, a larger tube with an ounce rubber bulb is a very convenient instrument. The sponge is now rarely used. The old "eye cup," whose edges fit within the margins of the orbit, is an easy and pleasant means of making free applications of soothing washes, but is not always cleanly, and is not recommended. The eye douche, for directing a spray against the closed lids, may be made by attaching a nozzle, perforated with small holes, to a rubber tube connected with a cup, or the fountain syringe, to be held above the head; but it is now generally superseded by the atomizer.

Oils are applied with the pipet or by means of a pledget of absorbent cotton. **Ointments,** when intended for the margins of the lids only, should be used in very small quantity, to avoid irritating the conjunctiva. A little is taken on the end of the forefinger and the edges of the lids are simply anointed, so that there shall be a delicate film of the ointment between them when they are closed. When it is intended to act upon the cornea, a piece of the ointment the size of a pin's head may be placed directly upon it, or may be applied to the conjunctival surface of the upper lid. **Powders** were formerly "insufflated," or blown from a glass tube or a quill upon the eyeball, but are now always "dusted" from a camel's-hair brush. The handle of the brush is held between the forefinger and thumb, while the brush is struck sharply with the little finger of the same hand. Drugs may also be applied to the eye in the form of soluble solids. Medicated **gelatin discs** for this purpose have long been made. The chief advantage claimed for these discs is that, by means of their slow solution, the drug is maintained continuously in contact with the conjunctiva, instead of being in great part carried off by the overflow of tears, as is the case with aqueous solutions. The discs contain atropin, cocain, eserin, pilocarpin, etc.

EYEGLASSES.—See Spectacles.

EYELIDS, DEFORMITIES. Narrowed Fissure.—The normal palpebral fissure in the adult is 26 to 28 mm. long, and about 1 cm. wide. Narrowing of the fissure is either called **ankyloblepharon** or **blepharophimosis.** The first condition is an actual union of the external angle of the lids, and may be congenital or due to a cicatrix following a burn or an ulceration. Blepharophimosis indicates that a fold of skin covers the external angle, and results from a contraction of the skin of the lid after a chronic conjunctivitis.

DIFFERENTIAL DIAGNOSIS OF INFLAMMATIONS OF THE EYE

Symptoms.	Acute Conjunctivitis.	Acute Iritis.	Keratitis.	Acute Glaucoma.
Color of the Injection.	Red, but less marked near the cornea.	Red; most marked near the cornea; bright zone of ciliary redness.	Rose-pink; conspicuous near the cornea.	Dark red.
Vessels.....	Superficial, tortuous, and irregular in distribution; freely movable.	Vessels run deeply and straight toward the corneal margin (ciliary region); not movable with conjunctiva.	Vessels run straight, and break into fine network in the immediate vicinity of the cornea.	Vessels widely distributed and dilated.
Conjunctiva....	Thickened; vessels on the everted lid concealed in the general redness; easily thrown into folds.	Not much thickened; distribution of vessels on everted lid easily seen; not easily thrown into folds.	No thickening in simple keratitis.	No thickening.
Secretion.....	Hypersecretion of mucus seen in flakes; lashes matted; lids glued together in the morning.	No considerable hypersecretion of mucus.	Free lacrimation, but no hypersecretion of mucus.	No hypersecretion.
Pain.....	Not severe; smarting and burning; sense of sand in the eye; no tenderness.	Neuralgic and paroxysmal; worse at night; eyeball tender.	Moderate, but constant; sticking, lancinating; no tenderness of the eyeball.	Same character as in iritis, but more severe; not markedly worse at night.
Photophobia....	None, unless the cornea is affected.	Slight.....	Severe and conspicuous.	Slight.
Iris.....	Normal.....	Thickened, dull looking, and, if light, discolored.	Normal.....	Slightly discolored.
Pupil.....	Normal.....	Small, sluggish, or fixed; irregular, not round.	Normal.....	Dilated, sluggish, and greenish in color.
Cornea	Clear, if not secondarily affected.	Clear, unless corneal complications.	Clouded or opaque, obscuring the view of the pupil and iris.	Haziness; or in extreme cases steamy, like ground glass.
Tension.....	Normal.....	Normal, or in ciliary involvement possibly slightly increased.	Normal.....	Increased. (The important diagnostic feature.)
Anterior Chamber.	Normal.....	Normal.....	Normal.....	Shallow; iris and lens pushed close to the cornea.
Corneal Sensitiveness.	Normal.....	Normal.....	Increased.....	Diminished (if touched with a wisp of cotton).
Vision.....	Little change.....	Dimmed, but not suddenly, and never complete blindness.	More or less impairment by corneal turbidity or opacity.	Suddenly and greatly diminished at the onset of the attack.
Field of Vision.	Normal.....	Normal.....	Possibly limited by opacities.	Contracted.
Atropin and Eserin.	No effect on condition.....	Atropin soothes; eserin aggravates pain.	Little immediate effect; both beneficial ultimately.	Atropin greatly aggravates the pain; eserin mitigates all symptoms.

Treatment of ankyloblepharon consists in an operation called **canthoplasty.** The adhesions are dissected up and the external canthus split, leaving a denuded V-shaped wound, the conjunctival edges of which are drawn together by sutures. Blepharophimosis may be corrected by cutting away the redundant skin and stitching the edges of the wound together.

Trichiasis is a condition in which the cilia are misplaced or misdirected and rub against the cornea, causing more or less corneal irritation. The condition may apply to all the cilia, or only a few may be misdirected. The common cause of trichiasis is trachoma, although blepharitis or any inflammation about the cilia may produce it. Cicatricial contraction after injury and operation is a cause. The treatment consists in curing the causative condition, and by epilation, electrolysis, illaqueation, excision, and plastic operation.

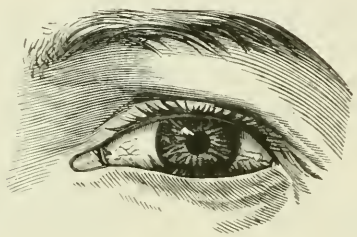
Distichiasis is a condition in which there is a double row of cilia, one directed inward and one

directed normally outward. The result of this condition is corneal irritation. The treatment is similar to that of trichiasis.

Entropion is inversion of the edge of the eyelid. It results from cicatrization following trachoma, blepharitis, wounds, burns, etc. Blepharospasm and pressure from bandaging are causes. It should be distinguished from simple trichiasis, in which the cilia alone are displaced. In entropion the edge of the lid is wholly or partly inverted, as well as the cilia.

Treatment.—If spasmodic entropion is due to a faulty bandage, such cause must be removed. One end of a piece of adhesive plaster fastened below the lashes and the other end to the cheek secures relief. The best operative measure for spasmodic entropion is the classic excision of a horizontal fold of skin parallel to the edge of the lid, with suture of the wound. Many other operations have been proposed. Canthoplasty may be performed especially in senile entropion.

In **von Graefe's operation** two vertical incisions are made through the skin of the upper lid, the

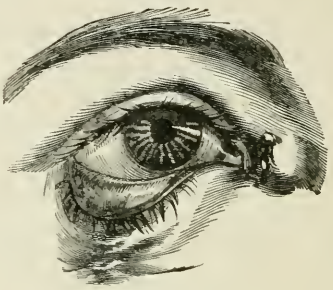


Entropion.

latter being split into an anterior and a posterior leaf; the cutaneous margins are then entered higher up along the vertical incisions. A horizontal incision is made through the skin of the upper lid, and a triangular piece of skin, with its base downward, is removed; a triangular portion of the tarsus, base upward, is also removed, and the wound sutured. This operation is recommended in senile entropion, when excision of a horizontal piece of skin or the application of subcutaneous sutures is not sufficient.

Hotz's operation for the same condition consists in excising the skin and muscle down to the tarsus, some 4 to 6 mm. from the lid-edge, laying bare the tarsus, and drawing the two skin-margins together and holding them until union is effected, thus giving a solid fulcrum for the everting force of the cicatrix and skin, which Hotz thinks is lacking in other methods.

Ectropion is eversion of the lid. It is not attended with the severe symptoms of entropion. Epiphora, with the consequent eczema that follows it, is the most prominent symptom. In severe cases the whole lid may be everted, leaving the conjunctiva unprotected, a condition popularly called *blear eye*. This deformity results from relaxation of tissues in old age, or from paralysis of the orbicularis, cicatricial changes due to injuries, burns, etc., and follows chronic conjunctivitis, blepharitis, or other inflammatory conditions about the lids. The scars of lupus and syphilis are occasional causes. Both lids may be affected.



Ectropion.

Treatment.—**For eversion of the puncta,** slitting the lacrimal canal and clearing the nasal duct may give relief. Any discernible cause should be treated. Mild antiseptic lotions should be used on the denuded surfaces. The patient should be instructed to wipe the eye from below upward, thus tending to reduce the eversion by a sort of massage.

Operations for ectropion are designed to raise the under lid or to stretch it out horizontally. The usual plastic operation is excision of a V-shaped piece of skin below the lid margin. The edges of the denuded triangular area are brought into position by sutures. **Snellen's sutures** are threads inserted on the conjunctival side of the lids from above downward, and brought out on the skin at about the level of the edge of the orbit, the ends being knotted over pieces of tubing or a ball of cotton. In cicatricial ectropion the first step is to sever the adhesion between the lid and the bone, and to cover the remaining scar by a transplanted flap or by skin-grafting.

In moderate degrees of ectropion or entropion a row of *galvano-cautery punctures* near the free edge of the lid has been used with success.

EYE-MUSCLES, ANOMALIES.

Functional Anomalies

Muscular Balance.—When the visual axes of the two eyes exactly meet at the object to which they are directed, the eyes are said to be balanced, or in equilibrium. This muscular balance is maintained by the constant and equally distributed innervation of the ocular muscles, and is directly dependent upon the relative anatomic formation and physiologic strength of the muscles. Any disturbance of these factors produces muscular imbalance. However, muscular imbalance does not imply inability to perform perfect binocular fixation, for in some cases the visual axes are rightly directly by increased innervation, and it is this necessary extra expenditure of nervous energy that causes the asthenopic symptoms so frequent in minor disturbances of muscular equilibrium.

Stevens, of New York, has suggested a descriptive nomenclature for the functional anomalies of ocular muscles that has been universally accepted in this country. For the different varieties of disturbance of muscular equilibrium, or latent squint, he suggests the use of the following terms:

Orthophoria, perfect binocular equilibrium.

Heterophoria, imperfect binocular equilibrium.

The varieties of heterophoria are:

Hyperphoria, a tendency of one eye to deviate upward.

Esophoria, a tendency of the eyes to deviate inward.

Exophoria, a tendency to deviate outward.

Hyperesophoria, a tendency of one eye to deviate upward and inward, or of its fellow to deviate downward and inward.

Hyperexophoria, a tendency of one eye to deviate upward and outward, or of its fellow to deviate downward and outward.

Tests for the strength of ocular muscles are based upon their ability to overcome prisms while both eyes are fixed on a small light about 6 meters' distance. In these tests the object is to measure the associated powers of the muscles concerned in abduction, adduction, and sursumduction rather than the strength of the individual muscles, which may never have individual action. To test adductions, the prisms are placed bases out; to measure abductions, bases in; to measure the elevators (supraduction), bases down; to measure the depressors (infraduction), bases up.

It is the measurement of the strength of the abductors and adductors that is of most practical importance in ordinary practice, and in all cases in which there is reason to suspect any muscular insufficiency in the causation of asthenopic symptoms not only should the tests for muscular equilibrium be applied, but also the power of adduction and abduction should be measured. The usual strength is adduction 20°; abduction, 6°.

Tests for Heterophoria.—The cover-test, although unreliable and not available in low degrees, sometimes enables the physician to detect the tendency toward deviation. For rough diagnosis the patient is placed in front of the physician, with his eyes about the level of the bridge of the physician's nose, at which he is told to look steadily. A card is placed over one of the eyes, and a moment afterward withdrawn; if there is a tendency to deviate out, a slight movement inward is noticed immediately after the withdrawal of the card. In the same manner a tendency inward will be detected by quick movement outward after the withdrawal of the card. Both eyes can be tested in this manner. The chief tests are with prisms and the Maddox rod.

Treatment of Functional Anomalies.—The most important treatment is the correction of the ametropia with proper glasses. A strong correction is ordered in esophoria, a weak correction in exophoria. Defective adduction is brought up by tonics and ocular gymnastics with prisms. High degrees of heterophoria are treated either with correcting prisms, prism exercise, tenotomy, or advancement.

Strabismus

Synonyms.—Heterotropia, or manifest squint.

Varieties.—The difference between strabismus and insufficiency is only one of degree. In strabismus the muscular insufficiency is uncorrected, the squint is manifest, and diplopia is produced. However, strabismus may be only **periodic**, as when the patient is fatigued or the systemic condition weak; or it may be present only when the patient looks at distant objects or accommodates for near work.

Concomitant strabismus is a variety in which there is equal movement of the eyes, but the eye still deviates on account of some defect in one of the ocular muscles.

Paralytic strabismus is due to paralysis of an ocular muscle, and when the eyes are turned toward the paralyzed muscle, one eye is deficient in movement. This form will be fully discussed in the section on Ocular Paralysis. See EYE-MUSCLES (Paralysis).

Spastic squint is a term applied by some authors to cases in which deviation is caused by spasmodic contraction of one muscle. It is very rarely, if ever, present, and must result from some peculiar central irritation.

Alternating strabismus is fixation with either eye, the other eye deviating. At times one eye squints and at others the other eye is at fault. It occurs when the vision is nearly equal in the two eyes, or when one eye is used for near work and the other for distance.

Monolateral or **constant strabismus** is the name given to those cases in which the squint is always in the same eye.

Internal strabismus, or **convergent squint**, is deviation inward of one or both eyes, and is usually due to the increased convergence of an ametropic eye. The converging eye is usually highly hyperopic. Homonymous diplopia is produced.

External strabismus, or **divergent squint**, is a deviation outward of the visual axis of one or both eyes, and in most cases is due to insufficiency of adduction rather than to overaction of the abductors in an ametropic eye. The diverging eye is usually highly myopic. Crossed diplopia is produced.

Disadvantages.—When there is uncorrected deviation of one eye, diplopia results. To overcome this anomaly of vision, the use of one eye is interdicted and the image suppressed, and if this amblyopia is untreated for any length of time, it gradually increases until the affected eye may become practically blind. Before the eye falls into disuse and the amblyopia exanopsia developed becomes discommoding, asthenopic symptoms are caused by the struggle for perfect binocular fixation.

Diagnosis.—Ordinarily, strabismus is apparent on simple inspection. However, we cannot depend on the symmetric situation of the cornea, as it sometimes happens that the visual axis is to one side of the center, and an eye is thought to squint

that is really properly directed for perfect binocular vision. The cover-test is reliable for the simple diagnosis of strabismus. The patient is told to fix his vision on an object, and the fixing eye is then covered, and immediately the other eye will turn into position and fix, while the other deviates.

The movement of the sound eye when covered is called secondary deviation. In concomitant strabismus the sound eye makes a movement in its deviation equal to that made by the squinting eye in its effort to fix. In paralytic strabismus the paralysis in the affected eye prevents full movement, and the secondary deviation is always greater than the primary squint. The *primary* and *secondary deviations* may be measured by marking on the lids the boundaries of the corneas before the test, and the boundary of the cornea of the affected eye when attempting to fix, and the boundary of the cornea of the sound eye diverging under cover. The markings on the lid of the squinting eye show the primary deviation, while those on the lid of the other eye show the secondary deviation.

Paralytic Squint.	Concomitant Squint.
1. Contraction of the field of vision.	1. Displacement of the field of vision, but no contraction.
2. Secondary deviation greater than the primary.	2. Secondary deviation equal to the primary.
3. Disturbance with double images.	3. No disturbance with double images.

It often happens that there is horizontal as well as lateral squint, and to properly study the exact character and degree of deviation, an attempt should be made to compel recognition of the double images that are received; unfortunately, after some time the image in the squinting eye becomes suppressed, and it is very difficult to get the patient to recognize two images; but by placing a deeply colored glass before the fixing eye, its image is so modified that the false image, which is ordinarily suppressed, may be recognized by the squinting eye.

Treatment.—As strabismus is often due to ametropia, or, more commonly, to anisometropia, the first object should be to correct the refractive error in both eyes and to strive to bring the squinting eye into function by the blinder-exercise, in the manner employed in the treatment of anisometropia. The muscular insufficiency should be treated by systematic exercise: at first by the finger-exercise, and afterward with prisms. Periodic squint is particularly amenable to this treatment. In young children in whom there is a tendency to strabismus, the constant use of a weak solution of atropin in the sound eye will bring the other eye into function and correct the squint, or it may be necessary completely to paralyze the accommodative effort for some time by using the mydriatic in both eyes.

When, however, binocular vision cannot be obtained by the foregoing procedures, an operation must be resorted to. For internal strabismus, tenotomy of the internal recti is indicated. For external strabismus, tenotomy alone of the external recti or in conjunction with advancement of one or both tendons of the internal recti may be necessary. In regard to the relative indications of tenotomy and advancement, it should be remembered that in concomitant squint with relaxed tendons advancement, and with tense tendons tenotomy, should be performed. However, it is sometimes necessary to advance an apparently tense tendon and to regulate a tenotomy by subsequent advancement. The great difficulty with tenotomy is that, despite the most careful and assiduous static and dynamic testing and operative dexterity, the exact effect of the operation, after cicatrization and contraction is completed, is not certain. Advancement seems to offer more definite results.

Paralysis

Varieties.—Suspension of the function of a muscle or of a set of muscles constitutes true *paralysis;* impairment of the function alone is called *paresis.* One muscle alone may be paralyzed, or a set of muscles may be affected, or there may be total paralysis of all ocular movement.

Total ophthalmoplegia is paralysis of all the ocular muscles, due to some destructive cerebral lesion.

External ophthalmoplegia indicates paralysis of the external muscles of the eye—the four recti and the two oblique. It is an occasional symptom of locomotor ataxia.

Internal ophthalmoplegia, or paralysis of the ciliary and pupillary muscles, is very rare, but partial internal ophthalmoplegia often follows an attack of diphtheria. This partial paralysis of the internal muscles is generally known as paralysis of accommodation.

Paralytic strabismus may also be divided and classified according to the nerve involved.

Paralysis of the third or oculomotor nerve causes paralysis of the muscles of the lid (ptosis), and paralysis of the superior, inferior, and internal recti and of the inferior oblique. The manifestations of such paralysis are inability to move the eye from its central position inward and upward, and hence divergent or vertical squint with crossed and more or less vertical diplopia. There are also mydriasis and loss of accommodation.

Paralysis of the sixth or abducens nerve produces convergent squint and homonymous diplopia, due to a loss of power in the external rectus, which is supplied by this nerve.

Paralysis of the fourth nerve is manifested by loss of power in the superior oblique muscles, causing imperfect movement of the eye down and out, and hence diplopia and slight convergent squint.

According to A. Graefe, the proportionate frequency is as follows:

32 percent, isolated paralysis of a rectus externus.
16 percent, isolated paralysis of an oblique superior.
8 percent, isolated paralysis of one of the four remaining muscles.
44 percent, combined paralysis of all these four remaining muscles in one or both eyes.

The objective symptoms are limitation of movement of the affected eye on the side and in the direction of a paralyzed muscle. This limitation can generally be perceived when the patient holds his head still and attempts to follow the movements of the physician in various directions. If the paralysis is slight, it may not be recognized objectively. Another significant objective sign is the tendency of the head to be obliquely inclined, in a characteristic position for each form of paralysis. The deficiency in the affected muscle is partly corrected and the diplopia controlled by keeping the head turned toward the side of the affected muscle.

Subjective Symptoms.—Diplopia, occurring when the patient looks at an object situated within the sphere of action of the paralyzed muscle. The two images of an object seen in the median line are more widely separated when the object is moved in the direction of the action of the paralyzed muscle. The image seen by the sound eye is the true image, and that seen by the affected eye the false image. A study of the relative position of the two images enables one to determine the special muscles or set of muscles paralyzed.

Vertigo, nausea, headache, and incorrect estimation of position in space are disagreeable symptoms of an ocular paralysis. As the patient forms incorrect location of objects, his gait is often uncertain.

Special diagnosis of the ocular palsies depends upon the relative position of the images in diplopia. To determine the eye and muscle affected, it is necessary to remember that the loss of motility and diplopia increase upon the side of the paralyzed muscle. The image of the affected eye is always found on the side opposite that to which the cornea is turned. A ready method is to tell the patient to look straight at a pencil, and to follow the movements given it until two images of the pencil are seen. Then one eye is covered, and according to which image disappears, it is known whether there is crossed or homonymous diplopia, and the relative position of the two images will give an idea of the muscles paralyzed.

Causes.—The lesion directly causing the paralysis may be a primary affection of the nerves themselves, or may be situated in the cerebral centers from which the nerves originate. Syphilis and tubercular meningitis are probably the most common causes. Of the infectious diseases, diphtheria is most active in causing ocular paralyses, which, however, in these cases, are more manifest in the internal muscles of accommodation. Influenza, rheumatism, typhoid fever, and diabetes have also been mentioned as causes. Poisons, like nicotin, alcohol, lead, the ptomains, carbonic oxid gas, and exposure to cold have all been reported as causes. Orbital tumors and abscesses, exophthalmic goiter, aneurysm, cerebral hemorrhage, and fractures at the base of the brain may cause paralysis by pressure.

Prognosis.—The duration of the paralysis is more or less chronic. In the most favorable cases several months are required for a cure. The prognosis is favorable when a paralysis is a sequel to diphtheria, some mild injury, or transient intoxication. Ocular paralysis associated with locomotor ataxia in the early stages is likely to disappear as the disease progresses. The prognosis is uncertain when the true nature of the causative disease cannot be made out. In cases of long duration muscular atrophy may occur. The prognosis is unfavorable when the paralysis is discovered to be the result of some grave spinal or cerebral lesion.

Treatment.—Treatment should be directed to the removal of the cause and the relief of the symptoms. Syphilis yields to mercurials and iodids and diaphoresis. Meningitis must be treated in the usual manner. Diabetes demands dietary and hygienic treatment. Paralyses of rheumatic origin require the salicylates, colchicum, and other ordinary rheumatic therapeutics. Diphtheritic palsies generally disappear with healthy bodily nutrition and the best tonic treatment. The influence of mercuric chlorid should never be overlooked. Both the galvanic and faradic currents are sometimes of value. For the relief of the diplopia it is well to occlude the unsound eye from vision, either by a bandage or by an opaque disc. The simple patch is the least cumbersome occlusive bandage. In all cases it is well to remember that a long period of diplopia and its consequent distressing symptoms will elapse before a cure can be effected. If the paralysis continues in spite of all treatment, it may be well to try to remedy the patient's discomfort by prisms, but these are rarely of value. In cases beyond the possibility of cure, in which strabismus has developed, tenotomy or advancement may be performed to relieve the disfigurement. In cases of secondary contracture an attempt should be made to oppose the development of the contracture by stretching the antagonist of the paralyzed muscle, by seizing the overlying tissues with fixation forceps, and strongly rotating the eye several times toward the side of the paralyzed muscle.

Nystagmus is involuntary oscillation of the eyeball due to spasmodic jerking movements of the eye, not interfering with the voluntary movements, but accompanying them. It is the result of defective coordination. The involuntary movements may be horizontal or vertical, oblique, or rotations about the visual axis. Internal squint is a frequent accompaniment, and there may be simultaneous shaking of the head.

The commonest form of nystagmus is that coming from some deficiency of vision in both eyes, beginning in childhood, particularly in amblyopia, the result of the destructive changes after ophthalmia neonatorum and in retinitis pigmentosa. It also exists in microphthalmos, albinism, and some varieties of congenital cataract. Miners who constantly strain their eyes in the darkness sometimes develop the disease. Nystagmus from cerebral disease is only of symptomatic significance. It is especially important in the diagnosis of multiple sclerosis.

Treatment beyond rest and the relief of the distressing symptoms is of little value. It must always be remembered that there is a possibility of improving the visual acuity and modifying the

PARALYSIS OF THE OCULAR MUSCLES

The black figure represents the image of the left eye throughout. The light figure, that of the right eye. (*Modified after Landolt.*)

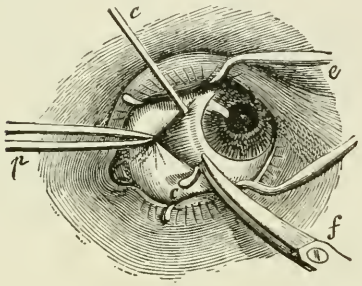
The muscle paralyzed.	Limitation of motion.	Direction of the affected eye.	The Images.	Position of the Images.		Direction of the sound eye during fixation of the paralyzed eye.	Position of the face.	Remarks.
				Paralysis of the Left.	Paralysis of the Right.			
Rectus externus.	Outward.	Inward. No inclination of vertical meridian.	Homonymous. The images are upon the same plane and parallel; their distance apart is increased by the patient directing his gaze to the side of the affected eye. The dividing line between single and double vision is, in the upper part, somewhat inclined toward the affected eye; in the lower, toward the sound one.			Inward	Turned upon its vertical axis toward the affected eye.	Pathologic convergence becomes clearer in looking downward, divergence in looking upward.
Rectus internus.	Inward.	Outward.	Crossed. On the same plane and parallel. Their distance apart increases when the patient looks to the side of the sound eye and upward. In looking upward and to the sound side, the image of the paralyzed eye is a little lower than the other, and its upper part is inclined inward. In looking downward and to the sound side, the image of the paralyzed eye is higher and its upper part inclined outward. The line between single and double vision is inclined to the vertical.			Outward.	Turned upon its vertical axis toward the affected eye.	
Rectus superior.	Upward and a little inward.	Downward. In looking upward, downward and outward.	One image is above the other and slightly crossed, especially in the upper half of the visual field. The image of the affected eye is above the other, and its upper part is inclined away from the image of the sound eye. The difference of elevation increases upon looking upward and inward. The lateral distance decreases in looking either to the right or to the left. The obliquity of the images increases in looking toward the sound side. The line between single and double vision is inclined to the horizontal from above, and from the side of the sound eye downward and toward the affected eye.			Upward.	Upward.	The upper lid of the paralyzed eye is slightly elevated in looking upward. In paralysis of the rectus superior or inferior, the deviation is particularly shown in the position of abduction. In paralysis of the superior or inferior oblique, the deviation is particularly shown in the position of adduction.
Rectus inferior.	Outward.	Upward and outward.	One image is above the other and slightly crossed, especially in the lower half of the field. The image of the paralyzed eye is below, with its upper end inclined to that of the sound eye. The perpendicular distance between the images increases in looking downward and to the affected side. The lateral distance decreases in looking to either side. The line between single and double vision is inclined to the horizontal.			Downward and outward.	Downward and slightly to the affected side.	

PARALYSIS OF THE OCULAR MUSCLES

The muscle paralyzed.	Limitation of motion.	Direction of the affected eye.	The Images.	Position of the Images.		Direction of the sound eye during fixation of the paralyzed eye.	Position of the face.	Remarks.
				Paralysis of the Left.	Paralysis of the Right.			
Obliquus superior.	Downward and outward. In complete paralysis of this muscle, rotation downward is lessened.	Upward and inward. Vertical meridian is inclined outward, especially in looking downward and outward.	The images are one above the other and homonymous, especially in the lower half of the field. The image of the paralyzed eye is below, its upper end inclined toward the image of the sound eye. Their perpendicular distance apart increases by looking downward and toward the sound side. The lateral distance is decreased by looking to either side. The obliquity increases toward the side of the affected eye. The image of the affected eye appears to be nearer than the other. The line between single and double vision is inclined toward the horizontal from above, and the sound side downward and toward the paralyzed eye.			Downward and inward.	Downward and to the sound side. To avoid this position of the head, the patient holds the object above and to the sound side.	In paralysis of either obliquus, the act of looking upward or downward is always accompanied by a convergence caused by the exclusive action of the recti muscles. Divergence is observed in paralysis of the recti. The inclination of the images is reversed. In paralysis either obliquus the vertical deviation toward the nose, and obliquity toward the temple, is increased; the reverse takes place in paralysis of the recti.
Obliquus inferior.	Upward and outward.	Downward and inward.	The images are one above the other and homonymous, especially in the upper half of the field. The image of the paralyzed eye is above, and its upper end turned away from that of the sound eye. The perpendicular distance increases in looking upward and inward. The lateral distance increases in looking upward and outward. The obliquity of the two images increases upon the side of the paralyzed eye. The line of division between single and double vision is inclined to the horizontal, and the end corresponding to that of the affected eye is above the other.			Upward and inward.	Outward and slightly inclined toward the sound side.	The maxima-elevation and intermediate positions result from the combined actions of the superior and external recti.
Recti, obliqui, levator palpebræ superior, ciliary, and iris circular.	Inward, upward, downward; and intermediate positions.	Outward.	Crossed. The image of the paralyzed eye is a little above that of the sound; its upper end is inclined to that of the sound eye, and it seems to the patient that it is nearer him than the other one is. The perpendicular distance is increased by looking upward, and likewise the obliquity. This is decreased by looking downward and to the affected side. The lateral distance is increased by looking to the sound side.			Outward.	Inclined to the sound side and slightly raised.	The affected eye is somewhat prominent. Ptosis of the upper lid, mydriasis, ophthalmoplegia interna.

disease by correcting lenses. The prognosis of nystagmus is never encouraging, even under the most favorable circumstances.

EYE-MUSCLES, OPERATIONS. Tenotomy.—The eye should be thoroughly cleansed and rendered aseptic. The section of the tendon is best performed under cocain or other local anesthetic, as in general anesthesia the result cannot be seen during the operation. The lids are held apart by an eye speculum. The eye is turned in a direction away from the muscle to be divided and held by fixation forceps. A fold of conjunctiva lying over the muscle is grasped with the fixation forceps and a short vertical incision is made about 4 mm. from the corneal margin through the conjunctiva and the capsule of Tenon. The conjunctiva is freed from the underlying tissue by means of a pain of blunt scissors or other blunt instrument; when the muscle is exposed, a strabismus hook is



Section of the Tendinous Insertion.
c. c. Tenotomy hook. *e.* Speculum. *f.* Tenotomy scissors. *p.* Fixation forceps.

passed underneath the tendon and the tendon is raised from the globe and divided close to the sclera with a pair of blunt scissors. If complete tenotomy is desired, any fibers remaining undivided may be caught by a strabismus hook and cut through with the scissors. As a rule, no conjunctival stitch is necessary, although it may be used in cases of tenotomy of the interni. After the operation the eye is cleansed and a light dressing applied for a few hours. A mild antiseptic lotion should be ordered. The divided tendon becomes reattached at a point beyond its former insertion.

Advancement.—In this operation the insertion of a muscle is advanced toward the corneal margin by means of a suture. It is performed on weak and relaxed muscles, and in connection with tenotomy of the opposing strong muscle. The process of separating the tendon is the same as in tenotomy, and the tendon is lifted away from the globe by a strabismus hook. A needle threaded with silk of sufficient strength is then introduced in the tendon near the upper margin, from behind forward, and a sufficient number of millimeters back of the insertion to produce the requisite advancement. Another suture is similarly introduced at the lower border of the tendon. The tendon is then divided near the sclera with the blunt-pointed scissors, and the needle of the upper suture is carried beneath the conjunctiva to a point near the upper corneal margin, where it is then brought through leaving the ends of the thread hanging free. In like manner the needle of the lower suture is brought out near the lower corneal margin. The ends of the two sutures are then tied together, the threads being drawn tight enough to slightly overadvance the tendon beyond the point of necessity. This latter precaution is taken to counteract the diminution of advancement with healing. If desired, the tendon may be divided last, after the sutures are brought out through the conjunctiva. The surgeon must be careful not only to pierce the conjunctiva, but also the capsule of Tenon, as sutures would tear through the conjunctiva alone. Some surgeons excise a small portion of the conjunctiva and the capsule of Tenon between the insertion of the tendon and the cornea. The sutures should be removed on the third or fourth day. A mild antiseptic solution may be used as a lotion. Various other operations of advancement have been suggested. Landolt's **capsular advancement** is a deservedly popular operation.

EYE-MUSCLES, TESTS.—See Eye-muscles (Anomalies).

EYE-STRAIN.—See Asthenopia.

F

FACE IN DIAGNOSIS.—By frequent recurrence the physiognomic changes produced by certain passions and emotions fix themselves permanently upon the face, so that what was in the beginning a passing impression upon the features, becomes a fixed change. Joy expands the face, while sorrow wrinkles the brow and deepens the facial lines. Conditions are transmitted through generations, so that slowly but surely certain types are established. In this way is seen the sympathetic face or the repulsive face; the attractive, pleasant face, and the hard, repellent face.

Facies of Bright's Disease. Wrinkled lids.—(*Greene.*)

The upper or frontal portion of the face (which corresponds to the convolutions of the cerebrum) is a medium of expression for the intellect; the middle portion for the emotions; the lower portion for the instincts; the relative development of these portions of the face indicates a corresponding development of the faculties that they represent.

Some faces are very significant of certain morbid conditions. A person with long, silky hair, large eyes with a bluish tinge of the conjunctiva, long eyelashes, prominent cheek bones, with the skin over them a bright red, lips retracted, is a type of consumptive.

Facies of Syphilis.

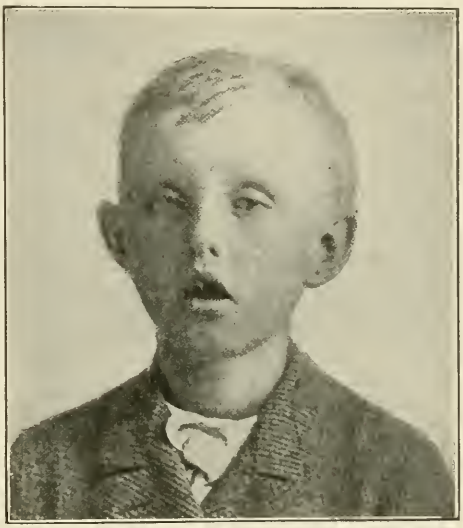
Gray areas of past alopecia. Saddle-nose. Patient and his father both showed perforated palate.—(*Greene.*)

Diseases of the abdominal organs bring about a characteristic appearance of the face. The features are somber and drawn, the skin is livid, its lines deeply marked, the eyes are sunken. The face of an infant is quite indicative of its condition of health, and significant of its malady. See Infantile Symptoms.

The various disease countenances are called the facies. Of these there are:

The Facies of Adenoids; of Bright's Disease; and of Syphilis. See Illustrations.

Cardiac Facies, an anxious expression occasionally seen in the early stages of chronic valvular disease. **F. Hepatica,** a peculiar earthy appearance of the face, often observed in organic disease of the liver. **F. Hippocratica,** the Hippocratic countenance, indicative of the rapid approach of dissolution: the nose seems pinched, the temples hollow, the eyes sunken, the ears leaden and cold, the lips relaxed, and the skin livid. **F. Ovariana,** the characteristic expression of women suffering from ovarian disease. The features are emaciated and sunken, the expression anxious, the forehead furrowed, the eyes hollow, the nostrils open and



Facies of Adenoids.—(*Greene.*)

sharply defined, the lips long and compressed, and the angles of the mouth depressed, with wrinkles encircling them. **F. Stupida,** the typhoid face.

FACE, DISEASES.—These are described under their separate headings. See Anthrax, Carbuncle, Erysipelas, Exanthems, Lupus, Syphilis, etc.

FACE, INJURIES.—Owing to the abundant blood supply, wounds of the face heal very rapidly. In burns, however, and in gunshot injuries in which there is much loss of tissue, great care is required to prevent deformity; the lower lip, for example, may be drawn down to the neck, or the lower eyelid permanently fixed in a position of ectropion. Even when they are badly bruised, the edges should always be brought accurately together and fastened by sutures; fine silver wire or silkworm-gut if the depth is not great; harelip pins if, for instance, the lip is divided through into

the mouth. It is essential to bring the scar into such a position that it will have the least effect upon the eyelids and the mouth. A double set of sutures is sometimes advantageous, one through the mucous and the other through the cutaneous surface; and the latter may be subcuticular, *i. e.*, carried through the corium from side to side, without appearing upon the surface. In this case fine catgut must, of course, be used. Bleeding generally ceases spontaneously, or as soon as the surfaces are brought into apposition; but the facial artery may require twisting or tying. Sutures should be removed as early as possible, and the edges of the wound supported by pressure, so as to avoid scarring. Many instances are on record of large portions of the nose having united again after complete detachment.

Fractures of the bones of the face are dealt with elsewhere. They are very frequently compound and comminuted; but extensive necrosis is unusual, and the prognosis, so far as life is concerned, is very good, unless the base of the skull (the roof of the nose, for example) is involved. Accurate apposition, however, so as to avoid deformity, is often a matter of great difficulty.

Division of the parotid duct is liable to be followed by salivary fistula, the opening of the cutaneous surface persisting, and the whole or greater part of the secretion pouring onto the skin, and giving rise to great discomfort and annoyance. To avoid this, the wound, if it does not already extend into the mouth, should be completed, and a catgut suture passed through the mucous membrane of the cheek and the adjacent wall of the duct on each side, and knotted on the oral surface. The edges of the wound in the skin must then be brought together accurately, and rendered as secure as possible with collodion. Even if union does not take place at first, the opening has a strong tendency to close, if only the saliva can find its way to the mouth.

FACIAL PARALYSIS (Bell's Palsy).—An acute paralysis of the seventh cranial—the facial nerve, the great motor nerve of the muscles of the face—the nerve of expression. Exposure to a current of cold air against the side of the face—over the pes anserinus—is the most frequent cause. It is also due to injury or disease of the middle ear and to syphilis.

Symptoms.—The facial nerve supplies the muscles of the face, the muscles of the external ear, also the stylohyoid, posterior belly of the digastric, the platysma, one muscle of the middle ear—the stapedius—and one palate muscle—the levator palati; by means of the chorda tympani branch it controls the secretion of the parotid and submaxillary glands, and, possibly, the sense of taste. It also furnishes motor power to the azygos uvulæ, the tensor tympani, and the tensor palati muscle.

The onset is usually sudden, with tingling of the lips and tongue, and upon looking into the mirror the patient is surprised by the perfectly blank, motionless side of the face; the corner of the mouth is depressed, the eyelids open, the face drawn toward the well side, and the patient is unable to expectorate, whistle, or swallow.

Any of the muscles innervated by the nerve may participate in the paresis. The electrocontractility is feeble or lost. The reflexes are abolished.

Diagnosis.—Paralysis of the muscles of the face occurs in hemiplegia; the points of differentiation are the presence of cerebral symptoms and the normal reflex excitability. Facial palsy with otorrhea, imperfect hearing, obliquity of the uvula, and loss of taste, determine its origin within the aquæductus fallopii. It is due to peripheral neuritis if the taste is normal and the uvula is straight. If other nerves are also involved, the origin is central.

The prognosis is favorable.

Treatment.—If the result of cold and damp, diaphoresis with pilocarpin, or diuresis with potassium acetate or iodid, and blisters in front of the ear, and the use of galvanism to the affected muscles.

FACIES.—See FACE IN DIAGNOSIS.

FAINTING.—The act of swooning. It may be the result of heart-disease, hemorrhage, pain, excessive emotion, tight lacing, indigestion, hunger, exhaustion, certain drugs, and hot and vitiated air. Eyestrain is a very common cause of fainting spells and swoonings. The face and extremities become cold, pale, and clammy. Unconsciousness may last a few seconds or several hours, usually a few minutes. It is not usually fatal.

The proper treatment is to assist the heart by lowering the patient's head, loosening any garment that may constrict any portion of the body's circulation, providing free, fresh air, sometimes sprinkling cold water over the face and chest, slapping the palms of the hands, chafing the feet, the application of weak ammonia water and smelling salts. The attendant should not hold any irritant to the air-passages too close to the nostrils. The head and face may be bathed with alcoholic solutions, as camphor, bay-rum, cologne, or whisky. No attempt should be made to administer stimulants by the mouth unless the patient is able to swallow, when whisky, wine, spirits, or ether, diluted, may be given. Dilute aromatic spirit of ammonia is serviceable and practicable.

After recovery from an attack of fainting, until the action of the heart and circulation are properly restored and strengthened, the patient must be kept quiet. See COMA, SYNCOPE.

FALLOPIAN TUBES, AFFECTIONS.—Inflammation of the Fallopian tubes, or salpingitis, is very common. It may occur as an acute or a chronic condition, the latter being most frequent.

Etiology.—The most important causes of salpingitis are septic infection (See COLON BACILLUS INFECTION), and gonorrhea. Gonorrhea very rapidly extends from the vagina or cervix to the body of the uterus, and from there extension to the tubes is a comparatively short and simple process. Septic infection involving the tubes usually follows labor or miscarriage. There are other less common causes of salpingitis, such as subinvolution, laceration of the cervix, fibroid tumors, and uterine displacements.

Pathology.—In the early stages of the disease the mucous membrane of the tube is swollen and congested, and the tubal walls become thickened.

The tube attains the size of the thumb. As the disease progresses, the abdominal and then the uterine end of the tubes closes, resulting in one of the forms of cystic distention of the tube. Thus the tube may become distended with pus (*pyosalpinx*), watery fluid (*hydrosalpinx*), or blood (*hematosalpinx*).

The ovary usually suffers as a consequence of this condition, any disease from a simple ovaritis to an ovarian abscess resulting from it.

The symptoms of acute salpingitis are not very distinctive. There is pain, which is more or less severe, confined to one or both ovarian regions; there are rise of temperature and increased rapidity of pulse. Examination reveals marked tenderness and fulness in the vaginal vaults. Occasionally, the enlarged tube may be distinctly palpated. In chronic salpingitis the most marked symptom is pain. This varies in character, but is almost constantly present. It is increased by exercise or exertion of any kind, such as walking, heavy lifting, defecation, and coitus.

At the menstrual period, when the pelvic structures are swollen and congested, the pain is intense. It begins usually 3 or 4 days before the appearance of the menstrual flow, and continues throughout the whole of the period. Marked exacerbations of pain may occur, caused by the occasional leakage of pus through the abdominal ostium into the peritoneal cavity.

Menorrhagia is commonly present, the patient usually menstruating profusely for a week or more.

Absolute sterility is present if the tubes are occluded by the inflammatory process.

The physical signs of chronic salpingitis are important. Usually the uterus is displaced backward, and lying behind or beside it can be felt the enlarged and indurated tubes. The isthmus of the tube, where it leaves the uterine cornua, can be felt as a hard, fibrous cord.

The treatment of acute salpingitis consists in rest in bed, purgation, vaginal douches, and hot applications. Purgation is best secured by the administration of Rochelle salts, 1 dram every hour, repeated as often as may be necessary. Vaginal douches of a gallon or more of hot water (110° F.) relieve the congestion and pain. Turpentine stupes or hot poultices applied to the lower part of the abdomen will also relieve the pain. If, under the foregoing plan of treatment, the patient does not improve; if the pulse-rate and temperature increase; if the pain and tenderness become more severe, celiotomy must be performed, and the diseased tubes and ovaries removed.

The treatment of chronic salpingitis may be either palliative or radical. If the pain is not severe; if there is no gross disease of the tubes; if the uterus is not retroverted, and if there are no extensive tubal adhesions, palliative treatment may be tried. This consists in rest during the menstrual periods; free purgation with saline laxatives; the administration of copious vaginal douches; painting the cervical and vaginal vaults with tincture of iodin, and the use of glycerin tampons.

A thorough preliminary curettage will be advantageous in the majority of instances.

If there are present the conditions previously spoken of, or if, in mild cases of salpingitis, palliative treatment fails, **operation** is usually demanded. This consists in freeing the tubes and ovaries from adhesions, in rendering patulous the tube, in replacing the retroverted uterus, and in removing the tubes and ovaries and, possibly, the uterus. Whenever possible, it is advisable to allow one tube and ovary to remain, or at least part of it, since in this way sterility and a premature menopause are avoided.

Tuberculosis.—This is a much more frequent condition than is commonly supposed, occurring in about 12 percent of all diseases of the tube. It may occur as a miliary form of tuberculosis, being part of a general condition, or, more frequently, it may be the chronic diffuse form, or a chronic fibroid condition.

Tuberculosis of the tubes is usually a secondary condition, the original focus of infection being in some other part of the body.

The symptoms of tubal tuberculosis are not distinctive. The same conditions are present as in an ordinary salpingitis. Should the patient have pulmonary tuberculosis, or should her husband have genitourinary tuberculosis, and should she present the ordinary signs of salpingitis, tubal tuberculosis should be suspected.

The treatment of tuberculosis of the tubes is operative. The tubes and ovaries should be removed, and the uterus also, if it is affected. The operation is usually favorable, cure resulting even though the peritoneal cavity is extensively involved.

Tumors.—Adenoma, myoma, and cancer rarely occur in the Fallopian tubes. The treatment consists of complete removal.

Impregnation.—See EXTRAUTERINE PREGNANCY.

FARCY.—See GLANDERS.

FAR-SIGHTEDNESS.—See HYPEROPIA.

FASTING.—Unless the supply of material in the form of food is equivalent to the loss occurring, a progressive wasting of the body and failure of power must ensue, and it is only a question of time when the continuance of life becomes impossible. The duration of life with complete abstinence from food and drink is usually from 8 to 10 days. A stout person may live longer than a thin one Exposure to cold hastens death; moisture in the atmosphere favors prolongation of life.

In treating cases of fasting both food and drink should be limited at first, and afterward gradually increased. To allow a sufferer from fasting to fully gratify his desires is generally fatal. Stimulants and external heat are demanded.

FATIGUE FEVER.—According to Vaughan and Novy, this affection frequently occurs after forced marching, especially during periods of war. It is accompanied by loss of appetite, chilly sensations, excessive cerebral excitement, fitful or unrefreshing sleep, and slight rise of temperature—1° to 3°. It is frequently mistaken for MALARIAL or TYPHOID FEVER (*q. v.*).

The prognosis is guardedly favorable when there is no organic lesion.

Treatment.—In the great majority of cases the

prime indications are to regulate the diet, which should be chiefly vegetable, to relieve indigestion, and to stimulate the emunctories of the body—the bowels, kidneys, and skin. Lavage may do good.

Intestinal antiseptics, such as naphthalin (6 grains) or naphthol (4 grains), are indicated, and may be given 3 times daily.

For relief of Constipation (*q. v.*) the ordinary measures are indicated.

To increase elimination of uric acid and urates Haig recommends the use of potassium iodid for a week or two, and afterward the substitution of sodium salicylate.

For inactivity of the kidneys diuretics should be used:

℞.	Lithium citrate,	ʒ j
	Wine of colchicum seed,	ʒ ij
	Sweet spirit of niter,	ʒ iv
	Elixir of curaçao,	ʒ iv
	Solution potassium citrate, enough to make	ʒ iij.

Two teaspoonfuls every 4 hours.

℞.	Potassium citrate,	ʒ ij
	Sweet spirit of niter,	ʒ iv
	Simple elixir,	ʒ iv
	Water, enough to make	ʒ iij.

Two teaspoonfuls every 4 hours.

For inactivity of the skin, hot baths, followed by massage and a sufficient amount of exercise, are of benefit in most cases. If not too depressing, the baths may be taken every 2 days, preferably in the forenoon or early in the afternoon.

The Diet.—Meats and highly nitrogenous foods are to be restricted, and fruits and vegetables, if obtainable, substituted. The excessive use of coffee, tea, alcohol, or tobacco increases the persistence of the symptoms, and should be prohibited, or only a limited quantity allowed.

FATNESS.—See Obesity.

FAUCES.—See Adenoids, Pharyngitis, Stomatitis, Tonsillitis, Tonsils.

FAVUS (Tinea Favosa).—A contagious vegetable parasitic disease, due to the Achorion schönleinii, characterized by cup-shaped, sulphur-yellow crusts perforated by hair.

Symptoms.—The usual seat of the disease is the scalp. The disease begins as a diffuse or circumscribed superficial inflammation with scaling, soon followed by the appearance of pinhead-sized, yellowish crusts seated about the hair follicles. The crusts increase to the size of peas, when they acquire the characteristics of the "favus-cup," scutulum. The typical favus-cup is split-pea sized, rounded, umbilicated, penetrated by a hair, and of a sulphur-yellow color. It is usually friable, crumbling between the fingers like dry mortar. When dislodged from its bed, there is exposed to view a reddened, shining, atrophic, cup-shaped, often suppurating excavation that heals up with the production of a scar. As a consequence, more or less permanent baldness results.

The crusts may be discrete or confluent, forming thick, irregularly shaped masses of a honeycomb appearance. In well-marked cases a peculiar mouse-like or damp-straw odor is present, which is quite characteristic of the disease. The hairs are dry, lusterless, and brittle, and are likely to split longitudinally, break off, or fall out. Itching, variable in degree, occurs in most cases.

Favus occasionally attacks the nonhairy portion of the body (*tinea favosa epidermidis*). It may also affect the nails (*tinea favosa unguium, onychomycosis favosa*), causing them to become thickened, yellowish, opaque, and brittle. The course of the disease is extremely chronic, lasting years, and in some cases a lifetime. The affection is contagious, but not to the same extent as ringworm.

Etiology.—The cause of the disease is a vegetable organism known as the Achorion schönleinii. The disease usually begins in childhood. It exists chiefly among the foreign poor. It is not infrequently contracted from cats and other lower animals.

Pathology.—The fungus occurs in the hair, hair follicles, and epidermis. The favus crust is made up almost entirely of fungus. The favus mycelium consists of slender threads, which appear as flattened tubes, either clear or containing spores. The threads are broader and the joints more numerous than in ringworm. The spores are rounded, highly refractive bodies, varying in size from 1/900 to 1/400 of an inch in diameter. They differ from the spores of ringworm in their greater variability both as to size and shape. Both spores and mycelium are abundant. Secondary inflammatory changes occur in the corium.

Diagnosis.—Tinea favosa is to be differentiated from tinea tonsurans and pustular eczema. The sulphur-yellow, cup-shaped, friable crusts, the scarring, the peculiar odor, and the history will usually enable one to make the diagnosis. Absolute proof is afforded by the microscope.

To examine for fungus, a fragment of crust or a hair is moistened in liquor potassæ and examined under a microscope, without preliminary staining.

Prognosis.—Favus of the scalp is extremely rebellious, lasting often for years. In long-standing cases extensive scarring and permanent hair-loss are likely to occur. Favus of the body responds readily to treatment.

Treatment.—The treatment of favus of the scalp consists of epilation of the diseased hairs and the use of parasiticide ointments and lotions. The hair should be closely cropped and the crusts removed by softening with oils and subsequent soap-and-water cleansing. The systematic extraction of the diseased hairs with an appropriate forceps is an essential part of the treatment. The parasiticide applications should be made twice daily.

Among the more important remedies may be mentioned the following:

℞.	Mercuric chlorid,	gr. iij to iv
	Water,	ʒ j.
℞.	Precipitated sulphur,	ʒ j to ij
	Petrolatum,	ʒ j.

℞. Oleate of mercury, 10 to 20 percent.

℞. Sodium hyposulphite, ℥ j
Water, ℥ j.

℞. Chrysarobin, ℥ j
Petrolatum, ℥ j.

To be used with caution.

The treatment is long and tedious, and is likely to tax the perseverance of the patient. The microscope should be repeatedly used before a case is pronounced cured. Treatment should be continued after apparent cure, to guard against relapse. Favus of the body is seldom rebellious, and may be treated with milder remedies than scalp cases. The crusts should be softened and removed, and a mercurial or sulphur ointment rubbed in. Favus of the nails is, as a rule, obstinate to treatment. The nails should be frequently pared and scraped and parasiticide ointments rubbed in twice daily.

FEBRIFUGE.—An agent that lessens fever. The best remedy for simple fevers is aconite in small, repeated doses. If given early, it will abate the fever. Veratrum viride is used as a febrifuge, and hyoscyamus or belladonna are beneficial, especially when there are head symptoms. Gelsemium is given for remittent or bilious symptoms, and arsenic in typhomalarial conditions. Four grains of phenacetin are given as a febrifuge in the simple fevers of children; and hydrochloric acid is beneficial to the same class. Lemon-juice, as lemonade or with potassium bicarbonate, and pomegranate-juice, are mildly febrifuge. One-half to 1 grain of the bromids is excellent for the febrile disturbances of children. Cold spongings and baths are of great use.

℞. Dilute hydrochloric acid, ℥ ss
Compound spirit of ether, ℥ jss
Syrup of rose, ℥ ss
Camphor water, enough to make ℥ iv.

Give a teaspoonful to a tablespoonful, according to age, every 6 hours.

℞. Potassium acetate, ℥ ij
Spirit of nitrous ether, ℥ iv
Simple syrup, ℥ j
Solution of ammonium acetate, ℥ ij
Camphor water, enough to make ℥ viij.

Give a teaspoonful to a tablespoonful, according to age.

See Antipyretics, Fever.

FECES.—Von Jaksch restricts the term "feces" to all those substances that, being formed from the food in the process of digestion, and mixed with the residues of the secretions of the alimentary canal, are finally expelled from the body by the rectum.

The importance of examination of the feces is gradually being appreciated. The basis of all such work is the determination of the time required for food to pass from the mouth to the rectum. The patient is merely given a teaspoonful of charcoal or a 5-grain capsule of carmin; this is easily recognized in the stool. Thus, "latent constipation" may be ascertained.

Macroscopic Examination.—The stool can be brought in a glass jar, or the patient may have one at the office at will, or by the aid of a suppository. A small piece of formed stool or a small amount of liquid feces is mixed well with distilled water and examined in a large Petri dish over a black background.

Mucus.—In constipation alternating with attacks of diarrhea the fluid stools contain flecks of mucus, and small hard fecal masses which are the cause of the diarrhea. In mucous colitis the mucus is in shreds. These strings should be searched for in all doubtful cases of abdominal pain before considering operation, since mucous colitis may simulate appendicitis, renal colic, floating kidney, gall-stones or ovarian colic. Thus a number of cases may be saved from unnecessary operation. Mucous colitis differs from membranous colitis in being a purely functional neurosis. Over 95 percent of the patients are nervous women; and in these the bowel condition should be let alone, attention being directed to the vasomotor system, rest in bed being the best treatment. The strips of mucus in the inflammatory form have cell inclusions, while in the neurotic type they are transparent. The higher the origin of the mucus the smaller the pieces. A definite colitis is usually indicated by purulent or bloody mucus, frequency of evacuation depending on the point of colon involved. In rectal carcinoma there are frequent stools, some mucus and considerable blood. Bloody mucus in children should suggest intussusception. Whenever mucus is found search should be made for amebæ, the stool being warmed, as by surrounding the container with warm water, in order to get the ameboid motion.

Intestinal sand consists of granules formed chiefly of phosphates and carbonates of calcium, magnesium, iron, etc., also of organic matter, fat, cholesterin, bacteria. It appears at intervals in the liquid stools of nervous persons, probably due to a secretory neurosis. *Pseudosand*—fruit seeds, vegetable structures—is common.

Acholic stools—clay-colored—result from (1) a milk or other fatty diet; (2) obstruction of the common duct (when relieved suddenly the stools may be orange in color, due to bilirubin); (3) bacterial ferment, which has changed the bile pigment to leukourobilin. When bile is apparently absent it may be found in the stool by extracting with alcohol or ether.

Fat is present in large amount in (1) acholic stools (the fat is not split up because of biliary stasis); (2) milk or oil diet; (3) disease of the intestinal wall preventing absorption, *e. g.*, tuberculosis or cancer of the intestine or retroperitoneal lymph glands, which blocks the flow of lymph; (4) true steatorrhea appears practically only in total destruction of the pancreas, and not always then. (The fat hardens on cooling.)

In malnutrition the stools are apt to be large, bulky, fetid, greasy, showing signs of active fermentation, containing gross particles of undigested meat and vegetables—showing a deficiency of

pancreatic fluid. Such gross particles in a firm stool are suggestive of pancreatic disease.

Black stools may be due to iron or bismuth or charcoal, or to gastric or duodenal ulcer.

Gall-stones.—If gall-stone colic is suspected, the stool should be mixed with water, strained through a coarse mesh and the stone looked for. The stone may have disintegrated in the bowel. If found it should be split open and examined, or dissolved in boiling alcohol to obtain cholesterin crystals.

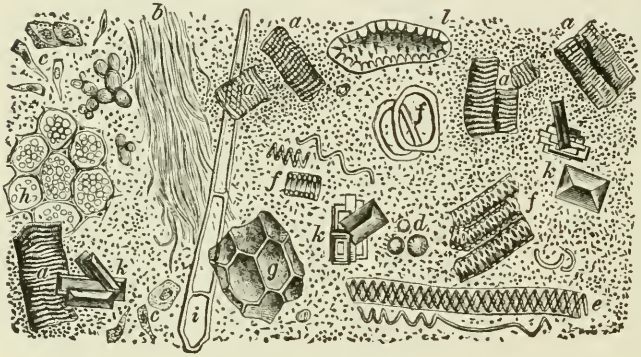
Pseudogall-stones are fat concretions or masses of vegetable or fruit tissues.

Azotorrhea, or excess of muscle fibers, denotes (1) absence of trypsinogen; or (2) its activating ferment enterokinase, *i. e.*, pancreatic destruction or intestinal destruction; or (3) abnormal motility.

Casein-curds in the stools of those on a milk diet often consist of almost pure fat.

Soaps may be present.

Intestinal worms, such as round worms, tapeworms, oxyuris, trichinæ, whipworms, uncinaria Americana and duodenalis, are frequently found and should be isolated and identified.



Normal Feces.—(*Landois.*)

a. Muscle fibers. *b.* Tendon. *c.* Epithelial cells. *d.* Leukocytes. *e-i.* Various forms of plant-cells, among which are large numbers of bacteria; between *h* and *b* are yeast-cells. *k.* Ammonium-magnesium phosphate.

Microscopic Examination.—For a correct estimate, a test diet is usually given the patient, though it has been suggested that the ordinary diet is more helpful in finding out the cause of the condition. The most popular diet is that of Schmidt and Strasburger, which consists of 2 3/4 pints of milk, 3 ounces of dried toast, 2 eggs, 1 1/2 ounces of butter, 1/4 pound tender rare steak, 6 ounces of mashed boiled white potatoes, and gruel made from 2 1/2 ounces oatmeal, 1/2 ounce of sugar. This, as translated by Steele, is given as follows: breakfast—2 eggs, 1/3 of the amount of toast and butter, 2 glasses of milk, oatmeal with milk and sugar. Dinner—Steak and potatoes, 1/3 of the amount of toast and butter, 1 1/2 glasses of milk. Supper—2 glasses of milk, remainder of toast and butter, 1 or 2 eggs, if desired.

From the aqueous mixture of the feces, particles should be selected with care, remembering that mucus and vegetable tissue tends to rise, eggs of parasites to sink with meat fragments, etc. The specimen selected is placed on a glass slide and examined. It is important to differentiate soap masses, vegetable cells, plant cells, etc., from animal cells. Unfertilized cells often resemble vegetable cells. In the search for intestinal worms and their eggs, the aqueous suspension should be centrifuged and the sediment examined, preferably after a dose of santonin or thymol.

In suspected liver-abscess or amebic dysentery careful search for amebæ should be made.

Starch granules are recognized by a drop of Lugol's solution. Charcot-Leyden crystals suggest intestinal parasites. Mucus containing pus cells is evidence of ulcer in the small intestine and colon. Blood cells from the lower bowel may be in the mucus. Fatty acid crystals are dissolved on warming and in ether. Soap may be present, if the specimen on a slide is warmed with acetic acid, crystals of fatty acid appear and droplets of neutral fat are soluble in ether. If an abnormal number of fat globules is seen there is an increase of fat in the stool—this condition is ascertained also by pressing a specimen under a cover-glass; if it is fatty, the glass will stay down when the pressure is released. In doubtful cases of malignant disease or ulcer of the stomach, a constant trace of blood in the stools is indicative of cancer; while periodic appearance of blood is suggestive of ulcer. The aloin test, though not always reliable, is preferable to the turpentine-guaiac, because it is more exclusive and is most valuable in differentiating between gastric ulcer and nervous gastralgia and in diagnosing gastric carcinoma. Tests for bilirubin indicate the location of the disturbance, if in the small bowel it will be found.

The fermentation test is helpful. An aqueous mixture of a small portion is placed in Steele's modification of Strasburger's instrument and kept at 37° C. for 24 hours. If gas is formed by fermentation it, will displace the water in the first tube, thus by the amount displaced, the amount of gas can be gauged. If more than 1/3 of the tube is filled, it is pathologic. If acid reaction is noted, there is carbohydrate fermentation; if alkaline and foul, there is albumin fermentation.

To diagnose intestinal autointoxication, cultures of the stool are made for bacteria. If intestinal ferment is suspected the bacillus bifidus should be searched for; if pernicious anemia, bacillus bifidus, and subtilis, tetani and aerogenes capsulatus; if ulcerative processes, various pathogenic and pyogenic organisms. In suspected tuberculosis search should be made for tubercle bacilli. To examine a blood stool, a fragment is mixed with 1.5 c.c. of distilled water to which is added 5 c.c. of a mixture of equal parts of alcohol and ether and after being whirled in a centrifuge 10 minutes, a smear is made from the sediment. The cholera spirillum, the Shiga bacillus, the typhoid and

tubercle bacilli are among the most important pathogenic organisms found in the feces.

The amount by weight of the bacteria in the feces is about one-third of the weight of the dry stool and represents one-half of the total nitrogen. To determine this amount Strasburger's method is the most accurate. Two c.c. of feces and 30 c.c. of 0.5 percent of hydrochloric acid are mixed in a mortar and centrifuged one minute. The supernatant liquid is poured out and the residue washed again in hydrochloric acid centrifuged and drained, the liquor being added to the first. This is repeated until the supernatant liquid is transparent. To the total liquid, which holds the bacteria, is then added an equal amount of alcohol. The mixture is placed on the water-bath at 40° for 24 hours, then partly evaporated and more alcohol added, then centrifuged for several minutes to get a deposit of bacteria. The liquid is poured off and whirled again in the centrifuge. The total bacterial sediment is washed with pure alcohol and ether in the centrifuge, dried at 100° and weighed. The dry weight of the fresh feces must have been determined in the meantime. Thus the amount of the bacteria in the dry feces can readily be ascertained.

Disinfection of Feces.—The chemicals of greatest value in the disinfection of feces are: (1) Chlorid of lime, (2) milk of lime, (3) carbolic acid, (4) mercuric chlorid.

Chlorid of lime is probably best for disinfecting the contents of privies, closets, army sinks, etc. Sternberg recommends 6 ounces to the gallon of water as a standard solution.

Milk of lime is best for disinfecting typhoid or cholera stools in the sick-room, being odorless and easily prepared by slaking lime with water, and adding 4 parts of water (Bissell). A quart of this should be added to each discharge.

Carbolic acid is frequently valuable, but on account of its odor is less used than lime. It should be used in the strength of from 3 to 5 percent.

Mercuric chlorid, under ordinary circumstances, is the best disinfectant known; yet for the disinfection of feces and sputum it is not so valuable as lime or carbolic acid, from the fact that it is quickly decomposed into an insoluble albuminate on being added to those substances to be disinfected. It may be used in strengths of from 1:500 to 1:2000. See DISINFECTION, DEODORANTS.

FEEDING.—See DIETETICS.

FEEDING, ARTIFICIAL.—See INFANT FEEDING, MILK, MODIFIED MILK.

FEEDING, FORCIBLE.—See GAVAGE.

FEEDING, RECTAL.—See ENEMA, SUPPOSITORY, etc.

FEET, EXCESSIVE OR FETID SWEATING.—See SWEAT-GLANDS (Diseases).

FEHLING'S SOLUTION.—See URINE (Examination).

FEIGNED DISEASE.—See MALINGERING.

FEL BOVIS.—The fresh bile of the domestic ox, *Bos taurus*. It is a dark green, viscid liquid, consisting mainly of sodium glycocholate and sodium taurocholate, together with cholesterin. It is a tonic, antiseptic, and purgative, useful in emulsifying the fatty portions of food. **Fel Bovis Purificatum,** ox-gall 3, alcohol 1 part. This should stand 24 hours before straining; then evaporate to the consistence of a pilular mass. Dose, 5 to 15 grains.

FELON.—See PARONYCHIA.

FEMUR.—See HIP-JOINT, THIGH.

FENNEL.—An umbelliferous plant, *Fœniculum capillaceum*. It contains a volatile oil, united with a terpene, and is a constituent of pulvic glycyrrhizæ compositus. **Oil of fennel** is a volatile, light-yellow liquid, having the odor of fennel, a warm taste, neutral reaction, and soluble in alcohol. It is an ingredient of spiritus juniperi compositus. Dose, 2 to 5 minims. **Fennel water** contains 2 parts of the oil in 1000 of distilled water. Dose, 1 to 8 drams.

Fennel is an aromatic stomachic and a mild stimulant. It is chiefly used as an agreeable carminative in flatulence and colic, and as a corrigent to senna, rhubarb, and other disagreeable medicines. An infusion is often used as an enema to expel flatus in infants.

FERMENTATION.—A general name for those processes of decomposition, during which certain carbon compounds called *ferments* act upon other carbon compounds, as on their food—splitting these latter up, setting free their elementary constituents, and thereby leading to the formation of still other carbon compounds, by the rearrangement of the freed molecules. These processes are of two kinds, viz.:

1. Those in which water is taken up (hydration), chiefly carried on by enzymes.

2. Those in which O is transferred from the H to the C association, as in lactic and alcoholic fermentation, and the putrefactive processes, which are chiefly carried on by the agency of organized ferments.

The ferments producing these fermentative changes are also carbon compounds, and are divisible into two groups, viz.:

Enzymes, or *Unorganized Ferments*, have no definite structures, as diastase, ptyalin, pepsin, etc.

Organized ferments are minute, living organisms, as the moulds, yeast-plant, bacteria, and other members of the protophytes, the lowermost class of plants, which, in the course of their life history, split up the carbon compounds in which they live, appropriating some part of their elements.

Agents which arrest or inhibit these fermentative processes either by destroying or by rendering inactive the causative ferments, are called **Antizymotics;** these are generally divided into two groups, ANTISEPTICS and DISINFECTANTS (*q. v.*).

FERROPYRIN.—An orange-red powder, containing about 64 percent of antipyrin, and 36 percent of ferric chlorid. It is used as a styptic in 20 percent aqueous solution or pure. It has given satisfaction in severe epistaxis, puerperal and other hemorrhages. Internally it has been used with benefit in anemic conditions accompanied by headache and gastralgia.

FERRUM.—See IRON.

FETATION, EXTRAUTERINE —See EXTRAUTERINE PREGNANCY.

FETOMETRY.—The measurement of the fetus, especially of its cranial diameters. The measurements usually made are as follows:

TABLE OF MEASUREMENTS

1. OF THE CHILD

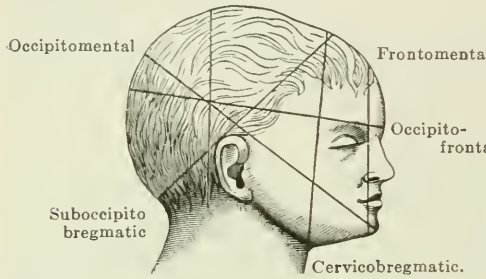
Length,	50 cm.	(20 in.?)
Bisacromial,	12 cm.	(4.8 in.)

2. HEAD

Bitemporal,	8 cm.	(3¼ in.)
Biparietal,	9½ cm.	(3¾ in.)
Occipitofrontal,	11¾ cm.	(4⅓ in.)
Occipitomental,	13⅓ cm.	(5¼ in.)
Suboccipitobregmatic,	9½ cm.	(3¾ in.)
Circumference, occipitofrontal,	34⅓ cm.	(13¾ in.)

Weight of Child, 2737 grams (7¼ pounds).

For practical purposes, it may be said that the occipitomental diameter is about 5 1/2 inches, the occipitofrontal about 4 1/2 inches, and all the others about 3 1/2 inches.



ANTEROPOSTERIOR AND VERTICAL DIAMETERS OF THE FETAL HEAD.—(*After Tarnier.*)

FETUS.—The young of viviparous animals in the uterus; the embryo in the later stages of development. The following is a table of the development of the embryo and fetus in the different months of pregnancy: *First Month.*—Indistinguishable from ovum of other mammals. It is a flattened vesicle. The embryo is nourished by a yolk-sac, which, even at the end of the first month, is larger than the cephalic extremity of the fetus. The visceral arches are distinct. The heart, first traces of liver and kidneys, eyes, rudimentary extremities, oral and anal orifices, are formed. The spinal canal closes (spina bifida results if this fails to occur at this time). Length, 1 cm. (0.4 inch). *Second Month.*—Grows to 4 cm. in length (1.57 inches), and is about the size of a pigeon's egg. The visceral clefts close, except the first, which forms the external auditory meatus, tympanum, and eustachian tube. At this time arrest of development results in harelip, umbilical hernia, or exomphalos. Eyes, nose, and ears are distinguishable. The first suggestion of hands and feet appears, and these are webbed. External genitals also now develop, but sex is not to be differentiated. *Third Month.*—Maternal blood affords nourishment; 9 cm. long (3.6 inches), and about the size of a goose-egg. Fingers and toes lose their webbed character, and nails appear as fine membranes. Points of ossification are found in most of the bones. The neck separates the head from the trunk, and sex is determined by the appearance of the uterus. Weight, 30 gm. (463 grains). *Fourth Month.*—Sixteen cm. (6 inches) in length. Lanugo is present. Intestines contain meconium. Sex is well defined. Weight, 55 gm. (848.76 grains). *Fifth Month.*—Twenty-five cm. (10 inches). Vernix caseosa appears in places. The face is senile in appearance and wrinkled. Eyelids begin to open. Quickening occurs. Heart-sounds are heard. Weight, 273 gm. (10.8 ounces). *Sixth Month.*—Thirty cm. (12 inches). Hair grows longer. Eyebrows and lashes appear. The testicles approach the inguinal rings. Weight, 715 gm. (23 ounces). *Seventh Month.*—Thirty-five cm. (14 inches). Pupillary membrane disappears. Weight, 1213 gm. (39 ounces). *Eight Month.*—Forty cm. (16 inches). Down on the face begins to disappear. The left testicle has descended. Ossification begins in the lower epiphysis of the femur. The nails do not project beyond the finger-tips. Weight, 1617 gm. (4 1/3 pounds). *Ninth Month.*—Forty-five cm. (18 inches). Subcutaneous fat increases. Diameters of the head about 1 to 1 1/2 cm. less than at term. Weight, 1990 gm. (5 1/3 pounds). *Mature Fetus.*—Fifty cm. long (20 inches); weight, 2737 gm. (7 1/3 pounds). Skin is rosy; lanugo has disappeared. The nails are perfect and project beyond the finger-tips. The eyes are opened. The center of ossification in the lower epiphysis of femur is 5 mm. in diameter, while that of the cuboid bone is just beginning to show. Diameters of head are normal.

LENGTHS AND WEIGHTS OF THE FETUS AT DIFFERENT STAGES OF ITS DEVELOPMENT

1st month,	1 cm. (0.4 in.)	
2d month,	4 cm. (1.57in.)	
3d month,	9 cm. (3.6 in.)	30 gm. (463 grs.)
4th month,	16 cm. (6 in.)	55 gm. (848.76 grs.)
5th month,	25 cm. (10 in.)	273 gm. (10.8 oz.)
6th month,	30 cm. (12 in.)	715 gm. (23 oz.)
7th month,	35 cm. (14 in.)	1213 gm. (39 oz.)
8th month,	40 cm. (16 in.)	1617 gm. (4⅓ lb.)
9th month,	45 cm. (18 in.)	1990 gm. (5⅓ lb.)
10th month,	50 cm. (20 in.)	2737 gm. (7¼ lb.)

FETUS, CIRCULATION.—Beginning at the placenta, or where the impure venous blood is transformed into pure arterial blood, the fetal circulation is as follows: From the placenta the blood passes to the under surface of the liver through the *umbilical vein*. Here it divides, the smaller portion going directly into the ascending vena cava through the *ductus venosus*, the larger portion passing through the liver and finally emptying into the ascending vena cava by means of the hepatic veins. This blood, in conjunction with the blood from the lower extremities, passes through the ascending vena cava to the right auricle, from which, guided by the eustachian valve, it passes through the *foramen ovale* into the left auricle. From here it passes into the left ventricle, and from here through the aorta, the greater portion going to the head and upper extremities. Returning by the descending vena cava, it enters the right auricle and passes from here into the right ventricle. A small portion is carried from here to the lungs through the pulmonary arteries; the remainder passes directly into the aorta through the *ductus arteriosus*. From here a small portion is carried by the aorta to the lower extremities; the remainder passes

through the *hypogastric arteries*, and finally reaches the placenta through the umbilical arteries.

The umbilical vein, ductus venosus, foramen ovale, ductus arteriosus, and hypogastric arteries are characteristic of the fetal circulation.

The fetal heart-beat is a positive sign of pregnancy. In character it is not unlike the ticking of a watch placed under a pillow. Its rate varies from 120 to 160 beats a minute. It is heard most distinctly at certain points on the abdomen, depending upon the position of the child. Thus,

THE FETAL CIRCULATION.

a. Umbilical vein. *b*. Ductus venosus. *c*. Ductus arteriosus. *d*. Hypogastric arteries. *e*. Mesenteric arteries and vein. *f*. Portal vein.

in anterior vertex presentations it is heard most distinctly about an inch below and to the right or left of the umbilicus. In posterior vertex presentations its point of greatest intensity is in the flank, right or left, about on a level with a line drawn through the umbilicus.

FETUS, DEATH.—This is not an infrequent occurrence. Quite a large proportion of children —probably 25 percent—die before reaching full term.

Causes.—The causes of fetal death are various. The most frequent and important is *syphilis*. A very large proportion of habitual fetal deaths are due to this cause. Following this come *apoplexies* of the ovum, decidua, or placenta; *acute or chronic diseases of the mother*, as pneumonia, typhoid fever, tuberculosis, nephritis, anemia, and plethora; *chronic poisoning*, as alcoholism and saturnism; *diseases of the father*, as phthisis, albuminuria, and chronic poisoning; *habit* and *heredity*.

Diagnosis.—A positive diagnosis of fetal death is extremely difficult. Among the important signs are continued absence of fetal heart-sounds and fetal movements, after they had formerly been appreciated; cessation of growth or diminution in size of the uterus; disappearance of the subjective signs of pregnancy; and the appearance of the milk secretion. If the umbilical cord can be palpated, a positive diagnosis can be made.

Results.—The most common result is spontaneous discharge of the fetus and membranes from the uterus (abortion). If, after death, the fetus is retained in the uterus, a number of changes in structure may occur. These are maceration, putrefaction, saponification, mummification, and calcification. If fetal death occurs before the third month, absorption may take place.

Treatment.—So long as a dead fetus remains inside the uterus, the mother is in grave danger of septic infection. As soon as the diagnosis is assured, the patient sould be anesthetized and the fetus and membranes removed.

FETUS, DISEASES.—A great variety of diseases may affect the fetus *in utero*. Among them may be mentioned the *infectious diseases*, as syphilis, smallpox, measles, typhoid fever, malaria, and tuberculosis; *intracranial diseases*, as tumors of the brain and hydrocephalus; *valvular heart-disease*, *rachitis*, *fractures of the long bones*, and *ankyloses* and *luxations*.

Syphilis.—This is the most frequent disease. It may originate in 3 ways: (1) From disease of the ovum; (2) from disease of the spermatozoon; from infection through the maternal blood.

The manifestations of syphilis in the fetus may be any or all of the following: (1) *The skin*—pemphigoid eruptions are frequently found on the soles of the feet and the palms of the hands. (2) *The bones*—one of the most constant manifestations is a jagged yellow line between the diaphysis and the epiphysis of the long bones. This is caused by a fatty degeneration of the embryonal bone-cells, due to a premature attempt at ossification. (3) *The liver and spleen*—both are frequently enlarged, due to an overgrowth of connective tissue. (4) *The lungs*—usually one of three conditions is found—an overgrowth of connective tissue (fibroid pneumonia), an overgrowth and fatty degeneration of the epithelial cells lining the air vesicles (white pneumonia), or gumma.

FETUS, MALFORMATIONS.—Every departure from the normal condition may be classified as: (1) Hemiteratic; (2) heterotaxic; (3) hermaphroditic; and (4) teratologic. See MONSTROSITY.

FETUS PAPYRACEAS.—The name given to the malformation resulting in a twin pregnancy, when, owing to an inequality in the circulation of the embryos, the weaker fetus dies, and, by the continually increasing pressure of the growing fetus, it is flattened more and more against the uterine walls, until the mass becomes as thin as stout parchment.

FETUS, POSITIONS AND PRESENTATIONS.—On the following page is presented a comparative table of fetal positions and presentations.

Breech Presentation.—Presentation of any part of the pelvic extremity of the child. Breech presentations occur in about 3 percent of all cases of labor.

Causes.—These are: (1) Decreased mobility of the child, as in twin births, hydramnios, and placenta prævia; (2) when the head cannot engage in the superior strait, as in hydrocephalus and contracted pelvis; (3) in abnormal growths of the fetus when the center of gravity is thrown nearer the pelvis, as in hemicephalus and tumors of the sacrum. Breech presentations are very frequent in premature births, on account of the disproportion in size of the fetus and uterine cavity.

Diagnosis.—Abdominal palpation reveals the head above, which is round, hard, and freely movable; the breech below, soft and irregular in outline. The heart-sounds are heard above the umbilicus. Vaginal examination shows a high position of the presenting part; after dilatation of the os the characteristic features of the breech may be detected—the sacrum and coccyx, the external genitalia and anus, the nates and thighs. There is usually evacuation of meconium.

Mechanism.—This comprises the following steps: (1) Dilatation of the lower uterine segment and cervix. This occurs very slowly, as the soft breech is a very ineffectual dilator. (2) Descent of the breech to the pelvic floor. (3) Forward rotation of the anterior hip. The anterior hip is the first part of the child to strike the pelvic floor. (4) Birth of the anterior hip, posterior hip, and trunk. (5) Engagement, descent, rotation, and birth of the shoulders. (6) Descent of the head. The head usually descends in an oblique diameter. (7) Forward rotation of the occiput. (8) Delivery of the head. The parts pass over the perineum in the following order: Chin, mouth, nose, eyes, and brow.

Abnormalities in Mechanism.—The most frequent and important is backward rotation of the occiput. This occurs very rarley in spontaneous births; more frequently in operative retraction. If the head remains flexed, the chin, mouth, eyes, and brow pass rapidly beneath the symphysis. If the head becomes extended, the chin catches upon the symphysis, and the small fontanel, cranial vault, and face slide over the perineum.

Prognosis.—The danger to the mother is no greater than in vertex presentations, except that there is greater risk of injury to the soft parts. The fetal mortality is about 30 percent.

Treatment.—Unless there is some indication for interference, breech presentations should be treated expectantly until the birth of the umbilicus. At this stage the cord becomes compressed between the pelvis and the child's trunk or head, and asphyxiation may occur. During this period of waiting the child's heart-beat should be listened to repeatedly, so that no danger may be overlooked. As soon as the umbilicus appears, the patient is placed in the lithotomy position across the bed; the trunk is delivered rapidly until the shoulders appear; the arms are released, and the after-coming head is extracted by one of the methods described below.

After-coming Head.—This may occur in normal breech presentations and after the performance of podalic or pelvic version. After the child is born as far as the umbilicus, the cord is compressen between the fetal head and maternal pelvis above, thus shutting off the supply of oxygen. Further delivery must be accomplished rapidly—within five minutes—if asphyxiation is to be prevented. This is effected as follows: If the arms are extended by the side of the child's head, they should be delivered first. The posterior arm may be located by the position of the trunk and shoulders, as it will be found the easiest to manipulate. If it is the right arm, the child's ankles should be grasped with the left hand—the middle finger above the internal malleoli, the index- and ring-fingers above the external malleoli—and the body raised upward and outward over the mother's right thigh. Sufficient force should be exerted to bring the right shoulder well down in the pelvis. The first two fingers of the right hand are passed along the posterior surface of the right scapula and arm, well beyond the elbow. The forearm is now pushed in front of the child's face; the fingers are hooked in the bend of the elbow, and slight traction causes it to appear at the vulva. The forearm is now easily delivered by extension. The left arm is delivered in a similar manner. Should the shoulders lie in the transverse diameter, either arm may be delivered first. The head should next be extracted by one of the following methods, tried in the order given:

The Wiegand-Martin Method.—The first three fingers of the supinated right hand are introduced into the vagina, the abdomen of the child lying upon the operator's forearm, with a leg hanging on each side. The index-finger is inserted into the child's mouth, and sufficient traction made to secure complete flexion of the head. The left hand now locates the occiput through the abdominal wall above the pubes, and its further delivery is accomplished by suprapubic pressure in the direction of the parturient axis and by elevation of the child's body toward the mother's abdomen.

The Mauriceau or Veit-Smellie Method.—The manipulations of the right hand are the same as in the preceding method. The pronated left hand is passed along the back of the child, the middle finger making pressure against the occiput, so as to aid flexion, the index- and ring-fingers hooked over the clavicles. Traction is now made in the direction of the axis of the parturient canal; first, downward and outward; finally, as the face emerges, upward and outward. Suprapubic pressure on the occiput by an assistant increases the efficiency of this method.

The Prague Method.—The child's ankles are grapsed by the pronated right hand—the middle finger above the internal malleoli, the index- and ring-fingers above the external malleoli. The pronated left hand is introduced into the vagina along

the child's back; the index-finger is hooked over one clavicle, the remaining fingers over the other. Traction is now made with both hands as directly downward as possible, until the occiput appears under the symphysis. The right hand now shifts its grasp on the ankles so that they are held as before described, except that the feet are now in contact with its dorsal surface. The feet are now raised by a circular movement toward the mother's abdomen, the left hand acting as a fulcrum around which the head moves until it is finally delivered.

TABLE OF THE POSITIONS AND PRESENTATIONS OF THE FETUS

Presentation.	Frequency.	Varieties.	Symbol.	Frequency of Varieties.	Position of Fetus.	Position of Fetal Heart-sounds.	Mortality.	
							Fetal.	Maternal.
Vertex.	95 per-cent of all cases.	Left occipito-anterior.	L.O.A.	70 percent.	Occiput to left acetabulum, forehead to right sacroiliac joint; back to left; extremities to right, above.	One inch below, and to left of umbilicus.	5 per-cent.	Less than 1 per-cent.
		Left occipito-posterior.	L.O.P.		Occiput to left sacroiliac joint, forehead to right acetabulum; back in left flank; extremities to right, anteriorly.	In left flank, below a transverse line through umbilicus.	Over 9 per-cent.	
		Right occipito-anterior.	R.O.A.		Occiput to right acetabulum, forehead to left sacroiliac joint; back to right; extremities to left, above.	Near median line; below umbilicus.	Over 9 per-cent.	
		Right occipito-posterior.	R.O.P.	20 percent.	Occiput to right sacroiliac joint, forehead to left acetabulum; back in right flank; extremities to left, anteriorly.	In right flank, below a transverse line through umbilicus.	5 per-cent.	
Face.	1/2 of 1 percent.	Left mento-anterior.	L.M.A.	Second in frequency.	Chin to left acetabulum, forehead to right sacroiliac joint; back to right; extremities to left.	Left side of abdomen, below umbilicus.	13 to 15 per-cent.	6 per cent.
		Left mento-posterior.	L.MP.		Chin to left sacroiliac joint, forehead to right acetabulum; back to right; extremities to left.	Left side of abdomen, below umbilicus.		
		Right mentoanterior.	R.M.A.		Chin to right acetabulum, forehead to left sacroiliac joint; back to left; extremities to right.	Right side of abdomen, below umbilicus.		
		Right mentoposterior.	R.M.P.	Most common.	Chin to right sacroiliac joint, forehead to left acetabulum; back to left; extremities to right.	Right side of abdomen, below umbilicus.		
Brow.	1/4 of 1 percent.	Left frontoanterior.	L.F.A.		Brow to left acetabulum; chin to right sacroiliac joint; back to left; extremities to right, above.	Left side of abdomen, below umbilicus.	30 per-cent.	10 per-cent.
		Left frontoposterior.	L.F.P.		Brow to left sacroiliac joint; chin to right acetabulum; back to left; extremities to right, above.	Left side of abdomen, below umbilicus.		
		Right frontoanterior.	R.F.A.		Brow to right acetabulum; chin to left sacroiliac joint; back to right; extremities to left, above.	Right side of abdomen, below umbilicus.		
		Right frontoposterior.	R.F.P.		Brow to right sacroiliac joint; chin to left acetabulum; back to right; extremities to left, above.	Right side of abdomen, below umbilicus.		

TABLE OF POSITIONS AND PRESENTATIONS OF THE FETUS

Presentation.	Frequency.	Varieties.	Symbol.	Frequency of Varieties.	Position of Fetus.	Position of Fetal Heart-sounds.	Mortality.	
							Fetal.	Maternal.
Shoulder.	1/2 of 1 percent.	Left dorso-anterior.	L.D.A.	Most common.	Head in left iliac fossa, back anterior; extremities on right side, in upper part of abdomen.	Left side of abdomen, below umbilicus.	Almost 50 percent.	11 percent.
		Left dorso-posterior.	L.D.P.		Head in left iliac fossa, back posterior; extremities on right side, in upper part of abdomen.	Frequently cannot be heard.		
		Right dorsoanterior.	R.D.A.		Head in right iliac fossa, back anterior; extremities on left side, in upper part of abdomen.	Right side of abdomen, below umbilicus.		
		Right dorsoposterior.	R.D.P.		Head in right iliac fossa, back posterior; extremities on left side, in upper part of abdomen.	Right side of abdomen, below umbilicus toward the flank.		
Breech.	3 to 4 percent. of all cases.	Left sacro-anterior.	L.S.A.	Most common.	Sacrum to left acetabulum; back to left anterior; abdomen to right posterior.	Left side of abdomen, above umbilicus.	30 percent.	Less than 1 percent.
		Left sacro-posterior.	L.S.P.		Sacrum to left sacroiliac joint; back to left posterior; abdomen to right anterior.	Left side of abdomen, above umbilicus and toward the back.		
		Right sacroanterior.	R.S.A.		Sacrum to right acetabulum; back to right anterior; abdomen to left posterior.	Right side of abdomen, above umbilicus.		
		Right sacroposterior.	R.S.P.		Sacrum to right sacroiliac joint; back to right posterior; abdomen to left anterior.	Right side of abdomen, above umbilicus and toward the back.		

The Forceps.—The child's body, arms, and legs are raised toward the mother's abdomen. The blades of the forceps are applied to the sides of the head, and delivery is effected by traction made in the direction of the axis of the parturient tract.

The Deventer Method.—The mother's buttocks are brought well over the edge of the bed. The child is grasped as in the Prague method, and traction is made downward and backward. This method may be tried when great haste is demanded. It is not necessary to first deliver the arms.

If in the delivery of the after-coming head the face is found looking toward the symphysis, the following rules for management should be remembered: If the head is flexed, deliver by direct downward traction; if extended, with the chin caught upon the symphysis, deliver by carrying the body of the child upward over the mother's abdomen.

Perforation of the after-coming head is necessary in cases of hydrocephalus and in certain degrees of contracted pelvis.

It is usually performed in one of two ways: (1) When the occiput is anterior under the symphysis pubis, an assistant carries the body of the child upward over the mother's abdomen, and the perforator is introduced through the anterior part of the neck and hard palate. (2) When the occiput is posterior, the child's body is held as before, and the perforator is introduced at the nape of the neck, beside the foramen magnum or just back of the ear. In cases of hydrocephalus when the head cannot be reached, the spinal canal may be opened and the fluid evacuated through a catheter passed into the cranium through the foramen magnum.

Brow Presentation.—This is a very rare presentation, occurring once in about 1800 cases. There are 4 positions, as in face presentation, depending upon the direction of the chin.

Diagnosis.—This is determined by a vaginal examination. A broad, bony surface is felt presenting; the supraorbital ridge and the base of the nose may be distinguished; also the large fontanel.

Mechanism.—The mechanism of labor in a brow presentation is similar to that of a face. Anterior rotation is extremely slow, and may be impossible. The mechanism is further discussed in the paragraph on face presentation.

Prognosis.—Of all presentations, this is the most unfavorable for both mother and child. The

maternal mortality is 10 percent; the fetal mortality, 30 percent.

Treatment.—Except in very rare instances, brow presentations require prompt and active treatment. It may be possible to convert a brow into a vertex presentation. This may be done by external pressure upon the occiput or by combined external and internal manipulation. If this fails, and the chin is looking anterior, an effort should be made to convert it into a face presentation. Failing in this, podalic version should be attempted. This should not be resorted to if the presenting part is firmly engaged. If the chin is anterior, forceps may be tried. Great care must be exercised here or serious injury to the mother may occur. Forceps should never be used for traction if the chin is posterior. Finally, if the foregoing plan of treatment fails, craniotomy is indicated.

Version is an operation or maneuver by which the presentation of the child is changed. There are two varieties of version—*cephalic*, in which the head is made to present, and *podalic*, in which the breech or foot is brought to present.

Indications.—These are (1) cross presentations, (2) minor degrees of contracted pelves, (3) malpositions of the head, (4) placenta prævia, (5) prolapse of the cord, and (6) some sudden danger to the mother, before engagement of the head, which necessitates rapid delivery.

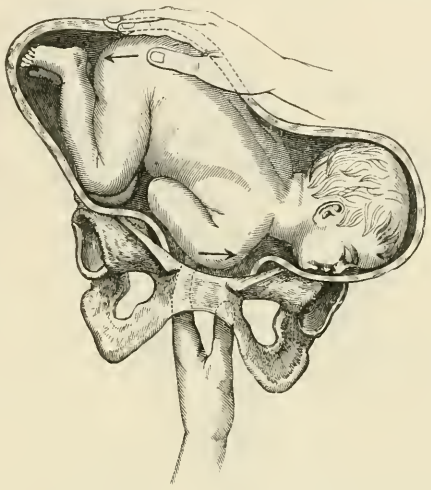
Contraindications.—Version must not be attempted (1) when the presenting part is firmly engaged, or (2) when there is a high position of the contraction ring. This latter condition is an indication of an overstretched and thinned lower uterine segment that might be ruptured by efforts at turning.

Methods.—The various methods resorted to in performing version are: (1) The postural method; (2) the method by external manipulation; (3) the combined method; and (4) the method by internal manipulation.

Version by the postural method is rarely resorted to. It may be tried in deviated vertex presentations, as a brow or an ear.

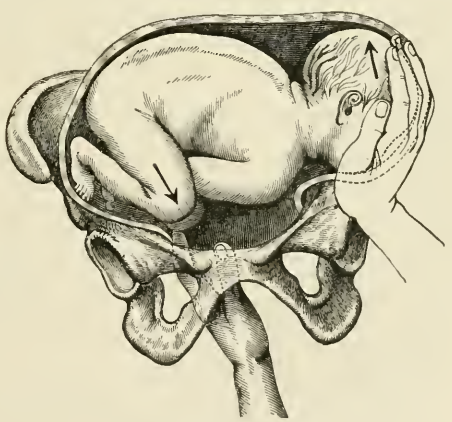
Version by the method of external manipulation is also of limited usefulness. It may be attempted in cross presentations, if seen early. For the operation to succeed, the abdominal and uterine muscles must not be too tense and the amount of liquor amnii must be at least moderate. After the head or breech has been brought to the pelvic inlet it must be fixed there by a pad and binder, or retrogression will occur. If the os is almost or quite fully dilated, the membranes may be ruptured; this will cause rapid fixation of the presenting part.

Version by the combined method is performed as follows: The patient is anesthetized and placed in the lithotomy position; the bladder is emptied; the vulva, vagina, and physician's hands are thoroughly disinfected. The operator, standing in front of the patient, uses that hand externally that corresponds to the part that is being brought to present. In this manner the external hand pushes the part downward toward the superior strait, while the index- and middle fingers of the internal hand, introduced through the cervix, push the other pole of the child upward. The head is preferably brought to the pelvic inlet, because it is easier manipulated externally, and because vertex presentations are more favorable for the child.



Combined Version (First Stage).

Version by the method of internal manipulation is the most generally useful of all the methods of performing version. It is performed as follows: The patient is anesthetized and placed upon that side toward which the fetal feet point; the bladder is emptied, and the vulva, vagina, and physician's hands are thoroughly disinfected. The operator,



Combined Version (Second Stage).

standing in front of the patient, introduces into the uterus that hand whose palm, midway between pronation and supination, corresponds to the abdomen of the child. The membranes are ruptured, the anterior foot is grasped, and traction is made until the child is born to the knee. Version is now completed, and unless there is some indication for

speedy delivery, the labor should be conducted as an ordinary breech presentation. The method of extraction of the arms and head is described under After-coming Head in the section on Breech Presentation.

Combined Version (Third Stage).

Face Presentation.—A face presentation occurs when the child's head, during labor, is extremely extended.

Face presentations are classified, according to the position of the chin, as *left mentoanterior* (chin toward the left acetabulum); *right mentoanterior* (chin toward the right acetabulum); *left mentoposterior* (chin toward the left sacroiliac joint); and *right mentoposterior* (chin toward the right sacroiliac joint).

Face presentations occur about once in 250 labors.

Cause.—This may be stated, briefly, to be: any condition preventing flexion of the head at the beginning of labor, as coiling of the cord around the neck, tumors of the anterior part of the neck, tonic contraction of the muscles of the back of the neck; any condition favoring extension of the head, as extreme mobility of the fetus, altered shape of the head, and distended maternal bladder pressing upon the child's back.

Diagnosis.—Abdominal palpation may reveal the deep groove between the child's occiput and back. Vaginal examination shows, at first, a high position of the presenting part; later, the characteristic features of the face, such as the mouth, chin, eyes, and nose.

Mechanism.—This comprises: (1) Extension of the head upon the trunk. When extension is complete, the cervicobregmatic diameter occupies the oblique diameter of the pelvis. (2) Molding of the face. This is imperfect, on account of the immobility of the bones of the face, and is very slow. (3) Lateral inclination of the face and head. This is for the purpose of accommodating the direction of the head to the direction of the pelvic canal. (4) Dilatation of the soft parts and descent of the chin to the pelvic floor. The descent of the chin is accomplished in part by extension of the fetal spine and in part by stretching of the neck. (5) Anterior rotation of the chin. This is extremely slow, and, under certain circumstances, impossible, the reasons for which will be explained under Abnormalities in Mechanism. (6) Delivery of the head by flexion. The chin engages under the symphysis pubis and is born, followed rapidly by the mouth, nose, eyes, brow, and occiput. (7) Restitution. This is an unimportant movement, which consists in a simple straightening of the neck, it having been twisted on account of the rotation of the chin. (8) External rotation of the head. This is due to the internal rotation of the shoulders. (9) Delivery of the shoulders and of the rest of the body.

Abnormalities in Mechanism.—The important abnormality in a face presentation is that occurring in the fifth step of mechanism—anterior rotation of the chin. This, as before stated, may be extremely slow or absolutely impossible. In order that forward rotation of the chin may occur, it must meet sufficient resistance: *i. e.*, it must strike the pelvic floor. If the chin is looking well anterior, when the depth of the pelvis is slight (1.5 inches), no difficulty is encountered. If it is looking to the side, when the depth of the pelvis is greater (3.5 inches), anterior rotation can be accomplished only after a most prolonged and difficult attempt, accompanied by excessive molding of the face and great stretching of the neck. If it is looking directly posterior, when the depth of the pelvis is even greater (5 inches), anterior rotation is absolutely delayed. If a case of this kind is left to nature, the upper part of the thorax (9 cm.) and the trachelobregmatic diameter of the head (9.5 cm.) are forced into the pelvis together, and this mechanism is impossible. If not terminated by artificial assistance, maternal death will occur from exhaustion or from rupture of the uterus, and the child will die from asphyxia or prolonged compression.

Prognosis.—The mortality for both fetus and mother will depend upon the position of the chin. If it is looking well forward, the death-rate should be no greater than in normal vertex presentations. The average mortality is 13 to 15 percent for the child and 6 percent for the mother.

Treatment.—The treatment of a face presentation will depend upon the direction in which the chin looks and upon the time at which it is first seen. If the chin is directed *forward*, little or no interference is necessary. If delay in anterior rotation should occur, labor may be assisted by supplying the deficient resistance. Thus, a single blade of the forceps or the fingers may be introduced into the vagina, making an artificial and more accessible pelvic floor, and in this way supplying the chin with a point of resistance upon which to rotate. Finally, if the chin is *anterior*, forceps may be used, a combination of rotation

and traction usually being necessary to effect delivery. Should the labor progress without interference, care should be exercised in the preservation of the membranes, as the hydraulic pressure of the liquor amnii is a particularly favorable factor in the mechanism of these cases.

If the chin is directed to the *side* or *backward*, prompt and active treatment will be necessary. If the case is seen early in labor, cephalic version (conversion of the face into a vertex presentation) may frequently be secured. This should first be attempted after the method of Schatz (external manipulation), which consists in making steady pressure upon the front of the fetal neck with one hand, while counterpressure is exerted upon the occiput with the other. An assistant at the same time presses the breech in the direction toward which the face is looking.

This failing, the method of Baudelocque (external and internal manipulation) should be tried. This consists in an effort to draw down the occiput with one hand introduced into the vagina, while with the external hand upward and backward pressure is made upon the thorax.

If cephalic version fail, and the face is not firmly engaged, podalic version should be performed. If the face is firmly engaged, and cephalic version fail, straight forceps may be applied and the chin forcibly rotated forward. This will usually fail or will fatally injure the child, but it may be tried before resorting to the next and final step, which is craniotomy. Forceps should never be employed as a tractor in face presentations with the chin *posterior*, for delivery by this means is impossible.

Shoulder Presentation.—A transverse position of the child *in utero*. Shoulder presentations are classified according to the position of the head and back. Usually the head is directed toward the left and the back looks anteriorly.

Causes.—These are: (1) Any disproportion in size between the fetus and uterus, as in premature births, hydramnios, and multiple pregnancy; (2) any condition preventing engagement of the head or breech, as contracted pelvis, placenta prævia, or monstrosities; (3) abnormalities in the shape of the uterus; (4) pendulous abdomen.

Diagnosis.—Inspection of the abdomen frequently reveals the peculiar shape of the uterus—the long axis is transverse instead of longitudinal. Palpation reveals the head in one iliac fossa, the breech and large extremities in the other. The heart-sounds are heard most distinctly below the umbilicus and to one side. Vaginal examination shows at first a high position of the presenting part. After the os has dilated, the characteristic parts of the shoulder can be distinguished—the triangular scapula, the long, thin clavicle, the axilla, the head of the humerus, and the ribs.

Mechanism.—The usual results in an unaided shoulder presentation are impaction of the shoulder, prolongation of labor, thinning of the lower uterine segment, and death of the mother from rupture of the uterus or exhaustion. The child dies from prolonged pressure.

Very rarely the child may be delivered by "spontaneous version," the breech or the vertex being substituted for the shoulder. This can only occur before rupture of the membranes.

"Spontaneous evolution," in which the breech slips past the shoulder and is delivered, is another remote possibility.

Delivery of the shoulder and then simultaneous birth of the head and trunk (corpore reduplicato) can only occur in premature births or when the child is macerated.

Treatment.—If the case is diagnosed early, it should be carefully watched, and as soon as the os has dilated sufficiently to admit 3 fingers, the membranes should be ruptured and podalic version performed. If an arm prolapses, it should be replaced or the hand may be introduced alongside of it and version accomplished. If the shoulder has become firmly impacted in the pelvis, decapitation is the only course that should be undertaken.

The expectant plan of treatment should never be pursued when the child is transverse, except in cases of miscarriage.

Vertex Presentations.—There are 4 positions of vertex presentations: (1) The *L. O. A.*, left occipitoanterior; (2) the *R. O. A.*, right occipitoanterior; (3) the *R. O. P.*, right occipitoposterior; and (4) the *L. O. P.*, left occipitoposterior.

Of these, the L. O. A. and R. O. P. are by far the most frequent, the former occurring in about 70 percent, the latter in about 20 percent, of cases. This is explained by the fact that the right oblique diameter of the pelvis is the longest, the left oblique being shortened by the position of the rectum. The longest diameter of the head will naturally adapt itself to the longest diameter of the pelvis, and an L. O. A. or an R. O. P. position is the result: the former if the occiput looks forward, the latter if it looks backward.

L. O. A.—Left occipitoanterior position of a vertex presentation.

Diagnosis.—Abdominal palpation reveals the child's back to the left; the extremities above and to the right; the head below. The heart-sounds are most distinctly heard to the left and below the umbilicus. Vaginal examination detects the sagittal suture in the right oblique diameter of the pelvis; the small fontanel looking toward the left acetabulum.

Mechanism.—This comprises: (1) Flexion of the head upon the trunk. This is for the purpose of accommodating the size of the fetal skull to the size of the maternal pelvis. (2) Molding of the head. This accommodates the shape of the child's head to the shape of the pelvic inlet. (3) Lateral inclination of the head. This is for the purpose of accommodating the direction of the head to the direction of the pelvic canal. (4) Dilatation of the lower uterine segment and cervical canal. (5) Descent of the head to the pelvic floor. This is accomplished by extension of the fetal spine. (6) Anterior rotation of the occiput. The occiput rotates in the direction of least resistance, which is forward, inward, and downward. (7) Delivery of the head by extension. The large fontanel, brow, eyes, nose, mouth, and chin pass in rapid succession over the perineum. (8) Restitution. This is an unimportant movement, which consists in a simple

straightening of the child's neck, it having been twisted on account of the rotation of the occiput. (9) External rotation of the head. This is due to the internal rotation of the shoulders. (10) Delivery of the shoulders and the rest of the body.

Abnormalities in Mechanism.—The important abnormalities are those that occur in labor complicated by a flat or contracted pelvis. These are: (1) The head descends in transverse diameter of the pelvis. In flat pelves the transverse diameter is the longest, and, naturally, the longest diameter of the head will engage in the longest diameter of the pelvis. (2) There is imperfect vertical flexion of the head. This occurs so that the shortest diameter of the head (bitemporal, 8 cm.) may engage in the contracted conjugate. (3) There is exaggerated lateral flexion of the head. This occurs so that it may take the direction of the sacral curve, which is always excessive in flat pelves.

Prognosis.—The maternal mortality in properly managed cases of normal labor should be less than 1 percent. In anterior positions of vertex presentations the fetal mortality is 5 percent.

Treatment.—For the treatment of normal anterior positions of vertex presentations see LABOR.

R. O. A.—Right occipitoanterior position of a vertex presentation.

Diagnosis.—Abdominal palpation reveals the child's back to the right; the extremities above and to the left; the head below. The heart-sounds are most distinctly heard to the right and below the umbilicus. Vaginal examination detects the sagittal suture in the left oblique diameter of the pelvis; the small fontanel looking toward the right acetabulum.

Mechanism.—Abnormalities, prognosis, and treatment are the same as in the L. O. A.

R. O. P.—Right occipitoposterior position of a vertex presentation.

Diagnosis.—Abdominal palpation reveals the child's back in the right flank; the extremities above and to the left; the head below. The heart-sounds are most distinctly heard in the right flank. just below the level of the umbilicus. Vaginal examination detects the sagittal suture in the right oblique diameter of the pelvis; the small fontanel looking toward the right sacroiliac joint.

Mechanism.—This is the same as the mechanism in anterior positions, except that the occiput must rotate through a much greater arc of circle—from the sacroiliac joint to the symphysis instead of from the acetabulum to the symphysis. It becomes necessary, therefore, for the body of the child to rotate with the head, a movement which is not seen in anterior positions. As a consequence of this increased rotation labor is more difficult and prolonged.

Abnormalities in Mechanism.—The only abnormality of importance is backward rotation of the occiput. This may be due to a variety of causes: (1) Anomalies of force, by interfering with normal mechanism, may cause backward rotation. This is seen in very large or small pelves, in diminished or increased expulsive power, and in cases in which the head is very large or very small. (2) Anomalies in flexion, by causing the large fontanel or brow to first strike the pelvic floor, will secure its anterior rotation, and therefore backward rotation of the occiput. (3) Insuperable hindrances to forward rotation, as occur in deformities of the pelvis, great size of the fetal head, or when an extremity prolapses by the side of the head.

Prognosis.—Although labor is prolonged and more difficult than in anterior positions, the maternal mortality should be less than 1 percent. Laceration of the soft parts is not an infrequent complication. The fetal mortality is about 9 percent.

Treatment.—In a large proportion of cases labor is entirely spontaneous, and requires no special treatment. In order to prevent backward rotation of the occiput the patient should lie upon her right side, so as to secure perfect flexion of the head. If the pelvic floor is torn or relaxed, it may be reinforced by a single blade of the forceps. If the expulsive forces are weak, forceps will usually have to be resorted to. Finally, if the occiput rotates into the hollow of the sacrum, forceps should be applied and the head extracted with the greatest care. The handles of the instrument should be raised more and more, until the perineum is well distended, when they should be depressed, thus sweeping the face out under the symphysis.

L. O. P.—Left occipitoposterior position of a vertex presentation.

Diagnosis.—Abdominal palpation reveals the child's back in the left flank; the extremities above and to the right; the head below. The heart-sounds are most distinctly heard in the left flank just below the level of the umbilicus. Vaginal examination detects the sagittal suture in the left oblique diameter of the pelvis; the small fontanel looking toward the left sacroiliac joint.

Mechanism, abnormalities, prognosis, and treatment are the same as in the R. O. P.

FEVER.—Fever is a condition in which the body temperature is above normal (98.6° F.) and which is attended by quickened circulation and respiration, marked tissue changes causing proportionate wasting of the body, and disordered secretions giving rise to anorexia, thirst, constipation, and scanty, high-colored urine of increased specific gravity.

The primary cause of the fever phenomena is still a moot question; it may be due to a disorder of the sympathetic nervous system inducing disturbances of the vasomotor filaments, or to a derangement of the nerve-centers adjacent to the corpus striatum which govern heat production, distribution, and dissemination. Fever may be said to result from a disturbance of the balance which normally exists between heat production and heat dissipation, and is usually toxemic in origin.

Rise of temperature is the most prominent feature of all fevers and can be accurately determined only by the use of the clinical thermometer placed in the mouth, axilla, rectum, or vagina. The mouth is usually selected by preference. There is a slight variation in the temperature of these various sites, as is shown in the following table:

Axilla, or groin,	98.4° F.
Mouth,	98.6° F.
Rectum, or vagina,	99.5° F.

The term *feverishness* is used when the temperature ranges from 99° to 100° F.; *slight fever*, if 100° or 101°; *moderate*, 102° or 103°; *high*, if 104° or 105°; and *intense*, if it exceeds 105°. The term *hyperpyrexia* is used when the temperature shows a tendency to remain at 106° F. and above.

Quickened circulation is the rule in fevers, the frequency usually maintaining a fair ratio with the increase of the temperature. A rise of 1° F. is usually attended by an increase of 8 to 10 beats of the pulse a minute.

The following table gives a fair comparison between temperature and pulse:

A temperature of 98° F. corresponds to a pulse of	60
A temperature of 99° F. corresponds to a pulse of	70
A temperature of 100° F. corresponds to a pulse of	80
A temperature of 101° F. corresponds to a pulse of	90
A temperature of 102° F. corresponds to a pulse of	100
A temperature of 103° F. corresponds to a pulse of	110
A temperature of 104° F. corresponds to a pulse of	120
A temperature of 105° F. corresponds to a pulse of	130
A temperature of 106° F. corresponds to a pulse of	140

Note.—This relation does not hold good in *yellow fever* after the first few days; in this disease the temperature remains high, while the pulse declines to 50 or even 40 per minute.

General Treatment of all Fevers.—All patients with fever should be placed at rest in bed in a moderately heated, quiet, and well-ventilated room; and, if possible, a sensible and well-trained nurse should be employed. The patient should be nourished by the administration of milk, beef-tea, animal broths, and peptonized or other highly nutritious food in small quantities at frequent but regular intervals. Solids should be interdicted. The secretions should be rendered free by the administration of laxatives, diuretics, and diaphoretics. Plenty of pure cold water should be given.

The temperature may be reduced by hydrotherapy or drugs. Hydrotherapy includes the cold pack, the cold bath, and sponging. The drugs employed to reduce temperature are quinin, antipyrin, antifebrin, and phenacetin, but their depressing action renders them somewhat dangerous, with the exception of the first named; and the tendency is now more and more toward hydrotherapy and less and less toward drugs (particularly the coal-tar derivatives). See BRAND TREATMENT, TYPHOID FEVER.

FEVER, SIMPLE CONTINUED.—A continued fever of short duration, mild in character, not the result of a specific poison; rarely fatal, and when death does occur, presenting no characteristic lesion.

Synonyms.—Febricula; ephemeral fever.

Etiology.—The following are causes: Fatigue, mental and physical; exposure to the sun; extreme heat or cold; excesses in eating and drinking, resulting in an attack of indigestion; excitement and violent emotion. It is most common in childhood. It is not a miasmatic fever, neither is it contagious.

Symptoms.—The onset is sudden, with an abrupt feeling of lassitude, followed by a decided chill or chilliness, a sudden and rapid rise of temperature, quick, tense pulse, headache, dry skin, great thirst, coated tongue, costive bowels, and scanty, high-colored urine. Cases due to errors in diet are accompanied by nausea and vomiting. Attacks occurring during childhood, due to excitement, fright, or the emotions, may be associated with convulsions. Within an hour or two the temperature may reach 103° F., or more, when slight delirium may occur. The affection has no constant or characteristic eruption. The duration is from 24 hours to 6 or 7 days.

The termination is usually within a few hours or in 1 or 2 days. The temperature rapidly falls to the norm (an instance of crisis), or it may continue for several days, gradually falling to the norm (lysis). Herpes about the lips and nostrils are often observed at the close of an attack. Convalescence is rapid.

Diagnosis.—Unless the fever can be attributed to some one of the causes that give rise to it, a doubt as to its character may exist for the first 24 hours, after which it is rarely mistaken for any other disease.

The following is a familiar instance of this affection: A child, apparently in the best of health, at play, or, may be, at school, suddenly complains of nausea and may vomit, the skin becoming hot, dry, and flushed, or soon covered with an erythematous rash; the pulse is quick and tense, there is headache, pains in the limbs, and great fretfulness or nervousness. The axillary temperature may reach 102° or even 104° F. The whole aspect is most alarming. A laxative is administered, the surface sponged with a tepid lotion, sleep follows, during which there may be free perspiration, and the following day the child is and continues perfectly well (Hughes).

Prognosis.—Recovery, without sequels, is the rule.

Treatment.—Rest in bed is indicated. If evidences of gastrointestinal disorder are present, prescribe a dozen or more powders containing calomel, 1/6 of a grain; sodium bicarbonate, 2 grains; powdered ipecac, 1/12 of a grain—1 every 2 hours; some hours after the last powder has been taken, an enema or a Seidlitz powder. Much comfort follows sponging the surface with tepid or cold water and the use of saline diaphoretics and diuretics. If the pulse is very quick, add small doses of aconite. The fever and nervous symptoms in cases not associated with digestive disorder may be relieved by acetanilid, 2 to 5 grains, according to age, every 2 or 3 hours. Liquid diet is most palatable. Cases in which nervous symptoms or insomnia are prominent should be given a few doses of potassium bromid during the day, or at bedtime a dose of trional, 5 to 20 grains. During convalescence administer tonic doses of quinin or tincture of nux vomica.

FEVERS.—The different fevers will be discussed under their separate headings. See SCARLET FEVER, TYPHOID FEVER, YELLOW FEVER, etc.

FIBROIDS.—See UTERUS (Fibroid Tumors).

FIBROLYSIN.—A sterilized solution of a double salt of thiosinamin and sodium salicylate. Its great use is to promote the absorption of cicatricial tissue. It has the action of THIOSINAMIN (*q. v.*), with the advantage of quicker absorption and freedom

from pain or irritation, on account of its free solubility. It is highly recommended by some in the treatment of deformities and fibrous contractions arising from chronic joint conditions, in keloid growths, and chronic X-ray dermatitis. Upon corneal nebulæ, it seems to have good effect when used locally. Dose, the contents of one vial (2. 3. c.c. = 0.2 gm. of thiosinamin) by subcutaneous, intramuscular or intravenous injection.

FIBROMA.—See Tumors.

FIBULA.—See Leg.

FIDGETS.—See Chorea.

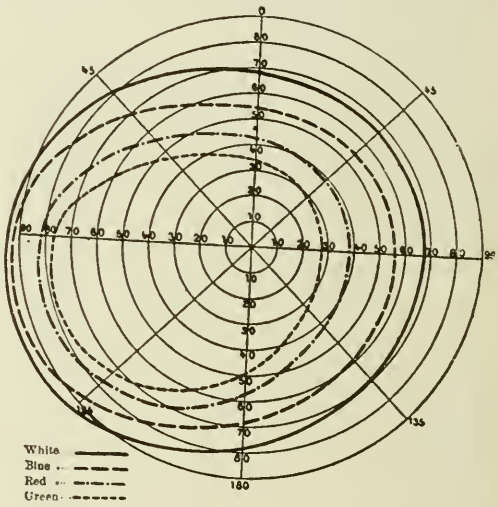
FIELD OF VISION.—The field of vision of an eye is that portion of space before the eye from which, when at rest, it can receive impressions of light. Ordinarily speaking, the field of vision is considered the space before the eye in which small objects can be seen while the visual axis is fixed in one position. The **binocular field** is the space in which objects can be seen by rotating the eyes without moving the head. The **field of fixation** designates that portion of the field of vision in which objects may be directly looked at.

Modes of Testing the Field of Vision.—The **simplest method** is to face the patient, covering the eye not under examination, the examiner closing his own eye opposite the patient's covered one: as, for instance, in testing the patient's left eye, his right eye and the examiner's left eye should be closed. The patient is told to look directly at the examiner's open eye, and while standing directly in front of him he meets his gaze; then, holding the finger off to the side beyond the field of vision, the surgeon gradually brings it in and notes the point at which the patient first sees the finger. This test can be tried in every direction, and if the surgeon's field of vision is normal, by comparison he can readily estimate any alteration in the patient's field. Due allowance must be made for extra prominence of the brow or nose. This test will serve for simple diagnosis, but it is somewhat unscientific, and does not bring out the finer points which it is so often necessary to detect.

The perimeter is an instrument for exact measurement of the field of vision. It consists of a graduated arc, which turns at its center upon a pivot. At the inner side of the arc, and directly opposite the pivot, is a small, white disc, upon which the patient's gaze must be steadily fixed. The most improved form of perimeter is self-registering, and marks on a special card the exact limitation of the field at every angle to which the graduated arc is turned. The patient is seated in front of the perimeter, with the chin on a rest, which brings the eye to be tested into the middle line directly opposite the point of fixation. The other eye is covered. During the whole examination the patient must gaze directly at the white spot in the center of the perimeter. A movable disc containing a small white surface is gradually brought in toward the center until it is seen by the patient as white. This is repeated at every angle, and the results recorded upon a special perimetric chart. The fields for color are obtained in the same manner, using instead of a white object a tinted one, corresponding to the color to be tested for. In order to detect scotoma, the disc should be moved all the way in to the center, and any point within the field at which the color disappears should be noted. If the patient is amblyopic or cataractous, instead of the ordinary disc a lighted candle may be moved along the arc of the perimeter and another light put at the point of fixation. The perimeter may also be used to examine the angle of deviation in strabismus.

The normal field of vision is naturally contracted at the nasal side, on account of the projection of the bridge of the nose. It contains a physiologic "**blind spot**" to the temporal side of the fixation point, between 10 and 20, as shown by the small circle in the diagram. The fields for blue and yellow are somewhat smaller than that for white, the field for red still more contracted, and green is the innermost field. However, the size of the field for any color varies considerably for different persons, and for the same person with different degrees of illumination.

Alterations in the field of vision may be concentric or regular contractions in all directions, or distinctly uneven and irregular contractions, according to the amount of fundus involvement. **Scotomata** are patches in the field of vision in which there is blindness to the object under observation. A **positive scotoma** appears as a dark spot before the patient's vision; a **negative scotoma** is generally only detected by examination with a perimeter, and appears as an appreciable interval in which there is blindness. It is usually due to some loss of perceptive power, which, when located at the macula, causes the well-known central scotoma, which is particularly noticeable for red. **Central scotoma** is an important sign in many toxic amblyopias. The physiologic scotoma, or **blind spot**, represents a point at which the optic nerve enters the eye. The changes in the field of vision are of diagnostic importance in many pathologic conditions of the fundus, and the perimeter is an efficient aid, not



Field of Vision of the Left Eye.

only in diagnosis, but in showing the exact results of treatment.

The disadvantages of limitation of the field of vision may be readily understood by looking through a long tube. Peripheral objects are not seen, and unless the patient continually moves the head from side to side and rotates the eyeballs, he will stumble over neighboring objects. It sometimes happens that the central vision may remain so good that the smallest print can be read while the peripheral vision is absolutely destroyed. In central scotoma the patient must look above, below, or to one side of the object, for if he fixes directly on it, the object is not visible. See HEMIANOPSIA.

FILARIASIS.—A condition associated with the presence of certain embryo nematode worms or filariæ in the blood. Of the several species of *filaria sanguinis hominis* the most common are the nocturna (f. Bancrofti), the diurna and the perstans, the night, day and constant worms.

Bancroft's filaria, the variety most frequently found, is observed in most tropical regions. It is held responsible for filarial diseases in man. The adult parasites are found in the lymphatic trunks while the embryos travel through the thoracic duct into the circulating blood and are observed in the peripheral blood during the night hours, or rather during the time, day or night, the human host takes for sleep. The embryo is about the thickness of a red blood-corpuscle and is encapsuled in a loose transparent sheath the ends of which project beyond the worm in a sac-like fashion. The embryo is actively motile—squirming, thrashing, curling—thus producing agitation among the corpuscles.

The intermediate host of the embryo filaria is the mosquito—the culex fatigans and probably the anopheles. Taken up by the bite of the mosquito it grows and develops within the insect and later re-enters human blood during the biting of the mosquito.

Symptoms may be absent for years. If, however, the worms, or their ova, obstruct the lymph circulation, dilated lymph-vessels may rupture and a fistula form communicating with the lateral surface of the body or the internal hollow organs. Such an opening into ureter or bladder results in **chyluria**—opaque urine due to the presence of chyle—or, if there is also a rupture of blood-vessels, in **hematochyluria**—admixture of chyle and blood with the urine.

Lymphatic obstruction may result in elephantiasis of scrotum, vulva, legs, arms, scalp and areas of the skin. The inguinal glands may enlarge to such an extent ("varicose glands") as to simulate hernia. In lymph scrotum and lymph varix the embryo filaria is usually present only in the early stages, the parent worm dying before the disease becomes far advanced. Manson's theory of the rôle played by the filaria in the production of elephantiasis is as follows: "Parent female filaria in the lymphatic stream of the affected part; injury of the filaria; premature expulsion of ova in consequence of injury; embolism of lymphatic glands by ova; stasis of lymph; lymphangitis from subsequent traumatism, or other cause (septic infection) in the congested area; imperfect absorption of the products of inflammation; recurring attacks of inflammation leading to gradual intermittently progressive inflammatory hypertrophy of the part."

Treatment by drugs is unsatisfactory. In certain regions, as the scrotum or vulva, surgical measures are valuable.

Prophylaxis is most important. Mosquitos should be destroyed and their breeding-places disinfected. Houses, and especially infected persons, should be screened. Water used in the preparation of food or for drinking should be boiled.

Filariasis has been found associated with the vague West African skin disease known as "craw-craw"—characterized by papules or pustules and itching—the etiology of which is still unknown.

Filaria medinensis is the cause of GUINEA-WORM DISEASE (*q. v.*).

Other filariæ are very infrequently found in man. **Filaria loa** occurs in Western Africa. The adults wander through the subcutaneous tissues especially of eyes, and face, producing inflammation.

FILIX-MAS.—See ASPIDIUM.

FILTER.—An apparatus for straining and removing from water or other liquid solution the impurities or suspended matters it may contain. Sponge, wool, etc., are liable to decompose, and should not be used. Asbestos acts only as a mechanic filter. Asbestos cloth may be used to support other materials when the water supply enters at the bottom, and it can be sterilized by fire. Tap-filters are insufficient, and soon clog. Pocket-filters are simply strainers, and have little oxidizing power, and should be frequently sterilized by boiling. Ordinarily, filters should not be placed in rain-water cisterns, but outside, where they may be easily cleaned.

The best filtering media are sand, gravel, animal charcoal, magnetic carbid of iron, spongy iron, etc. Unglazed porcelain or bisque is used in the Pasteur-Chamberland filter, and is an excellent medium, practically germ-proof. Stone filters resemble those of porcelain and are safe, but are slow, and must be cleansed often. Sharp, clean sand, not too fine, stops most suspended matters and bacteria, besides oxidizing dissolved organic matters. Crushed quartz is of practically the same nature. A mixture of pyrolusite and sand or crushed quartz makes an excellent filtering material.

A most economic filter is one made of clean sand, above which layers of gravel of a gradually increasing size are placed. Sand filtration is, in most cases, the most available, satisfactory, and efficient. A cheap and efficient filter is made by placing a sheet of druggist's filtering-paper in a glass funnel and filtering through it. The paper should be renewed daily. The Chamberland filter is claimed to be absolutely germ-proof, but these properties are not permanent. The Pasteur filter is one of the most efficient and successful.

All filters easily become fouled, and require frequent renewing or cleansing. Intermittent filters might prove better for the purification of sewage

or a very impure water, though their efficiency in removing bacteria seems inferior to that of continuous filters. The sides and bottom of filter-beds should be water-tight. The form is immaterial.

House-filters are dangerous unless properly cared for. The substances removed from the water remain in the filter, and, unless removed, the impurities cannot improve the water passing through them. A filter has no power to annihilate filth.

The requisites of a good filter are: (1) That every part shall be easily accessible for cleansing or renewing; (2) that the filtering medium shall have a sufficient purifying power and be present in sufficient quantity; (3) that the medium shall give nothing to the water favoring the growth of low forms of life; (4) that the purifying power shall be reasonably lasting; (5) that there shall be nothing in the construction of the filter itself capable of undergoing putrefaction or of yielding metallic or other impurities to the water; (6) that the filtering material shall not clog, and that the flow of water be reasonably rapid; and (7) that the filtering medium shall be such that it can be readily cleansed and sterilized or else so cheap that the removal and replenishing may not be neglected when necessary on account of expense.

House-filters are mainly of three kinds: (1) Those entirely disconnected from water-supply pipes of the house; (2) those connected with water-pipes, but intended to filter only a limited quantity, and (3) those connected with the house service-pipe and intended to filter all the water used. A settling tank is advantageous in those of the first class.

FILTERING-PAPER.—The best filtering-paper is made in Sweden (by Munktell) and is white. For ordinary use the "Prat Dumas White" is employed for filtering alkaline or alkaloidal solutions. For fluidextracts, tinctures, or colored liquids the gray French papers suffice, but they should not be used for solutions containing free alkali.

To fold filtering-paper, double the sheet upon itself and then fold again directly in the middle. Four distinct sections will appear when opened, one of which is separated from the other three, and the filter thus formed is placed in a funnel of glass or other material held by the ring or a retort stand. This filter is known as a plain filter, which, by repeated creasing, is converted into a plaited filter.

FINGER.—See HAND.

FINGER, BASEBALL.—See BASEBALL FINGER.

FINGER, MALLET.—See BASEBALL FINGER.

FINGER, TRIGGER.—See TRIGGER FINGER.

FINGERS, WEBBED.—See WEBBED FINGERS.

FINSEN LIGHT.—The ultra violet rays of the spectrum. They are used in the treatment of lupus, in which they are said to be very beneficial, and also occasionally in the treatment of epithelioma. Their power of penetration is slight, and as they do not pass through blood, compression upon the part treated is usually made with a piece of quartz, so that it may become anemic and permit their passage. See PHOTOTHERAPY.

FISH-POISONING.—The most serious form is produced by the mussel, from which a poison, *mytilotoxin*, existing chiefly in the liver, has been separated. The mussel, in all probability, becomes poisonous from its surrounding conditions.

The symptoms of fish-poisoning are those of acute general poisoning, with profound action on the nervous system. The eating of stale and decomposed oysters has been followed by symptoms of poisoning, usually gastrointestinal in character. The salted sturgeon of Russia has proved poisonous, as has the barb of middle Europe. In China and Japan species of the tetrodon are also toxic, sometimes proving fatal within an hour.

The treatment is mainly symptomatic. If the purgative and emetic effect of the poison has not already promptly rid the stomach or intestinal canal of any residue, calomel or other purge may be administered. Counterirritation by mustard, 1/4 of a grain of morphin hypodermically, 10 to 30 minims of digitalis, and 1/30 of a grain of strychnin may be employed. Stimulants by the mouth may be given if retained. Champagne or carbonated milk are very serviceable. Chlorate of potassium may be freely administered, and liquid acetate of ammonium, opium, capsicum, and chloroform employed as indicated. See PTOMAIN-POISONING.

FISHSKIN-DISEASE.—See ICHTHYOSIS.

FISSURE.—See ANUS, BREAST, etc.

FISTULA.—See ANUS, VAGINAL FISTULA.

FIT.—A popular name applied to any sudden paroxysm of a disease, but especially to one of epilepsy. See CONVULSIONS, EPILEPSY, TETANUS.

FIXING.—The first stage in the preparation of tissues for histologic or pathologic examination. The chief fixing agents are corrosive sublimate, nitric acid, alcohol, osmic acid, Flemming's solution, Zenker's fluid, Orth's fluid, Müller's fluid, picric acid, picrosulphuric acid, acetate of copper. See PATHOLOGIC TECHNIC.

FLAT-FOOT.—See TALIPES (Valgus, Pes Planus).

FLATULENCE.—The undue generation of gases in the stomach and intestines (flatus). The principal cause of flatulence is fermentation or decomposition of the contents of the stomach and bowels, usually induced by embarrassed function. It is a common symptom in so-called dyspepsia, particularly in the atonic forms. It is present in the debilitated and the aged. Constipation, gastritis, enteritis, hepatic disorders, and intestinal obstruction are causes. Tympanites, when too rapidly developed, overpowers the contractility of the hollow viscera.

Friction of the abdominal wall, or gentle kneading of the distended parts, large drafts of hot water, spirits and hot water, ammonia, ether, spirit of chloroform, the aromatic stimulants, such as ginger, capsicum, cloves, mint, anise, cajuput, camphor, or cascarilla, will often dislodge the flatus. Turpentine, rue, or the compound pill of asafetida, with nux vomica in tincture or fluidextract, and an aperient, are most useful measures. Enemata are often demanded.

The generation of flatus may be checked by sodium phenolsulphonate or sulphite, sulphurous

acid, carbolic acid, creosote, terebene, salol, or charcoal, and by correcting and improving the impaired digestive functions. Repeated doses of calomel are useful. Food likely to ferment, such as sugar, starches, fruits, or green vegetables, and warm liquids, are to be avoided. Alkalies and the bitter tonics are often useful. Pepsin or ingluvin after meals promotes digestion. Physostigma is given for flatulence in women at the climacteric.

℞. Tincture of nux vomica,
Tincture of physostigma,
Tincture of belladonna, } each, ʒ j.

Fifteen drops twice daily in a little water.

℞. Bismuth salicylate,
Magnesium calcinate, } each, ʒ iv
Powdered wood charcoal, ʒ vj
Oil of anise, ʒ ij.

A teaspoonful before meals.

FLAXSEED (**Linseed**).—The seed of *Linum usitatissimum*. Flaxseed, when reduced to a powder, forms the *ground flaxseed* of the U. S. P. It is of a dark gray color, and highly oleaginous. When mixed with hot water, it forms a soft, slightly adhesive mass. Much of the linseed of commerce is simply "cake-meal," left after the extraction of linseed oil, which is made by compressing the ground seeds. This cake-meal is unfit for medicinal purposes, not only because of its poverty in oil, but owing to the fact that exposure to the air may cause it to become rancid. The U. S. Pharmacopeia directs that flaxseed for medicinal uses should be freshly ground and free from unpleasant and rancid odors, and should contain at least 30 percent of oil. Flaxseed is demulcent and protective. When used in the form of a poultice, it is a convenient means of retaining heat and moisture, as well as of maintaining degrees of heat higher than that of the part upon which it is applied.

A flaxseed poultice, when properly made, is soft, moist, and bland. Its effects can be obtained from warm water, but the method of applying the agent last named, as a rule, is less convenient. The composition and mode of administration are described under Poultice. See Linseed.

FLOATING KIDNEY.—See Kidney, Movable.

FLOATING LIVER.—See Liver.

FLOATING SPLEEN.—See Spleen.

FLUCTUATION.—The wave-like or undulating sensation elicited by palpation of one hand while percussion is made with the fingers of the other. It is due to the presence of a fluid in a natural cavity. In surgery fluctuation means the sensation of the presence of a fluid felt when alternate pressure with the fingers is made, as over the seat of an abscess. On the abdomen fluctuation is sometimes mistaken for the vibrations of the abdominal wall. The edge of a hand placed along the linea alba will arrest these vibrations.

FLUIDEXTRACTS (**Fluidextracta**), are permanent and concentrated solutions of vegetable drugs, of uniformly definite strength if the crude drugs are so, a cubic centimeter in each case representing the medicinal powers of 1 gram of the drug; or, approximately, a minim of the finished preparation representing the active constituents of a grain of the drug. There are 85 official fluidextracts, which may be classified according to dose, as follows:

1 minim: Fluidextract of Aconite, belladonna root, cannabis indica, capsicum, digitalis, gelsemium, ipecac (expectorant), nux vomica, scopola, staphisagria, stramonium.

1 1/2 minims: Phytolacca (alterative) sanguinaria, squill, veratrum.

3 minims: Conium, quillaja.

5 minims: Savin.

8 minims: Convallaria, euonymus, lobelia, lupulin, podophyllum, quassia.

15 minims: Apocynum, aromatic, calamus, chirata, cimicifuga, cinchona, cubebs, cypripedium, eriodictyon, frangula, gentian, ipecac (emetic), krameria, leptandra, phytolacca (emetic), quercus, rhamnus purshiana, rhamnus pur. aromatic, rhubarb, rhus glabra, rubus, scutellaria, senega, serpentaria, zingiber.

30 minims: Berberis, buchu, calumba, chimaphila, coca, colchicum, ergot, eucalyptus, glycyrrhiza, granatum, grindelia, guarana, hamamelis, hydrastis, hyoscyamus, lappa, pilocarpus, prunus virginiana, rose, sarsaparilla compounds, senna, stillingia, sumbul, uva ursi, valerian, viburnum opulus, viburnum prunifolium, xanthoxylum.

1 dram: Matico, spigelia.

2 drams: Taraxacum, triticum.

For External Use: Mezereum.

FLUORESCIN.—$C_{20}H_{14}O_5$. A colorless, amorphous product of the reduction of fluorescein. On account of its neutral quality and green fluorescence, it has been used to study the movements of the intraocular fluids. The use of fluorescin has recently been introduced as a guide to the application of the actual cautery in sloughing keratitis. It outlines the precise area requiring cauterization, by giving a greenish tint to the portions of the cornea deprived of epithelium. "The finest divisions radiating from the ulcer into the clear cornea are, by means of fluorescin, exhibited to the naked eye with a distinctness formerly to be attained only by means of a lens or corneal microscope. Thus, the lateral spreading, and also the depth of the ulcer, are clearly shown, the green tint of the floor of the ulcer standing out sharply against the yellow pus on the posterior layers of the cornea and in the anterior chamber." Two percent of fluorescin can be dissolved in a 3 1/2 percent solution of carbonate of sodium.

FONTANEL.—A membranous space of the infant's skull, from delayed ossification of the cranial bones.

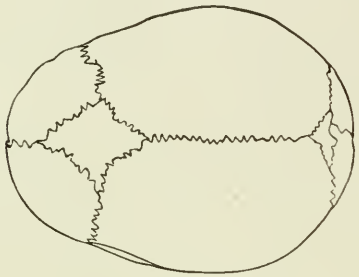
The anterior fontanel is the one at the point of union of the frontal, sagittal, and coronal sutures. It is larger than the posterior, sometimes remains open for two years, and occasionally persists throughout life. It is also known as the bregma, and occasionally as the sinciput. It is diamond-shaped.

The posterior fontanel is situated at the point of

juncture of the lambdoid and sagittal sutures, and is triangular in shape. It ceases to be a space during labor. The remaining fontanels are situated at the inferior angles of the parietal bones. The anterior and posterior fontanels are of importance, indicating as they do the variety of presentation of the head in labor.

Significance.—1. Involution of the fontanel occurs normally from the fifteenth to the eighteenth month. From birth to the ninth month the fontanel decreases gradually in area, and from this time until complete closure the decrease is more rapid. Retardation of normal involution indicates rachitis or hydrocephalus.

2. The fontanel presents pulsatory and respiratory phenomena. The pulsation increases if the tension is slightly increased; diminishes or is lost if the tension is greatly increased.



Fontanels of Fetal Skull.

3. A murmur over the fontanel occurs in certain children, most commonly in those who are anemic or rachitic. It is not pathognomonic.

4. A slightly prominent and pulsating fontanel indicates a cerebral hyperemia, such as occurs in fevers.

5. A protuberant and tense fontanel indicates an exudation or inflammation in the cranial cavity.

6. Retracted fontanel indicates a condition of collapse brought about by acute intestinal disease with profuse watery discharges, infantile atrophy from any cause, hemorrhage, effects of prolonged acute infectious disease, or marantic sinus thrombosis.

7. In acute infectious diseases with meningeal symptoms, examination of the fontanel shows no protuberance or tension, whereas in true meningitis these conditions are marked.

8. In the so-called hydrocephaloid, a terminal condition of cholera infantum marked by the occurrence of striking meningeal symptoms, the fontanel is retracted (Abt).

FOOD.—See Dietetics, Alcohol, Infant Feeding, etc.

FOOD-ADULTERATION.—Foods are unwholesome and deleterious to the health of the consumer under certain circumstances: (1) when prepared under unsanitary conditions; (2) when adulterants such as chemical preservatives, coloring matters, inferior and cheaper substitutes or "fillers," are used; (3) when pathogenic microorganisms are present; (4) when fermentation or putrefaction is taking place; (5) when the substance of which the container is composed acts chemically upon the food; (6) when, in the case of meats and dairy products, the animals are diseased or have eaten poisonous substances.

Fish.—Canned fish of all kinds should be completely sterilized. All material which is not absolutely fresh from water should be rejected. It has been a reprehensible practice to ship shrimps preserved in boric acid or sulphites. All chemical preservatives (the chief ones used being benzoic acid and sodium benzoate, boric acid, borax, sulphites and formaldehyd) should be excluded. The addition of fluorin compounds is reprehensible. Instead of olive oil in the packing, peanut, cottonseed or sesame oil is often substituted. Cod-liver oil is adulterated by fish-liver oil of lower quality, or blubber oil. The treatment of oysters with fresh water to swell them—"floating"—is reprehensible, because of the danger of their becoming infected with germs; this "floating" process is also a deception, in that it makes the oysters appear larger and firmer than they really are. See Fish-poisoning.

Preserved Chicken or Turkey.—The chief objection to preserved chicken meat is the use of old chicken, the substitution of cheaper meats, unlimited cold storage, and exposure in market in unsanitary condition and for an indefinite time. The keeping of poultry in edible condition depends most of all on its being properly killed and dressed and submitte do the action of cold immediately after killing.

Eggs.—Broken eggs preserved in borax are unfit for food. Dry egg products may be considered unobjectionable if made by rapid drying of fresh eggs, but they are sometimes made of decayed eggs.

Eggs with or without coating of surface, the best coating being soluble glass (silicate of soda), may be kept for months in cold storage, without deterioration, provided they are fresh when placed in cold storage. Gradually they acquire a different taste or aroma from the fresh article. The average age of cold storage eggs is probably more than 6 months—such eggs should be marked.

Egg products sold under the guise of eggs are often adulterated. Even fresh eggs, unless sanitary conditions in which the fowls live are well cared for, may become very poisonous. Injurious organic matter rich in microbes and parasites may contaminate the egg. Eggs contaminated in this way may give rise to toxic phenomena, even in a fresh state. Experiments have shown that the food material of eggs if directly injected into the blood of an animal produces toxic effects, whereas, if injected into the stomach no such action ensues. It is advisable in all cases in which eggs must be kept for some time, even in cold storage, to varnish them in some substance impenetrable to air.

Meat.—Noncondimental chemical preservatives are highly objectionable. Those chiefly used are sulphite of sodium, as a preservative of color, boric acid and borax. By their use less care need be taken in the preserving process, which becomes therefore less expensive. No matter how small the quantity of an injurious substance or pre-

servative, it will still produce an injurious effect which may be infinitely small if the dose is infinitely small. Even in small quantities ultimate injury may result.

The best way to preserve meat is by cold, or sterilization, *i. e.*, canned meats. Meats selected should be free from disease, obtained under sanitary conditions, and subjected to cold or sterilization before decomposition occurs.

Canned ham, bacon and tongue are adulterated with coloring matter (usually saltpeter) and preservatives.

Potted meats, deviled meats, minced meats, sausages, prepared meats are adulterated chiefly by saltpeter, starch, as a "filler," benzoic acid, sulphite of sodium, borax, boric acid, sometimes tin and zinc from the solder or can.

Canned Fresh Meat, or Canned Cured Meat.—If it is properly sterilized no additional preservative (such as saltpeter, sulphite of sodium (which are used as color preservatives), boric acid, or borax) is necessary. Adulteration with cheaper meat or use of tainted meat is a most serious one.

Canned sausage is adulterated by (1) admixture of meat of unknown and miscellaneous origin and possessing inedible character; (2) starch; (3) preservatives.

No tinned, canned or sterilized meat should be allowed to enter into consumption, except when prepared under inspection. Health of animals should be ascertained by inspection both before and after slaughter, all diseased animals being excluded. The sanitary conditions under which meats are prepared are of highest importance. Workmen should be free from disease, neatly dressed and required to observe all necessary sanitary precautions.

Lard is adulterated by admixture with other, and sometimes cheaper, fats (stearin, beef fat, cottonseed oil especially). Cottonseed oil is detected by the Halphen test or Bechi test; but it must be remembered that animals fed on cottonseed meal will give a reaction for cottonseed oil. Though the vegetable oils are as wholesome as animal, to those who prefer the animal the pure article should be available.

Beef extract as food has little value—its chief value is in the ease and speed with which it may be absorbed. Beef juice is a misnomer so far as the commercial product is concerned. Few, if any, of the so-called beef juices are true to name, and it is doubtful if beef juice can be or is preserved.

Dried and powdered meats are of less value than fresh. Somatose is a meat powder, largely made up of albumoses rather than peptones.

Meat preparations are adulterated by salt, glycerol, alcohol—reprehensible preservatives which are seldom used. In some cases of meat extract 30 percent of the total extract is composed of common salt; sometimes artificial coloring matter is added. Another adulterant is extract of yeast, detected by treating mixtures with a strong solution of zinc sulphate and filtering—in meat extract the filtrate is clear, in yeast extract the filtrate is turbid. Addition of lecithin or glycerophosphoric acid to meat extract is sometimes practised.

Gelatin is adulterated by raw material unfit for food and prepared under unsanitary conditions, by bleaching agents—sulphurous acid or sulphites, mineral acids, by the presence of tetanus bacilli.

Lard oil is adulterated by the addition of cheaper animal or vegetable oils. Neat's foot oil is adulterated with cheap vegetable oils, as cottonseed, or fish oil.

Halphen Reaction for Cottonseed Oil.—Carbon disulphid, containing about 1 percent of sulphur in solution, is mixed with an equal volume of amyl alcohol. Equal volumes of this reagent and the oil under examination are mixed together and heated in a bath of boiling brine for fifteen minutes. In the presence of as little as 1 percent of cottonseed oil an orange or red color is produced, which is characteristic.

Lard and lard oil from animals fed on cottonseed meal will frequently give a decided reaction; also the fatty acids thereof.

Bechi Test for Cottonseed Oil.—Two grams of silver nitrate are dissolved in 200 c.c. of 95 percent alcohol and 40 c.c. ether, one drop of nitric acid being added; 5 c.c. of this reagent are mixed with 10 c.c. of oil or melted fat and 10 c.c. of amyl alcohol. One-half is heated in a boiling water-bath for 10 minutes and compared with the half not heated. Any blackening due to reduced silver shows the presence of cottonseed oil.

Sugar.—White earth and flour have been added, but in America the only adulterant is incident to its manufacture. A trace of sulphurous acid may adhere when sulphur is used before clarifying, or particles of ultramarine blue may attach themselves when bluing is used. If in washing the sugar tin salts are used, a trace of these may be found. Cane-sugar has also been mixed with dextrose.

Syrups.—Instead of pure maple, sorghum, or cane syrup the consumer is usually furnished with syrup made of glucose, melted brown sugar or molasses, or a mixture of these. Table syrups are made up largely of glucose colored and flavored with maple sugar or cane-sugar. The glucose often contains sulphurous acid, or sulphate or chlorid of lime incident to its manufacture. The final molasses in the sugar refining is used extensively for mixing purposes. This product, deprived as it is of all the sugar possible to extract from it, is practically inedible and should be eliminated from human food. The molasses, too, may contain sulphurous acid, lime, salts of tin, excess of bluing, large quantities of acid phosphates acquired in its manufacture. Then, too, metallic salts may be found from the addition of a metal or acid in order to get nascent hydrochloric acid to bleach the molasses if it is very dark.

Confections.—The use of harmful colors such as anilin dyes should be forbidden. The abandonment of sulphur in the bleaching of glucose is the only safe way of protecting the consumer against the presence of sulphurous acid in glucose. The use of poisonous artificial flavors, such as benzaldehyd

or its derivatives, etc., is not uncommon and is absolutely reprehensible. Alcohol enclosed as drops in candy is a serious adulteration by reason of the danger of children acquiring the habit and sustaining injury.

Honey.—Perhaps no common food product, with possibly the exception of condiments like pepper and spices, has been subjected to such general adulteration. Glucose has been extensively used with the minimum of honey to give its flavor and taste. Inverted sugar and also cane-sugar are other adulterants.

Ginger.—The roots are often sent to canners covered with lime, *i. e.*, for the purpose of preserving or bleaching them. This is such a common condition that limed or bleached ginger is a legitimate article of commerce.

Nutmeg.—The seed is sent into commerce with a thorough coating of lime, which, of course, must be removed before the nutmeg is used.

Mustard is often ground before sold and frequently mixed with other spices and oils and known as prepared mustard. This latter variety is subjected to all kinds of adulterations, frequently containing very little mustard, but with enough turmeric to give the preparation a yellow color resembling that attributed to the pure article. Prepared mustard should be a thick paste composed largely of ground mustard seed mixed with salt, various spices and vinegar. It may also be ground in oil.

Milk.—The character of milk is greatly influenced by the environment in which the cow lives. Cleanliness and good ventilation of the stable are of paramount importance. Cows should be supplied with an abundance of pure water and not allowed access to stagnant pools when pasturing in the summer. From time to time they should be examined by a competent veterinarian for tuberculosis, and if diseased should be isolated and killed. Dairies should be subjected to the most rigid expert inspection periodically and frequently. Only by the exercise of unusual care is it possible to keep milk from becoming contaminated. Every part of the cow, especially the udder, should be kept scrupulously clean. The milk should be collected in clean vessels with as small an orifice as possible, then strained and cooled to 30° F., or lower. It should be put into sterilized bottles, stoppered with sterilized cork and kept cold until delivered and used.

Certified milk is the ideal food of a milk character. The dairies furnishing it are inspected at frequent intervals by experts.

Pasteurized Milk.—The killing of the beneficial organisms of milk by heating it to 140° or 160° is only justified when there is danger of pathogenic germs being present. It is desirable when the origin of the milk supply is unknown or when it is necessary to keep the milk for some time. Hence, Pasteurization of milk cannot be regarded as a substitute for inspection and certification.

Curd Test for Purity of Milk.—The Wisconsin curd test is conducted as follows: 1. Milk containers are sterilized so as to destroy all bacteria in the vessels. . This step is very important, and can be done by heating cans in boiling water or steam for no less than one-half hour.

2. About one pint of milk is placed in a covered jar and heated to about 98° F.

3. Ten drops of standard rennet extract are added and mixed thoroughly with the milk to quickly coagulate.

4. After coagulation, the curd is cut fine with a case knife to facilitate separation of whey; curd is left in whey one-half to an hour; the whey is then drained off at frequent intervals until the curd is well matted.

5. Curd mass is incubated at 98° to 102° F. by immersing jar in warm water. Jars are kept covered to retain odors.

6. After 6 to 9 hours of incubation, jar is opened and odor observed; curds are examined by cutting same with sharp knife and texture observed as to presence of pin holes or gas holes. Odor is noted.

7. Very bad milks will betray presence of gas-producing bacteria by the spongy tissue of the curd and will have an off flavor.

8. If more than one sample is tested at the same time, knife and thermometer are dipped in hot water each time before being used.

"Normal" milk contains practically no organisms but the straight lactic acid bacteria. These germs produce no gas and no bad odors, but purely lactic acid and the curd formed therefrom.

Milk contaminated by the introduction of dust, fecal matter, or kept in imperfectly cleaned cans becomes fouled with gas-producing bacteria that break down the milk-sugar and so produce gases and usually undesirable odors. Therefore milks showing the presence of gas or bad odors in any considerable degree are milks that have been more or less polluted with extraneous organisms or carelessly handled, and as a consequence such milks show various types of curd, containing pin holes, the number of which extend upon the extent of contamination.

Butter.—Coloring butter with anilin dyes is very prevalent and is unnecessary. If cows are properly fed during the winter with wholesome nutritious food to which a small proportion of roots, such as carrots or ruta bagas are added, or with yellow maize, or clover hay, even in winter the butter produced will have an attractive amber tint.

Salting butter excessively is common. The more salt it contains the less value it has as butter, hence the quantity should be limited to the smallest possible amount demanded by the consumer's taste. It should not exceed 2 percent.

Normal butter has 12 to 14 percent water. It is sometimes adulterated by being rechurned with water to raise the water-content to 16 percent.

When cows are fed cottonseed meal or its products the quality of cottonseed oil which responds to the Halphen test is transmitted to the butter, sometimes with an intensity claimed to be equal to that of the admixture of 5 percent cottonseed oil with the butter.

Oleomargarin is a food product, the only objection to which is its sale as butter. Coloring (usually with anilin dyes) is permitted on payment of a

tax. It is sometimes adulterated by the admixture of preserved egg yolks. Preservatives are not used to any extent in this country.

Cheese.—The most common adulterant is the misbranding. Next is the artificial coloring, usually with coal-tar dyes, because they are cheaper and more natural looking than the vegetable colors, such as annoto and saffron. These in a concentrated form are highly poisonous and injurious. Adulteration by impure raw material can be excluded only by careful sanitary inspection of cheese factories. Filled cheese now under the law requires a label and payment of a tax.

Rennet.—The material most useful in the precipitation of the curd in cheese-making is sometimes treated with borax to preserve it during transit. This may be found in ripened cheese. American cheeses are often colored artificially. In the curing of the cheese sometimes it is coated with paraffin to prevent loss of weight. This may interfere with the normal ferments and be injurious if swallowed.

Preparations of Casein.—Samose contains 8 percent casein, 20 percent protein derived from white of egg. To avoid this unstable form, casein has been adulterated with alkalies—nutreose and eucasein. Casumen and sanatogen are preparations of casein with alkalies or glycerophosphates.

Olive Oil.—By reason of its close resemblance to many of the edible vegetable oils, extensive adulterations may be practised. In the United States the chief one is cottonseed oil, to which no objection can be made from a dietetic point of view, though its price is probably not greater than one-fifth of the olive oil. In Europe, peanut oil or sesame oil is used.

Baudouin's test for sesame oil is characteristic. A few drops of a 2 percent solution of furfurol are added in a test-tube to 10 c.c. of the oil under consideration, and 10 c.c. hydrochloric acid of 119 specific gravity. After the mixture is shaken 1/2 minute an aqueous layer which forms will have a distinct crimson color if sesame oil is present.

Peanut oil is distinguished by the saponification of the oil, separation of fatty acids and consequent crystallization of the arachidic acid. Other adulterants are rapeseed oil, poppyseed oil, castor oil, lard oil, fish oil and petroleum oil. Sesame oil is often adulterated with cheaper vegetabel oils. So, too, is almond oil, apricot and peach oil especially being used.

The degree of absorption of iodin is in a measure the test for the varieties of oil. This degree expressed in the percentage by weight of the oil itself is known as **the iodin number.** If, for instance, a gram of any particular oil absorbs 1 gram of iodin it is said to have an iodin number of 100. Nearly all adulterations of olive oil have high iodin numbers, therefore, whenever an iodin number is above 89 to 90, it may be regarded with suspicion.

Cocoa butter is often adulterated with cheaper vegetable fats. These are detected by increase of the percentage of iodin absorbed. As they reduce the melting-point of cocoa-butter, however, they are not used extensively as adulterants. Beeswax, paraffin wax and tallow are other adulterants.

Cereals.—Adulteration of **buckwheat flour** is extensive, other flour being substituted, and is easily detected by the microscope (the buckwheat grain being very characteristic). Any mineral adulteration is easily detected by incineration.

Rice is adulterated by coating with talc, paraffin, glucose.

Rye flour is frequently mixed with other flours. It has characteristic starch granules.

Wheat flour may contain dirt, rust, smut, etc., mixture of wheat flour or other cereals. Flour is extensively bleached with oxids of nitrogen; although, owing to adverse court decisions under the Food and Drug Act, such bleaching is not common in this country. Admixture of inert substances with wheat flour are found mostly in times of famine.

Other adulterations are the mixture with the flour of maize or other cereals.

The principal part of the protein in wheat is gluten, formed when the wheat flour is mixed with water. To determine the character of a wheat flour determine the quantity of gluten it contains, and the separation of the gluten depends on the fact that by washing and kneading the flour nearly all the starch can be removed from the mass. A simple test is the following: Place 10 grams of the sample in a porcelain dish and moisten with 6 or 7 c.c. of water, knead, stand 1 hour. Work into a ball carefully so that none of the material adheres to the dish. Knead in the hands in a slow stream of cold water till all the starch and soluble material is washed out. Place the ball of gluten thus formed in cold water and let stand 1 hour. Remove, press dry as possible between the hands, roll in ball, weigh in a flat-bottomed dish. After weighing place the ball of moist gluten in the drying oven for 20 hours, cool and weigh.

The principal objection to the use of **baking powder** lies in the fact that the residue arising from the chemical reaction is necessarily left in the loaf. Cream of tartar baking powder leaves a residue of Rochelle salts; phosphate powders, a residue of sodium and calcium phosphate; alum powders leave a sodium sulphate and aluminum hydroxid. It must be acknowledged that the ferment with yeast also introduces extraneous matter into the food, viz., alcohol and allied products of fermentation.

Cakes are colored artificially by coal-tar dyes or derivatives as naphthol yellow, or by mineral matters which are even more objectionable. They are further adulterated by molasses, and by sulphurous acid in the sugar. Too often passé storage eggs or eggs broken and preserved with borax or formaldehyd have been used.

Canned corn is adulterated with sugar to cover up defects of corn and maize starches. Sulphurous acid is detected by adding to 25 grams of a sample (in water if necessary) pure zinc and several centimeters hydrochloric acid. If sulphites are present hydrogen sulphid is generated and may be tested for with lead paper. Traces

of metallic sulphides are occasionally present in vegetables and by the above test will indicate sulphites. Hence, positive results obtained by this method should be verified by the distillation method.

Detection of saccharin (formerly often present in canned peas and corn). Add 25 to 40 c.c. water to 20 grams of sample; macerate and strain through muslin; acidify with 2 c.c. sulphuric acid (1:3) and extract with ether. Separate the ether and allow it to evaporate spontaneously and take up the residue with water. If saccharin is present a sweet taste will be imparted to the water. To confirm this test add 1 to 2 grams sodium hydroxid and place in oil-bath at 280° for 20 minutes. The saccharin will be converted into salicylic acid; cool and acidify with sulphuric acid, extract, and test for salicylic acid. If salicylic acid is present in original sample it must of course be removed before making this test.

Canned Vegetables.—Beans and peas are adulterated by copper sulphate—a highly poisonous substance—and by saccharin.

Test for Copper.—Peas rubbed to a fine paste are mixed with water and acidified by 2 or 3 drops of hydrochloric acid. The paste upon boiling will deposit copper on silver, steel or iron, *i. e.*, a steel knife or iron nail.

Canned tomatoes are often adulterated. Antiseptics are unnecessary—tomatoes become sterile easily; and sometimes unripe unfit tomatoes are used. Water is sometimes added; and very commonly the can only partially filled with tomatoes is filled up with the juice which escapes on the peeling table, and which is piped into a tank and held for the purpose of filling the cans.

Tomato ketchup is unnecessarily adulterated with salicylic acid, benzoic acid, artificial coloring, or sometimes imperfect tomatoes.

Tapioca is adulterated by other starches.

Starches are adulterated by sulphurous acid as a bleach. Starch may be an adulterant as when maize starch is mixed with wheat flour or powdered starch mixed with granulated sugar.

Fruit.—Evaporated apples are subjected to a bleaching process—exposed to sulphur fumes, *i. e.*, sulphurous acid. This has a deleterious effect, decreasing the number of red corpuscles, etc.

Lime juice is often marketed in spurious forms, *i. e.*, mixtures made up with flavoring of an acid character resembling that of the natural juice. Often also adulterated by preservatives, especially sulphurous acid and salicylic acid—not necessary if sterilized.

Pineapple is not extensively adulterated.

Cherries, Canned.—The addition of artificial coloring matter is reprehensible. Maraschino cherries are bleached in the brine of common salt and sulphurous acid, washed thoroughly, then saturated with sugar or glucose and colored by coal-tar dye or cochineal. Then, if the natural flavor is destroyed by bleaching, artificial flavor is added. They are preserved in alcohol.

Canned fruit is adulterated by (1) unnecessary artificial colors (2) saccharin. This is reprehensible.

Fruit syrups are extensively adulterated. By reason of laws against salicylic acid, benzoic acid or benzoate of sodium are used as preservatives. This is unnecessary for they can be preserved by sterilization. Imitation fruit syrups should never be used.

Jams, jellies, preserves and fruit butter are artificially colored and flavored; glucose and preservatives are found in them. Pure glucose being simply a hydrolyzed starch is not injurious. By converting the starch from which it is made with diastase and avoiding bleaching agents all objections to glucose for food purposes can be removed.

Brandied fruit should be restricted, especially with children. An imitation of brandy is used.

Mince meat usually contains artificial colors and chemical preservatives of which sodium benzoate is chiefly used. In view of the fact that waste materials from table or factory and poor fruit enter into the manufacture of mince meat and pie fillers, it is wisest to make them at home.

A most exacting supervision over the preparation of **fresh mushrooms** for the market should be required. In **canned mushrooms** the presence of sulphurous acid as a bleaching agent is an adulterant, for it is not needed as a preservative, if sterilization is complete.

FOOT, AMPUTATIONS.—Amputation of the foot may be performed by one of the following methods:

Disarticulation at the ankle-joint (Syme's amputation) consists in removing the foot at the ankle-joint, cutting off the ends of the tibia and fibula, and retaining the integuments of the heel as a covering for the bones. An incision down to the bone is made across the under surface of the heel from the tip of the external malleolus to a little behind and below the internal malleolus, *i. e.*, to a point exactly opposite its commencement. This incision should incline slightly backward, so as to cross the os calcis just in front of the tubercles. A second incision is next made across the front of the ankle, the joint is opened, the lateral ligaments are divided, and the os calcis cleared from its posterior and lateral connections by cutting from above downward. Syme, however, formed the heel-flap by dissecting it from the bone from below upward, a more difficult procedure than cutting from above downward. The knife should be kept close to the bone, to avoid injuring the posterior tibial artery or buttonholing the integuments. The malleoli and a thin slice of the tibia are finally sawed off. The anterior tibial and plantar arteries require ligating; the latter are situated at the extremity of the inner side of the heel-flap.

Pirogoff's operation is a modification of Syme's. It differs in that the posterior part of the os calcis is left in the heel-flap to unite with the sawed end of the tibia. It is performed in a similar manner, except that the sole incision is carried slightly forward instead of backward; after the ankle-joint is opened and the os calcis exposed, the posterior part of the latter is sawed off instead of being dissected out. The sawed surface of the os

calcis is then turned up and placed in contact with the sawed end of the tibia, to which it may advantageously be fixed by an ivory peg driven through the heel-flap and os calcis into the lower end of the tibia.

The mediotarsal amputation (Chopart's) consists of amputation of part of the foot through the transverse tarsal joint, *i. e.*, the joint formed by the os calcis and astragalus behind, and the cuboid and scaphoid in front. A curved incision with its convexity forward is made across the dorsum of the foot from immediately behind the tubercle of the scaphoid to a point midway between the tip of the external malleolus and the base of the fifth metatarsal bone. The extremities of this incision are connected by tracing out from the sole a flap that should reach just above the balls of the toes, and should be longer on its inner than on its outer side. The dorsal ligaments are now divided, and the knife is passed beneath the bones and made to cut its way outward, thus completing the flap already marked out on the sole. The astragalus and os calcis are, of course, left in the stump. The chief objection that has been urged against the operation is the tendency of the tendo Achillis to draw up the os calcis, and consequently depress the anterior part of the stump so that the cicatrix becomes the lowest part. But if care is taken to make the dorsal incision nearly straight across the foot, this drawing up of the heel can, to a great extent, be prevented, and an excellent and useful stump may be obtained; or Tripier's suggestion may be adopted, and the under surface of the os calcis be sawed off, so as to leave a flat surface for walking upon.

The tarsometatarsal amputation consists of removing the anterior part of the foot at the joints between the tarsus and metatarsus, leaving the tarsus intact. It may be done (1) by disarticulating the metatarsal bones; (2) by sawing across the bases of all the metatarsal bones; (3) by disarticulating the four outer metatarsal bones and sawing across the projecting internal cuneiform bone; (4) by disarticulating the three outer and the first metatarsal bones, and sawing across the prominent base of the second. The disarticulating method is usually called Lisfranc's operation; the disarticulating, with sawing across the internal cuneiform or base of the second metatarsal bone, Hey's. Hey, however, it appears, performed all of the first three operations, but not the last; and so much confusion has arisen as regards what is meant by Lisfranc's and what by Hey's operation that the terms should be disregarded (Walsham). In the disarticulating method, which alone need be described, an incision is made across the tarsus, from the fifth metatarsal bone to an inch in front of the prominence of the scaphoid; a sole-flap is next traced out, as in Chopart's amputation, but it should reach as far as the web of the toes. The metatarsus is then disarticulated from the tarsus, the only difficulty in doing this arising from the second metatarsal bone dipping in between the cuneiform bones. The knife is now placed behind the bones and made to cut its way out, thus completing the sole-flap, or the flap, if preferred, may be dissected up from without inward.

The great toe may be amputated at its tarsometatarsal joint by a flap taken from the inner side of the foot, or by an oval incision, which is carried along the metatarsal bone to about the middle of its shaft, then made to diverge to the web between the first and second toes, and carried round the plantar surface of the big toe and back to the spot at the middle of the metatarsal bone. The incision should extend down to the bone, which should next be freed from its remaining connections and disarticulated, the knife being kept close to the metatarsal bone to avoid injuring the communicating branch of the dorsalis pedis with the external plantar artery. When the operation is completed, merely a single longitudinal scar remains on the inner side of the foot (Walsham). See AMPUTATION.

FOOT, DEFORMITIES.—See TALIPES.

FOOT, INJURIES.—**Fracture of the tarsal bones** is rare, and is generally the result of direct crushing force or of a severe fall upon the foot. The tuberosity of the os calcis may be torn off by sudden violent action of the calf-muscles. The fragment is drawn up by the muscles and can be replaced by flexion of the knee and fixation dressings, or perhaps best by direct suture. With this exception, fracture of the other bones is difficult to detect without the aid of the X-rays, and is generally uncertain.

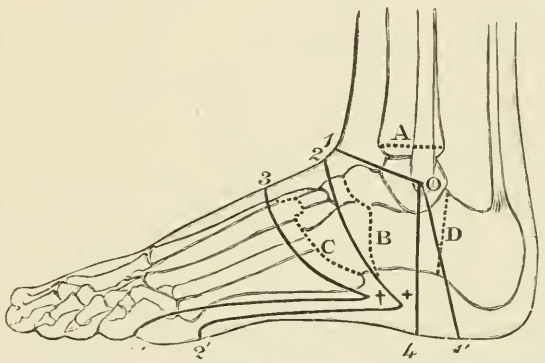


DIAGRAM OF THE ARTICULATIONS OF THE FOOT, SHOWING THE LINES OF INCISION IN THE VARIOUS AMPUTATIONS.—(*From Walsham.*)

A. Line of incision through malleoli in Syme's amputation. 1—O, O—1'. Lines of incision through soft parts in Syme's amputation. D. Line of incision through os calcis in Pirogoff's operation. 1—O, O—4. Lines of incision through soft parts in Pirogoff's operation. B. Line of articulation between os calcis and astragalus behind, and cuboid and scaphoid in front. 2—+, +—2'. Lines of incision in Chopart's operation. C. Line of articulation between tarsus and metatarsus. 3—†, †—3'. Lines of incision in tarsometatarsal operation.

Treatment consists of rest in fixed dressings, and then massage and passive movements. Some of these injuries are followed by considerable impairment of function and a persistent painful condition.

Fracture of the metatarsal bones is infrequent;

it is the result of direct injury, which frequently compounds the fracture.

Fracture of the phalanges is easily recognized, and requires simple treatment (fixation, rest, protection).

Dislocation of the metatarsal bones occasionally happens upward, downward, or laterally (chiefly upward). The displacement is marked by a corresponding prominence on the dorsal or plantar aspect of the foot, and by a shortening of the toe affected. Reduction is by traction and direct pressure.

The phalanges of the toes are occasionally dislocated as a result of the extreme dorsal or plantar flexion. These dislocations are less frequent than similar displacements of the fingers, and are marked by a corresponding prominence, with a shortening of the toe. Traction, with hyperextension and direct pressure over the displaced bone-end, produces reduction easily. See ANKLE.

Compound fractures and dislocations are common, but no definite rules can be given for their treatment. Warm antiseptic lotions are generally used for the first day; after that, if there are signs of vitality and healing, the immovable plaster dressing may be applied. In lacerated wounds amputation of any but gangrenous tissue should be a last resort. In operations the tread of the sole should be interfered with as little as possible, and it must always be remembered that stability is the first consideration.

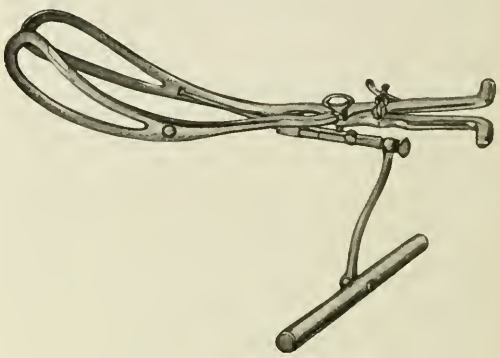
FOOT-AND-MOUTH DISEASE.—Aphthæ epizooticæ. An acute infectious disease of animals transmissible to man especially during epidemics. It is a severe form of aphthous stomatitis due to drinking milk or eating cheese or butter from infected cattle, or through contact with the fluid of the vesicles in the mouth or on the teats. It is characterized by vesicles containing yellow serum on the lips, tongue, pharynx, and on the skin especially of the fingers and toes, and on the nipples in women. Salivation is profuse and the mouth is swollen and hot. There is fever, malaise, anorexia. Prophylaxis consists in boiling suspected milk, and cleanliness of man and cattle. Treatment is mainly symptomatic. See STOMATITIS, APHTHOUS.

FORCEPS, OBSTETRIC.—An instrument devised for the purpose of grasping the child's head and aiding its extraction during labor.

Varieties.—Of the large number of obstetric forceps manufactured at the present day, 3 are deservedly the most popular. These are: (1) **The Tarnier axis-traction forceps,** which is used when the head is at or above the superior strait (high forceps operation). The special advantage of the axis-traction forceps is that its construction is such that traction can be made in the direction of the parturient tract. (2) **The Simpson forceps,** which is used when the head is in the pelvic canal (median forceps operation). (3) **The Sawyer forceps,** which is used when the head is on the perineum (low forceps operation).

Uses.—The most important use of the forceps is *traction.* This should be made in the direction of the parturient tract. No more strength should be exerted than that possessed by the arms and forearms. Traction should be made with the pains, when present; at corresponding intervals, when absent. To avoid slipping of the blades, the tip of the index-finger of the right hand should be kept in contact with the scalp.

Forceps may occasionally be used to secure *anterior rotation,* as in face or brow presentations with chin posterior. Finally, forceps may be used as a *lever* or as a *compressor.*



TARNIER'S AXIS-TRACTION FORCEPS. LATEST PATTERN.

Indications.—The indications for the use of forceps are the following: (1) *Lessened expulsive power,* as occurs in uterine and abdominal inertia. (2) *Increased resistance,* as in certain degrees of contracted pelvis, great rigidity of the cervix or vagina, and oversized child. (3) *Endangered fetal or maternal life,* as prolapse of the cord, prolonged compression of the fetal head, heart-clot, eclampsia, and hemorrhage. The best indication of the condition of the child is its heart-beat; should this fall to 100 beats a minute, its life is seriously endangered. (4) *Acute or chronic diseases of the mother,* as pneumonia, typhoid fever, phthisis, and valvular heart-disease. Under these circumstances the mother's strength is weakened, and forceps should be applied as soon as the os dilates, in order to prevent exhaustion. (5) *Abnormal positions and presentations,* as face or brow with chin posterior, and persistent posterior position of the occiput.

Contraindications.—(1) *An undilated os.* If forceps is applied before full dilatation of the os, the cervix will probably be lacerated. Should any grave danger threaten the child or mother, however, it would be perfectly justifiable to assume this slight risk. (2) *Nonengagement of the head at the superior strait.* While this is a general contraindication, it is not absolute, since forceps may be applied to *secure engagement* in minor degrees of contracted pelvis, and also to bring down the head in placenta prævia. (3) *Unruptured membranes.* This is an absolute contraindication, since traction on the membranes may cause premature separation of the placenta. (4) *Too great disproportion between the child's head and the parturient canal.* In this case some other operation is indicated, such as symphyseotomy, cesarean section, or

craniotomy. (5) *Impossible presentations and positions.* Forceps should never be used *as tractors* in face or brow presentations with chin posterior.

Application.—Before application the forceps should be sterilized, preferably by boiling; the physician's hands and the patient's vulva and vagina should be thoroughly cleansed. If the operation promises to be an easy one, no anesthetic is required; as a rule, however, it is best to anesthetize the patient. She should then be placed across the bed, in the lithotomy position, with her buttocks extending well over the edge. The steps of the operation are as follows: (1) Introduce two fingers of the right hand into the vagina, if possible, between the cervix and the child's head. (2) With the thumb and two fingers of the left hand grasp the left blade at the lock, holding it almost perpendicularly. (3) Introduce the tip of the blade into the vagina, passing it along the floor toward the sacrum. (4) Rotate the blade outward in its long axis, in order to escape the promontory of the sacrum. (5) Depress the handle toward the perineum, and carry it to the left side of the vulva. (6) The right blade is introduced in a similar manner—held in the right hand and passed to the right side of the pelvis. It will now be found that the forceps will not lock. To facilitate this and to grasp the head properly, one of the blades must be rotated forward. If the head occupies the *right oblique diameter* of the pelvis, as in the L. O. A. and R. O. P. positions, the *right* blade must be rotated; if it occupies the *left oblique diameter*, as in the R. O. A. and L. O. P. positions, the *left* blade must be rotated.

Delivery.—The blades having been properly applied, the handles should be grasped with the left hand, the index- and middle fingers hooked over the shoulders of the instrument, the base of the right palm resting upon the knuckles of the left hand, and the tip of the right index-finger touching the scalp. Traction is now made in the direction of the pelvic axis, until the occiput has well distended the perineum. The grip on the forceps is now changed; the right hand grasps the handles firmly, the four fingers encircling them; the left hand protects the perineum, and the face is swept over it by an upward movement of the instrument.

In posterior positions (R. O. P. and L. O. P.) the instrument is first applied in the usual manner, and the head drawn down to the pelvic floor. It is then removed until anterior rotation of the occiput is secured, when it may be reapplied and the head delivered in the manner just described. Should the occiput rotate into the hollow of the sacrum, the handles of the instrument should be depressed as the face is finally swept out under the symphysis pubis.

FORCIPRESSURE.—The arrest of a minor hemorrhage by catching the end of the divided vessel with a pair of spring-forceps, the pressure being kept up for from 24 to 36 hours, or very gently withdrawn after a short interval; the surrounding tissues are caught up with the forceps at the same time. It is a means often used to control hemorrhage during an operation, and is sometimes employed to check hemorrhage from a vessel that from its depth or other cause, cannot be tied.

FOREARM, AMPUTATIONS.—These operations should always be performed as near the wrist as possible.

Circular.—The limb being supported with the thumb uppermost, and an assistant drawing up the skin, a circular incision is made through it, down to the fascia. When the integument is retracted and folded back about an inch, the muscles and tendons are divided by a second circular incision; the interosseous parts and the remaining fibers are next cut through; the bones are then sawed through together and of equal length, and projecting tendons trimmed off. The *radial*, *ulnar*, and one or two *interosseous* arteries require ligatures.

Flaps.—The limb being placed in a state of pronation, the surgeon makes a flap from the extensor side by cutting from without inward; in width the flap should be one-half of the circumference of the limb at the point to be removed; its length should be a little more than its semidiameter. The posterior flap is to be of the same size and made in the same manner as that for the flexor side. The interosseous parts are then divided, the flesh drawn upward, the bones sawed through, and the tendons trimmed off. The vessels to be secured are the *radial*, *ulnar*, and *interosseous* articles, and probably some of their muscular branches.

Long Rectangular Flap (Teale).—This flap is made from the back of the forearm. The radial vessels are included in the shorter flap. In tracing the long flap a longitudinal line is drawn over the radius external to the vessels; at the distance of half the circumference of the limb another line is drawn parallel over the ulna. These are joined across the dorsum by a transverse line. The short flap is formed by a transverse line across the front, joining the long at the upper fourth. When dissecting the long flaps from below upward, the tissues must be separated close to the periosteum and interosseous membrane, and the bones sawed through at the angle of union. The vessels having been ligated, the stump is to be placed in the prone position, so that the long flap may fall over the ends of the wound and be approximated to the short flap, in the usual method.

FOREARM, FRACTURES.

Fractures of the Ulna

Fracture of the olecranon results directly from a fall or blow upon the elbow; rarely from muscular pull of the triceps or from hyperextension. The fracture is generally transverse through the center of the olecranon, the fragments becoming distinctly separated by the muscular pull of the triceps drawing the upper fragment upward. The superficial position of the parts makes the condition easy of recognition; the forearm being flexed, the patient has lost the power to extend it voluntarily. Sometimes the periosteum and lateral tendinous fibers remain intact in whole or in part. In such case the fragments remain in contact, or nearly so, and the prognosis as to bony union is favorable. The more the fragments are separated, the more improbable

is bony union and the greater the probability of connective-tissue union.

Treatment.—The most important point in treatment is to fix the arm in the position that permits the nearest apposition of the fragments. This, of course, is one of complete extension. Aspiration of the joint for the removal of effused blood is sometimes useful and necessary. After bringing

Fracture of the Olecranon.—(*Liston.*)

the upper fragment down as far as possible by manual force, the effort is made to hold it there by passing a strip of adhesive plaster over the tip of the olecranon and bringing the two ends obliquely downward on each side toward the flexor side of the forearm; it is better still to bring the ends obliquely downward, and to cross and fasten them around a splint that has already been made fast to the flexor surface of forearm and arm. This serves the purpose much better as a point from which to make traction.

If the fragments cannot be nearly apposed, and in chosen cases, primary bone suture of the fragment promises brilliant results. But it must be borne in mind that such invasion is dangerous unless proper understanding of and facilities for aseptic work are at hand. As a matter of course, this injury is to be treated as an articular fracture. The triceps should be massaged early. Recently the massage treatment alone of this fracture has given good results.

Fracture of the coronoid process is not frequent, occurring generally in association with backward dislocation of the forearm. Only when the fracture is through the base of the process does the brachialis anticus control the separated fragment, the muscle being inserted not at its point, but below it, toward the base. The depth of the soft parts over the anterior aspect of the joint usually prevents satisfactory direct palpation of the fragment; the olecranon is likely to project backward, this being corrected by traction on the forearm. By slightly flexing the forearm this displacement may be readily produced by backward pressure on the forearm. Crepitation may be evident. The fracture is an articular one, but as such the prognosis is fairly good.

Treatment demands reposition by forward traction on the forearm, and then fixation by splints with the forearm acutely flexed. Further treatment is the same as that of articular fracture in general.

Fracture of the ulna at its upper third is frequently associated with dislocation of the head of the radius over the external condyle or the anterior surface of the joint. Such an injury is always accompanied by marked displacement and shortening of the ulna. No difficulty exists in recognizing the fracture, but the dislocation of the radius is not infrequently overlooked. The prognosis is good if the condition is recognized early, as reposition by vigorous traction on the forearm offers no special difficulties. The head of the radius is brought into place by direct pressure of the thumb during flexion of the forearm. The dressing is a right-angled splint, which is best applied with the elbow at a right angle, the hand almost supine, with a pad at the bend of the elbow to make pressure over the head of the radius, and so combat any tendency to recurrence of the dislocation.

Fracture of the diaphysis of the ulna usually results from striking on the forearm with the elbow bent, as in falling or in warding off a direct blow (parrying fracture). The superficial position of the bone renders the ordinary diagnostic signs very distinct. When only one bone of the forearm is broken, marked displacement is not likely to occur.

The treatment is best effected by fixing the forearm from elbow to fingers in two splints slightly wider than the forearm, one applied to the flexor and the other to the extensor side of the forearm, the hand meanwhile being held midway between pronation and supination. This position of the hand brings the two bones parallel and effects the widest separation between them, in contrast to the position of pronation, which causes the bones to cross and brings them into closer apposition. In fracture of one or both bones of the forearm the possibility of callus-formation interfering with or abolishing the power of pronation and supination is to be borne in mind. Fixation with the forearm midway between pronation and supination is the best safeguard against this misfortune.

The styloid process of the ulna is rarely fractured alone. Fibrous union frequently results.

Fractures of the Radius

Fracture of the head of the radius is altogether intraarticular, and may be complete or incomplete; in the latter case the diagnosis is only problematic. Undoubtedly, this fracture is often mistaken for a simple contusion of the joint. Complete fractures are sometimes recognizable by the demonstration of the abnormal mobility of the head under crepitation. Resulting sometimes directly, the fracture is more frequently caused by a fall upon the hand, a marginal portion of the head of the bone being thereby forced off against the eminentia capitata (chisel fracture). The X-ray should be employed in all fractures involving or in close relation to the joint.

Treatment calls for fixation of elbow-joint and wrist-joint by means of an internal right-angled splint, with a sling for the forearm; considerable stiffness of the elbow-joint frequently results from this injury, and may demand subsequent resection of the capitulum.

Fracture of the neck of the radius below the head is rare; in such cases the head does not move in pronation and supination of the hand, and sometimes a bony prominence may be made out at the point of injury. Treatment is the same as that given for fracture of the head of the radius. Traumatic separation of the upper radial epiphysis is rare.

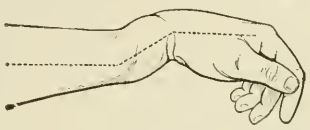
Fracture of the shaft of the radius is rare, and may be caused by direct or indirect force. The

symptoms are distinct and the diagnosis is easy. The ulna remaining intact, displacement is not likely to be marked. If the fracture is oblique, the fragments sometimes have a tendency to slip by each other, shortening the radial side of the forearm and giving a bowed appearance, the convexity being toward the ulna. This position is best

Fracture of the Radius.

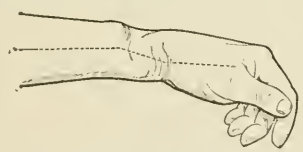
corrected by first applying a narrow, well-padded, and stiff splint to the ulnar side of the arm, with a pad under the middle of the ulna; the two ends of the radius are now bandaged securely to this splint, care being taken not to make pressure over the seat of fracture with any circular turns of the bandage; the arm, meanwhile, is held in a position midway between pronation and supination. Two splints slightly wider than the forearm are now applied to the flexor and extensor sides respectively, including the hand, the dressing being completed by the application of a sling.

Fracture at the lower epiphysis of the radius (Colles' fracture) is very frequent and is of grave importance. This fracture is typical, and occurs from 0.5 to 2 or more cm. above the lower articular



Colles' Fracture. Showing silver fork deformity.—(*Stewart.*)

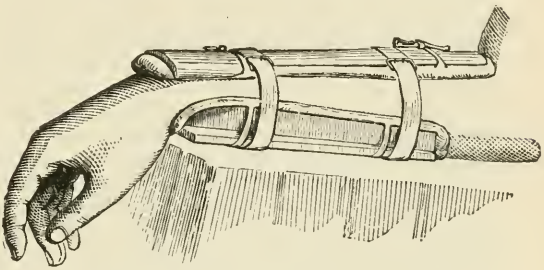
surface, just where the compact bone of the shaft passes into the cancellous expansion of the distal end. The line of fracture may pass through the epiphysis proper, causing in such cases the separation of a smaller fragment. The fracture nearly always results from a fall in which the weight is



Fracture of Lower End of Radius With Anterior Displacement. Showing gardener's spade deformity.—(*Stewart.*)

caught on the palmar surface of the hand, causing at first a hyperextension of the hand on the forearm, and then, by traction of the very strong ligamentum carpi volare, fracture of the radius at the point named. The force acting in this way always causes a dorsal displacement of the separated lower fragment. The ulna has no direct connection with the wrist-joint itself, and, as a rule, does not suffer injury in this fracture. The chief symptom of this fracture is the typical displacement; the lower fragment of the radius is displaced dorsally and at the same time radially, producing the classic "silver-fork" deformity; the styloid process of the ulna is thrown out conspicuously, and there is a prominence on the volar side of the arm and a depressed angle on the dorsal side. Abnormal mobility and crepitation are not demonstrable, as a rule, owing to the partial impaction that generally results. Of great importance is the demonstration of the painful spot above the joint, which corresponds to the line of fracture.

Treatment.—This fracture is serious, the prognosis depending, in the main, upon the intelligence with which it is treated. An anesthetic should nearly always be employed in effecting reposition, which is accomplished by forcible extension and then flexion. Sometimes this flexion is impossible until the fragment has been loosened by forcibly hyperextending the hand. At the same time the hand must be carried into ulnar flexion, otherwise there will result an ugly prominence of the styloid

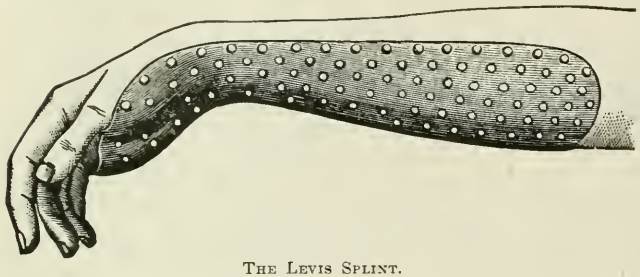


Gordon's Splint for Colles' Fracture.

process of the ulna. As a rule, the displacement has little tendency to recur after reposition. The hand is now to be fixed in this position of partial volar and ulnar flexion, the forearm being in a position half way between supination and pronation. For this purpose a "pistol" splint is most convenient; it is usually applied to the flexor aspect of the arm, extending from the elbow to the bases of the fingers; a soft pad is placed under the end of the diaphyseal fragment; a shorter splint, extending to the root of the hand, is applied to the extensor side of the arm, a soft pad being placed just over the epiphyseal fragment. A roller bandage holds the splints in place; the shape of the splint and the position of the pads insures the maintenance of the hand in the desired position of volar and ulnar flexion. The fingers are left free, and the patient is encouraged to move them both passively and actively, as they are prone, otherwise, to become excessively stiff. The dressing is to be removed during the first week, when passive motion with massage, should be carefully begun; further treatment is to be carried out as for other articular fractures. At the end of about the second week, or even earlier in some cases, the whole hand is to be left free of the splint and movements encouraged, thus combating the decided tendency to stiffness.

Several forms of splints are serviceable in this fracture, as Levis' metal splint, Sands' splint, Gordon's splint, etc. The plaster-of-Paris splint is the least satisfactory of all. After reposition, as stated, the displacement is not likely to recur, so

that the fracture may be dressed by simply supporting the site of fracture by a circular adhesive plaster strapping, and then placing the arm in pronation in a sling, the hand hanging down free over the edge of the sling. This dressing requires careful watching, but gives the best possible result in so far as mobility of the joint is concerned.



The Levis Splint.

Sometimes fracture of the styloid process of the ulna is associated with the epiphyseal fracture of the radius. In such case the wrist-joint is particularly liable to be implicated. The fracture is to be treated on much the same principles as the foregoing. Imperfect mobility may later demand the resection of the styloid process of the ulna.

Fracture of both forearm bones, resulting, as a rule, directly from a fall or a blow, occurs generally in the median third of the forearm. Here the usual signs of fracture are easily recognized. Displacement is likely to be greater when the bones are fractured at the same level than when at different levels. If there is a lateral approximation of the two bones, together with marked injury of the interosseous ligament, the functions of supination and pronation may suffer, as a result either of osseous union of the two bones or of conic articulation. In the leg such complications are of no moment functionally, but in the arm they may gravely compromise the capacity for work.

Treatment.—After reposition the dressing must hold the fragments steadily, without forcing them together by compression. Therefore, the two splints must be wider than the arm; they are best made of board, leather, or heavy cardboard—one longer, one shorter. They encase the hand and fingers, should be well padded, and are applied with the forearm midway between pronation and supination, as this is the position, as already pointed out, that places the two bones parallel and the most separated from each other. Furthermore, as most of these fractures occur below the attachment of the tendon of the biceps muscle to the radius, this muscle pulls the upper radial fragment into supination. If the lower arm, then, remains in a partially prone position, it is manifest that union of the radius will take place with the fragments rotated on one another, and a subsequent loss of the power of supination results. This dressing must be well padded, and carefully and not too tightly applied; it is especially following this injury that gangrene and ischemic contractures have occurred as a result of too tight dressings.

FOREIGN BODIES.—See Cornea, Ear, Nose, etc.

Foreign Bodies Swallowed.—Children frequently swallow pins, marbles, coins, fruit-stones, etc. While any of those that are sharp pointed or have sharp edges may perforate or cause an injury to the walls of the digestive canal, such results are very rare, considering the variety of objects of this class that a child may swallow. Anything that is not too large to swallow will usually pass safely through the intestines without giving any symptoms of distress.

Treatment.—The best methods of hastening the expulsion of the article swallowed is to give for 24 hours *dry, solid, bulky food,* such as bread, potatoes, and rice, which will form a mass in the bowels that, when expelled, will carry the offending substance with it. If there is constipation after this food has been given for the time mentioned, a purgative, as, *e. g.*, 1 to 4 teaspoonfuls of castor oil, should be given, and repeated if necessary. If sharp-pointed or sharp-edged substances are swallowed, immediate administration of a saline or other purgative, producing a very liquid stool, should be forbidden.

FORMALDEHYD.—A gaseous body prepared by subjecting methyl alcohol to oxidation. It is readily absorbed by water, and is sold in the form of a 40 percent aqueous solution named Formalin (*q. v.*). It is powerfully antiseptic and disinfectant, ranking next below mercuric chlorid as a germicide. It has considerable penetrating power, and is much better than chlorin or sulphur dioxid for disinfecting clothing, rugs, hangings, etc. Matting, bedding, and pillows are, perhaps, better disinfected by steam. It does not act destructively on clothing or furniture, and is virtually nonpoisonous. For the production or liberation of formaldehyd in rooms and buildings, the best results are obtained from formalin heated and vaporized. Trillat's apparatus allows the solution of formalin to flow in a fine stream through a copper coil heated to redness by a flame beneath, the gas and vapor passing directly into the room. The apparatus may be operated outside of a room, and the amount of gas liberated depends directly upon the strength and quantity of the solution evaporated. In Schering's method the solid paraform is heated in a receptacle over an alcohol lamp, and is especially valuable in disinfecting small rooms, closets, and cases for instruments, dressings, etc. The cheapest and most common form develops the gas directly by the oxidation of methyl alcohol, the vapors of the latter passing over or through tubes or coils of heated metal. The amount is uncertain and results indefinite.

Whenever used, the apertures in a room should be carefully and tightly closed, and the vapor and gas should be allowed to act as long as possible, preferably 24 hours. About 5 ounces are required for each 1000 cubic feet of space. Its odor may be quickly dissipated from a room by evaporating a little ammonia therein. See Disinfection.

FORMALIN (Liquor Formaldehyd).—A 40 percent aqueous solution of the gas formaldehyd, or formic aldehyd, a powerful antiseptic, disinfectant, and deodorant. It has been used heretofore mainly as a preservative of meat, for injecting the cadaver, and in histologic work as a fixing agent. It is superior to mercuric chlorid in that it is far safer and is not actively poisonous. It will disinfect instruments without dulling their edges, and is useful in sterilizing catgut. A 2 percent solution is used to wash wounds, and a weaker solution to irrigate foul ulcers, abscess cavities, and sinuses. Such strengths are not irritant. Strong solutions are irritant even to sound tissues, and may be used to produce caustic effects. Formalin vapor is used to sterilize catheters, and may be introduced into the abdomen after incision in peritonitis. A 1 percent solution deodorizes feces, destroying all pathogenic spores within an hour. It is made by adding to 40 parts of water 1 part of formalin (1 ounce to 2 1/2 pints). Weak solutions (0.5 percent) are used as gargles and mouth-washes, and stronger ones (2 1/2 percent) as lotions for psoriasis, lupus, and other skin-diseases. In abrasions of the cornea ending in ulceration and hypopyon a solution of 1:2000 or 1:3000 is advised. Applied to the skin it gives it a leathery quality; it has marked toxic properties when inhaled in quantity. As a local application it has been highly recommended in superficial cutaneous cancer.

It is a most energetic disinfectant, and may be sprayed over floors or walls or dropped on hot plates or sheets of metal. See FORMALDEHYD.

FORMICATION.—A sensation like that produced by ants or other insects crawling upon the skin. The sensations are prickling or tingling in character, and are usually observed in organic diseases of the spinal cord; very rarely in hysteria.

FOUL BREATH.—See BREATH, FOUL.

FOURTH DISEASE.—A mild eruptive affection simulating measles, rötheln, scarlet fever, but considered a separate entity by Dukes. Many observers, however, doubt its existence. It has been suggested that it may be an infection with scarlet fever and rötheln conjointly.

FOURTH OF JULY ACCIDENTS.—A record of the accidents in the United States, due annually to the celebration of Independence Day, is thus given in the Journal of the American Medical Association:

Year.	Killed.	Injured.	Total.
1903	466	3,983	4,449
1904	183	3,986	4,169
1905	182	4,994	5,176
1906	158	5,308	5,466
1907	164	4,249	4,413
1908	163	5,460	5,623
1909	215	5,092	5,307
1910	131	2,792	2,923
1911	57	1,546	1,603
1912	41	947	988
1913	32	1,131	1,163
1914	40	1,466	1,506
1915	30	1,135	1,165
1916	30	820	850
Total, 14 years	1,892	42,909	44,801

The decrease from 466 deaths in 1903 to 131 in 1910 is due to more intelligent methods of celebration; the most marked decrease taking place in States where the agitation for restrictive measures has been strongest.

Treatment.—It is the duty of every doctor to warn his clientele of the danger of these "Fourth of July" injuries. Every case is to be treated as if lock-jaw is not merely a remote possibility, but a probability. Free cleansing and douching with peroxid of hydrogen is indicated.

Luckett says: "These wounds should be freely incised, particularly if not seen on the first day of the injury, and thoroughly curetted with a small sharp spoon until all the small pieces of wad, the unburned grains of powder, and all the dirt have been removed. If the wad has entered a metacarpal space a counter-incision must be made for through-and-through drainage. Having cleaned the wound as thoroughly as can be done mechanically, we now resort to chemicals and irrigate with some mild antiseptic. After next drying the wound thoroughly, the entire cavity should be swabbed out with one of the following, named in order of choice:

1. Pure carbolic acid followed by alcohol.
2. Twenty percent tincture of iodin (made by dissolving iodin crystals, 20 parts, in ether and alcohol, each 40 parts).
3. Plain tincture of iodin.

The wound should now be packed with moist iodoform gauze. A wet dressing is then applied, to be *changed daily*. Permission should be obtained for a prophylactic injection of antitetanic serum. Ten c.c. are intramuscularly injected in the buttocks or thigh, under thorough antiseptic precautions.

FOWLER'S SOLUTION.—See ARSENIC.

FOXGLOVE.—See DIGITALIS.

FRACTURE. Causes.—A fracture implies a breaking of bone wholly or in part, and is produced by **direct violence**, as a blow directly over the shin bone; by **indirect violence**, as catching the weight of the body on the hand in falling, producing a fracture of the bone or bones of the forearm above the wrist; by **muscular contraction**, as by violent contraction of the quadriceps extensor muscle, with the leg flexed and foot fixed, producing a transverse fracture of the patella.

Varieties.—Fractures are **complete** or **incomplete**: complete when the solution of continuity between the fragments is entire; incomplete when the solution is only partial, as in the greenstick fracture, which occurs most commonly in the long bones of children. In this case the fracture occurs on the convex side of the bent bone, while the continuity of the bone on the concave side is not disturbed.

When, on fracture, one fragment is driven sharply into the other fragment and sticks fast, the fracture is termed **impacted.** Impaction is commonly the result of indirect violence.

Fractures are, further, **single** or **multiple**: single when only one bone is fractured in one place; multiple when one bone is fractured in two or more places, or when two or more bones are fractured in one or more places.

It is at once evident that fractures the result of direct violence are most likely to be accompanied by more or less extensive injury of the contiguous and surrounding soft parts. This may vary from a simple contusion to a complete mangling and destruction of all the soft parts surrounding the broken bone. Fractures the result of indirect violence, most commonly the result of bending the bone beyond its limits of elasticity by forcing

Greenstick Fracture of Radius, Showing the Longitudinal Splintering.—(*Moullin.*)

the two ends of the bone nearer together, are less likely to be accompanied by serious injury to the soft parts. In such cases injury to the soft parts results from the sharp, broken edges of bone, which perforate the skin or wound muscle, vessels, or nerves. Fractures the result of violent muscular action alone are, in the nature of things, not commonly associated with any great amount of injury to the soft parts.

Fractures are described as **simple** when there results no open wound communicating with the outer surface of the body, and as **compound** when such communication is established. When extensive laceration of surrounding parts occurs, or when a fracture near a joint is accompanied by a dislocation of the head of the bone, the fracture is described as **complicated.** When the bone is shattered, usually by direct violence, and a number of larger or smaller pieces of bone are separated from the bone mass, the fracture is **comminuted.** A complicated or comminuted fracture may be at the same time a compound one, but in defining should not be described as **simple,** even though there exists no communication with the outer surface. Such fractures are best described as **closed,** complicated, or comminuted fractures.

Certain pathologic conditions predispose to fracture of bones, as atrophy from disuse or dis-

Comminuted Fracture of Clavicle.—(*Moullin.*)

ease, necrosis and caries, malignant disease, osteomalacia, partial absorption of bone from pressure of an aneurysm, a tumor, or ecchinococcus cysts; rachitis is also a common predisposing factor. A fracture under such conditions is termed a **pathologic fracture.** Under this head are also to be included the **epiphyseal separations** occurring in bones that are still growing, in which the diaphysis and epiphysis are still connected by a cartilaginous symphysis. In such bones separation may occur as a result of an inflammatory process, as in syphilis, scurvy, and primary infectious inflammation of bone (osteomyelitis).

In addition to the fragility from the causes enumerated there also exists another variety, fragilitas ossium, the etiology of which remains as yet unknown. This condition is known technically as idiopathic **osteopsathyrosis.** In these cases fracture may have resulted from the very slightest degrees of violence, such as a light blow or a thrust, a misstep, or even turning over suddenly in bed.

As regards direction, a fracture is **transverse,** the bone being broken square off and straight across; **oblique,** the fracture line running higher on one side than on the other; **longitudinal,** the fracture line running up and down the length of the bone and not infrequently extending into a joint; **spiral** or **torsional,** the fracture line running obliquely around the bone in a spiral curve.

The transverse fracture is usually the result of direct violence, and is not very common if the epiphyseal separations are not included. The most frequent fracture is the oblique; in this the breaking force is applied longitudinally, fracturing by forcible bending. The spiral fracture results from a violent twisting of the bone. Longitudinal fracture is rare, and when it does occur, is most frequently the result of a shattering of the bone due to a gunshot injury.

Displacement after fracture may be angular, the fractured ends of the bone coming together at an angle; **lateral,** when the end of one fragment rests in part on the end of the other fragment (this form of displacement is observed usually in transverse fracture, and may be associated with a certain amount of rotary displacement); **rotary,** one fragment being turned on its long axis to one side or the other (this form of displacement is very likely to accompany fracture of the long bones of the extremities, especially fracture of the femur and the bones of the leg); **longitudinal,** occurring chiefly in oblique fracture, because of one fragment being made to overlap or override the other fragment, as a result of the initial application of the breaking force or the subsequent muscular pull. Muscular action may also cause **longitudinal separation, diastasis** of the fragments, as in transverse fracture of the patella and of the olecranon process. In fractures with depression one or more fragments are depressed below the general surface of the bone. This deformity occurs chiefly in fracture of the skull and face, but may occur in comminuted fracture of the long bones.

The objective signs of fracture are:

1. **Abnormal mobility,** the cause of which is obvious. The range of such mobility is very great, all the way from a scarcely appreciable motion to a complete and easy mobility in all directions, the degree depending on the completeness of the fracture and the fixation afforded by the surrounding structures; in impacted fracture this sign is absent.

2. **Crepitus,** which is the rubbing or grating sensation or sound produced by the rubbing of one fragment against the other fragment. Crepitus may usually be produced in fractures of the long bones especially, and, when present, is the most certain and valuable sign of fracture; it may be determined by the sensation imparted to the hand

placed over the part during manipulation, but can sometimes be distinctly heard. Subjectively, the patient can ordinarily feel this grating himself. Sometimes crepitus may be absent because of the interposition of soft parts between the fragments, as muscle or fascia. In impacted fracture, of course, no crepitus can be elicited.

3. **Deformity**, which is in proportion to and in consequence of the mobility of the fragments on one another and their displacement. The presence and degree of deformity are always best determined by comparing the fractured part with the corresponding sound part, both by means of eyes and hands. By following up the sound limb with one hand and the injured limb at the same time with the other hand, any deformity becomes more certainly apparent than by simple inspection. While abnormal mobility and crepitus are necessarily absent in impacted fracture, the symptom of deformity may or may not be present.

The subjective symptoms are:

1. **Pain**, which may be felt continuously, or may only be elicited by attempts at motion, voluntary or passive; or may only be produced by local and direct pressure over the seat of fracture.

2. **Disturbance of function**, due, of course, to the break in the longitudinal axis along which muscular action exercises its mechanic function.

The constitutional symptoms are sometimes marked. Fever may manifest itself in subcutaneous and uncomplicated fractures, particularly during the first few days following a fracture, the temperature frequently rising to 102° F., sometimes even to 104° F. This is due essentially to a ferment intoxication the result of absorption of dead tissue elements, especially of fibrin ferment and others formed in the blood extravasated at the point of fracture.

Suppuration may occur; in such event microorganisms have gained access to the seat of fracture through some contiguous cutaneous wound or have been carried and deposited there by the blood. The injured and contused tissues around the seat of fracture and the extravasated blood furnish a congenial soil for their growth.

In **compound fracture** the external wound may close up quickly without any infection, the fracture then following the course of a subcutaneous fracture. On the other hand, virulent infection may occur, with considerable destruction of the injured parts, or even complete loss of the limb. Between these two extremes may occur any grade of infection and attendant inflammation. Further, the clinical course of a compound fracture is materially affected by the way it is treated. The earlier the wound is thoroughly cleansed, effective drainage provided, and sufficient dressings applied, the earlier a favorable course of repair is to be expected.

If infection is virulent and drainage insufficient, there may occur considerable and serious extensions of inflammation and burrowing of pus. The formation of any new pocket of pus or the invasion by inflammation of any new area is marked by a rise in temperature; for this reason a close inspection of the temperature-chart should be kept up during the period of the reparative process. If the inflammation and suppuration about the ends of the fragments have been sufficient to cause necrosis of bone, the process of repair may be very tedious; fistulæ leading down to remaining carious areas or sequestra may persist for a long time after the actual repair of the fracture is complete.

The urine after fracture sometimes contains a varying amount of fat, which is derived as fluid fat from the crushed medullary substance of the bone; it finds its way into the blood and is excreted by the kidneys. It can sometimes be seen by the naked eye in the form of small fat globules swimming on the surface of the urine. Its excretion begins from the second to the fourth day; ordinarily its presence is not attended by any symptoms, but it sometimes accumulates to a dangerous degree, death even ensuing as a result of its accumulation in the capillaries of the lungs and brain.

Albumin and **casts** may also occur, but are without any grave significance.

Hematogenous jaundice sometimes occurs, and is explained by the presence in the blood of disintegrated red blood-cells and blood coloring-matter.

Repair of fracture begins with the deposition at the seat of fracture of a germinal tissue rich in cells and blood-vessels, termed the provisional callus. This tissue replaces the extravasated blood, which takes no part in its formation. It is produced from the inner layer of the periosteum (the external callus), the medulla of the bone (the internal callus). The intermediary callus is that part between the broken ends of the bone, and is derived chiefly from the periosteum, the medulla and the opened Haversian canals having little part in its formation. The amount of callus depends on the mobility of the fragments and on the conditions of blood supply, being greatest when there is much motion and a plentiful blood supply, least when there is perfect fixation and a meagre blood supply. The further steps of repair are essentially those of an ossifying periostitis and osteomyelitis. By the deposition of lime salts the soft cellular tissue gradually becomes more firm, while osteoclastic action hollows out trabeculæ. By about the second week the two fragments are bound together by a medium of wide-meshed bone tissue; by the end of the third week the periosteal callus usually consists of fairly firm spongy bone. Meantime the medullary callus develops in the same way, sometimes occupying the whole of the medullary cavity. There now begins a retrogressive metamorphosis of the callus, the provisional callus being transformed into the permanent bone cicatrix by becoming more compact, so that later on this cicatrix may scarcely be visible. The closed medullary cavity may also become opened and completely reestablished by this process of absorption and compaction. The amount of callus remaining permanently seems to be in proportion to the functional necessity of the union. Thus, if perfect reduction has been accomplished and the limb has been held in a mechanically correct axial line, a minimum of permanent callus remains, forming the bone cicatrix. On the other hand, if reduction is imperfect and the axial line faulty, a much larger permanent

callus will result. In this manner the structure of the bone at the point of fracture is regenerated as completely as possible and in accordance with the demands of the laws of statics.

When, in consequence of splintering, fragmentation results, such fragments as remain attached to the periosteum or bone heal in place most readily. In subcutaneous fracture and in compound fracture healing without infection and suppuration, frequently even wholly detached fragments heal in place. Very small entirely detached splinters may become completely absorbed, while larger ones may die and much delay or prevent union of the fracture, unless or until this dead portion of bone (sequestrum) is removed.

Bony union of fracture is sometimes delayed or fails entirely; in this latter event the union by fibrous tissue may be sufficiently firm and close to restore in part or fully the usefulness of the limb. Many cases of fractured patella heal in this way; or a condition of **false joint**, or **pseudoarthrosis**, results, the fragments being bound together less securely by fibrous tissue and the false point of motion persisting. This delay or final failure of union is due in the majority of cases to a tendency to arrest of callus-formation before the stage of ossification is reached, and is particularly likely to occur when certain constitutional anomalies exist, as syphilis or scurvy, or during typhoid fever or pregnancy, in diabetes mellitus, and in certain diseases of the peripheral nerves and central nervous system. Sometimes failure of union and pseudoarthrosis result from the interposition of the soft surrounding structures, as a fragment of muscle, between the fragments, whereby the continuous callus-formation cementing the divided ends together is prevented.

Pseudoarthrosis may also result from a diastasis of the fragments, as in transverse fracture of the patella, in which case the powerful quadriceps extensor pulls the upper portion upward, causing a wide separation of the two. Insufficient nourishment of one of the fragments may bring about a similar result, as in intracapsular fracture of the neck of the humerus and femur.

The time required for the healing of a simple subcutaneous fracture is given by Gurlt as follows:

For a broken phalanx, about 2 weeks; metatarsus, metacarpus, and the ribs, 3; the clavicle, 4; the forearm, 5; the humerus and the fibula, 6; the neck of the humerus and the tibia, 7; both bones of the leg, 8; the femur, 10; and the neck of the femur, 12 weeks before consolidation is complete. Compound, comminuted, or complicated fracture requires relatively a longer period of time.

After healing of the fractured bone, more or less disability of the limb involved is likely to persist for a greater or less length of time. While it has been well determined that the larger joints, when not diseased, can be immobilized indefinitely without producing ankylosis or anything more than temporary limitations of motion, this is not true of the smaller joints, as the fingers and the joints in the neighborhood of fractured bones. Here inflammatory deposits may result in a persisting interference with free motion, or even in complete ankylosis; stiffness is also caused sometimes by the implication of contiguous tendons in the callus-formation. Very serious disability is frequently produced by the atrophy of muscle caused by the long-enforced immobilization and the interference with the circulation. Great injury to the muscular structure may result from tightly constricting bandages applied for a long time; sometimes an ischemic paralysis may follow this shutting-off of the blood supply. In such cases the muscle is altered and maimed. Pain may also persist for a long time, or permanently, due to the pressure on nerves by a large callus. It happens sometimes in fracture of the humerus that the musculospiral nerve is included in the callus-formation, in which event the muscles supplied by this nerve are likely to be disabled. After fracture, edema of the skin and subcutaneous soft parts of a limb may persist for a long time.

Separation of the epiphyses runs essentially the same course as fractures of the bone, except that sometimes marked shortening occurs as a result of the interference with the growth of the bone. This is most prone to occur when the epiphysis and diaphysis are driven into each other and heal in this position.

The diagnosis of fracture is included in the enumeration of symptoms already made. A systematic and careful examination of the injured and of the corresponding sound part should be made, any change in shape or outline and any disturbance of function being carefully noted. Palpation of the place where the fracture is presumed to be, combined with passive motion, will demonstrate crepitation, false point of motion, and the characteristic pain along the line of fracture, which in itself may be enough to establish the existence of fracture. Diastasis of fragments and careful measurement of the length of limb from fixed points will do much to help the determination. Frequently it becomes necessary to administer an anesthetic before the existence or exact condition of a fracture can be discovered. Sometimes it is necessary to distinguish between fractures and dislocations.

Fracture.	Dislocation.
1. Crepitus may be present.	1. Crepitus never present.
2. Preternatural mobility.	2. Rigidity rather than mobility.
3. Easily reduced—but	3. Difficult to reduce—but
4. Deformity more liable to recur after reduction.	4. Deformity less liable to recur after reduction.
5. The head of the bone is in its proper place.	5. The head of the bone is not in its proper place.
6. The socket containing the head of the bone is not empty.	6. The socket which should contain the head of the bone is empty.
7. When rotated the bone does not move as one piece.	7. When rotated the bone moves as one piece.

When available, the **X-ray** furnishes an invaluable and almost sure means of diagnosis. The conditions of city and hospital practice more and more demand that the surgeon shall have at command this wonderful aid, both in diagnosis and as a means of control during the time of repair of the fracture.

Complications of Fracture.—(*a*) *Simple fracture* may be complicated by: (1) local concomitant conditions, as dislocation, extravasation of blood, rupture of the main artery, vein, or nerve, implication of a joint; (2) circulatory complications, venous thrombosis, embolism, fat-embolism; (3) nervous complications, shock, retention of urine, traumatic delirium; (4) later complications, gangrene from tight bandaging, crutch paralysis, or involvement of a nerve in callus; (5) late septic complications, bed-sores, sloughing over the fracture, followed by erysipelas, tetanus, or malignant growth.

(*b*) A *compound fracture* may in consequence of the open wound becoming septic be complicated, in addition to the above mentioned suppuration and sloughing, by any of the following, viz., osteomyelitis, necrosis, acute arthritis, septic intoxication, septicemia, pyemia, hectic fever, and tetanus.

The prognosis of subcutaneous fracture without complications is good, as a rule. Transverse fractures heal more readily, and are less likely to cause lasting deformity, than oblique fractures.

Fractures of the hip and thigh in old persons, which necessitate confinement to bed for weeks, are always to be regarded as severe and serious injuries. In such cases the dorsal decubitus readily produces hypostatic processes in the lungs, together with a general disturbance of nutrition, frequently with a fatal termination. When the articular ends of bones are involved, the prognosis is generally unfavorable as regards the complete restoration of the function of the joint. The prognosis of complicated and compound fracture varies, naturally, within wide limits, dependent on the extent of the initial injury to surrounding soft parts and on the aseptic or infected course of the fracture.

Treatment.—In the treatment of fractures the question of **first aid** is of the very greatest importance. The layman, to whom this task generally falls, frequently offers assistance with hands more full of sympathy than of wisdom, and succeeds in doing harm instead of intended good. When an upper extremity is broken, the patient himself usually places the fractured member in a good position. But he has not this power in the case of fracture of the lower extremity. In this instance he should be lifted cautiously only after securely supporting the point of fracture, so as to prevent any unnecessary pain or further displacement of the ends of the fragments, or further injury to soft parts from the rough ends of the fragments. By a little ingenuity one can always find materials for these temporary dressings close at hand. It should always be borne in mind that a broken arm can be well splinted against the thorax for first transportation, and a broken leg against its fellow.

In general terms, the treatment of fracture consists in reposition or reduction, bringing the displaced ends of the bone in as nearly normal a relationship as possible, and then in maintaining them there by means of splints or dressings until the process of repair is complete. In order to put the fracture at complete rest, such dressings should always include the two joints adjoining the seat of fracture. For such dressings use is made of a great variety of materials; of these, the most generally serviceable are bandages made of plaster-of-Paris and splints of wood, metal, heavy cardboard, felt, and leather. In the treatment of many fractures, especially of the lower extremity, extension by means of weight and pulley is of the greatest service. While it is true that surgeons possessed of skill and experience attain excellent results by the exclusive use of one or the other method, it is still desirable that certain definite principles should be followed. It is still the practice of many surgeons to inclose a recent fracture in plaster-of-Paris at the first visit, and to leave the dressing undisturbed for weeks, until the fracture is supposed to be consolidated. This is wrong in principle, and it is not surprising that, as a result, recovery frequently takes place with more or less marked deformity. It is practically impossible to apply plaster-of-Paris to a fractured limb and to keep it in close apposition to the limb after the expiration of the first week. Swelling is either present at the time of such application, or it must be provided for by liberal padding. In either event the splint is bound to become loose when swelling begins to subside, which is ordinarily by the eighth day. After this time the plaster-of-Paris splint can no longer be expected to grasp and hold the fragments firmly; and as they are not yet fixed by the callus, more or less displacement usually results. It is dangerous to apply a plaster-of-Paris dressing excessively tight, with the idea of compressing the fracture. In such cases interference with the circulation may lead to ischemic paralysis and contracture, or to gangrene at the seat of fracture, or even of the whole limb. Furthermore, it is frequently very difficult to reduce and hold a fracture while plaster-of-Paris is being applied and is hardening. Even with skilled assistants, who are by no means always at hand under such circumstances, there is frequently lack of assurance after the dressing is complete that the reduction has been maintained, and that the axial line of the limb is correct. With splints this assurance is much more readily gained, as the maintenance of reduction during the application of the dressing is easier. If it were deemed especially important for particular reasons to employ plaster-of-Paris, there would seem to be no good reason why it should not be applied as a final layer over the splints. Plaster-of-Paris is especially indicated in fractures of the lower extremity after the second week.

Reduction is to be accomplished by means of extension and counterextension and manipulation. While an assistant makes traction on the proximal side of the fracture, the surgeon grasps and extends with one hand the distal portion of the limb,

manipulating and controlling the fractured ends of bone with the other. When the patient is sensitive, or muscular relaxation cannot be otherwise attained, a general anesthetic should always be administered. Failure to do this not infrequently permits an unsatisfactory and blameworthy result.

The first dressing of a fracture must take into consideration the fact that swelling of the soft parts will give an increased diameter to the limb; hence the splints must be well padded. At the end of the first week the swelling will ordinarily have begun to subside, and the dressing will begin to loosen. It should be reapplied, less thickly padded than before; careful attention should be given the position of the broken ends, and any axial error corrected. At the end of another week, or about two weeks from the time of fracture, the dressing will again have become somewhat loose, and should be reapplied. By this time the swelling will have largely subsided, and while the callus completely surrounds the seat of fracture, it still remains so soft as to permit of reduction of any still existing malposition. This third dressing will ordinarily remain in place until complete consolidation has occurred. Finally, a light and removable dressing may be supplied, to be worn as necessity demands.

After consolidation of the fracture great importance attaches to the **after-treatment** that is instituted to restore the injured limb to usefulness. Massage and passive movements are of great service. Indeed, daily massage alone has been urged, as an excellent method of treating fractures, the claim being made that union is thereby facilitated and hastened, and that after consolidation the limb is in much better and more useful condition than after ordinary fixation treatment. However, treatment by massage alone will hardly come into general use. But in those cases in which the blood supply is poor, or when there is reason to suspect a delayed union, massage is a most important adjunct to treatment. In all cases in which it is found expedient to change the dressings massage should be practised, and the neighboring joints should be carefully subjected to passive movement. The importance of passive movement increases as the size of the joint diminishes, being most important and imperative in fractures of the phalanges or about the wrist, when the possibility of entanglement of the tendons exists.

When a fracture involves a joint, the difficulties of treatment are necessarily much increased, as the task set for the surgeon is to immobilize sufficiently to secure consolidation of the fracture in good position and yet prevent ankylosis of the joint. In such injuries the joint capsule is usually distended with effused blood, whose removal is effected either by aspiration or by a dressing that will exercise compression and favor absorption. Dressings must be changed frequently, massage and passive movements being practised almost from the first, and active movements being early encouraged. Such treatment entails much labor upon the surgeon, but consolidation, with good mobility, may result.

Sometimes as a result of inadequate, and occasionally despite the most intelligent, effort of the surgeon, the result of treatment will be unsatisfactory, and union of a fracture will occur in malposition. Such deformity should be treated by speedy refracture of the bone by hand, osteoclast, or chisel, after which treatment will not differ from that of ordinary fracture. In badly united articular fractures such operative interference is most urgently indicated.

The callus forms sometimes in excess, and may even produce true tumors (osteoma, enchondroma), though this rarely occurs; on the other hand, its development may occasionally be very much retarded, as already stated. In such case the employment of proper measures will usually result in consolidation. Besides an appropriately strengthening diet, measures should be adopted to improve and increase the blood supply to the part: notably massage and such dressings as will permit the patient to move about, and, in the case of the lower extremity, to use the limb for weight-bearing purposes. A favorable effect is also produced by the application of a moderately tight rubber tube above the seat of fracture, the distal portion of the limb being protected by bandages. This establishes a venous hyperemia at the seat of fracture. A more vigorous measure is to rub the fragments against each other under anesthesia, and so to excite a more decided formative action on the part of the periosteum and medulla.

See Arm, Forearm, Leg, Thigh, etc.

FRAMBESIA.—See Yaws.

FRANGULA.—The bark (one year old) of *Rhamnus frangula*, or alder buckthorn. The fresh bark is a violent irritant; the old bark is a non-irritant purgative, much used in the constipation of pregnancy. **F., Fluidextract.** Dose, 10 to 30 minims.

FRECKLES (Lentigo, Ephelis).—The lesions commonly known as freckles are pinhead- to pea-sized, round, oval, or irregular, and of a yellowish, brownish, or blackish color. They occur chiefly upon the face and the backs of the hands, although they are occasionally observed on the trunk. They are more common during adolescence than at any other period, and are most marked in individuals of blond complexion, particularly red-haired subjects. They ordinarily make their appearance during the summer and fade partially or completely during the cold season. The condition is due to exposure to the light and heat of the solar rays. Some writers believe that a congenital predisposition is necessary. Freckles are due to an increased deposition of pigment in circumscribed areas of cells in the basal layer of the epidermis. A disappearance of the freckles may be brought about by treatment, but they are extremely likely to return.

Treatment.—The object of treatment is to produce an exfoliation of the epidermal cells containing the pigment. For this purpose solutions of mercuric chlorid, acetic acid, and similar preparations are used. Bulkley advises the following.

℞ Mercuric chlorid, gr. vj
Dilute acetic acid, ʒ ij
Borax, gr. xl
Rose-water, ʒ iv.

Apply night and morning; at first gently, later vigorously.

℞. Mercuric chlorid, gr. iij to viij
Zinc sulphate, Lead acetate, } each, ʒ ss
Water, ʒ iv.

Apply 2 or 3 times daily. Discontinue for 2 days when irritation is produced.

Hardaway obtains satisfactory results from the use of the electrolysis needle.

Equal parts of glycerin and lactic acid may be used as an application to remove freckles from the face.

FREEZING.—See Cold.

FRIAR'S BALSAM.—A name given to the *Balsamum traumaticum*, N. F., and also to the very similar *Tinctura benzoini composita*, U. S. P. See Benzoin.

FRIEDREICH'S ATAXIA.—See Hereditary Ataxia.

FRONTAL SINUSES.—See Nose (Disease of the Accessory Sinuses).

FROST-BITE (Chilblain, Pernio).—A form of inflammation of the skin and deeper parts produced by prolonged exposure to cold and tending to terminate in gangrene. Chilblains may be defined as cutaneous inflammation due to cold. The toes and neighboring parts of the lower extremities, the fingers and hands, the nose and the ears, are most frequently affected. Anemic persons and those debilitated from insufficient nourishment or from fatigue are especially prone to suffer. Transient redness of the parts first occurs, accompanied by hyperesthesia and tingling. Purplish lividity quickly follows, with diminished sensibility. Blanching, with numbness, supervenes. Coagulation next takes place, signalized by hardness, whiteness, and absolute insensibility. If the process is severe, dry gangrene is soon established, and the parts shrivel up and blacken. An inflammatory line of demarcation shows itself later.

Treatment.—Chilblain, or frost-bite, in which the skin is not yet livid or gangrenous, should be treated by friction with snow or with towels soaked in ice-water. When the congestion has disappeared and the parts have become warmer, they should be wrapped up in cotton-wool. The patient suffering from frost-bite should not be brought suddenly into a warm room. If the cold has induced coma, the best remedy is friction with flannel all over the surface of the body. Warm drinks must be administered, such as coffee, tea, weak wine, and water, to which a few drops of ammonia water may be added. If the patient cannot swallow, an enema of milk containing a little brandy may be resorted to. When reaction is restored, the temperature of the room may be gradually raised. Stimulating applications are to be used to relieve the itching and burning that accompanies chilblain; of these, tincture of iodin painted over the part; Wardrop's liniment, consisting of tincture of cantharides, 3 drams; soap liniment, 9 drams; diluted turpentine and carbolic acid, are most highly recommended. Cod-liver oil, quinin, and tonic treatment generally are necessary.

If small areas only are involved, which are dead or gangrenous, allow them to come away spontaneously, meanwhile treating antiseptically. If cartilage, ligament, or bone delays the removal, the retaining structure should be cut through and the part removed. When amputation becomes necessary, await a line of demarcation, and amputate above it, when tissue damage has not extended. Parts that have been severely frost-bitten are likely to suffer permanently from more or less serious impairment of nutrition. The skin is often hyperesthetic, and sometimes more or less numb, and is prone to become inflamed and to ulcerate.

FUCHSIN.—One of the anilin dyes much used in histologic and bacteriologic work for staining solutions.

The Ziehl-Neelsen's **carbolfuchsin** dye is very powerful, stains quickly, keeps well, and can be employed for a variety of purposes, particularly for staining tubercle:

Saturated alcoholic solution of fuchsin, 10 c.c.
Five percent carbolic acid water, 90 c.c.

Anilinfuchsin dye:

Saturated alcoholic solution of fuchsin, 16 c.c.
Anilin water, 84 c.c.

See Pathologic Technic.

FUMIGATION.—See Disinfection, Formaldehyd, Sulphur.

FUNIS.—See Umbilical Cord.

FURUNCLE.—See Boil.

FURUNCULUS ORIENTALIS.—Oriental boil, Aleppo boil, Delhi boil, Biskra button, Gafsa button, Kandahar sore, Pendjeh sore, Natal sore. A local disease, marked by the successive formation of papule, tubercle, scab, and sharply circumscribed ulcer on the face, especially on the cheeks and at the angles of the mouth. It is frequently seen in those residing along the shores of the Mediterranean Sea. See Boil.

G

GAIT.—See Nervous Diseases (Examination), Locomotor Ataxia, Paralysis Agitans, etc.

GALACTAGOGS.—Medicines that increase the lacteal secretion. The value of galactagogs is doubtful. Pilocarpus approaches the true galactagog, but its influence is very transient. One-eighth of a grain given in brandy at bedtime is efficient directly in proportion to its diaphoretic and sialagog effects. See Breast (Diseases), Milk (Mother's).

GALACTORRHEA.—See Breast (Diseases).

GALL-BLADDER, DISEASES.

Carcinoma

It is usually primary, often undoubtedly due to the prolonged irritation of a stone. Secondary cancers develop by contiguous invasion from the liver or adjacent abdominal organs.

There is usually a history pointing to chronic cholecystitis or gall-stones; on this follows the growth of an irregular, nodular tumor, continuous with the liver, which is invaded directly from the gall-bladder. The tumor moves with respiration. Malignant disease involving the hepatic or common duct may begin quite insidiously in a painless manner, with slowly increasing *jaundice* until there is complete obstruction. When there is also rapid loss of weight and distention of the gall-bladder, cancer of the head of the pancreas is indicated. If with the jaundice the loss of weight is not so rapid, the cancer may have formed around a calculus in the lower part of the common duct, but pancreatic fluid can still escape and fat is absorbed. Increasing jaundice with steady enlargement of the liver, painless and without fever, points to malignant disease involving the hepatic ducts, and this is generally secondary to a growth in the pancreas or elsewhere. In the biliary passages cancer may be primary or secondary, the first symptom generally being jaundice. If the disease is in the gall-bladder alone there is no jaundice. Enlargement of the gall-bladder is characteristic of carcinoma of the common duct.

Gall-stones

Synonyms.—Biliary calculi; cholelithiasis.

Definition.—Hard concretions formed in the gall-ducts or gall-bladder.

Etiology.—(1) Women after the age of 30; (2) sedentary habits; (3) constipation; (4) tight lacing; (5) catarrh of the biliary passages; (6) gouty diathesis.

Microorganisms play an important rôle in the causation of gall-stones by exciting a catarrhal inflammation which modifies the chemical composition of the bile.

Pathology.—The gall-stone is usually brownish in color externally, and has a roughened appearance. In some cases gall-stones are almost round, while in others they show distinct facets, due to constant attrition from the presence of other calculi. Interiorly, they may be dark in color, with here and there yellowish or brownish spots. Bacteria are usually found in the center of gall-stones along with epithelial débris, lime salts and *cholesterin*. See Colon Bacillus Infection.

Symptoms and Clinical Course.—In a great many cases so long as the calculus remains free in the gall-bladder, no symptoms are produced, but when impaction occurs in the common bile-duct or cystic duct, certain phenomena manifest themselves.

Symptoms of Stone in the Common Bile-duct.—*Jaundice* is the cardinal symptom in chronic catarrhal cholangitis. This jaundice is usually transient, coming on after an attack of hepatic colic, nausea, and vomiting, lasting a few days, but recurring again after an indefinite interval. Intermittent attacks of jaundice occur at intervals during the course of years, becoming more frequent as the occlusion becomes more complete. In the diagnosis of common duct obstruction, the absence of dilatation of the gall-bladder is an important sign (Courvoisier's law).

Hepatic colic (biliary colic) indicates the impaction of a stone in the cystic or common duct, but it is by no means constant in cholelithiasis. The attack may occur at any time during the day or night, with sudden onset, ushered in by a sharp pain in the right hypochondriac or epigastric region, frequently radiating toward the right scapula. In some cases the pain may be of a girdle sensation, and in others may be so severe as to be indescribable. Persistent nausea is present, and a burning sensation occurs in the epigastrium. *Nausea* and *vomiting* often occur, but are not invariably present. Profuse *sweating* and grave depression nearly always occur. The attack usually passes off in the course of a few hours, though slight intermittent pains may follow for several days. Rarely the stone may be found in the stool. Gall-stone crepitus may sometimes be elicited over the gall-bladder.

Hepatic fever (Charcot's intermittent fever) occurs from autointoxication, and is characterized by *rigors*, sweats and an intermittent fever (101 to 103°) of an indefinite duration. In clinical manifestations it closely resembles malarial fever.

Symptoms of Stone in the Cystic Duct.—Jaundice is less common, and only occurs when the gall-bladder is distended to such an extent as to cause pressure-symptoms. Hepatic colic is very severe, and occurs when any concretion passes downward through the cystic duct into the common bile-duct; after lodgment there, jaundice is produced.

Dropsy of the gall-bladder (hydrops vesicæ felleæ) occurs when the cystic duct is occluded. This is due to the fact that one of the functions of

the gall-bladder is to secrete mucus, which, if pent up, will so accumulate as to produce a tumor often so large as to extend below the umbilicus and beyond the median line.

Complications and Sequels.—(1) Suppurative cholangitis, and suppurative cholecystitis (empyema of the gall-bladder); (2) secondary abscesses; (3) permanent jaundice, with production of Charcot's intermittent fever; (4) ulceration and passage of stone into the intestine; (5) obstruction of the bowels from gall-stone; (6) stricture of the ducts and atrophy of the gall-bladder.

Diagnosis.

Biliary Calculi.	Gastralgia.	Intestinal Colic.	Renal Colic.
1. Usually in women after the age of 30.	1. Adult life.	1. Age has no influence.	1. Adult life more frequently.
2. History of previous attacks of hepatic colic, transient jaundice, often of intermittent fever (Charcot).	2. Absence of jaundice and intermittent fever.	2. Absence of jaundice and intermittent fever.	2. Absence of jaundice and intermittent fever.
3. Pain in right hypochondriac or epigastric region.	3. Pain in epigastric region relieved by pressure.	3. Pain in umbilical region.	3. Pain in right or left lumbar and inguinal region, radiating toward penis and causing retraction of the testicle.
4. Urine dark amber color and contains bile: feces may contain gall-stone.	4. After attack copious secretion of clear urine.	4. Urine normal.	4. Urine often contains blood.

The prognosis depends upon the position of the stone and upon the length of time the condition has existed. Hepatic colic nearly always terminates favorably.

Treatment.—If the pain is severe, morphin, 1/4 grain, with atropin, 1/125 grain, should be given hypodermically. Care should be exercised, however, in its use to prevent the morphin habit. An accidental overdose taken by the patient has destroyed life. In many cases, however, nothing else will so quickly relieve the pain. Chloroform or ether may be inhaled. Locally, hot applications may be made over seat of pain, and, if persistent, a series of small blisters may be produced by means of cantharidal plaster. As soon as relief of pain is afforded, the bowels should be opened by means of saline purges.

The preventive treatment is important. Sodium phosphate (1 dram) may be given 2 or 3 times daily to keep the stools semisolid. Large doses of sweet oil, frequently repeated, are recommended. Chloroform internally has been of great service. Carlsbad salts (1 dram), Hunyadi János, and the Saratoga mineral waters may also be used. If constipation is persistent, possibly nothing is better than the fluidextract of cascara (1/2 dram) and glycerin (1/2 dram) taken at bedtime.

If nausea and vomiting continue, and there is an excessive eructation of gas, with dyspeptic symptoms, lavage may be practised 2 or 3 times a week. Flushing the colon by means of a rectal tube and a fountain syringe, as recommended by the older writers, gives much comfort. If flatulence is present, naphthalin, 5 grains every 4 hours, may be tried. Autointoxication is always pronounced, and may be prevented in a measure by lavage, irrigation of the bowels, and intestinal antiseptics.

Between attacks salicylic acid or the bile salts may prove of value. Sodium succinate in doses of 5 grains three times a day and sodium glycocholate in doses of 1/2 to 3 grains are extremely effective.

The diet is very important. There are few diseases in which the diet needs careful supervision than in cases of biliary calculi. Doubtless a catarrhal condition of the stomach and bowels is nearly always present, and dyspeptic symptoms are a constant menace. For several days subsequent to the attack liquid food is best. If sweet milk disagrees, light broth, beef-juice, soup, whey, malted milk, or barley-water may be substituted.

Carbohydrate foods, such as potatoes, rice, and bread, produce eructation of gas and gastric distress. Desserts are distinctly contraindicated. Fruits and vegetables are well borne, and may be largely used.

Surgical Treatment.—Should the attacks of hepatic colic become greater in severity, or recur at more frequent intervals after the proper medicinal treatment has been tried, should the patient's strength show signs of failing, if there is permanent jaundice, or if there is tenderness over the gall-bladder with associated digestive disturbances, surgical interference is advisable. If an operation is too long delayed, suppurative cholecystitis or suppurative cholangitis may supervene and add to the gravity of the case. The trend of surgical opinion at the present time is toward early operation.

Inflammation (Acute Cholecystitis)

This affection is always due to infection by pathogenic bacteria, especially the colon bacillus and typhoid bacillus. See Colon Bacillus Infection. Occasionally the pneumococcus, staphylococcus, and streptococcus are the exciting causes. It may follow irritation from gall-stones, pneumonia, or typhoid fever and occasionally result from adhesive inflammation between the gall-bladder and intestines.

The inflammation may be of varying grades. In mild forms the exudate is mucoid or mucopurulent; in the more severe forms it is purulent (*empyema of the gall-bladder*) and the inflammation may proceed to ulceration, perforation, or gangrene. In rare instances the gall-bladder may be distended with blood.

Pain at the border of the thorax to the right of

BREWER'S DIAGNOSIS OF DISEASES

Pathological Condition.	Pain.	Fever.	Vomiting.	Jaundice.	Tumor of Gall-bladder.
I. Calculous Disease.					
(*a*) Stone in healthy gall-bladder, ducts free.	No.	No.	No.	No.	May be present from large number or size of stones.
(*b*) Stone in healthy gall-bladder, cystic duct temporarily obstructed.	May be absent; generally present during obstruction; paroxysmal.	No.	May be present when colic occurs.	No.	May be present from distention.
(*c*) Stone impacted in cystic duct.	No.	No.	No.	No.	Present; may attain large size.
(*d*) Stone in hepatic duct.	Frequently present; irregular type.	Occasionally present.	May be present during pain.	Frequent.	No.
(*e*) Stone in common duct; acute obstruction.	Present; acute, paroxysmal, radiating to back.	Generally present	Present.	Present.	No.
(*f*) Stone in common duct; movable; chronic.	Periodic attacks of acute radiating pain.	Present with chills and sweats.	Present.	Present; intermittent.	Rarely present.
(*g*) Stone in common duct; impacted; chronic.	May be absent; frequently present early; may be intermittent; variable.	May be present; variable.	Often present.	Present; progressive; may vary in intensity.	Rarely present.
II. Inflammatory Disease.					
(*a*) Cholecystitis subacute.	Present; paroxysmal during periods of cystic duct closure from stone or swollen mucous membrane.	Present during attacks of colic.	May be present.	No.	Present during attacks of cystic duct obstruction.
(*b*) Cholecystitis acute.	Acute paroxysmal radiating pain; extending to back and shoulder; may be very severe.	Present with chills and sweats.	Present often: severe.	No.	Present; tenderness; often muscular rigidity.
(*c*) Cholecystitis chronic (empyema of gall-bladder).	Severe radiating pain at first; may disappear later; tendency to recur.	Present; severe at first, may diminish later.	Present at first.	No.	Present; with tenderness; may attain large size.
(*d*) Cholecystitis in previously diseased and contracted gall-bladder.	Present; often severe; paroxysmal.	Present; often with chills and sweats.	Present.	No.	No (occasionally present due to pericystic exudate).
(*e*) Cholangitis of hepatic and common ducts.	May be absent; generally present when obstruction exists, or severe infection; tenderness and pain over liver in intrahepatic cholangitis.	Present; chills; sweats; severe prostration; general sepsis.	Present.	Present; variable.	No.
III. New Growths.					
(*a*) Carcinoma of gall-bladder.	No; may occur late in disease.	No.	No.	Present late (portal glands).	Hard, irregular, movable tumor at first, later diffuse infiltration.
(*b*) Tumor of cystic duct.	No; may occur late.	No.	No.	No.	Present when obstruction exists.
(*c*) Tumor of hepatic or common duct.	No; may occur late.	No.	No.	Present; progressive.	May be present from distention with bile.
(*d*) Tumor of neighboring viscera producing chronic obstruction of common duct.	No; may occur late.	No.	No.	Present; progressive; may become extreme.	Present; generally from distension with bile.

OF THE GALL-BLADDER AND DUCTS.

Urine.	Stools.	Liver.	Spleen.	Ascites.	Remarks.
Negative.	Normal.	Not enlarged.	Not enlarged.	No.	Generally discovered by accident; often unrecognized.
Negative.	Normal.	Not enlarged.	Not enlarged.	No.	All symptoms promptly relieved as soon as obstruction removed.
Negative.	Normal.	Not enlarged.	Not enlarged.	No.	Hydrops of gall-bladder often unrecognized.
Contains bile pigment at times.	May be clay-colored if obstruction occurs.	Frequently enlarged.	Not enlarged.	No.	Diagnosis extremely difficult; symptoms generally due to coexisting cholangitis.
Contains bile pigment.	Clay-colored.	Not enlarged.	Not enlarged.	No.	Symptoms rapidly disappear when stone passes papilla.
Contains bile pigment.	Clay-colored.	May be enlarged during attack.	May be enlarged from pressure of stone on vein.	No.	"Fièvre intermittente hépatique" of Charcot resembles malaria: all symptoms disappear during interval.
Contains bile pigment.	Clay-colored.	Enlarged.	May be enlarged.	No.	Condition may remain for many years; may only be jaundice with digestive disturbances and loss of weight; history of previous attacks (?). Ascites may be present from pressure of large stone or possibly from hydremia.
Negative.	Normal.	Not enlarged.	Not enlarged.	No.	Tenderness over gall-bladder; tendency to recurrence; generally associated with stones in gall-bladder.
May contain albumin and casts.	Normal.	Not enlarged.	May be enlarged (sepsis).	No.	May follow typhoid or other septic diseases; onset often sudden; rapid development of severe symptoms resembling appendicitis; may be necrosis of walls of gall-bladder with perforation: local or general peritonitis.
Negative.	Normal.	Not enlarged.	Not enlarged.	No.	Frequently follows acute cholecystitis; occasionally becomes quiescent, presenting practically no symptoms.
Negative.	Normal.	Not enlarged.	May be enlarged (sepsis).	No.	Generally tenderness over gall-bladder area, but no tumor; local peritonitis; diagnosis often extremely difficult.
May contain bile pigment, albumin and casts.	May be clay-colored.	Enlarged.	Enlarged (sepsis).	No.	Often follows severe infections of gall-bladder; generally associated with stones in common or hepatic duct; severe sepsis; generally fatal in virulent infections (streptococcus).
Negative (at first).	May be clay-colored late.	Enlarged late in disease.	May be enlarged late (pressure on vein).	Present late.	Digestive disturbances, progressive loss of weight and asthenia; cachexia; rapidly fatal.
Negative.	Normal.	Not enlarged.	Not enlarged.	No. (?)	Very rare; both benign and malignant growths have been reported; diagnosis difficult.
Contains bile pigment.	Clay-colored.	May be enlarged.	Not enlarged.	May be present late.	Very rare; diagnosis difficult.
Contains bile pigment.	Clay-colored.	Enlarged.	May be enlarged late.	Present late.	Malignant tumors most common; chronic interstitial pancreatitis from previous infection of biliary passages may remain after cause has disappeared; enlarged portal glands; Hodgkin's disease.

BREWER'S DIAGNOSIS OF DISEASES

Contains bile pigment.	Clay-colored.	Not enlarged.	Not enlarged.	No.	Symptoms rapidly disappear when stone passes papilla.
Contains bile pigment.	Clay-colored.	May be enlarged during attack.	May be enlarged from pressure of stone on vein.	No.	"Fièvre intermittente hépatique" of Charcot resembles malaria: all symptoms disappear during interval.
Contains bile pigment.	Clay-colored.	Enlarged.	May be enlarged.	No.	Condition may remain for many years; may only be jaundice with digestive disturbances and loss of weight; history of previous attacks (?). Ascites may be present from pressure of large stone or possibly from hydremia.
Negative.	Normal.	Not enlarged.	Not enlarged.	No.	Tenderness over gall-bladder; tendency to recurrence; generally associated with stones in gall-bladder.
May contain albumin and casts.	Normal.	Not enlarged.	May be enlarged (sepsis).	No.	May follow typhoid or other septic diseases; onset often sudden; rapid development of severe symptoms resembling appendicitis; may be necrosis of walls of gall-bladder with perforation: local or general peritonitis.
Negative.	Normal.	Not enlarged.	Not enlarged.	No.	Frequently follows acute cholecystitis; occasionally becomes quiescent, presenting practically no symptoms.
Negative.	Normal.	Not enlarged.	May be enlarged (sepsis).	No.	Generally tenderness over gall-bladder area, but no tumor; local peritonitis; diagnosis often extremely difficult.
May contain bile pigment, albumin and casts.	May be clay-colored.	Enlarged.	Enlarged (sepsis).	No.	Often follows severe infections of gall-bladder; generally associated with stones in common or hepatic duct; severe sepsis; generally fatal in virulent infections (streptococcus).
Negative (at first).	May be clay-colored late.	Enlarged late in disease.	May be enlarged late (pressure on vein).	Present late.	Digestive disturbances, progressive loss of weight and asthenia; cachexia; rapidly fatal.
Negative.	Normal.	Not enlarged.	Not enlarged.	No. (?)	Very rare; both benign and malignant growths have been reported; diagnosis difficult.
Contains bile pigment.	Clay-colored.	May be enlarged.	Not enlarged.	May be present late.	Very rare; diagnosis difficult.
Contains bile pigment.	Clay-colored.	Enlarged.	May be enlarged late.	Present late.	Malignant tumors most common; chronic interstitial pancreatitis from previous infection of biliary passages may remain after cause has disappeared; enlarged portal glands; Hodgkin's disease.

the median line is invariably present; and the gall-bladder is enlarged and tender. Vomiting is common. Fever accompanies the condition and jaundice may or may not be present. In the presence of pus the fever becomes irregular and attended by chills and sweats, and an examination of the blood will show leukocytosis.

The features of this affection that serve to distinguish it are the history, the preceding affection and the location of the pain and circumscribed tenderness. The presence of a tumor in the region of the gall-bladder is confirmatory.

Many mild catarrhal cases undoubtedly terminate in recovery without being recognized. Suppurative cases are unfavorable and tend toward a fatal termination. The case should be placed in the care of a skilled surgeon as soon as detected. See GALL-BLADDER (Surgery).

GALL-BLADDER, SURGERY.—Operation is required in nearly all cases of empyema, dropsy, and persistently recurring colic. When jaundice is present, the prognosis is much more grave, not only for the reasons mentioned, but because of the much greater risk of hemorrhage and the feeble power of repair. Still, it may be necessary to avoid the occurrence of cholemia, and sometimes, even under these conditions, it is possible to effect a permanent cure—by crushing, for example, a calculus impacted in the common duct.

Aspiration through the abdominal wall cannot be recommended; it is not likely to effect a permanent cure, and it may lead to leakage through the puncture and to peritonitis. Free incision can only be practised when there is an abscess pointing through the skin.

Cholecystotomy.—Incision of the gall-bladder after exposure through an opening in the abdominal parietes is a most successful operation. A vertical incision is made over the most prominent part of the swelling, and the muscles and peritoneum are divided in the ordinary way; the finger is then introduced to ascertain the condition of the gall-bladder, and, if it is much distended and not too much bound down by adhesions, a fine trocar and cannula are thrust into it to draw off some of the contents, thus allowing the organ to be pulled out through the wound, the greatest care being taken that the fluid does not enter the peritoneal cavity. If catch-forceps or tooth-forceps are used, they should be placed above and below the opening of the trocar, so that if the tissues, which are often very thin, are bruised, the injured part may lie in contact with the parietal peritoneum. As soon as the wall of the bladder is drawn out through the wound, a free incision is made into it, the rest of the contents are allowed to escape, the interior is carefully sponged out, and the finger is introduced to ascertain if there is any obstruction present. Loose calculi present no difficulty, but if they are impacted far down in the neck or in the cystic duct, the greatest care is required to avoid injury. Sometimes they may be removed by special forceps, the surface being gradually nibbled away while the stone is fixed by the forefinger of the other hand pressing against it from outside the duct. On one or two occasions the stone has been broken by pressure from the outside, forceps guarded with rubber tips being used to avoid bruising as far as possible. Needling has been recommended. The mucous membrane has been very carefully nicked from the inside. The calculus has been left and the fistulous opening syringed out constantly with warm water for a fortnight, and, finally, when everything else has failed, the gall-bladder has been excised.

In a few cases the wound in the gall-bladder has been successfully sewed up, and the emptied sac returned into the abdomen, but Tait condemned this strongly. The walls are frequently exceedingly thin, it is very often impossible to make sure that the opening into the bowel is patent, and if any further operation is required, it is decidedly advantageous to have the fundus of the gall-bladder adherent to the cicatrix. The walls of the sac, the parietal peritoneum, and the skin should be accurately sewed together. Tait used two continuous sutures, one for each side of the wound, the ends being tied together afterward, above and below. A large drainage-tube is inserted, in order, if possible, to carry all the bile away from the wound, and ordinary absorbent dressings are applied. When the wound is healed, the drainage-tube may be withdrawn. If the obstruction has been removed, the bile soon finds its way into the intestine again; if, on the other hand, this is impossible, a biliary fistula is left, which may be dealt with later on.

Cholecystectomy, or removal of the whole gall-bladder, is a more serious operation, and should be practised only when, from the condition of the parts at the time of the operation, it is clear that incision and drainage are either impracticable or would fail to give relief. Sometimes this occurs after prolonged inflammation; the gall-bladder is so utterly disorganized that it is not possible to suture it securely to the abdominal wound; and this may happen in cases of impacted calculus, if it is not possible to extract or crush the stone without injuring the wall of the duct. The preliminary steps are the same: the gall-bladder must be separated from adhesions, all hemorrhage carefully arrested, the peritoneal flaps united with continuous suture, and the end of the cystic duct tied.

Cholecystenterostomy may be performed by uniting the gall-bladder to the intestines by means of the Murphy button, Senn's bone plate, or other mechanic appliance. See INTESTINES (Surgery).

GALLIC ACID.—From tannic acid. An astringent and hemostatic feebler than tannic acid. It differs from the latter in that it does not coagulate albumin and gelatin. It is preferable to tannic acid when an astringent effect is desired on a part reached only through the circulation. Dose, 15 grains in powder or capsule.

GALVANISM.—See ELECTRICITY.

GALVANOCAUTERY.—The thermal effects of galvanism used for the heating of cauteries. The chemic effect of the negative pole of a galvanic battery has been used as a caustic to destroy

tissues and tumors of considerable size. The forms in use are numerous, but one general plan of construction prevails The cauteries consist of small loops of platinum wire mounted on straight or curved copper supports, insulated from one another and bound together to form a convenient stem. They fit into a handle provided with binding screws and a key for easily opening and closing the circuit. The current should be turned on only when the cautery is in actual use. Besides simple loops, cutting instruments of various shapes are made by hammering the platinum flat or by bending it in various ways. A loop of wire is sometimes used as an ecraseur, being adapted cold and then heated. The temperature of the galvanocautery must never be allowed to rise above dull redness. At white heat the cauterizing action is so rapid that searing of the surface does not take place, and hemorrhage follows as profusely as after the knife. Currents for use in the cautery vary from 8 to 10 amperes for the smallest to 20 for the largest. For cautery batteries, large bichromate cells have been used, but are untrustworthy, rapidly polarizing at times. The most convenient form of battery for cautery purposes is an accumulator to which an electric current is attached. See ELECTRICITY.

GAMBIR.—Pale catechu. An extract prepared from *Ourouparia gambir*. Owing to its tannic acid, it is an astringent and hemostatic. With chalk-mixture it is efficient in the diarrhea of children, and with opium in dysentery. Dose, 15 grains. **G. Tinct. Comp.,** contains gambir 5, cinnamon 2 1/2, diluted alcohol to 100. Dose, 1/2 to 1 1/2 drams. **G. Trochisci,** each troche containing nearly 1 grain of gambir.

GAMBOGE (Cambogia).—A resinous gum from *Garcinia hanburii*, a tree native to Southern Asia. Its properties are due to *gambogic acid*. It is a drastic hydragog cathartic, decidedly diuretic. It is officially a constituent of **Pil. Cath. Comp.** See COLOCYNTH. Dose, as a cathartic, 2 to 5 grains; as a diuretic, 1 grain.

GANGLION.—A small, tense, round swelling, firm and growing progressively, although slowly, in connection with a tendon sheath. It is painless when uninflamed, and the simple ganglion is found to contain a fluid in appearance and consistence not unlike glycerin jelly. The most common situations are the dorsum of the wrist or hand, the dorsum of the foot, the palm of the hand at the root of the finger, and behind the inner or outer malleolus. The size varies from that of a pea to that of a pigeon's egg. Fluctuation is not distinct, and the tumor is not adherent to the skin or tendon with which it is in relation. Persons who constantly use the wrist-muscles are most likely to develop ganglions. The *simple ganglion* is supposed to be due to cystic degeneration of a synovial fringe inside a tendon sheath. The fluid of the ganglion does not communicate with the fluid of the tendon sheath.

A *compound ganglion* is almost entirely confined to the sheath of the common flexors of the fingers, and most usually contains melon-seed-like bodies that give rise to a sense of soft crackling when manipulated. The compound ganglion is a chronic tubercular thecitis.

Treatment.—In treating a simple ganglion forcible rupture of the cyst by a blow or by pressure sometimes effects a cure. Puncture with a clean, grooved needle, squeezing out the contents and afterward applying pressure over the collapsed cyst is another method. Aspiration, followed by the injection of iodin, has been of service in treating both the simple and the compound ganglion. The seed-like bodies are to be removed. Aseptic puncture with a tenotome, evacuation, scarification of the walls, antiseptic dressing, and pressure is the modern treatment. Recurrent ganglions should be dissected out.

GANGRENE.—Mortification, or death in mass of a portion of living tissue, *i. e.*, macroscopic or molar death, in contradistinction to ulceration, or death of molecular parts—too small to be seen. Molecular death of the bone is called caries, whereas a gangrenous portion of the soft tissues cast off is called a slough or sphacelus. Molar death of a portion of bone is known as necrosis, the dead mass being termed a sequestrum. See NECROSIS. The parts in gangrene may either dessicate or putrefy.

Three chief forms of gangrene are recognized: *dry*, *moist*, and *septic*. The first is due to interference with the arterial supply, the venous return of the blood being still active. The tissues dessicate and mummify. Moist gangrene is due to interference with both the arterial and the venous circulation, the parts remaining moist and putrefying. Septic gangrene arises from virulent septic matter, and is rarely seen since the introduction of asepsis and antisepsis.

Dry and moist gangrene may coexist in different parts of the invaded structure. Dry gangrene is usually dependent on senile changes, chiefly arterial degeneration, and is more limited and more chronic than moist gangrene.

Examples of moist gangrene are inflammatory gangrene, hospital gangrene, cancrum oris, or noma, bed-sores, traumatic gangrene, phagedena, carbuncles, and diabetic gangrene.

Examples of dry gangrene are senile gangrene, Raynaud's disease, gangrene from frost-bite, and gangrene from embolism or ligation of a main artery.

Traumatic gangrene is of common occurrence. It may be local or spreading, and is usually the result of a severe injury, such as a crush, or it may be due to rupture of a main artery or vein without any skin-lesion. Spreading traumatic gangrene (emphysematous gangrene, malignant edema) is usually due to the *bacillæ œrogenes capsulatus* and pyogenic organisms especially the *streptococcus pyogenes;* sometimes, however, it is due to the bacillus of malignant edema. The first symptoms are those of cellulitis rapidly extending, then gangrene and a grave septicemia.

Gangrene due to infective organisms comprises traumatic spreading gangrene, hospital gangrene, phagedena, noma vulvæ, and cancrum oris, or noma.

The causes of gangrene are local or constitu-

tional. Of the former, injuries, mechanic violence, caustics, extremes of heat and cold, as in burns and in frost-bite, the application of a ligature, embolic plugging, strangulated hernia, intussusception, ligated hemorrhoids, very tight bandaging, paraphimosis, even extravasation of urine and feces, and continued pressure, as in bedsores, may be given. Of constitutional causes, a deficient blood supply or senile changes may be cited. In certain diseases, as diabetes, typhus, typhoid, measles, and scarlatina, embolism is the usual cause of gangrene. Gangrene from ergotism is due to the effect of this drug on the vessels. Septic gangrene is due to septic infection.

Treatment of Gangrene.—The general rule in **dry gangrene** is to wait for a line of demarcation before amputating, but the treatment depends much upon the cause and nature of the gangrene. The general indications are: (1) To remove, when possible, the cause, as a tight bandage, putrefactive processes, tension, pressure, etc.; (2) to prevent gangrene, whenever threatened, from actually occurring by maintaining the warmth of the part and relieving the embarrassed circulation by elevation of the limb and gentle friction when there is venous congestion; (3) to check the spread of the process; (4) to promote the separation of the dead from the living tissue, and to remove it by amputation; (5) to control the formation of the products of putrefaction by keeping the parts dry and by the free use of antiseptics; (6) to support the patient's strength and counteract the deleterious effects on the constitution from the absorption of septic poisons and to soothe pain by opium.

More particularly, in those disposed to senile gangrene, caution should be advised against injuring the feet, as from carelessly cutting the corns, etc. Woolen stockings should be worn, the feet kept warm—especially at night and in cold weather, as by the use of the hot-water bag—and the general health supported. A small amount of whisky after meals is useful and strengthening. If exhaustion ensues or sepsis develops, and gangrene has actually occurred, amputate at once, but high up—at least above the knee. The tubercle of the tibia is too low a place at which to amputate for senile gangrene. If the disease confines itself to one or two toes, treat antiseptically, and do not amputate, unless it spreads to the sole or dorsum of the foot. Generally, in senile gangrene it is best to wait for a line of demarcation before amputating high up. The presence of fever is no contraindication to amputation.

Moist gangrene is treated antiseptically until a line of demarcation between healthy and diseased parts has formed. Stimulants, good food, tonics, and opium are used simultaneously. When the line of demarcation forms, amputation is made clear of and above it, far enough to reach sound tissues and arteries.

In **traumatic gangrene**, when it is spreading, no line of demarcation can form, and it should not be waited for, but amputation should be done at once, and high up, and a very great amount of stimulation, continued for some time, should be provided.

Hospital gangrene has practically disappeared. Antiseptic fomentations until the sloughs separate, removal of the large sloughs by the scissors or forceps, under ether, and the use of bromin after drying the parts with cotton are indicated. To use bromin, pour it into a tumblerful of water and draw up with a syringe and inject into the depths of the wound. If damaged hopelessly, the limb should be amputated.

In the treatment of symmetric or **Raynaud's gangrene** massage is useful. The patient should be in bed, the parts affected elevated, if possible, and kept warm by heat applications. When a line of demarcation forms, the parts should be removed by scissors, forceps, and antiseptic poultices, or amputation may be performed, which is rarely necessary.

In **diabetic gangrene** there is little tendency to the formation of a line of demarcation, but amputation should be performed at once, and, if the leg is involved, above the knee.

Gangrene from ergot usually affects the toes and fingers. A line of demarcation forms, when amputation can be performed.

In gangrene from **frost-bite** the dead parts should be allowed to come away spontaneously, covering them in the meantime with antiseptics. If a structure—as, *e. g.*, a ligament, cartilage, or bone—retains the dead portions, it should be cut through. When amputation becomes necessary, the surgeon should wait for a line of demarcation before operating.

The treatment of **cancrum oris**, or **noma**, must be energetic, and should consist in the destruction of all the diseased tissue by caustics or nitric acid, and in the use of antiseptic washes and hydrogen peroxid and internal stimulation, giving food and tonics. **Phagedena**, of which noma vulvæ is a form, is treated by repeated applications of the tincture of chlorid of iron, the local use of an antiseptic powder, such as iodoform, continued irrigation, and the actual cautery or acids. A high degree of stimulation is to be maintained and a nutritious diet given.

Bed-sores may be prevented by changing the posture, by frequent cleansing, by rubbing the skin with alcohol, and by keeping the sheet clean and smooth. The use of an air-cushion or water-bed will sometimes check a beginning sore. Spirit of camphor, glycerol of tannin, boroglycerid, alcohol, salt, and alum may be used. Solutions of 20 grains of silver nitrate to 1 ounce of water may be applied to a sore on the verge of breaking. The spot may be covered with protective collodion or with zinc ichthyol gelatin. Antiseptic poultices may be used when sloughing threatens. Stimulation, nourishment, and plenty of sleep are indicated.

General Rules.—In dry gangrene, ordinary moist gangrene, hospital gangrene, Raynaud's gangrene, ergot gangrene and frost gangrene, it is well to wait for a line of demarcation. In senile gangrene the parts may be allowed to sever spontaneously. In traumatic spreading gangrene and in diabetic gangrene the rule is immediate amputation.

GARGLE.—A wash for the throat and upper

part of the pharynx. A gargle should never contain any very active drug that will produce dangerous symptoms if swallowed, or any agent that will injure the teeth or the mucous membrane. It is ordered and compounded in the same manner as a mixture, and usually contains astringent or disinfecting salts, such as alum, borax, zinc sulphate, potassium chlorate, with a vegetable astringent, and often honey. Von Troltsch's method of gargling is performed by taking a mouthful of fluid, throwing back the head, and then, instead of making the customary gurgle, allowing the liquid to pass as far down as possible. The act of deglutition is then performed, without, however, swallowing the fluid. By this procedure contact is made with a large portion of the pharyngeal mucosa, and the effort involves an effectual means of exercising the muscles of the throat. A tablespoonful is the usual quantity for a single gargle. With most persons, unless the head is thrown back, a gargle usually goes little beyond the uvula and the base of the tongue. When it is desirable to gargle the back of the pharynx and the posterior nares, the patient must take a mouthful of the gargle and use it while he lies on his back with his tongue drawn forward.

Gargles are contraindicated in parenchymatous inflammation of the tonsils, and in all cases when movement of the fauces causes severe pain, and when, in some persons, an inability to retain liquid beyond the anterior pillars of the fauces exists. Gargles of cold or iced water are sufficient to exercise the muscles of the soft palate and to increase their tone.

To allay inflammation of the throat, solutions of chlorate or nitrate of potassium, of borax or acetate of ammonium, combined with infusion of linseed, thin gruel, or warm water, are used. Excitation of mucous glands and membrane calls for stimulating gargles, such as contain tincture of capsicum, of arnica, or myrrh, pyrethrum, or eucalyptus. To check secretion, the salts of iron and zinc, of alum, tannin, or rhatany are used. Antiseptic gargles check ulceration and purify foul or putrid secretions. Of these are potassium permanganate (5 grains to 1 pint), chlorinated soda (20 grains to 1 pint of water), sulphurous acid and water (1:4), and boroglycerid (10 to 20 percent). In syphilitic sore throat a solution of mercuric chlorid (3 grains) and water (8 ounces) is advised. Water, barley-water, rose-water, or orange-flower water sweetened with honey, glycerin, or syrup, form bases for most gargles.

℞. Ammoniated tincture of guaiac, } each, ℥ ss
Compound tincture of cinchona, }
Clarified honey, ℥ jss.
Mix well together and add mixture of—
Potassium chlorate, ℥ ijss
Water, enough to make ℥ viij.

GARROD'S THREAD TEST.—It is generally agreed that there is an excess of uric acid in the blood in gout. Garrod devised a rough method for the detection of uric acid in the blood, as follows: Two drams of blood serum are obtained from a blister, and 10 drops of strong acetic acid are added. These are mixed in a watch glass, and one or two linen threads are immersed in the mixture, and allowed to remain therein for 24 hours. At the end of that time the threads are examined with a low power of the microscope, and if there is excess of uric acid in the blood, numerous rhombic crystals of uric acid will be found on the thread. Apart from gout, an excess of uric acid in the blood has been observed in several other diseases, chief among which are anemias, leukemias, splenic tumors, malignant growths, pneumonia, malaria, endocarditis, and some forms of nephritis, and granular kidney.

GAS GANGRENE.—See War Surgery.

GAS, POISONING.—See Coal-gas.

GASTRALGIA. Synonyms.—Gastrodynia; cardialgia.

Definition.—A form of neuralgia of the stomach occurring at irregular intervals.

Etiology.—(1) Nervous temperament; (2) mental anxiety; (3) certain habits, as the tobacco-habit; (4) certain diseases, as anemia, gout, gastric ulcer, carcinoma; (5) abnormal action of stomach, causing hypersecretion or hyperacidity; (6) reflex from ovaries, uterus, or bladder. True idiopathic cases of gastralgia are perhaps rare.

The pathology is undetermined. It may be looked upon as a symptom, rather than as a definite disease.

Symptoms and Clinical Course.—Mental depression, headache, fullness in the epigastrium, great increase of saliva, may mark the onset of the disease.

Other cases are met in which these prodromes are absent, and there may be a sudden, sharp, agonizing cutting or boring pain, occasionally localized, but sometimes radiating throughout the entire epigastrium and relieved by pressure over that area.

The patient's forehead may be bathed in a cold perspiration, pulse small and irregular, the extremities cold, and all the outward manifestations of collapse supervene. The frequency of the attacks is variable with reference to periodicity, seeming to depend upon some peculiar condition of the system that brings about the crisis. Eructation of large quantities of gas, and nausea and vomiting may occur late in the attack. The paroxysms occur without reference to time of taking food; sometimes after a meal, and again in the early morning hours, when the stomach is empty. Considerable depression follows these attacks, and often there is a copious discharge of urine. The temperature may remain normal or be slightly subnormal. The bowels are usually constipated.

Diagnosis.

Gastralgia.	Angina Pectoris.	Cancer.	Ulcer.
1. Neurotic or anemic women.	1. Sex has no influence.	1. Sex has no influence.	1. Sex has no influence.
2. Pain occurs at irregular intervals.	2. Same as gastralgia.	2. Pain continuous.	2. Pain after eating.

Gastralgia.	Angina Pectoris.	Cancer.	Ulcer.
3. Pain in epigastric region, often extending toward right hypochondrium.	3. Pain in region of heart extending up neck and down left arm, which may feel numb.	3. Pain localized at all times: jaundice: high fever.	3. Localized pain.
4. Pain relieved by pressure or on taking food.	4. Pressure has no effect on symptoms	4. Pressure increases pain.	4. Pressure increases pain.
5. Often terminates with nausea, vomiting, and copious discharge of urine.	5. Same as gastralgia.	5. Copious vomiting some time after eating; material color of ground coffee.	5. Vomiting occurs soon after eating.
6. Food undigested and hyperacid.	6. Vomiting uncommon.	6. Undigested food or ground coffee appearance.	6. Vomitus often mixed with blood.

The prognosis for the immediate attack is favorable, but there is a great tendency to recurrence.

Treatment.—If the pain is extreme, with symptoms of collapse, morphin (1/4 grain) with atropin (1/125 grain) may be given hypodermically. Hot applications may be made over region of epigastrium.

Pepper and Tyson recommend:

℞. Chloroform, ʒ iv
Compound tincture of cardamom, ʒ iv
Aromatic spirit of ammonia, ʒ iv
Brandy, ʒ iv.

Teaspoonful every half hour until relieved.

℞. Codein sulphate, gr. iv
Antipyrin, gr. xl
Tincture of belladonna, ♏ xl
Simple elixir, ʒ iij
Peppermint water, enough to make, ʒ iv.

Tablespoonful every 3 or 4 hours.

℞. Compound spirit of ether, ʒ j
Compound tincture of valerian, ʒ j.

Teaspoonful every 3 hours.

Bicarbonate of sodium in hot water sometimes relieves the pain by neutralizing the excess of acid in the stomach. The following powder may be ordered:

℞. Calcined magnesia, gr. x
Sodium bicarbonate or potassium bicarbonate, gr. x
Anesthesin, gr. iij
Aromatic powder, gr. 1/2.

One powder every hour until relieved.

The galvanic current often gives relief quicker than drugs by the mouth. It is best to apply the anode, which has been heated, to the epigastrium, and kathode over spinal column in cervical region.

If anemia is present, elixir of the phosphates of iron, quinin, and strychnin (1 dram), 3 times daily after meals, is indicated.

GASTRECTASIA.—See Stomach (Dilatation).

GASTRIC NEUROSES.—It is difficult to attach precise limitations to the use of the term "gastric neuroses," owing to the fact that there is a class of gastric derangements that are undoubtedly functional in nature, but in which the chain of events leading up to their appearance varies so widely as to tempt the pathologist to separate them into different orders. There are objections to this, however, for the reason that the clinical picture presented is practically identical, even when the etiology and the previous history show a real difference in nature. The difficulty is still further increased by the fact that in certain affections the functional disorder seems closely allied to, and sometimes is actually associated with, definite structural changes in the digestive organs. Occasionally the process may be traced from a state that in the beginning was apparently purely functional, to one in which structural changes are unquestionably present. There would seem to be no doubt but that a functional disorder may lead to a structural disease. On the other hand, certain clinicians believe that sometimes the symptoms that are attributed to the neuroses are, as a matter of fact, symptoms arising in mild inflammatory processes, not easily recognized until the disease is considerably advanced.

Classification.—Perhaps the difficulty can be lessened and the real nature of the gastric neurosis made more evident by discussing the subject under two heads:

1. Gastric neuroses occurring as one of a series of manifestations in individuals who are distinctly neurotic, and that attacks are no more to be considered diseases of the stomach than is migraine a disease of the brain. This class comprises a varied array of conditions, such as nervous anorexia, bulimia, rumination, and nervous vomiting; yet, taken as a whole, instances of it are infrequent as compared with other functional stomach disorders.

2. Gastric neuroses associated with continued irritation of the nervous system, sometimes local and sometimes general, accompanied by diminished nervous resistance. This state is often secondary to physical or mental strain; to the exhaustion of one or more of the special apparatus of the body; to weakness, oversensitiveness, and depravity of the nervous system, such as results from lack of suitable physical exercise in the open air, unnatural emotional excitement, and other disobediences to hygienic laws. To this second class belongs the great majority of those functional derangements of digestion that are usually classified as gastric neuroses, and here may be found the causes of the disease with most of those individuals who confess to being victims of dyspepsia or indigestion.

Etiology.—The right understanding of this question is so important as guiding one to the

rational management of cases, that it should be closely studied. When the nervous system is subjected to excessive irritation, and when it is denied the proper opportunity for recuperation, it cries out in one of a number of ways. Headache, neuralgia, insomnia, lassitude, are common examples of this. The fact that gastric distress of some form is one of the most frequent of these complaints seems not to have attracted enough attention. Stomach symptoms are often so prominent that indigestion is regarded as the real trouble, and to this the other evidences of depreciated health are attributed. While the stomach derangement undoubtedly adds much to the general discomfort and the further loss of health, it will be found, as a rule, that the gastric symptoms are secondary, and that the symptom-complex depends upon some common cause or causes to be ascertained. The mistake lies in looking to the stomach alone, whereas the individual as a unit should be studied if permanent relief is to be obtained. Very often the chief fault is to be found in brain irritation following too close application to study, or in continued mental tension, produced by business or social life. There is no one cause so important in this connection as eye-strain, particularly when the general health is at the same time below the standard.

It would appear that when eye-strain expends itself in headache it is less likely to produce gastric symptoms; in other words, headache, and disorders of digestion depending upon this cause, are less frequently associated than might be supposed. Often there is a history of previous headache, which has subsided to give way to dyspeptic symptoms. It seems reasonable to suppose that the stomach disturbances are the result of irritation reflected from the brain through the pneumogastric nerve to its terminal fibers in the abdomen. Remembering that the pneumogastric is a cranial nerve, the fact that the organs supplied by it may suffer through reflex action when the brain is irritated does not seem difficult to accept. The ocular errors most likely to give rise to gastric derangement are astigmatism and anisometropia. Hyperopic astigmatism more often than myopic leads to stomach disorders, particularly when the axes are unsymmetric or irregular. Anisometropia, even when slight, is competent to produce serious functional disturbance in the stomach. Imbalance of the ocular muscles is also commonly concerned.

Symptoms.—When a gastric neurosis is closely studied, it will be found that in some cases it is represented by symptoms of excitement and irritation, and in others by symptoms showing lack of activity and depression. It is, therefore, common to divide all cases into, first, gastric neuroses showing excitement; and, second, gastric neuroses showing depression.

In a given case the symptoms may at first denote excitement, to be succeeded by those showing depression, and occasionally the clinical pendulum swings back and forth from one of these states to the other. The stomach is seldom equally disturbed in all its activities at the same time. As a rule, it would be found that the disorder is chiefly one of motion, and, again, that sensation or secretion is mainly involved. Although it is true that two or more of these varieties of disturbances may be present at the same time, it is usually practicable to classify cases into motor neuroses, secretory neuroses, and the sensory neuroses. Any of these three may show either excitement or depression, as previously stated.

Motor Neuroses of the Stomach Showing Excitation

To this group belong spasm of the cardia, spasm of the pylorus, gastric spasm, gastric unrest, or hyperperistalsis, some forms of regurgitation, eructation, and vomiting.

Cardiospasm is often a symptom of local irritation at the cardia, and may occur in gastritis, round ulcer, carcinoma, etc. It, nevertheless, occurs as a pure neurosis, sometimes in the hysteric and sometimes in the neurasthenic. The effort to swallow solid food, and perhaps even liquids, is unsuccessful, owing to the sudden closure of the cardia. The food accumulates in the esophagus, and gives rise to sensations of pressure, distress, and, sometimes, palpitation of the heart and a feeling of apprehension. In aggravated cases the patient suffers from innutrition, and the neurosis is thereby exaggerated. This symptom is usually relieved by the passage of the stomach-tube. The attack may recur, but after the practice of gavage and treatment directed toward the general health the condition is overcome.

Pyloric spasm is more often associated with structural disease causing irritation at the pylorus, round ulcer being the most common. While it has been denied, there are good grounds for believing that it also occurs as a pure neurosis. The condition is followed by food stagnation, by increased acidity of the gastric contents, accompanied by a feeling of distress in the epigastrium, and sometimes by severe pain. The symptoms are relieved by vomiting. The stomach-contents show good digestion. There is usually an excess of hydrochloric acid, both free and combined. The condition is relieved by lavage, followed by physiologic rest of the stomach and rectal alimentation; by the application to the gastric mucosa of bismuth, cerium, ichthyol, resorcin, menthol, and other gastric sedatives; and by electricity. General faradization, hydrotherapy, and other measures directed toward the nervous state are of decided use.

The condition known as **gastrospasm**, in which the walls of the stomach violently contract, sometimes accompanied by pain, is similar in nature to the conditions described, and should receive similar treatment.

Gastric unrest, or hyperperistalsis, sometimes called *tormina ventriculi*, is an infrequent affection, characterized by unusually vigorous and frequent gastric movements that are excited by taking food, but that continue at times when the stomach is empty. Occasionally the peristalsis reverses the direction, the waves going from right to left. It differs essentially from the vigorous peristalsis

often to be seen through the stomach-wall in cases of gastrectasis from pyloric obstruction. Occasionally, however, in cases of gastroptosis, it is possible to see as well as to feel the movement of the stomach during the violent contractions. Like the other conditions of excitement, it requires local sedatives, a bland and unstimulating diet, and measures looking toward the improvement of the nervous equilibrium.

Rumination, or merycismus, usually begins as a neurosis, and presents features that suggest a psychosis. The habit, once established, is broken with difficulty. The patient regurgitates food before peptonization has occurred, and remasticates like a ruminant. It is, at times, a purely hysteric manifestation, and subsides under appropriate treatment. It requires a psychic treatment as well as measures addressed to the improvement of the general health.

Nervous eructation, or the upward discharge of gas from the stomach, and regurgitation—that is, discharge of the ingesta through the esophagus—may result from great irritability of the gastric mucosa, from disturbance in structure, or from purely nervous causes. It is at times difficult to determine to what extent the matter is to be attributed to the violence of the contractions of the stomach, and to what extent to weakness in the sphincter-like power of the cardia. When it is owing to a relaxed cardia, the disturbance is, of course, one of depression rather than of excitement.

Nervous Vomiting.—One of the most common, and at times unmanageable, of this class of affections is nervous vomiting. It is usually seen in neurotic women, and occasionally occurs with almost cyclic regularity. It is excited by mental disturbances, and often depends, at least partly, upon exaggerated eye-strain. As a rule, the gastric chemistry is without special fault, although at times hypochlorhydria or hyperchlorhydria is present. Gastric juice, with fragments of food or drugs, mucus (sometimes blood-stained), and at times bile, are discharged after exhaustive efforts. It is sometimes difficult to differentiate between this affection and the vomiting of pregnancy, disease of the pancreas, certain forms of uremia, and gastric crises dependent upon disease of the cord. The diagnosis is reached by the process of exclusion. Much judgment is required in the treatment of this condition. When it depends upon eye-strain, prompt relief sometimes follows the paralysis of the accommodation by a mydriatic. All substances should be withheld from the stomach, and rectal alimentation practised. The nervous system should be kept at rest, which is usually possible by chloral or chloralamid by the rectum. When there is an hysteric element, mistura asafœtidæ should be added. Occasionally the only relief obtainable is by keeping the patient temporarily under the moderate influence of morphin used hypodermically. Often gastric lavage with very hot water, and local treatment through the tube by sprays of menthol, chloroform water, and other substances having a soothing action, prove effectual.

Motor Disturbances Depending upon Depression

Relaxation of the Cardia.—This weakness shows itself sometimes intermittently, sometimes almost continuously, and the chief symptoms are the upward discharge of food and gas from the stomach as soon as that viscus begins its peristalsis. Various degrees of relaxation may exist. Recognizing that belching accompanies the distention of acute indigestion, the patient erroneously attributes the eructations to flatulence. Many instances of so-called water-brash and belching depend upon relaxation of the cardia. Occasionally, in nervous belching the air is swallowed as fast as it escapes, a condition somewhat different from cardiac relaxation.

Relaxation of the pylorus is a common condition, often associated with achylia gastrica, and sometimes seen when the secretion of the stomach is normal. As a result of pyloric incompetence the ingesta are pressed on into the duodenum without being properly changed by gastric juice. A sensation of emptiness and hunger is frequently present.

Atonic dyspepsia, or myasthenia gastrica, is commonly the result of degeneration of the gastric muscle or of lowered innervation of the stomach. Like relaxation of the cardia and pylorus, it may also occur as a neurosis. It may or may not be associated with the last-mentioned conditions. As a rule, not without exception, the gastric secretions are diminished. As a result of the weakened gastric movements the stomach-content is too long retained, so that some food will be found present from 7 to 12 hours after a meal, when the stomach should be empty in from 4 to 7 hours after eating. This laziness of the stomach leads to anorexia and gastric distress, sometimes nausea, the accumulation of gas, and the whole group of symptoms usually called dyspeptic. There is loss of flesh and strength; it is often associated with neurasthenia; it responds to treatment more quickly than those instances of myasthenia dependent upon disease of the walls of the stomach. For this, as well as for the preceding conditions, the most useful therapeutic measures are gastric faradization, douching of the stomach with alternating hot and cold water, and the external application of hydrotherapy, electricity, and massage, and life in the open air. Strychnin is the most valuable drug, and may be employed in large doses. Physostigma, the carminatives, and simple bitters are useful adjuvants. The relief of an accompanying neurasthenic state is indispensable.

Secretory Neuroses

Hyperchlorhydria is an important disturbance of secretion depending upon a neurosis. The quantity of gastric juice need not be greater than normal, but the percentage of hydrochloric acid, free as well as combined, is in excess of physiologic requirements. The amount of free hydrochloric acid present in pure stomach-content is the criterion upon which, by chemic methods, the diagnosis is made. Just what the standard should be is a matter of discussion. The physiologic limit has

been called 0.24, and when the free acid occurs in greater abundance, hyperchlorhydria is said to exist. Recently a number of clinicians have felt that this standard is too high, and they believe that many persons develop the symptoms of hyperacidity when the total free acid rises above 0.14 or thereabouts. The exciting causes of hyperchlorhydria, aside from local irritation, such as gastric ulcer, are lodged in the vagaries of the nervous system. It is usually assignable to nervous strain, and is not infrequently accompanied by ocular errors. Hayem and his followers believe that hyperchlorhydria is a symptom of parenchymatous gastritis, basing this belief upon postmortem studies and upon microscopic examinations of fragments of the mucosa vomited or withdrawn by aspiration. This view has not met with uniform acceptance, but may be true in a comparatively limited number of cases. Hyperchlorhydria is a frequent manifestation, and produces a train of suggestive symptoms. From 1 to 3 hours after meals there occurs a gnawing, burning sensation in the epigastrium, which is often accompanied by eructations of gas or by water-brash. When regurgitation or vomiting occurs, the fluid is intensely acid. The symptoms are usually relieved by eating, but are aggravated by acids, condiments, and all substances that excite gastric secretion. The one symptom—that of distress some hours after eating, which is relieved by taking bland food—is indicative of this disorder. However, the diagnosis must rest upon a chemic examination of the STOMACH-CONTENTS (*q. v.*) withdrawn 1 hour after Ewald's[1] test-breakfast or 3 hours after a test-dinner.[2]

If it is found that more than 6 c.c. of decinormal sodium hydrate solution are required of the gastric filtrate, and that the total free hydrochloric acid is above 0.20, and particularly if free hydrochloric acid is found during fasting, the existence of hyperchlorhydria is established. Usually starch digestion is suspended. This neurosis is sometimes confounded with ulcer, from which it may be distinguished by the absence of localized tenderness and pain, gastrorrhagia, and also by the fact that pain and distress are relieved, rather than exaggerated, by eating.

Hyperchlorhydria is occasionally accompanied by dilatation of the stomach. When true, it probably results from spasm of the pylorus following hyperacidity. Excess of free hydrochloric acid occurs in stenosis from the retention and concentration of gastric juice, but under such circumstances there is found more or less food stagnation. This troublesome affection is fortunately amenable to treatment. The exciting causes should be sought for and removed, the diet should be bland, and the meals frequent; the patient should have mental and physical rest. A milk diet alone is sometimes sufficient to effect a cure. In most cases remedies are needed, and the most important are alkalies and sedatives. A combination of cerium oxalate, bismuth subcarbonate, and light magnesium carbonate, whipped up in a little water, or in the form of the hydrate, is most serviceable. Sodium or potassium bicarbonate assures prompt but temporary relief. It must be given in large doses, from 1/2 dram to 2 drams, and frequently repeated. Its effects are transient. It is well to dilute the stomach-contents with an abundance of water not too cold. Nitrate of silver in 1/4-grain doses, three times a day, may be given for short periods. As the patient improves, the milk may be omitted during a portion of the day, when a meal of albuminoids, preferably beef or mutton, may be allowed. Patients do best upon an amylaceous and milk diet, provided the excess of acid is controlled.

[1] An ordinary sized breakfast roll and eight or ten ounces of water.

[2] From four to six ounces of beef finely minced. a roll, and eight ounces of water.

Reichmann's disease, or **gastrosuccorrhea periodica,** and also **gastrosuccorrhea chronica,** are functional disturbances in which there is either periodic or continued flow of gastric juice in excess. The so-called Reichmann's disease is characterized by the profuse secretion of gastric juice, occasionally highly acid, most likely to occur between meals and with an empty stomach. The attacks are accompanied by distress or pain, often with headache and vomiting. The vomitus is usually transparent, abundant, and acid, and examination shows it to be practically pure stomach secretion. The patient is usually found to have suffered from mental exhaustion. The French believe that the accumulation of gastric juice follows temporary pyloric obstruction. Relief follows the emptying of the stomach (lavage), the administration of antacids and alkalies, as in hyperchlorhydria, the taking of frequent and unstimulating meals (milk diet), and improvement of the general tone of the patient. Rest of the nervous system is of the utmost importance.

Hypochlorhydria is one of the most interesting of the gastric neuroses, and may be said to exist when the total free HCl is habitually below 0.04 at a time when it should be 0.10 or 0.15. In nature hypochlorhydria is closely associated with achlorhydria, in which there is complete disappearance of free hydrochloric acid, and is also nearly related to achylia gastrica, in which occurs the disappearance of digestive gastric juice. Many cases beginning as hyperchlorhydria descend through the scale until a condition of chronic achylia gastrica has developed. In not a few cases it has been shown that the lowered secretion is preceded by a period in which there are gastric excitement and hyperchlorhydria. In some cases there will at times be an absence of free hydrochloric acid, and at others, under precisely the same conditions, it will be present in excess. See ACHYLIA GASTRICA.

Hypochlorhydria depends upon depression of the nervous system, and there appears to be a special exhaustion of the secretory nerves of the stomach. The stomach often empties itself prematurely, and may be found without contents in from 1/2 to 1 hour after eating. The rapid gastric peristalsis is, in certain cases, followed by an equally marked intestinal peristalsis, and, as a result, lienteric diarrhea develops. While it is true that hydrochloric acid disappears from the stomach as a

result of gastritis and other diseases of structure, it has been shown that the condition exists as a true neurosis, but is accompanied by depression or exhaustion. The condition yields to treatment if applied sufficiently early. The most useful local measure is the application of electricity by the gastric electrode, using either the faradic current or the continuous current with slow interruptions. Besides this, the needle bath, massage, and medical gymnastics are of great use. The alternate hot and cold intragastric spray is serviceable. One c.c. of the dilute hydrochloric acid should be given, and repeated at intervals of a half hour for 2 or 3 doses. Preceding the meals, nux vomica, capsicum, and the carminatives are of service. Although such patients often retain their weight, they do not when diarrhea occurs; therefore, the disease should be combated, and astringents are often necessary.

Sensory Neuroses

Hyperesthesia is a common condition, depending upon excitement. It is often present in hysteria and neurasthenia, in which the symptoms may very from discomfort to unbearable distress; it is made worse by taking food, either solid or liquid. The diagnosis is reached by excluding organic disease of the stomach, and the treatment should be directed to the improvement of the nervous system, the local application of electricity, the administration of sedatives and analgesics, and a bland, unstimulating diet.

By the term GASTRALGIA (*q. v.*) is meant extremely severe pain in the epigastric region, usually paroxysmal in character, and, as a rule, accompanying a neurotic state. The pain somewhat resembles that of peptic ulcer, but is more diffuse, not necessarily related to the time of eating, lacks the point of local tenderness, and is often relieved by electricity and stimulating local treatment. It is often a most intractable affection, particularly when connected with disease of the central nervous system. It is sometimes mistaken for angina pectoris, and for hepatic, pancreatic, or appendicular colic. The best treatment is the application of the continued electric current by the gastric electrode, the anode applied internally; douching with water at a temperature of 105° F.; spraying with a solution of menthol, oil of cinnamon, or chloroform water; and by the administration of bismuth subcarbonate, cerium, and other gastric sedatives. In severe cases anodynes are necessary for the relief of pain.

Hyperorexia signifies an exaggerated appetite, which is not satisfied by eating. It differs from bulimia, in which not only is the appetite voracious, but in which the patient eats enormously. The latter condition is sometimes based upon a disturbed mentality.

Among the functional disturbances depending upon depression may be mentioned **parorexia**, in which the patient has a desire—sometimes almost uncontrollable—for unusual and, occasionally, disgusting articles of diet. The condition is occasionally a real psychosis.

A more common affection is that known as **anorexia**, in which appetite diminishes, and, as a result, the patient loses flesh and strength; it is occasionally a very trying condition, and its relief is procured by forced feeding, sometimes by the practice of gavage.

Another condition belonging to this class is **nausea without vomiting.** It is undoubtedly a neurotic state, and may occur when the digestion is undisturbed. Real relief may be had only by improvement of the disturbed nervous system. Measures otherwise directed may produce temporary relief, and are useful in occupying the patient's attention.

GASTRITIS, ACUTE. Synonyms.—Acute catarrhal gastritis; acute gastric catarrh; acute dyspepsia; gastric fever.

Definition.—Acute inflammation of the stomach.

Etiology.—(1) Indigestible food; (2) insufficient mastication of food; (3) alcoholism; (4) certain diseases, as scarlet fever, yellow fever, etc.; (5) some drugs, as quinin in large doses, arsenic, antimony, etc.; (6) pregnancy.

Pathology.—The mucous membrane is swollen, often showing minute hemorrhages. The surface of mucosa is covered with a tough, clear-colored or reddish secretion. When the epithelium remains intact, bacteria are absent in the mucosa; but if detached, the organisms soon invade the deeper tissues.

Symptoms and Clinical Course.—There is fulness or tightness across the epigastric region, with a sense of discomfort until relieved by eructation of gas. In the later stages the gas may not all be expelled, causing a general restlessness. Often there is eructation of a bitter, sweet, or sour fluid, and with it particles of undigested food, especially observed in the morning.

The tongue usually has a thick whitish coating and the breath is offensive. The appetite is lost, and there is often loathing of all varieties of food placed before the patient. The pulse is small and rapid.

The nervous symptoms are: Headache, indisposition to exertion, palpitation of the heart, excessive sweating, and, in children, delirium and loss of consciousness. In a large proportion of cases fever may be entirely absent, but when the process is progressive, the temperature may remain elevated for several days, often simulating typhoid fever during the onset.

The duration of an attack of acute gastric catarrh is usually from 4 to 5 days. Analysis of the gastric contents after a test-breakfast shows a deficiency of hydrochloric acid and pepsin, with retarded motor power of the stomach. See STOMACH-CONTENTS.

Diagnosis.—After the fourth or fifth day typhoid fever may be excluded. In malignant diseases, such as carcinoma, there is usually a cachectic appearance and more pain, with deficiency of hydrochloric acid in the gastric contents. In gastric ulcer pain is pronounced, especially after eating, and there are frequent attacks of hematemesis.

The prognosis is favorable.

Prophylactic Treatment.—Avoid trauma from

constant pressure, such as tight lacing. Guard against sudden chilling of the body, especially after a hearty meal.

Dietetic Treatment.—In acute attacks, when everything is rejected, it is a good policy not to introduce anything to increase the irritation. Both solids and fluids are often quickly ejected.

In many cases a total abstinence from all solids for a period of 24 hours will give relief.

Administration of liquids should be so regulated that the intervals may be of sufficient length to allow the disabled organ to perform its proper functions.

During the first day or two milk, soup, or beef-juice should be given, and when the stomach becomes more tolerant, a small amount of solids may be allowed.

Medicinal Treatment.—At the time of onset an emetic should be given, as recommended by Ewald and Boas:

℞.	Powdered ipecac,	gr. xxiij
	Antimony and potassium tartrate,	gr. 5/6.

Take at once.

In children the syrup of ipecac (1 dram) is advised. Apomorphin (1/6 grain) hypodermically acts quicker than other emetics, and is valuable.

Locally, hot applications to the epigastrium are comforting. When there is much fever, cold applications are best. After from 24 to 36 hours have elapsed from the onset of the symptoms, the following may be given:

℞.	Calomel,	gr. jss
	Cerium oxalate,	gr. xx
	Bismuth subnitrate,	gr. xl.

Make 6 powders; 1 every hour.

When there is hyperacidity of the stomach, alkalies are useful, such as magnesium carbonate (5 to 10 grains) or sodium carbonate (4 to 7 grains), repeated every 3 or 4 hours. In some cases Hemmeter recommends evacuating the stomach by means of a rubber tube, and subsequently introducing:

℞.	Thymol,	gr. viij
	Boric acid,	ʒ iv
	Warm water,	Oj.

Lavage fluid.

When the vomiting is so severe as to produce symptoms of collapse, morphin (1/4 of a grain) with atropin (1/125 of a grain) should be given hypodermically. See Lavage.

GASTRITIS, CHRONIC.—A chronic inflammation of the stomach that may be parenchymatous or interstitial.

Etiology.—Chronic gastritis occurs most commonly in men, owing partly to the fact that their stomachs are greatly abused. It is a disease that is present usually after middle life, because diseases to which it is secondary more frequently exist at that age. The affection sometimes follows acute gastritis, or may result from frequent attacks of subacute inflammation depending upon infections, dietetic errors, or alcohol. Excessive use of tobacco, especially when the juice or the leaves are swallowed, is likely to cause it. Large quantities of tobacco-leaf have been washed from the stomach of a man who had a habit of carrying an unlighted cigar between his teeth and slowly chewing it. Excessive use of alcoholic drinks or of highly seasoned or coarse, irritating foods or condiments sometimes induces the disease.

As chronic gastritis is essentially a secondary affection, the primary or predisposing causes, aside from those mentioned, may be classified as: (1) Unhealthy state of the mouth, nose, or throat, such as dental caries or ozena; (2) chronic heart-, lung-, or liver-disease, causing passive congestion of the stomach; (3) chronic toxemia or wasting disease, such as gout, diabetes, tuberculosis, grave anemia, nephritis, syphilis; and (4) organic diseases of the stomach: for instance, carcinoma or gastrectasia. Gastritis may also result from long-continued functional disturbance, as has been emphasized by Stockton, who considers that obstinate functional failure frequently leads to structural change; in this connection the question of the trophic nerve supply is interesting.

Morbid Anatomy.—The macroscopic appearance of the mucous membrane shows a large amount of mucus lying upon its surface, though some cases lack the mucus, owing to the total obliteration of the muciparous glands. The lining of the stomach is pale or dark bluish-red, or grayish and pigmented, according to the extent of congestion and capillary dilatation, or of the opposite condition, connective-tissue increase and obliteration of minute blood-vessels. The most marked congestion and thickening are seen at and near the pylorus. The gastric wall is thick in some cases and thin in others, while the organ is small in some and dilated in other instances. Occasionally, the pyloric orifice is considerably narrowed by inflammatory hyperplasia and thickening of the coats of the stomach at that point; this may be so extensive as to cause stenosis and gastrectasia. The surface of the stomach is smooth and shining in some cases, but in other instances there are numerous elevations (teat-like, "état mamelonné"), giving rise to a marked irregularity and roughening. Minute ulcers or erosions of the mucous membrane are sometimes seen.

Microscopically, in the catarrhal form the glands appear dilated and cyst-like, and show an irregular distribution. The glandular cells are swollen and in a state of fatty degeneration, and the parietal and principal cells are not distinguishable. Some of the glands have narrowed necks, and the mouths of the ducts are filled with desquamated cells and mucus. The interglandular structure is the seat of round-cell infiltration. In some places a mucoid degeneration of the glandular cells takes place (Ewald, Einhorn, and others).

If the process continues long enough, the secreting portion of the stomach is entirely obliterated. This occurs in two ways: In one the morbid change

begins in the glands (parenchymatous), and their cells disappear by fatty degeneration, their places being usurped by interstitial tissue, until, finally, the stomach lining is thin, smooth, and shining. This process extends from the upper part downward to the submucosa. The other process is fibrous, proliferation beginning in the deeper layers and extending upward, constricting and destroying the glandular structure. In the latter form the gastric wall is often very thick and the capacity of the stomach is small (cirrhosis ventriculi).

Symptoms.—The disease may exist for a considerable period of time without symptoms, and when these supervene, they are likely to be indefinite and changeable; indeed, almost any symptom of the various gastric neuroses may, at times, be present in chronic gastritis. It is impossible to diagnose the disease by symptoms alone. Usually the patients are poorly nourished, pale, sallow, and thin; the weight may, however, be maintained at a certain point for many years. Fatigue is easily induced, and the muscles are small and flabby. Anorexia is marked and persistent in some cases, but parorexia, or excessive appetite, may be present in others. The tongue is usually coated brownish-gray from tip to base, especially in the morning on rising. Cankered mouth is of common occurrence. A sweetish, unpleasant taste is often complained of, and the throat feels irritable and husky. Hemmeter emphasizes the point that pharyngitis, glossitis and gingivitis not infrequently exist; thus the breath may be offensive. The gastric symptoms usually consist of a feeling of weight, distention, and distress after meals, especially when too much food has been taken. Pain is not common; if present, it is usually dull, and is aggravated by food, especially when this is of an irritating character. Vomiting in the morning is likely to occur, especially in those who use alcohol to excess. Vomiting also takes place after meals in some cases. Nausea may be frequent and persistent; eructation and regurgitation are not uncommon. In some instances the ingestion of food is followed by dull headache and a feeling of general nervous distress. Constipation is usually quite marked. In cases with greatly impaired gastric digestion diarrhea, from secondary over-taxation, irritation, and catharrhal inflammation of the intestines, is likely to occur (Allen Jones, Joseph Wiczkowski, and others). Constipation often alternates with diarrhea. Insomnia and depression of spirits are common. The urine will probably be superacid, scanty, and hyperlithic. The skin is loaded and sluggish.

Examination of the Stomach.—In thin women more or less gastroptosis and nephroptosis are often found, and the stomach may be somewhat enlarged, owing to the atony of its walls or to hypertrophic pyloric stenosis. As a rule, however, there is not gastrectasia or ischochymia.

One hour after an Ewald test-breakfast, consisting of a roll and water, or 3 hours after a test-meal of broiled, finely scraped meat-ball, bread, and water, the gastric contents contain no free HCl, but combined HCl is present; lactic acid is usually absent; butyric and acetic acids are seldom found. The proteoses are present, showing digestion of albumin. Rennet ferment and rennet zymogen are much diminished, as has been specially pointed out by Boas, and also by Friedenwald. Achroodextrin and sugar are usually found. See STOMACH-CONTENTS.

At the first examination of the stomach-contents there is usually an excessive quantity of mucus holding food elements in its meshes. The amount of mucus varies, being large in some cases and quite small in others. In the form described as "chronic mucous gastritis" there is an abundance of mucus, whereas in many cases of glandular gastritis, and also of the sclerotic form, there is very little. The total acidity of the gastric contents is subnormal. Microscopically, epithelia, leukocytes, mucus, food elements, and ordinary bacteria are found, with the addition of red blood-cells and minute fragments of tissue in case there is ulceration or erosion. Boas describes a form of chronic gastritis in which a copious secretion of mucus and HCl exists. In this acid gastritis the problem is much the same as that presented by hyperchlorhydria, and treatment for the latter usually relieves the former. In these cases a secretory neurosis probably exists, accompanied by an inflammatory element. From simple chronic gastritis, with only moderate impairment of the secretory function, there are all gradations to complete atrophy, in which stage and form the food is washed from the stomach wholly undigested, appearing as though merely water-soaked. Crust of bread floats on the wash-water, and there is, as a rule, but little mucus. Hydrochloric acid, free or combined, is absent, lactic acid and lactates are present if taken preformed in the food; other organic acids are absent; pepsin and rennet, also their zymogens, are absent; starch digestion is carried on, provided mastication is thorough, and saliva is plentiful and active.

As will be readily seen, there can be no hemialbumose or peptone in such contents, and the total acidity is from 2 to 5 percent: merely the acidity of the food taken. The gastric contents correspond in this condition, stage, and form of gastritis to the pathologic state, and there is "anadenia gastrica" (Ewald) and "achylia gastrica"—no gastric juice—(Einhorn). Allen Jones has described the condition under the caption "Gastric Anacidity." Reichmann, of Warsaw, in discussing the diagnosis of gastritis atrophicans, speaks of the occurrence of painful sensations in the abdomen, nausea, and regurgitation of 50 to 100 c.c. of an alkaline fluid containing serum, albumin, and mucus.

Diagnosis.

CHRONIC GASTRITIS.	ULCER OF THE STOMACH.	CARCINOMA OF THE STOMACH.
Subjective Symptoms.	*Subjective Symptoms.*	*Subjective Symptoms.*
1. Due to indiscretion in diet and to mental anxiety.	1. Often due to mechanic injury or to bacterial invasion.	1. Tendency inherited.
2. Any period of life.	2. Most cases occur between ages of 20 to 40.	2. Usually after fortieth year.

Chronic Gastritis.	Ulcer of the Stomach.	Carcinoma of the Stomach.
3. Onset slow; gradual loss of flesh and strength.	3. Onset slow; gradual loss of flesh and strength.	3. Frequently develops rapidly after metastasis has occurred; rapid cachexia and emaciation.
4. Pain diffused over epigastric area, generally occurring after eating.	4. Localized pain in stomach after eating.	4. Localized pain at all times.
5. Morning nausea and vomiting of a fluid containing particles of undigested food, alkaline in reaction.	5. Vomiting occurs soon after eating.	5. Copious vomiting of material a long period after eating; vomitus has a "coffee-ground" appearance.
6. Hemorrhage rare.	6. Hemorrhage is common.	6. Hemorrhage is common.
7. Normal temperature.	7. Temperature slightly elevated.	7. Temperature elevated.
Objective Symptoms.	*Objective Symptoms.*	*Objective Symptoms.*
1. Inspection negative; palpation often detects enlarged stomach; percussion yields increased area of dulness.	1. Inspection negative; palpation determines position of localized tenderness; percussion confirms palpation.	1. Inspection often detects an enlargement or tumor; palpation confirms inspection; percussion confirms inspection and palpation.
2. Examination of contents of stomach 1 hour after a test-breakfast shows free HCl normal or absent.	2. Examination of contents of stomach 1 hour after a test-breakfast shows free HCl in excess.	2. Examination of contents of stomach 1 hour after a test-breakfast shows free HCl absent.
3. Examination of blood shows slight reduction in red cells, hemoglobin, and leukocytes.	3. Examination of blood shows moderate reduction in red cells, hemoglobin, and leukocytes.	3. Examination of blood shows severe anemia with leukocytosis.
4. Absence of cancerous fragments in vomitus.	4. Absence of cancerous fragments in vomitus, unless due to cancer.	4. Cancerous fragments sometimes present in vomitus.

Prognosis.—The prognosis of chronic gastritis depends upon the stage the affection has reached. If treatment is commenced early, the outlook is very good, though a considerable time is usually required to restore the integrity of the stomach. If atrophy has taken place, the prognosis is grave so far as restoration of structure is concerned, though treatment may improve the function both of the stomach and intestines. The outlook often depends upon the primary cause of the disease.

Treatment.—The treatment of the cause should receive first attention. If there is cardiac incompetence, the Nauheim treatment or digitalis and strychnin will be useful; if there is gout, rheumatism, or syphilis, salines, alkalies, mercury, or the iodids should be employed. The diet should be restricted to the tender meats delicately cooked, tender chicken, turkey, or other fowl, fresh fish (not too fat), sweetbreads and animal jellies, very soft-boiled or poached eggs, thoroughly cooked white bread, rolls, zwieback and wafers, vegetables (well cooked, and, preferably, rubbed through a colander), avoiding cabbage and those that are indigestible. Soups, consommé, bouillon, and purées are advisable, provided they are not rich, greasy, acid, or highly seasoned. Milk agrees in some cases and positively disagrees in others. Bulkley, of New York, urges taking the milk warm and fresh an hour before meals on a supposedly empty stomach, with the hope that it will be absorbed directly as an alkaline fluid, and not be precipitated by rennet and go through the stages of gastric digestion. In chronic gastritis this should be tried, and soda may be given with the milk to render it distinctly alkaline. Peptonized milk should be employed in some cases. Pickles, sauces, salads, condiments, pastries, cakes, excessive amounts of alcoholic drinks, nuts, raisins, ices, etc., should be avoided.

Hemmeter allows a small quantity of whisky or brandy, because of Chittenden's and Mendel's observations in regard to their stimulant action on gastric digestion, but most clinicians interdict the use of alcohol in any form; it should rarely be allowed. Mastication should be very thorough; the teeth should be regularly cleaned with antiseptic tooth-washes, and should receive a dentist's attention regularly every few months. Meals should be regular, and should be preceded and followed by a quarter or a half hour's rest, if possible. The stomach is to be favored, and it is better that 4 to 5 small meals be eaten each day than that the organ should be overtaxed at any one meal.

Hygienic living is extremely important. It is necessary that the patient should take the proper exercise out-of-doors, not, however, inducing fatigue. Cold spinal douches, cold affusion, shower bath, salt-water bathing, and other tonic hydrotherapy will be beneficial. In gouty or nephritic cases thermal or Turkish baths are indicated.

Massage and gymnastics are useful, and general faradization improves innervation. An ocean voyage, travel, or a stay at the seashore or in the mountains is usually beneficial, provided the dietetic regimen is not seriously interfered with. The bowels should receive proper attention, and a desire to evacuate them should not be disregarded. Regularity in going to stool at a certain hour daily should be observed. By these measures alone much good may be accomplished, but it is usually advisable to employ local treatment and judicious medication.

Lavage is the most important of all measures. It should be practised 3 or 4 hours after a meal or before breakfast, and a normal salt solution should be used. After thoroughly cleansing the stomach, a weak silver nitrate, argonin, or protargol solution (2 grains to 8 ounces), or the aqueous fluidextract of hydrastis, or tannic acid solution, may be employed. Boric acid, borax, or Carlsbad salts make excellent solutions for the purpose of lavage; plain warm water is commonly used. The intragastric spray of menthol in albolene is often of benefit, especially in cases with gastric hyperesthesia or pain. Lavage should not be employed too often or too long: usually 2 or 3

times a week, unless practised before breakfast, in which case it may be done every day. Intragastric galvanism and faradism are useful.

Few drugs should be given, beyond nux vomica and strychnin, with, perhaps, quinin or cinchonidin and capsicum before meals, and hydrochloric acid after meals. Pepsin is indicated if there is serious impairment of gastric secretion. See Lavage.

℞. Dilute hydrochloric acid, ℥ j
Compound tincture of gentian, Aromatic elixir, each, ℥ iv
Water, enough to make ℥ iij.
Two teaspoonfuls after meals.

The compound tincture of cardamom or the simple tincture of calumba may be substituted for the gentian in the foregoing prescription.

℞. Tincture of nux vomica, ℥ ij
Fluidextract of cascara, ℥ jss
Glycerin, enough to make. ℥ iij.
Teaspoonful at bedtime.

℞. Pepsin, ℥ j
Dilute hydrochloric acid, ℥ jss
Simple syrup, ℥ iv
Water, enough to make ℥ ij.
Teaspoonful during or just after meals.

Neither hydrochloric acid, pepsin, nor the other remedies just mentioned should be given in cases of acid gastritis in which there are present a proliferation of the glandular cells, an increased secretion of HCl, with symptoms of hypochlorhydria; nor should the intragastric application of electricity be practised in these cases. On the contrary, the treatment in such instances should be sedative, including the exhibition of bismuth subcarbonate or subnitrate, cerium oxalate, and light carbonate of magnesia, preferably in the following formula:

℞. Oxalate of cerium, ℥ ijss
Subcarbonate of bismuth, ℥ ij
Carbonate of magnesium (light), ℥ iv.
Even teaspoonful stirred in water, between meals and at bedtime; more frequently if in pain.

Lavage with warm soda solution is excellent in these cases, and the diet should be nitrogenous.

The general management of chronic gastritis always demands careful attention, and the relations of morbid renal, hepatic, and intestinal conditions to the affection of the stomach should always be borne in mind. Thus, an occasional dose of blue mass or calomel, followed next morning by hot Carlsbad solution, is beneficial, and many patients are much improved by drinking mineral waters, both alkaline and saline. For the acid and in recent cases when the stomach shows no late serious changes, alkaline waters may be chosen; whereas in the cases showing depression of secretion, saline waters are, perhaps, to be preferred.

GASTRITIS, TOXIC.—An acute inflammation of the stomach due to corrosive poisons, such as caustic potash, sulphuric or nitric acid, arsenic, or corrosive sublimate.

Pathology.—The mucous membrane in many areas is detached, and localized spots occur in which a black eschar forms. If the case progresses to a sufficient degree, there may be fatty degeneration of the peptic glands, hemorrhagic spots, and subsequent ulceration.

Symptoms and Clinical Course.—There are intense thirst, nausea, and vomiting, the material often containing red blood-corpuscles. The pulse is small and rapid, the skin cold and clammy, and there are evident symptoms of collapse.

The prognosis is guardedly favorable.

Treatment.—If the nature of the poison is known, a chemic antidote should be given at once. In case of poisoning by arsenic the freshly prepared precipitate of ferric hydrate may be administered immediately. This antidote may be quickly prepared by the addition of magnesium carbonate (in fine powder) to the tincture of ferric chlorid. This precipitate requires no subsequent treatment before administration. If more time is permitted, it can also be prepared by the addition of ammonia water, collecting the precipitate on a filtering-paper and washing with water until the odor of ammonia is no longer detected. A tablespoonful of this precipitate, made in either manner, may be given every hour or two for 4 or 5 doses. If the poison is due to one of the corrosive acids, weak alkalies, such as lime-water, combined with olive oil, may be given. If it is due to alkalies, dilute acids (vinegar) will be indicated. In case of poisoning by mercuric chlorid the stomach-tube should be introduced and the contents removed at once. It is then well to give the whites of several eggs; allow to remain a few moments, then irrigate thoroughly. In the absence of white of egg a thick paste made of flour and water should be introduced and subsequently withdrawn in a few moments with the stomach-tube. After all the poison has been removed, a thick emulsion of gum arabic may be introduced.

Collapse will call for hot blankets, hot-water bottles, inhalations of nitrite of amyl, and hypodermic injections of strychnin, atropin, and tincture of digitalis. See Poisoning.

GASTRODIAPHANY.—A method of exploration of the stomach by means of the gastrodiaphane. This consists of a soft stomach-tube, at the gastric extremity of which is placed an Edison's hard-glass lamp, from which conducting wires, containing a current-interrupter, run to a portable storage battery. The stomach should be free from food and moderately distended with water. The gastric extremity of the gastrodiaphane, after being lubricated with oil or glycerin, is introduced into that viscus, and the circuit is closed. If no pronounced thickening of the anterior stomach-wall exists, transillumination in a dark room, with the patient erect, permits the outlines of the stomach to be seen as a zone of reddish hue on the abdominal wall.

GASTRODYNIA.—A mild pain in the stomach. See Gastralgia.

GASTROPTOSIS.—See VISCEROPTOSIS.

GASTROTOMY.—See STOMACH. (Surgery).

GAULTHERIA (Wintergreen).—The leaf of an American evergreen plant, *G. procumbens*, of which the oil and the spirit are official. The oil contains about 90 percent of methyl salicylate, and its physiologic action is almost identical with that of salicylic acid. It is volatile, of peculiar and aromatic odor, and sweetish and warm taste. It is successfully used as a substitute for salicylic acid; especially in rheumatic and gouty disorders, and does not so commonly disturb the digestion. It is best given in capsule or emulsion or dropped on a teaspoonful of sugar. Death has been caused by a 1-ounce dose. Dose, 3 to 10 minims.

The spirit of gaultheria is given in the dose of 1/2 to 2 drams. It contains 5 percent of the oil, and is used for flavoring.

℞. Ether,
Alcohol,
Oil of wintergreen, } each, ℥j
Soap liniment, enough for Oj.

Use as a liniment.

GAUZE.—Gauze is usually a sheer material, commercially known as cheese-cloth or tobacco cloth. Having a very open mesh, it absorbs well the materials with which it is impregnated, or the discharges from a wound when applied as a dressing. It can be easily obtained, is cheap, pliable, and forms a pleasant dressing when in contact with wounds. It is readily impregnated with various materials to render it antiseptic. Almost any variety of gauze may be obtained from dealers in surgical supplies.

The most common and generally employed is the **mercuric chlorid gauze,** which is prepared by soaking clean cheese-cloth, freed from all oily matter, in a solution of corrosive sublimate of the strength of 1:1000 for 24 hours. It is then cut into pieces of the desired sizes and packed in closely covered glass jars. If gauze has been kept long and exposed to the air, it is well to resoak it in a 1:2000 solution of mercuric chlorid before using Corrosive sublimate gauze, when applied in contact with a wound and covered with waxed paper or mackintosh, will sometimes irritate the skin. It should be anointed, therefore, with boric acid ointment or vaselin. In wound treatment two dressings are employed, the superficial and the deep, each usually composed of 8 layers of the gauze. Often the deep dressing is applied moist, and is much smaller than the superficial, which is preferably used dry.

Iodoform gauze is prepared by incorporating powdered iodoform into the meshes of sterilized gauze; it should then be carefully rolled up and packed in a glass jar. A mixture (5:50 percent) of iodoform and glycerin may be made, in which strips of gauze are immersed. This preparation is convenient for packing bone cavities, fistulous tracts, etc.

Carbolized gauze, the variety that was first introduced by Lister as a surgical dressing, is made by soaking clean gauze for a few hours in a mixture composed of: Resin, 1 pound; alcohol, 5 pints; castor oil, 24 ounces; carbolic acid, 12 ounces. The excess is removed by passing the cloth through a clothes-wringer and then packing away for future use in glass jars.

The double cyanid of mercury and zinc gauze is more difficult to prepare than the other varieties, requiring the following: Potassium cyanid, 130 grains; mercuric cyanid, 251.7 grains; zinc sulphate, 268.9 grains; hematoxylin, 1.3 grains; solution of ammonia, 6 minims; gauze (prepared, cleansed), 10 ounces; mercuric chlorid solution, 7.6 pints; distilled water, q. s. In charging gauze with this substance 100 grains of the salt are dissolved in 4 pints of a 1:4000 bichlorid solution, which will give from 2 to 3 percent of the cyanid to the dry gauze. It should be freshly prepared and used moist. The advantages claimed for it are that it is unirritating to the skin, and, as the antiseptic is insoluble, it is not soaked out by the wound discharges. A rubber dam should always overlay the dressing made of gauze, in order to diffuse the discharge and prevent its coming to the surface; the dressings should be changed as soon as soaking is apparent. See DRESSINGS.

GAVAGE (Forced Feeding).—Gavage consists of the forcible introduction of food into the stomach through a tube; it is a very simple procedure, and one that a nurse can easily be taught. It has a wide application among infants and young children, and the indications for forced feeding are many. It is of great value in the rearing of premature infants and of young infants or other children who are so weak that the effort of sucking and swallowing exhausts them, and who refuse to take the breast or bottle. It is extremely useful in persistent vomiting in infants, and in these cases, when they are unable to retain any food swallowed, they will frequently retain it when it is given through the tube.

This method of feeding is also useful when swallowing is interfered with by pain due to sore mouth or throat, in cerebral diseases, narcotic poisoning, and tetanus, in diphtheritic paralysis affecting the pharynx, and is frequently very useful in many of the acute diseases, as diphtheria, scarlet fever, or typhoid fever.

Apparatus and Method.—A soft-rubber catheter (18 to 24, French) is connected by a short glass tube and about 18 inches of rubber tubing to a glass funnel holding from 4 to 5 ounces. The child should be placed flat upon its back and the head steadied by an assistant. While the tongue is depressed by the forefinger of the left hand, the catheter is passed rapidly back into the pharynx and down the esophagus. About 10 inches of the catheter should be passed beyond the lips. The funnel is then raised for a few moments, to allow the escape of gas from the stomach, and the food is then poured into it, and, when the funnel empties, the tube is tightly compressed and quickly withdrawn. When withdrawn slowly or clumsily, it is likely to excite vomiting. In children who have teeth it is necessary to use a gag, to prevent the tube from being bitten, but in older children the

process is not so easy as in young infants, and not so generally useful.

Sometimes when there is great resistance to the introduction of the tube through the mouth, it may be passed through the nose. After feeding, the child should be placed upon its back, absolutely quiet.

The food should be partially or wholly peptonized, and the intervals of feeding should be considerably longer than when feeding is conducted in the ordinary way. The stomach should be washed before the first feeding, and thereafter at least once a day.

Gavage is also used in adults when, for any reason, food is not accepted by the mouth and rectal feeding is insufficient. See MEDICINES (Administration).

GELATIN.—An albuminoid substance of jelly-like consistence, obtained by boiling skin, connective tissue, and bones of animals in water. The glue of commerce is an impure variety.

Isinglass, or ichthyocolla, is the purest form of gelatin known. It occurs in horny sheets, is semi-transparent, iridescent, soluble in 24 parts of boiling water, and forms, on cooling, a transparent jelly. It is slightly nutritious, is used for clarifying liquids, and, in solution, as a test for tannin. The plaster is used as a protective. Gelatin is of especial value in the treatment of poisoning by iodin, bromin, and the alums, but requires too much time for its preparation, as it should be broken up, soaked in water for half an hour, and reduced to the consistence of honey.

Gelatin capsules are made in various sizes from 0 to 10, and are a convenient means for administering oils, balsams, or nauseous solids, and, when filled, may be swallowed as easily as a large pill. Castor oil, cod-liver oil, etc., are put into soluble elastic gelatin capsules, making a bolus that may be swallowed with little effort, as they are compressible and change their shape to suit the size and caliber of the passage. Ordinary capsules are filled by the aid of a paper funnel, with the end of a penholder used as a packer.

Gelatin culture medium, a jelly made by a solution of the best commercial food-gelatin in the proportion of 6, 8, or 10 parts to 100 water, with 1 or 2 parts of dried peptones or glucose (the latter not to be used if the culture is to be made on slides) for increased nutritive value. Bicarbonate of sodium is used to neutralize the acid reaction. This, in bacteriology, is known as *gelatin*.

Liquid gelatin is a substance for fastening paper to glass, wood, or paper; its formula is:

Gelatin or clear glue,	75 to 100 grams
Commercial acetic acid (No. 8),	100 c.c.
Water,	100 c.c.
Ninety-five percent alcohol,	100 c.c.
Glycerin,	15 to 30 c.c.

Crush the glue and put it into a bottle with the acid; set in a warm place and shake occasionally. After three or more days add the other ingredients.

Medicated gelatin is a soft basis consisting of gelatin 3, zinc oxid 3, glycerin 5, water 9 parts, to which antiseptic or other medicaments may be added. It is preferable to greasy ointments.

GELSEMIUM (Yellow Jasmine).—The rhizome and roots of *G. sempervirens*, a climbing plant with showy yellow flowers that grows in the forests of the southern United States, forming festoons from one tree to another. It contains a volatile oil, a resin, and two alkaloids, *gelsemin*, which forms crystalline salts and is only slightly active, and *gelseminin*, which is amorphous and highly toxic. Dose, 1/2 to 2 grains.

The preparations are the **fluidextract** (dose, 1/2 to 2 minims) and the **tincture** (strength 10 percent; dose, 5 to 15 minims). **Gelsemin** is an amorphous, colorless, inodorous, nearly insoluble solid, of intensely bitter taste and strong basic properties, neutralizing the strongest acids, and with them forming soluble salts. Dose, 1/60 to 1/20 grain. **Gelsemin hydrochlorid.** Dose, 1/134 to 1/33 grain.

Therapeutics.—Gelsemium is a powerful depressant to the circulation, acting particularly on the heart. It is a mydriatic of considerable power, causing wide dilatation of the pupil from paralysis of the oculomotor nerve. The drug is used in nervous headache and migraine, malarial fever, the early stages of pneumonia and pleurisy, asthma, whooping-cough, laryngismus stridulus and nervous cough, torticollis, and spasmodic dysmenorrhea. Eight grains of gelsemin to the ounce of water, instilled drop by drop into the eye every 15 minutes for 1 hour, and then every half hour, is an effective mydriatic, but more transient than atropin.

In facial neuralgia:

℞.	Tincture of gelsemium,	♏ xv
	Anise water,	ʒ j.

To be taken every 6 hours.

Poisoning.—The most prominent symptoms of gelsemium poisoning are ptosis and dropping of the jaw. Languor, relaxation, and muscular weakness precede. Temporary internal squint is sometimes present, and is caused by the paralyzant action on the sixth pair of cranial nerves. Sensation is impaired very late in poisoning, the pulse is rapid and feeble, the voice is lost, and death ensues from centric respiratory failure. The treatment of the poisoning consists in the administration of cardiac stimulants—as ammonia, atropin, and digitalis—the application of external heat, and the employment of atropin and strychnin hypodermically to stimulate the respiratory center. Emetics are to be given when the heat is not too much depressed, in which case the stomach-tube must be used.

GENERAL PARALYSIS OF THE INSANE.—See PARALYSIS (General).

GENTIAN.—The root of the yellow gentian, *G. lutea*, containing an active bitter glucosid that is crystalline and soluble in water; also an inert, amorphous body, gum, sugar, and a trace of volatile oil, but no tannin.

Gentian is a simple bitter, without astringency or aroma, its action corresponding to that of calumba, but it is more likely to disagree with the stomach. It is very serviceable in atonic dyspepsia, or in that connected with a gouty diathesis, in malaria, in hysteria, in jaundice, and

in ordinary convalescences. It makes an excellent vehicle for cod-liver oil. On account of the gentesic acid it is discolored by the addition of iron salts.

In hypochondriasis:

℞. Gold chlorid, gr. j to jss
Extract of gentian, gr. xv.
Make 30 pills. One thrice daily.

Preparations.—**G., Ext.** Dose, 1 to 5 grains; **G., Fluidextract.** Dose, 10 to 30 minims. **G., Infusum, Comp.**, unof., gentian 10, bitter orange-peel 2 1/2, coriander 2 1/2, alcohol 40, water to make 320. Dose, 1 to 2 ounces. **G., Mist., Alkalin.**, unof., diluted hydrocyanic acid 3 minims, sodium bicarbonate 15 grains, compound infusion of gentian to make 1 ounce. Dose, 1 ounce. **G. et Sennæ, Mist.**, unof., infusion of senna 3 drams, compound tincture of cardamom 1 dram, compound infusion of gentian 6 drams. Dose, 10 drams. **G., Tinct., Comp.**, contains gentian 10, bitter orange-peel 4, cardamom 1, diluted alcohol to make 100. Dose, 1/2 to 2 drams.

GENU RECURVATUM.—See **Genu Varum.**

GENU VALGUM (Knock-knee).—Knock-knee, or genu valgum, is the result of over-growth of the internal condyle of the femur or of the internal half of the head of the tibia or of absorption of the outer portions of these articulating bones and curving inward of the shaft of the femur at its lower part, or of the tibia at its upper portion. In this condition three bony deformities are found: the condyles of the femur differ in size; the articular facets of the tibia are unequal; the shafts of the bones may curve.

It is a deformity that manifests itself in infancy or at adolescence, and it is most frequent between the ages of 2 and 4, when it is usually due to rickets. In adults it is seen as the result of occupation. Attention is generally called to it when the child begins to walk. Flat-foot sometimes accompanies this deformity and stands in a causative relation to it. Knock-knee may affect one or both legs. Exceptionally, it occurs as the result of late muscular paralysis. Sometimes this deformity may be seen in one leg, while bow-leg occurs in the other.

The simplest and most reliable method to measure the amount of deformity is for the patient to sit upon a large sheet of paper, with the legs extended and the feet pointing upward; and then, with a pencil held perpendicularly to the paper, to trace the outline of the legs. From time to time similar tracings may be made, and in this way the patient's progress noted. Many cases of mild type undergo spontaneous cure, and under proper treatment the prognosis in all cases is good.

The diagnosis is easily made by inspection; however, it is always advisable for the patient to sit on a table or any flat surface, keeping the internal condyles together, and then to note the distance between the internal malleoli.

Expectant treatment depends largely on nature. Gratifying results are obtained in children who live in the country. Strict attention to diet and hygiene, and gymnastics that strengthen the leg-muscles are very essential. In rachitic knock-knee the child should receive the constitutional treatment for rickets. Daily manipulation of the legs, properly applied, is an important adjuvant not only of expectant, but also of mechanic treatment.

Mechanic treatment is called for in cases in which the expectant plan fails and when the deformity is pronounced. It is usually most efficient between the ages of 2 and 5, and the most brilliant results are attained in rachitic children whose bones are still somewhat soft, a condition which is quite satisfactorily determined by corrective manipulations. Beyond the age of 5 little or nothing can be accomplished by mechanic treatment. Many methods have been devised in order to correct the deformity by mechanic means. One method that is quite commonly used is for the child to sleep with pads between the knees, the feet being bound together. In mild cases building up the shoes from 1/8 to 1/4 of an inch on the inner side, so as to throw the weight toward the outer part of the foot, has proved itself to be an efficient method. Many forms of apparatus have been suggested, but the one most commonly used consists of outside steel uprights extending from the sole of the shoe to the crest of the ilium, with joints at the hip and ankle, or, if desired, only a joint at the hip. Perpendicular to the upright is a small bar, which is inserted into a steel plate just in front of the heel. At the upper end of the uprights is a steel waist-band, to hold the brace in place. A posterior bar from the popliteal space to the lower portion of the calf is joined to the side bar by means of cross-bands at each end. At a point opposite the knee is a leather pad, which is attached to the outside bar by straps, so that traction may be made in order to overcome the deformity. As the child becomes accustomed to the apparatus, the outside bar may be bent out so as to admit of greater force in drawing the knee toward this bar. A very convenient way is simply to bandage the knees daily to the outside and posterior bar. No motion must be allowed at the knee. When the child goes to bed, the shoes are removed and the apparatus is kept on. Mikulicz has reported some excellent results from the use of plaster-of-Paris; however, beyond the age of 5 years there is rarely any elasticity of the bones, or much, if any, yielding to lateral pressure at the knee; and, unless the bones yield to manipulation, but little, as a rule, can be accomplished by this means. In all cases in which apparatus is used the correction must be made gradually and gently.

Operative Treatment.—In the order of simplicity the operations are: (1) Manual correction under an anesthetic; (2) subcutaneous division of ligaments and tendons; (3) osteoclasis; (4) osteotomy.

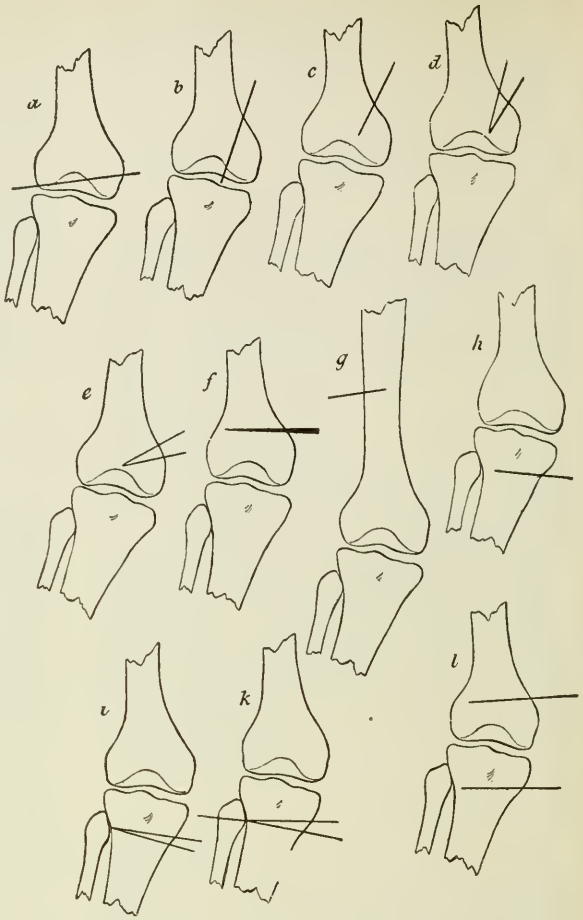
Forcible reduction of the deformity by manual pressure may be of value in children under 6 years, but after this age little can be accomplished. The operation is performed as follows: The patient lies on the back and the leg is rotated outward. The surgeon then bears his weight on the inner side of the knee until the deformity yields and can be rectified. The leg is then encased in plaster-of-

Paris, and at the end of two weeks this is changed; at the same time further correction is made without an anesthetic.

When the child is able to walk, mechanic support must be applied for at least two months. In performing this operation great care must be exercised in order not to injure the knee-joint, and cases have been reported in which the periosteum has been severely injured, and at times necrosis, superficial or deep, has resulted.

At the present day **subcutaneous myotomy and tenotomy** are rarely performed for the correction of the deformity in knock-knee, except possibly in cases that occur as the result of tumor albus and infantile paralysis, when it may be desirable to divide the biceps tendon, at the same time resorting to some straightening operation.

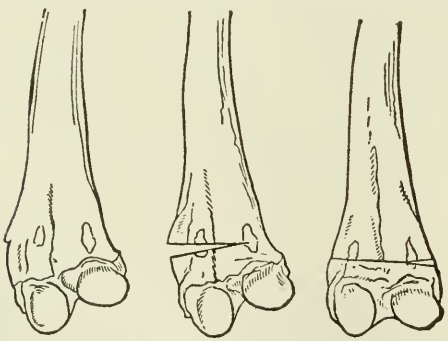
Osteoclasis is a method very frequently employed in these cases. It may be accomplished by the hands over a firm, hard object, such as a Koenig's block, or by the use of an osteoclast, such as Grattan's, Little's, etc. If manual correction is used, the limb is inverted and the point of resistance made above or below the knee on the inner aspect. The ankle and thigh are firmly grasped and downward pressure exerted sufficient to break the bone at the desired part. If the osteoclast is used, the leg is adjusted upon the two rests and the breaking lever applied over the point where fracture is desired. The force is then quickly applied by screw or lever (according to the type of osteoclast) and the part broken. It is then fixed in plaster-of-Paris and treated as an ordinary fracture.



Operations for Knock-knee.—(*Hoffa*).

a, Anuandale; *b*, Ogston; *c*, Reeves; *d*, Macewen's cuneiform osteotomy; *e*, Chiene; *f*, Mac wen's supracondyloid; *g*, Reeves; *h*, Billroth; *i*, Mayer; *k*, Schede; *l*, Barwell.

Osteotomy stands foremost among the operative procedures, particularly in the older cases. When done subcutaneously, it is practically devoid of any danger. The best osteotome



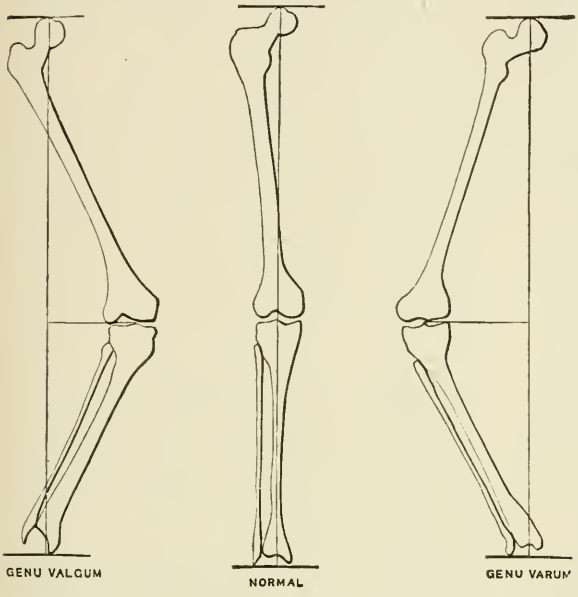
Macewen's Operation.

is one that has a sharp cutting-edge with square corners. Macewen's operation is performed as follows: The leg is rendered aseptic; the patient lies on his left side with the leg extended, the outer side of the knee resting on a sand-bag. An incision is made in the skin, and the osteotome is gradually forced into the bone on the inner side of the thigh, at a point 1/2 of an inch above the adductor tubercle; it is then turned at a right angle to the long axis of the femur, and successive blows are made with the mallet until the bone is divided through two-thirds of its thickness, when the osteotome should be gradually withdrawn, a piece of antiseptic gauze placed over the opening, and the fracture completed by manual force. An antiseptic dressing is then applied, and a plaster-of-Paris spica put on while the leg is held in a corrected position. Union takes place in about 4 weeks, and in 6 weeks the patient may be allowed to walk. If, however, the incision is made on the outer side of the femur, a green-stick fracture may be produced with less danger of displacement.

In some cases it may be found advisable for the patient to wear a brace for a few months following the operation, although this is rarely necessary.

When knock-knee occurs in adults, as the result of the patient being obliged to stand in a peculiar position for a certain number of hours each day—for example, in bakers—the treatment consists of confinement in bed with side splints applied to the leg, and subsequently a walking apparatus. This failing, osteotomy is indicated with probable tenotomy of the external hamstrings.

GENU VARUM (Bow-legs).—Genu varum, or bow-legs, is the name applied to the deformity that is the opposite of knock-knee. In general it is the result of an outward yielding of the long bones of the leg, especially of the tibia, and the anatomic changes found are those of rickets. **Anterior bow-leg** is forward curve of the tibia, generally associated with some lateral deviation. **Posterior bow-leg, or genu recurvatum,** is the reverse of anterior bow-legs. The greater part of the deformity will usually be found at the junction of the knee with the middle third of the tibia, but the exact location of the curvature can only be determined by placing the patient upon the edge of a table or chair, with the legs flexed at right angle and the knees and ankles in contact. If the curve is in the femurs, the thighs will be separated by a varying space and a like condition will be found between the tibias, but if both thighs and legs are in contact the change is in the knee-joints. It may begin before the child walks or stands, and is due to the tonic action of the muscles on the bones softened by disease. Early walking rarely causes bow-legs; as a rule, children in this condition learn to walk late. The symptoms of rickets are usually present, as bow-legs is essentially a rachitic deformity.



(Thomson and Miles' *Manual of Surgery.*)

The presence of the deformity is sufficient to establish the **diagnosis,** and it is much more conspicuous in the standing position. Its existence is further indicated by the turning-in of the feet and the rolling walk, and in well-marked cases of bow-legs the feet are in a condition of flat-foot. The only condition with which bow-legs is likely to be confounded is double congenital dislocation of the hip in young children, but there are many points of distinction that enable one to discriminate between them. In some cases of rickets an anterior bowing of the tibia occurs, angular in deformity, and usual at the lower third. Bow-leg is rarely observed on one side and knock-knee on the other.

The prognosis in bow-legs is favorable. Spontaneous correction sometimes occurs; much more frequently than in genu valgum. Children under 4 years of age, presenting even a marked degree of bow-legs, may be completely cured by the use of apparatus. When the deformity occurs in older children and is extreme, operative measures will entirely rectify it.

The treatment is governed by the same general rules as in genu valgum.

A reference to the remarks on the expectant treatment of knock-knee will enable one to judge equally well about the indications in bow-legs; however, its range of applicability is much greater in bow-legs. Tracings of the legs should be taken frequently, and the child kept under close observation.

The patient should be given constitutional treatment for rickets. If after several months no improvement is evident, or if any increase of deformity is noticed while the patient is being treated expectantly, then the indication for mechanic apparatus is imperative.

The form of apparatus used in the mechanic treatment is of little consequence, so long as it answers the indications and holds the knee extended. One very commonly used consists of a steel upright, which is attached below to a foot-plate. It runs to a point just a little below the origin of the adductor muscles, and ends with a semicircular pad-plate, which is applied against the inner part of the thigh. Just below the knee is a band that serves to attack the brace to the leg. On the outer side another upright runs from the foot-plate to this band. The foot fits snugly into the heel-cup, and is held on the foot-plate by means of the ankle-pad, triangular in shape. A piece of stiff leather attached to the inner upright, when laced, will serve to draw the deformed tibia toward the inner bar, and by degrees the amount of traction may be increased. At a point 1 1/2 inches above the attachment of the uprights to the foot-plate there is a joint, thus permitting the patient to walk with ease. When the curve is wholly in the tibia, it is sufficient to carry the upright just above the knee; if, however, the thighs are decidedly bowed, or the tibias twisted on their long axes, the upright must extend to a pelvic band. The latter applies also to cases in which the child shows a tendency to "toe in."

Repeated attempts at correction by manual force, supplemented with plaster-of-Paris, are sufficient to cure a large number of cases. After the age of 3 or 4 mechanic treatment becomes ineffectual and operative precedures are indicated.

The operations are: (1) Osteoclasis; (2) osteotomy. **Osteoclasis** may be either manual or by the aid of mechanical appliances as described under genu valgum, and the technic is entirely similar.

Osteotomy for bow-legs is an operation similar to that which has been fully described under knock-knee. It is usually performed subcutaneously, with brilliant results, the osteotome being inserted, and the limb fractured at the point of greatest angularity. The after-treatment is the same as in osteoclasis, the fractured leg being held in a retaining apparatus until union is complete.

No precise rules can be laid down as to the choice between osteoclasis and osteotomy, but in general it may be said that the latter is preferable in adult life, as it can be done with much less risk to the patient.

Cuneiform osteotomy should be performed for extreme degrees of anterior tibial curvature, but never for bow-legs; an exception may be made, however, when the articular surfaces of the joint are defective. In performing this operation it is necessary to make a free skin incision; then carefully incise and scrape away the periosteum and remove a wedge-shaped piece of bone from the tibia. The periosteum should then be stitched together, the wound dressed antiseptically, and the leg encased in plaster-of-Paris. The result of this operation is usually complete removal of the deformity, and it is unattended by any risk.

GERANIUM.—Cranesbill-root. The root of *G. maculatum*, with properties due to tannic and gallic acids. It is useful in diarrhea, infantile colic, etc. **G. Fluidextract**, dose, 5 to 30 minims.

GERMAN MEASLES.—See Rubella.

GERMICIDES.—See Antiseptics, Disinfection.

GESTATION.—See Pregnancy, Extrauterine Pregnancy.

GIDDINESS.—See Vertigo.

GIGANTISM.—An excessive overgrowth, resulting in an individual of enormous size as compared with that of the average person of the same period of development.

Etiology.—Gigantism in its perfect condition is believed to be due to a normal hypertrophy of the pituitary body, rather than to an enlargement of the sella turcica. There is slight evidence that it may be a manifestation of late hereditary syphilis. The thymus is not concerned in its etiology.

Morbid Anatomy.—There is found a symmetric enlargement of all organs and members and an increase in bulk of all tissues. Histologically, the tissue elements are increased in number rather than enlarged, individually considered.

Pathology.—In the perfect form of gigantism there should be no pathology, death occurring as in normal individuals. Inasmuch as in about one-half of the instances of this condition akromegaly supervenes, the pathology of the latter is likely to impress itself upon the picture.

Symptoms.—While gigantism itself gives rise to no symptoms save those attributable to mere bulk, it is nevertheless true that most giants are easily fatigued on muscular exertion, suffer from intellectual torpor, and are prone to reticence and melancholy, and that in men diminished sexual power, in women amenorrhea, are quite constant symptoms. The functions of the skin may be perverted.

Diagnosis.—This must be made after consideration of the period of life and normal development of persons in similar conditions. Absolute diagnosis is reached only after akromegaly is excluded. The writers on this subject frequently confound the two conditions, even claiming that akromegaly is an anomaly of gigantism. Only about one-half of the examples are those of essential gigantism. This manifests itself during the period of growth, while akromegaly is observed after stature is obtained. Infantile akromegaly is cretinism. The distinction as to period of life suffices, but in detail the following are important: (1) Symmetry—the hypertrophy of bones means increased growth of shaft in length and diameter, and not of ends, as in akromegaly. The face and cranium are well proportioned. The body, head, and limbs are enlarged in proportion; the foot may be small. (2) Nervous and trophic phenomena are absent, as well as eye and ear symptoms, unless the giant becomes the subject of akromegaly.

Prognosis.—There seems to be a greater increase of liability to intercurrent disease than in individuals of normal stature. The feebleness, both bodily and mental, would indicate lessened resistance to disease. For the prognosis of the akromegaly that supervenes reference should be made to that subject.

Treatment.—Attempts to lessen growth by limiting the amount of food ingested or by interference with digestion or absorption would be likely to increase the few symptoms that are associated with gigantism. Since excess of normal secretion of the pituitary body gives rise to gigantism, direct therapeutic measures should be those that will tend to check this secretion. At present none are known. Varices, which are frequently encountered, and nutritive changes in the skin should be treated as such.

GIN.—Common grain spirit distilled and aromatized with juniper berries. The finest gin, known as "Holland," is made in the distilleries of Schiedam, whence arises the name "Schiedam Schnapps."

Pure gin and the compound spirit of Juniper (*q. v.*) are therapeutically identical. When diuresis is needed in atony of the kidney without inflammation, gin is a useful medicament. Cirrhosis of the liver is most likely to follow the ingestion of gin as an alcoholic drink.

In England gin is often flavored with hops, and also with the oil of turpentine, various cheap aromatics, lead acetate, zinc sulphate, cayenne pepper, etc.

GINGER.—(Zingiber).—The rhizome of *Z. officinale*. *Green ginger* is the fresh rhizome; *black ginger* is the dried rhizome with its epidermis on; *white* or *Jamaica ginger* is the dried rhizome

deprived of its epidermis. It is most active when fresh, becoming inert by the action of age and exposure. Its active principles are a soft, acrid and aromatic *resin*, and a yellow, pungent *volatile oil*. Dose, 10 to 30 grains.

Ginger is sialogogue when chewed, sternutatory when inhaled, and externally a rubefacient. Internally it is a grateful stimulant and carminative, produces a sensation of warmth at the epigastrium, promotes the expulsion of flatus, and reflexly stimulates the heart and the central nervous system. In large doses it is a gastrointestinal irritant. It is used in domestic medicine as a stimulant carminative in colic, also in hot water for the cramps of suppressed menstruation due to exposure to cold. It may be employed with advantage in flatulence and atonic dyspepsia, in the latter being usually combined with other remedies. Though decidedly constipating by itself the oleoresin is frequently used in purgative pills, to prevent griping; also as a stimulant ingredient of tonic pills. The troches are employed to increase the secretion of saliva, also in relaxed conditions of the throat; and the syrup is a favorite flavoring ingredient for prescriptions. Preserved ginger is a favorite condiment, and carbonated water flavored with ginger is a common beverage under the name "ginger ale."

Preparations.—**Fluidextractum Z.** Dose, 10 to 30 minims. *Essence of ginger* is an unofficial preparation of various strengths, generally about 1 in 2, sometimes 1 in 1 as the fluidextract. **Tinctura Z.**, 20 percent. Dose, 10 to 60 minims. **Syrupus Z.** Fluidextract 3 percent in sugar and water. Dose, 1 to 8 drams. **Oleoresina Z.** Dose, 1/2 to 1 grain. **Trochisci Z.** (Unofficial). Each troche contains about 2 minims of the tincture, also tragacanth, sugar, and syrup of ginger. Dose, 1 to 5 troches.

Ginger is a constituent of Pulvis Aromaticus, and Pulvis Rhei Compositus; also through the former it is an ingredient of Pilulæ Aloes et Ferri, and Pilulæ Aloes et Myrrhæ. The tincture is used in preparing aromatic sulphuric acid.

GINGIVITIS.—See GUMS.

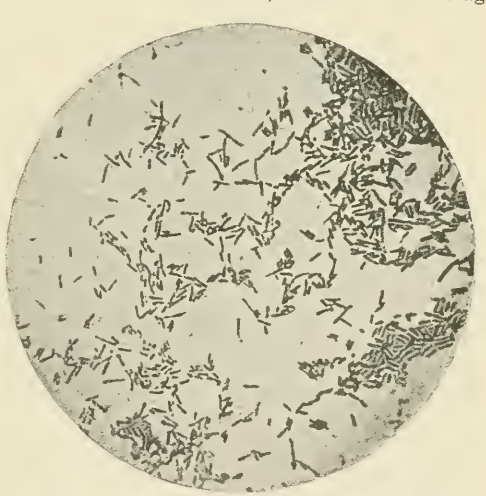
GIRDLE-PAIN.—The sensation of a band tightly encircling the trunk, or a "drawing-together" pressure on the lateral portions of the trunk. The girdle feeling is due to irritative processes in the region of the lower dorsal or upper lumbar nerves. It is comparatively frequent, and often appears quite early in tabes dorsalis or LOCOMOTOR ATAXIA (*q. v.*).

Antipyrin and acetanilid are the best drugs for the relief of these pains. When they fail, acetphenetidin, exalgin, cocain, chloralamid, or cannabis indica may be resorted to. A recurrence of the paroxysms may be prevented by a course of aluminium chlorid, 3 grains 3 times daily, but sometimes hypodermic injections of morphin are necessary. The application of the ether spray, chloroform, or menthol to the parts often relieves the pain. Galvanism and potassium iodid may give marked improvement, and the latter is indicated when there is a history of syphilis.

GLANDERS (Farcy; Equinia).—Glanders is a contagious specific disease derived from horses, characterized by constitutional disturbance and by lesions of the respiratory and cutaneous systems. The site of inoculation is marked by an inflammatory papule or pustule, which soon degenerates into a ragged, undermined, spreading ulcer, with accompanying lymphangitis and glandular swelling. Later, numerous cutaneous and subcutaneous nodules develop, which break down and discharge (farcy buds). There is usually nasal ulceration, with a foul-smelling discharge. Most cases run an acute course, ending in death. Those that last several months have a better chance to recover. The constitutional symptoms are fever, prostration, joint pains, and the typhoid state.

The disease is due to the **glanders bacillus** (*bacillus mallei*), discovered by Lœffler and Schütz in 1882. It is shorter and slightly broader than the tubercle bacillus. It has rounded ends, and usually remains isolated. Long threads are not formed. It is nonmotile, and up to the present time no spores have been found within the organism and no flagella have been demonstrated. Many animals, such as the goat, hog, field-mouse, cat, and guinea-pig are susceptible to the infection; while cattle, white-mice, house mice, and rats are immune.

The glanders bacillus is aerobic, and is grown upon agar-agar, bouillon, glycerin agar, blood-serum, and potato. A substance called *mallein* is prepared from this bacillus, and is used for diag-



BACILLUS OF GLANDERS, FROM A PURE CULTURE.—(*Fränkel and Pfeiffer.*)

nostic purposes in the same manner in which tuberculin is used in tuberculosis. A febrile reaction of more than 1.5° C. indicates that the animal is suffering from glanders. The nasal discharges from the noses of horses contain few bacilli. For the purpose of isolating the bacillus the nasal secretion should be injected into the abdominal cavity of a guinea-pig, and studied postmortem in tissues.

Method of Staining in Tissues (*Kühne*):

Methylene-blue,	1.5
Alcohol,	10.0
5 percent aqueous solution of phenol,	100.0

Place the section in the stain for half an hour, wash in water, decolorize in hydrochloric acid (10 drops to 500 c.c. of water); immerse at once in a solution of lithium carbonate (8 drops of a saturated solution of lithium carbonate in 10 c.c. of water); place in a bath of distilled water for a few minutes; dip into absolute alcohol colored with a little methylene-blue; dehydrate in anilin oil containing a little methylene-blue solution; wash in pure anilin oil, not colored, then in a light ethereal oil; clear in xylol and mount in Canada balsam.

The treatment of glanders consists in the destruction of the lesion by curet or caustic. In chronic cases large doses of quinin and stimulants are indicated.

Mallein is a glycerin extract of the culture products of the bacillus mallei, the micro-organisms of glanders. When this toxin is injected into animals affected with that disease, it produces a strongly marked febrile reaction, similar to that caused by tuberculin in tuberculous subjects. It is extensively employed in veterinary practice for the purpose of testing horses suspected of being infected with glanders. An antitoxic serum, obtained in the usual manner, has been used in a few cases of human glanders; one of which, reported by Dupuy, recovered under its administration from a severe attack of the disease.

GLANDULAR FEVER.—Glandular fever is an acute infectious disease generally occurring in childhood, and characterized by sudden onset, moderate fever, swelling of the cervical lymphatic glands, and constipation; but there is no rash. It is probably contagious.

Etiology.—The cause is unknown. The infectious agent, whatever it may be, is said to enter: (1) Through the tonsils or pharynx, or (2) by way of the intestines. Predisposing causes are: winter months, previous illness, lowered vitality, and general malnutrition.

Symptoms.—The incubation period is about five to eight or ten days, and is without symptoms. The acute symptoms appear suddenly; there are pain and tenderness in the neck, and these are made worse by movement of head or neck and by swallowing; fever occurs early, it is remittent, and not severe, running to about 101° or 103° F. The face may be flushed, but there is no rash. There may be nausea, anorexia, vomiting, and abdominal pain. The throat and pharynx show inflammation, and there is some dysphagia. The lymphatic glands are enlarged, and some of them can be palpated, particularly those in the cervical and carotid regions, just below and near the anterior border of the sternomastoid. The posterior cervical, axillary and inguinal glands may also be affected; and abdominal tenderness with enlarged liver and spleen will then be noticed. The fever abates as the gland involvement reaches its height, and the latter may last twelve or fourteen days, while the fever remains only three or four days.

Complications.—The most serious complication is nephritis; suppuration of the glands is not very common; otitis media and retropharyngeal abscess may also occur. In severe cases the beginning of convalescence is often marked by the passage of thin greenish stools, containing mucus.

Diagnosis.—This is to be made from the symptoms, particularly the cervical adenitis; the diseases to be excluded are pharyngitis, tonsillitis, parotitis, and leukemia.

Prognosis is favorable, except when the case is complicated by nephritis.

Treatment.—This is almost entirely symptomatic. Isolation should be insisted on so as to prevent the spread of the disease. Rest is necessary; the pain may be relieved by hot applications; iron, cod-liver oil, light but nutritious food, and general hygienic precaution are all indicated. Calomel in small doses has been recommended, and also condemned. For the adenitis, applications of belladonna should be made; and when the fever is high (in the early stage of the disease) or the pain is severe, sodium salicylate may be given. If the glands suppurate, incision and drainage will be in order.

GLAUBER'S SALT.—See Sodium.

GLAUCOMA.—Glaucoma is a disease in many respects not thoroughly understood, but characterized by the essential sign of increase of intraocular tension. However, every case of simple increase in intraocular tension is not glaucoma, and in some cases of *simple glaucoma* no increase of tension exists.

The direct cause is increase of the contents within the eye, either from *hypersecretion*, due to ciliary engorgement and disturbances of the nervous mechanism controlling secretion, or to *retention* of the intraocular fluids by obstruction or obliteration of the drainage-passages at the periphery of the anterior chamber. Conditions causing changes in the composition of the aqueous also interfere with filtration: as, for instance, serous iritis and cyclitis. There is much discussion and difference of opinion among equally erudite oculists about the cause of glaucoma.

Among the predisposing causes are mentioned old age (with normal diminution of the circumlenticular space), gout, rheumatism, nephritis, certain cardiac diseases—in fact, any condition leading to circulatory and vascular changes. The general tendency to waste-tissue accumulation—the so-called uric acid diathesis—is a fundamental cause in these cases. The opinion is entertained by some that long-continued eye-strain, from uncorrected or improperly corrected ametropia, is a potent factor in the etiology of many cases of glaucoma.

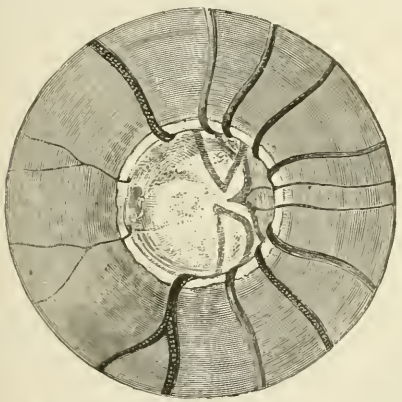
Pathologic Changes.—If there is a rapid rise in tension, the lens is pressed forward—a fact proved by the shallowness of the anterior chamber—and the suspensory ligament is stretched beyond the power of the ciliary muscle to relax it, as is shown in the lessening in the range of accommodation. There are marked circulatory changes in the eye. Pulsation is noticed in the retinal arteries, and the retinal veins are tortuous and swollen from the increased pressure. As the venæ vorticosæ are also squeezed by the intraocular pressure, an extra amount of blood is discharged through the anterior ciliary veins, which, in consequence, become

dilated and tortuous. The cornea becomes cloudy from pressure, and even the aqueous and vitreous participate in this change. From pressure on the ciliary nerves neuralgia is produced, and paralysis of the sphincter pupillæ and anesthesia of the cornea result. By increase in the vitreous the intraocular pressure is raised. The most important diagnostic change is the excavation or cupping of the disc and atrophy of the nerve-fibers. The final result of intraocular tension is active inflammation and swelling of both the internal and external coats of the eye. Naturally, vision is very much impaired.

Subjective Symptoms.—The patient complains of dimness of vision, diminution of the visual field, and pain about the eye, the intensity of which varies with the acuteness of the attack and the inflammatory symptoms accompanying. The appearance of colored rings or halos about any source of light, so often noticed in glaucoma, is a phenomenon due to the corneal disturbance, and is not confined especially to glaucoma.

Objective Symptoms.—The tension of the affected eyeball is abnormally high. If the rise in tension has been abrupt, the cornea is hazy and less sensitive to the touch than usual. The pupil is sluggish and often widely dilated, and has a greenish hue; the anterior chamber is shallow. In the inflammatory form there is considerable superficial and deep pericorneal injection.

With the **ophthalmoscope** the most characteristic symptom is excavation or cupping of the optic disc,



Ophthalmoscopic View of Glaucomatous Excavation.

which is to be distinguished from the physiologic cupping in extending the whole surface of the disc, and in having abrupt or overhanging sides; and from atrophic excavation of the disc by the depth and peculiar "broken-off" appearance at the edge of the disc, so that no continuity can be discovered between the arteries at the bottom of the cup and the vessels on the edge of the disc. Arterial pulsation of the retinal arteries is noticed, especially where the artery bends over the edge of the cup; it may be made particularly distinct by slight pressure on the eyeball. The degree of cupping may be estimated by the parallax test or by comparison of the refractions of the edge and bottom of the cup.

Diagnosis.—In inflammatory glaucoma, on hasty inspection, the disease may be confounded with keratitis, iritis, cyclitis, etc. In such cases it is well to discard the injection, and to rely on the *dilated pupil* and *shallow anterior chamber*, the *increase of tension*, the *visual disturbance*, the *peculiar ciliary neuralgia*, and the characteristic *cupping of the disc.*

For the differential diagnosis between acute glaucoma and the ordinary inflammatory conditions of the eye, see Eye Diseases (Diagnosis).

Prognosis.—Unless treated, glaucoma is almost certain to result, sooner or later, in complete and incurable blindness. It is of the utmost importance to make an early and absolute diagnosis of this condition, especially in the simple variety, in order to prevent a fatal termination. Glaucoma has been repeatedly mistaken for iritis, notwithstanding the dilatation of the pupil in the former disease and contraction in the latter; and, to the detriment of the patient, atropin has been repeatedly instilled, soon aggravating the condition to blindness. Generally speaking, if promptly and properly treated, the prognosis of acute glaucoma is favorable; it is doubtful in simple and infantile glaucoma, and unfavorable in the other varieties.

Treatment consists of 3 methods: (1) *Miotics*, as eserin and pilocarpin, to contract the pupil; (2) *operation* by paracentesis, iridectomy, sclerotomy, and incision of the ligamentum pectinatum; (3) *massage.*

Miotics are the first resort, and often cut short single attacks of glaucoma, and they are also valuable before and after operation. Pilocarpin and eserin are commonly employed, and are long continued.

Paracentesis relieves tension only for a short time. **Iridectomy** is of great value, and has some remarkable curative influence, both in dissipating the increased tension and in relieving the visual disturbances, and, eventually, curing the process. It should be broad and done upward, for cosmetic reasons and to prevent subsequent dazzling. The earlier the iridectomy, the better the result. Restoration of vision cannot be expected if there is much excavation and atrophy of the nerve-head. **Sclerotomy** has been advocated in cases of simple glaucoma in which the visual disturbance depends on the changes of the optic nerve, and in infantile and hemorrhagic glaucoma. A Graefe's cataract knife is introduced into the anterior chamber at a point corresponding to the puncture in cataract extraction, but 1 mm. removed from the corneal margin. The counterpuncture is made at a point corresponding to this at the other side of the anterior chamber. With a sawing motion of the knife the section is enlarged upward until only a bridge of tissue, about 3 mm. broad above, remains undivided. The knife is then slowly withdrawn from the eye, care being taken that the aqueous humor is gently evacuated through the lips of the wound. A drop of eserin is applied and the eye bandaged. Prolapse of the iris must be met on general principles. **Incision of the ligamentum pectinatum** is performed by cutting through the filtration angle, or spaces of Fontana,

with the point of the knife as it is withdrawn in sclerotomy. The good effects of sclerotomy have not been definitely established. **Cyclodialysis**, suggested by Heine, 1905, is a substitute for the more radical operation of iridectomy when the latter is contraindicated or is unsuccessful in reducing the tension. The object is to establish an artificial communication between the anterior chamber and the suprachoroidal space by separation of the fibres of the ligamentum pectinatum.

Massage of the eyeball, systematically pursued, is of undoubted value. The result of massage is almost instantaneous: immediately the eyeball grows softer, but the effect is not lasting. However, 5 minutes' massage, exerting considerable pressure together with simple palpation of the eyeball, practised several times daily, is an important aid in the treatment of glaucoma. Pure vaselin, a very weak yellow ointment, or a salve containing eserin and cocain, may be used in conjunction with massage.

Correcting lenses, both for distance and for near, should be applied if vision is still serviceable.

Excision of the superior cervical ganglion has been performed in very severe cases.

GLEET.—See GONORRHEA, URETHRA (Stricture).

GLENARD'S DISEASE.—See VISCEROPTOSIS.

GLIOMA.—A variety of round-celled sarcoma, consisting of a tumor of neuroglia cells, occurring in the central mass of the brain or of the spinal cord. Glioma of the retina (encephaloid of the retina) is a glioma springing from the connective tissue of the retina, usually occurring in the young, and involving the choroid, optic nerve, and extending finally into the brain. Pseudoglioma of the retina is a metastatic purulent choroiditis, simulating the appearance of retinal glioma. See RETINA, TUMORS, CHOROIDITIS.

GLOBUS HYSTERICUS.—A term for a choking sensation, as of a lump in the throat, felt by hysteric persons. It usually begins in the epigastric region or lower abdomen, and gradually rises into the throat. It is most likely caused by irregular spasmodic contractions of the esophageal or pharyngeal muscles. It is one of the warnings or auras of a hysteric fit. See HYSTERIA.

GLONOIN.—See NITRITES (Nitroglycerin).

GLOSSITIS.—See TONGUE.

GLOSSOLABIOLARYNGEAL PARALYSIS.—See PARALYSIS (Bulbar).

GLOTTIS, EDEMA.—See LARYNGITIS (Edematous).

GLUTEAL ANEURYSM.—This term is applied to aneurysms of the gluteal artery itself, of the sciatic, or of the pudic where it winds over the spine of the ischium. Aneurysms in this location may be the result of a wound or other injury, or may occur spontaneously. They are frequently attended with pain and interference with the movements of the hip-joint. The pulsation and bruit will generally serve to distinguish them, but there may be no pulsation, as when the aneurysm has burst, or when blood has been effused into the tissues as the result of a wound of the artery; a tumor of bone, moreover, may also pulsate. Under such circumstances exploration with a grooved needle will be necessary.

Treatment.—When of traumatic origin, an incision should be made over the tumor and the clot turned out. Hemorrhage is controlled by pressure on the common iliac artery through the rectum. When spontaneous, if the various measures of the aorta or common iliac have failed, ligation of the internal iliac may be necessary. Galvanopuncture and the introduction of coagulants have been employed successfully.

GLUTEN.—A substance resembling albumen; it occurs abundantly in the seed of cereals, in the form of cubic cells surrounding the starchy fecula of the seed. It consists mainly of gluten fibrin, gluten casein, gliadin, and mucedin. Gluten is of value as an antidote in mercuric chlorid poisoning, but it is of less use than albumen (the whites of eggs), and is not so easily obtained. Gluten bread is a variety of nonstarch-containing bread for use by diabetics. It is made as follows: Take 1 quart of sweet milk, or milk and water, 1 heaping teaspoonful of good butter, 1/5 of a cake of compressed yeast beaten up with a little water, and 2 eggs well beaten. Stir in the gluten flour until a soft dough is formed, knead as in making ordinary bread, put in pans to raise, and when light, bake in a hot oven.

GLYCERIN (Glycerol).—A triatomic alcohol existing in fats and fixed oils in combination with fatty acids. A viscous, syrupy, colorless substance, derived from certain fats—mainly palm oil—by decomposing them with superheated steam.

Glycerin is hygroscopic, nondrying, odorless, of warm and very sweet taste, neutral reaction, specific gravity 1.250, soluble in water and alcohol, but insoluble in ether, chloroform, and fixed oils. It dissolves tannin, gallic acid, carbolic acid, salicylic acid, bromin, iodin, etc., and, with the aid of heat, metallic salts and oxids, alkaloids, etc. With strong nitric acid it forms nitroglycerin, and it reduces potassium permanganate, chromic acid, and chlorinated lime with great violence. An impurity frequently present in it is *acrolein*, formed by the use of too high a heat in its manufacture, and which is very acrid and poisonous. Glycerin is a constituent of the six glycerites, pilulæ phosphori, mucilago tragacanthæ, massa hydrargyri, and several fluidextracts. Dose, 1 to 2 drams, diluted.

Therapeutics.—Glycerin is highly antiseptic, abstracts water from tissues with which it comes in contact, and, unless pure, is often very irritating to the skin. It is freely absorbed by all surfaces, cutaneous and mucous, and is decomposed in the system, passing out as formic and other acids. It has no particular action on the stomach, but in large quantities it is laxative and is said to cause the solution of the red blood-corpuscles and hemoglobinuria. Glycerin is a good emollient, and is considered nutritive by many authorities.

In chronic constipation excellent results are obtained from rectal enemata of glycerin or from the official suppositories. It is used as a vehicle for many drugs, and is a good ingredient of solutions for hypodermic use, promoting the

solubility of many alkaloids and acting as an antiseptic. It is also employed to preserve and aid the action of the digestive ferments, as well as to prevent the decomposition of vaccine lymph. Locally, it is valuable in many cutaneous affections as an emollient and softening agent. In acute coryza it gives great relief if applied with a brush or as a spray to the nasal mucous membrane. It is applied on cotton to the cervix uteri as a depleting agent, and mixed with an infusion of flaxseed as an enema to relieve tenesmus in acute dysentery. With tincture of benzoin it is an excellent application to chapped hands or lips and to fissured nipples. In the external auditory canal it will soften cerumen, diminish the secretion of pus, deplete the tissues, and keep the surface moist.

Preparation.—**Glycerini, Suppos.,** each contains 3/4 grain of sodium carbonate, 3 grains of stearic acid, and 46 grains of glycerin.

GLYCERITES.—Mixtures of medicinal substances with glycerin. There are six official glycerites:

Title.	Constituents.	Properties and Dose.
Glyceritum.		
G. Acidi Tannici.	Tannic acid, 20 gm.; Glycerin, 80 gm.	Astringent, 30 minims.
G. Amyli. (*Glycerite of Starch*).	Starch, 10 gm.; glycerin, 80 gm.; water, 10 c.c.	Emollient, base, and excipient.
G. Boroglycerini.	Boric acid, 310 gm.; glycerin, to make 1000 gm.	Antiseptic.
G. Ferri et quininæ et Strychninæ Phosphatum,	Soluble ferric phosphate, 80 gm.; quinin, 104 gm.; strychnin, 0.8 gm.; phosphoric acid, 200 c.c.; glycer., 500 c.c.; water to 1000 c.c.	For making syrup, etc., 15 minims.
G. Hydrastis.	Hydrastis, 1000 gm.; glycerin, 500 c.c.; alcohol and water, to make 1000 c.c.	30 minims.
G. Phenolis (Glycerite of Carbolic Acid).	Liquefied phenol, 20 c.c.; glycerin, 80 c.c.	5 minims.

GLYCERO-PHOSPHORIC ACID.—The acid and its salts have been used with benefit as tonics in neurasthenia, lithemia, phosphaturia, etc. Dose, of the acid, 1 to 5 minims; of the calcium, iron, lithium, magnesium, and manganese salts, 3 to 10 grains; of the sodium and potassium salts, 7 to 10 grains; of the quinin salt, 5 grains; of the strychnin salt, 1/60 to 1/20 of a grain.

GLYCOSURIA.—The occurrence of glucose in the urine.

Physiologic.—(1) During pregnancy and lactation; (2) often in infants under 2 months old, and in old age (70 to 80); (3) in persons who live upon starchy or saccharine food.

Pathologic.—(1) Diabetes mellitus; (2) exceptionally in diabetes insipidus; (3) organic and functional diseases of the liver; (4) diseases of brain (tumors around fourth ventricle, abscesses of brain, epilepsy, dementia); (5) la grippe; (6) chloroform narcosis. See Diabetes, Urine (Examination).

GLYCYRRHIZA (Licorice-root).—The root of *G. glabra*, a demulcent and mild laxative of sweet taste. In combination with other medicaments it is an excellent expectorant, and is much used as an excipient in pills, troches, etc. **G., Ext.,** the licorice of commerce, occurring in black rolls. Dose, 10 to 30 grains. **G., Ext., Purum,** made with ammonia water and water by percolation and evaporation. **G., Fluidextract,** prepared with glycerin, ammonia water and alcohol. Dose, 10 to 60 minims. **G., Mist., Comp.,** brown mixture, pure extract, acacia, each 3 parts, syrup 5, camphorated tincture of opium 12, wine of antimony 6, spirit of nitrous ether 3, water to 100 parts. Dose, 1 to 8 drams. **G. et Opii, Trochisci,** each contains extract of glycyrrhiza, 2 grains; powdered opium, 1/12 grain; acacia, sugar, oil of anise q. s. Dose, 1 to 2. **G., Pulv., Comp.,** compound licorice powder, composed of senna 18, glycyrrhiza 23, oil of fennel 4, washed sulphur 8, sugar 50. Dose, 1/2 to 2 drams. **G., Ammoniatum.** Dose, 1 to 6 grains.

GOITER.—See Thyroid Gland, Exophthalmic Goiter.

GOLD (Aurum).—Au = 196.7; quantivalence, 111. One of the metals characterized as "noble" by the ancients, because of its weight and luster. It has a brilliant yellow color, and will not tarnish. The metal is sometimes used as a plate on which artificial teeth are set. The chlorid locally is an escharotic. Internally its action resembles that of mercuric chlorid. In small doses it promotes digestion and stimulates the functions of the brain; in large doses it is a violent poison. It is useful in certain forms of dyspepsia, hypochondriasis, amenorrhea, and functional impotence. Poisoning is treated by egg-albumen or flour and by evacuation of the stomach. **A. et Sodii Chlor.,** soluble in water. Dose, 1/30 to 1/5 of a grain. Gold chlorid is also valued as a stain for sections of brain tissue and of nerve ganglia; it has been vaunted as a cure for the alcohol habit.

GOLDEN SEAL.—See Hydrastis.

GONORRHEA (Urethritis; Clap).

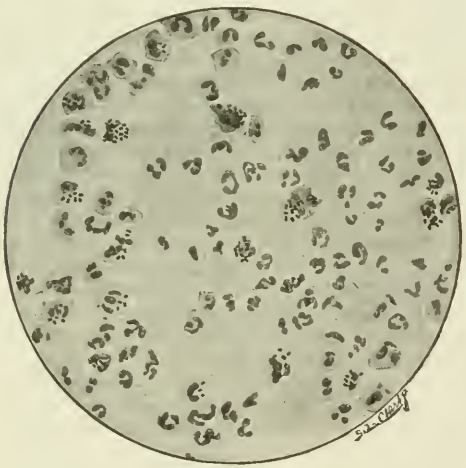
Definition.—Gonorrhea is a contagious, purulent inflammation affecting the mucous membrane of the genitals of both sexes. Some authorities claim that the disease may attack any of the mucous membranes, but this has not been demonstrated.

The male urethra is divided into anterior and posterior by the compressor urethræ muscle. The anterior section of the canal extends from the meatus to the compressor urethræ muscle, and is generally called the penile portion of the urethra. The posterior portion embraces the membranous and prostatic urethra. When the disease is confined to the portion of the urethra situated in front of the compressor urethræ muscle, it is denominated anterior urethritis; when the inflammation affects the membranous and prostatic portion of the canal, it is known as posterior urethritis. When the entire canal is affected by gonorrheal inflammation, the term anteroposterior urethritis is used. If the urethra and bladder are implicated, the disease is known as urethrocystitis.

Gonorrheal inflammation may be acute, subacute, or chronic; the acute stage may pass gradually into either of the other conditions. It is not unusual to meet with instances in which the disease has been subacute from the onset. When this condition pertains, the case, as a rule, follows essentially a chronic course, the discharge usually continuing for many weeks.

Etiology.—Urethritis may be either nonspecific or specific. The causes which give rise to **nonspecific urethritis** are injection of chemicals, traumatism, gout, rheumatism, syphilis, herpes, chancroids, tuberculosis, prolonged use of cathartics, employment of infected instruments, cohabitation during the menstrual discharge, or when discharges exist incident to a chronic inflammatory disease of the uterus or its appendages.

The nonspecific variety of urethritis is probably due to an infection by the staphylococcus or a small streptococcus, the gonococcus being absent. It may also be caused by the pneumococcus and the colon bacillus. Cases continually arise in which the urethritis is sufficiently severe to be called virulent, usually followed by complications involving the posterior urethra; these pursue a chronic course and are very difficult to cure. As a rule, nonspecific urethritis pursues a benign course, yielding readily to treatment; but this is not invariably the case.



Gonococcus.
Film from urethral pus.—(*Coplin.*)

Specific urethritis is a typical, virulent, inflammatory process, due to a specific microorganism known as the **gonococcus** of Neisser. This organism is of hemispheric shape and is found in pairs, the inner surfaces separated from each other by an interval. Sometimes groups of 4 are seen. The gonococcus is not motile, like other cocci, is not provided with flagella, and does not have spores. It stains readily with all the aqueous anilin dyes—best with rather weak solutions—but not by Gram's method. The gonococci are not easily killed, but withstand drying very well. See SUPPURATION.

Specific gonorrhea is produced by direct infection through the transference of gonorrheal pus from the genitals of one person to those of another during coitus. By mediate infection it takes place when instruments, syringes, towels, dressings, or hands that have been contaminated with gonorrheal pus are brought into contact with the meatus or urethral mucous membrane.

Symptoms of Acute Anterior Urethritis.—The period of incubation varies from 24 hours to 14 days. The disease usually makes its appearance from 3 to 4 days after contamination, the symptoms appearing within 24 hours after intercourse, especially if there is a history of previous attacks, in which case a latent chronic disease patch that has lain dormant in the urethra from some antecedent attack is brought into activity, and is not a fresh infection. An attack of gonorrhea does not render the patient immune from a fresh invasion of the disease. Reinfection can take place immediately on the patient's recovery from the malady. An attack of gonorrhea apparently leaves the patient in a condition of greater liability to recontract the disease; this is probably due to the lowering of the normal resisting power of the urethra to microbic invasion.

The symptoms vary with the progress of the disease, which is ordinarily divided into three stages: The *prodromal*, the *acute*, and the *stage of decline*.

The prodromal stage, as a rule, begins, especially in a first attack, with a tickling or an itching sensation in the vicinity of the fossa navicularis. The meatus is red, glazed, and often coated with a film of grayish, opaline mucus. At first the discharge is very scanty, gradually increasing in quantity, and at times causing the lips of the meatus to adhere to each other, or, on pressure, it may be expressed from the canal as a mucoid drop. Under the microscope the discharge is seen to be composed of flat epithelium, containing the gonococci; later there is an admixture of pus-cells. At this period the urine is clear, with a few flakes of gray infected epithelium floating about, sometimes resembling rice in appearance.

Acute Stage.—The redness and congestion about the meatus increase, frequently extending over the whole glans, producing edema of the prepuce, with phimosis, or, should the foreskin become retracted, paraphimosis. The inflammation may involve the body of the penis, giving rise to a condition known as penitis. The lymphatic vessels on the dorsum of the penis enlarge, and are frequently tender to the touch; in some instances the glands in the groin swell and are sensitive. The discharge becomes thick and purulent, the pus having a greenish hue; if the inflammatory symptoms are severe, it is not unusual for the secretion to be tinged with blood. When the inflammation extends to the submucous tissue, causing contraction of the caliber of the urethra, a burning, scalding pain is experienced whenever an attempt is made at urination, the stream being lessened and often twisted or forked. The symptoms are commonly reached by the end of the second or the beginning of the third week, when the disease

has extended as far as the bulbous portion of the urethra, resulting in a feeling of weight and pain in the testicles. Painful erections and chordee, with occasional nocturnal pollutions, are not uncommon at this stage of the disease, adding greatly to the discomfort of the patient. Hematuria, ordinarily occurring after urination, takes place in a small proportion of cases as a complication. The amount of blood lost is small; beyond giving rise to mental anxiety on the part of the individual, it is generally harmless. When the disease is at its height, a microscopic examination of the secretion will disclose an abundance of pus-cells, a large number of which will be filled with the gonococci. Both pus-cells and gonococci diminish in numbers as the disease declines, epithelia taking their place. Gradually the pus-cells decrease in number and the epithelia become more copious, until finally the pus-cells entirely disappear, the epithelia cease to proliferate, the discharge is arrested, the urine becomes clear, and a cure is effected.

The *two-glass urine test* is most valuable in differentiating acute anterior from acute posterior gonorrhea, and should always be employed. The patient should be instructed to void his urine into two glass vessels: that in the first glass will be cloudy and that in the second clear; this is due to the fact that the urine that first flows through the urethra washes the secretion out of the canal; while the urine that is discharged into the second glass passes through a cleansed canal, from which the morbid secretions have been washed away, and hence the urine in the second glass will be found clear.

Stage of Decline.—The inflammatory symptoms abate usually about the fourth week. The discharge becomes less copious, loses its greenish color, and becomes mucopurulent, slowly diminishing until only a slight drop of mucus can be detected, generally present in the morning, often gluing together the lips of the meatus. In favorable cases this condition may exist for a few days and gradually disappear; but owing to some indiscretion on the part of the patient, a relapse may, and frequently does, occur, producing an acute exacerbation, so that when the stage of decline is again reached, it may be prolonged until a chronic condition pertains.

The local complications of acute anterior urethritis are phimosis, paraphimosis, chordee, painful erections, penitis, lymphangitis, adenitis, balanitis, periurethral abscess, cowperitis, hemorrhage, and preputial folliculitis.

Symptoms of Acute Posterior Urethritis.—As a rule, when acute posterior urethritis sets in there is a very marked and sudden decrease, and in many instances entire disappearance, of the discharge, with an increased frequency of micturition, which may be slight in amount, requiring the patient to discharge the contents of his bladder at intervals of about every 2 hours; or there may be violent vesical tenesmus, making it necessary for the individual to attempt to void his urine every 10 or 15 minutes. This is attended by a great deal of pain. In some instances there is inability to retain the urine, which dribbles away continually. When the desire seizes the patient, the contents of the bladder must be evacuated at once. It is observed that the desire for urination is frequently produced by the sound of running water. As a rule, especially when there is great increase in frequency of urination, each act is followed by the emission of a few drops of blood; great pain is experienced in the glans penis, prostate, and rectum. Nocturnal pollutions are not uncommon; they are frequently stained with blood and are attended by great pain. Retention of urine may occur at any time if the inflammation of the prostatic portion of the canal is severe. Albumin in greater or less quantity is always present in the urine in this condition; it is due to spasm, and usually disappears after the administration of an anodyne.

In inflammation of the posterior urethra the pus passes backward into the bladder, so that when the patient urinates into the two beakers, both specimens will be cloudy; this is owing to the fact that the first portion of the urine contains the pus that was in the urethra, while the second glass contains the secretion that had passed back and settled at the base of the bladder. When the intervals between urination are very short, the second glass may be either clear or cloudy, as frequent micturition renders it impossible for the pus to accumulate in the posterior urethra and flow back into the bladder. If the test is made with the urine first voided in the morning after the individual has had a period of repose, it will be found that both specimens will be cloudy. An alternating clear and cloudy second glass always indicates posterior urethritis.

The intensity of an attack of posterior urethritis varies greatly in different individuals, being so slight in some instances as to give the patients but little discomfort, while in others the symptoms are very marked, and are attended by great suffering. The attack lasts from a few days to several weeks, sometimes ending in a chronic condition.

The local complications of posterior urethritis are prostatitis, seminal vesiculitis, inflammation of the cord, epididymitis, orchitis, cystitis, nephritis, pyelitis, abscess of the prostate, abscess of the kidney, and retention of urine. **The extragenital complications** are ophthalmia, arthritis, endocarditis, tendovaginitis, bursitis, myositis, achillodynia, phlebitis, and transverse myelitis. They may occur in either the anterior or the posterior form of the disease. The **sequels** are hypochondriasis, sexual neurasthenia, stricture, impotence, sterility, hyperesthesia, spermatorrhea, and melancholia.

Treatment of acute anterior urethritis may be divided into hygienic, local, and constitutional.

Hygienic Treatment.—Absolute cleanliness is essential. The clothing of the patient should be protected from the discharge by appropriate dressing. Frequent ablution with very hot water should be enjoined. Highly seasoned foods, condiments, salads, rich gravies, salt meat, cheese, salt fish, asparagus, and strawberries should be eschewed. Malt, spirituous, and vinous liquors

and carbonated waters should be prohibited. The digestion should be watched and the bowels kept regular. The patient should be warned of the danger incurred by the gonorrheal discharge reaching the eye, and instructed to be especially careful in cleaning his hands after handling the penis. During the acute stage absolute rest, as nearly as possible, must be prescribed; no exercise that has a tendency to congest the pelvic viscera should be allowed. It is well to direct the use of a properly fitting suspensory bandage.

Local Treatment.—**Abortive** treatment may be attempted, provided the individual is seen within 24 hours after the onset of the disease, and a microscopic examination shows that the discharge contains epithelium and gonococci only, *pus-cells being absent.*

There are several methods employed when attempting to abort gonorrhea. The most satisfactory method, after telling the patient to urinate, is to place him in a recumbent posture on a couch; a No. 12 (French) soft catheter, which has been thoroughly lubricated with glycerin, is then to be passed into the urethra, when the canal is to be irrigated with a hot solution of boric acid, after which the catheter is to be removed; a meatus endoscope is next inserted, whereby an application of a solution of nitrate of silver, not stronger than 15 grains to the ounce of water, is made by means of an applicator to the walls of the urethra as the endoscope is withdrawn. The patient should then be put to bed, receive soft diet, and cold sedative applications made to the penis. This treatment will be followed by an acute virulent discharge, with great pain in the urethra, blood being mixed at times with the secretion or following the last drops of urine. If the treatment is about to prove successful, the inflammatory symptoms subside within two days, when the discharge becomes mucopurulent in character and can be arrested by means of any of the astringent injections usually employed in the treatment of gonorrhea. If the abortive treatment is successful, the case is brought to the stage of decline in a few days.

Before resorting to this method of cutting short the disease, the consent of the individual should first be obtained. He must be made to understand that it frequently fails, when the pain and discomfort will be incurred without any benefit accruing; that it is not free from danger: periurethral abscess, posterior urethritis, prostatocystitis, and epididymitis have frequently been known to follow its use. Many authorities agree that this method of treatment is productive of stricture.

A method largely practised at the present time is one suggested by Prof. Jules Janet, of Paris. It consists in **irrigation of the urethra** with hot solutions of potassium permanganate, varying in strength from 1:4000 to 1:1000; the irrigation is to be employed twice daily by means of hydrostatic pressure, no instruments being inserted into the urethra. The advocates of this treatment claim that if the disease is taken in its incipiency, it will be aborted within the course of a few days, a cure being effected in about 18 days.

There is ground for doubt as to the results claimed by Prof. Janet and his followers. It is true that the stage of decline will commence within a short period; but, unfortunately, this is often prolonged for a great length of time before a cure is effected, which would not have occurred if the ordinary method of treatment had been followed. Irrigation of the urethra with solutions of potassium permanganate in the acute stage of the disease superinduces an inflammatory condition of the periurethral structures, accompanied by a congested irritable condition of the canal, attended by a most intractable watery discharge, mucoid in character, which often proves most rebellious to treatment. Relapse after the cessation of irrigations is quite common. The employment of irrigation in acute urethritis is not recommended.

Since the introduction of the organic silver salts the local treatment of acute urethritis has been more generally resorted to than it was a few years ago. It has been demonstrated that these preparations are destructive to the gonococcus and that they are only slightly irritating to the urethra. Many genito-urinary surgeons of large experience recommend them highly, and use them either in the form of injections or irrigations from the very beginning of the attack. Chief among these preparations are argonin, which is used in 1 to 2 percent solution; albargin, 0.1 to 0.2 percent; argyrol, 3 to 10 percent and protargol, 0.25 to 2 percent. A very efficient method is to employ one of these solutions alternately with weak permanganate of potassium solution or a 1 percent solution of thallin sulphate or resorcin as recommended by Casper, Christian and others.

The strength of the permanganate varies according to the degree of inflammation, namely from 1:8000 to 1:4000. In lieu of the organic silver salts, silver nitrate solution 1:10,000 to 1:4000 is sometimes employed after the first stage has subsided. At this time astringent injections may also be used, but they must be weak at first. Many surgeons do not use them until the third week of the disease. They replace one of the previously mentioned antiseptic or germicidal injections, and finally the second one is discontinued when the gonococci are no longer demonstrable in the discharge or the filaments contained in the urine.

The syringe should be of glass, with a conic end, tipped with rubber, or of hard rubber with a blunt point, capable of holding about 4 drams. Care should be taken to see that the piston works smoothly in the barrel of the cylinder. When making an injection, the patient should be instructed to first pass his urine, insert the nozzle of the syringe gently into the meatus, which should be held in contact with the nozzle of the syringe by means of the index-finger and thumb of the left hand; the solution is then slowly and gradually injected into the urethra until it produces a slight feeling of discomfort. If the injections does not give rise to severe pain, the patient should be instructed to retain the fluid from 3 to 5 minutes.

The following formulæ for astringent injections will be found beneficial:

℞. Lead acetate, ℥ ss
Zinc sulphate, gr. xvj
Tincture of opium, ℥ ss
Fluidextract of krameria, ℥ ss
Distilled water, q. s. ad ℥ vj.
Shake and use as an injection.

℞. Zinc acetate, } each, gr. xx
Tannic acid, }
Rose water to make ℥ iv.
Shake and use as an injection.

The injection should be employed until the discharge ceases and the urine becomes clear. It should be discontinued gradually; a syringeful of water is to be added to the contents of the bottle containing the injection every time that quantity of the injection is abstracted; so that the strength of the injection is rendered weaker as often as it is used, until the treatment is finally discontinued.

When the discharge has become mucoid in character and is present only in the morning, the urine being clear, containing only some threads of epithelium, irrigation with weak solution of potassium permanganate, nitrate of silver, or alum (of a strength of 1:500) will often complete the cure.

Attention is called to **Ballenger's treatment of incipient gonorrhea** by sealing argyrol in the anterior urethra with collodion, thus causing it to be retained in contact with the infected mucosa until the patient urinates. The prolonged action of a 4 or 5 percent solution of argyrol has a most satisfactory effect, and if the organisms have not extended more deeply than the part so medicated, the patient will be cured in 4 or 5 days. Little irritation is produced by the treatment, and the discharge often is not seen after the first treatment. If such remedial measure be employed it is of the utmost importance that it be applied within 24 to 48 hours of the appearance of the discharge. Failure to obtain a rapid cure is likely when coitus has occurred during the incubation period of a previous infection. During the past 5 years Ballenger has cured more than 700 cases, with an average of 5 days or less for each patient. A careful study of Ballenger's technic is advised: The patient empties his bladder and reclines upon an operating table; the penis is well cleansed and surrounded with a clean towel; a small blunt-pointed urethral syringe, so gauged that exactly 25 minims may be injected, is now used to place this amount of a 5 percent solution of argyrol in the canal. The meatus is pressed from side to side as the syringe is removed and the towel is then used to dry well the glans penis. The lips of the meatus are pressed closely and smoothly together and are lightly brushed twice with collodion on a camel's-hair brush. The collodion may be made to dry more rapidly by fanning, and it is of great importance to hold the argyrol solution back until the collodion has thoroughly dried and feels firm to the touch. The collodion may be removed by applying a pledget of cotton wet with acetone which readily dissolves it. The meatus should be compressed by the patient at the time that he applies the acetone (to prevent the soiling of his linen with the argyrol). After the collodion has been removed the patient should drink at least a half gallon of lithia water before he retires so as to flush well the canal and overcome the slight chemical and mechanical irritation produced by the solution of argyrol. He should also be instructed to take very little of water and liquid food on the following morning in order that the next treatment be not interfered with by a free flow of urine. He should also report early for treatment so that it may be repeated later in case the sealing should not hold satisfactorily. It is better not to bind up the penis in cotton to protect the clothing, as it may prevent his detecting it when the medicine escapes in case the collodion breaks, and thus he may lose valuable time. The solution of argyrol should be freshly prepared each day, as a stale solution is less potent and is more irritating.

Internal Treatment.—Many authorities prefer to employ sedatives at the outset of the disease, combined with such remedies as may render the urine alkaline, leaving those that have a tendency to relieve the blennorrhea until the inflammatory stage is on the decline.

The employment of the balsamic remedies from the outset is the method of treatment commended. Blennorrhagic medicines should not be continued for a long period. When the discharge is very slight, mucoid in character, and the urine clear, containing but a few threads, internal treatment should be suspended and the cure completed by local measures. Various drugs are in vogue, each having its advocates. Those in general use are cubebs, copaiba, sandalwood, methylene-blue, salol, alum, matico, and turpentine; with the exception of turpentine they are best administered in capsules, and may be given either separately or combined. Turpentine is usually given in emulsion or by being dropped on lump sugar; it is often efficacious, but its employment is frequently followed by unpleasant symptoms, and it has a tendency to derange the digestive organs; it is not much resorted to at the present time. Methylene-blue is of great value at the beginning when the microscope has demonstrated the presence of gonococci. It will not abort the disease, but will cause prompt disappearance of gonococci, tend to shorten the inflammatory period, and hasten the stage of decline and lessen the tendency to complications. When prescribed, the patient should be informed that the remedy will tinge the urine of a deep blue color, and thus avoid unnecessary apprehension.

The following formulæ are most commonly employed:

℞. Salol, ℥ ij
Oleoresin of cubebs, ℥ j
Balsam of copaiba, ℥ ij
Pepsin, gr. xij.
Make 12 capsules; take 1 capsule 3 times daily.

℞. Oleoresin of cubebs, gr. ij
Oleoresin of copaiba, gr. iij
Oleoresin of matico, gr. j
Oil of sandalwood, } each, gr. ij
Salol, }
Taka-diastase, gr. j.
Make 1 capsule; one 3 times daily.

℞. Methylene-blue, gr. xx.
Make 20 pills; take one 3 times daily.

℞. Salol, ʒ j
Oil of sandalwood, ʒ ij.
Make 12 capsules; one 3 times daily.

℞. Methylene-blue, }
Oil of sandalwood, } each, gr. iij
Oleoresin of copaiba, }
Oil of cinnamon, gt. j.
Make 1 capsule.

℞. Balsam of copaiba, ʒ j
Liquor potassæ, ʒ ij
Extract of glycyrrhiza, ʒ ss
Spirit of nitrous ether, ʒ j
Syrup of acacia, ʒ vj
Oil of gaultheria, gtt. xvj.
From 1 to 2 teaspoonfuls as a dose 3 times a day.

Treatment of Acute Posterior Urethritis.—If the symptoms are severe, the patient should be placed in a recumbent posture, a light diet should be ordered, the bowels should be kept free, and either a hypodermic injection of 1/3 of a grain of morphin or a suppository containing opium and belladonna administered. Great relief will be found to follow the administration of a capsule containing cubebs, copaiba, and salol before meals, with a tablespoonful of the following mixture after meals:

℞. Tincture of belladonna, ʒ ss
Sodium bromid, ʒ iv
Liquor potassæ, ʒ ij
Syrup of ginger, ʒ iij
Water, q. s. ʒ vj.
Tablespoonful in water after meals.

A suppository may be used, if preferred, composed of:

℞. Extract of belladonna, gr. iij
Pulverized opium, gr. xij
Ichthyol, ʒ j
Oil of theobroma, q. s.
Make 12 suppositories; 1 to be used daily.

Should the individual suffer from violent tenesmus, benefit will often result from the instillation by means of the Keyes-Ultzman syringe, of a few drops of silver nitrate solution, not stronger than 1:1000 or 1:500. All injections and irrigations should be discontinued during the acute stage of the disease. Retention of urine must be treated in accordance with the recognized methods pursued in such cases.

Alkaline mineral waters and lemonade may be allowed; but an alkaline condition of the urine must be guarded against, as it is likely to be productive of cystitis.

Chronic Anteroposterior Urethritis.—This condition, commonly known as **gleet**, is due to the fixation of the malady at one or more points in the urethra. The favorite sites at which the disease becomes established are the fossa navicularis, bulb, prostatic urethra, glands of Littré, and crypts of Morgagni.

Examination of the urethra by means of the endoscope will reveal one or more of the following conditions: Chronic congested patches, usually in the vicinity of the bulb; granular patches, which may be found in any portion of the canal, but more commonly in the neighborhood of the meatus; erosions and ulcerations, the former usually occurring in the deep urethra and the latter in the vicinity of the meatus; nacreous patches, looking as if the urethra had been touched with nitrate of silver, generally situated in the vicinity of the bulbous portion of the canal (they are always connected with cell infiltration in the submucous structure, and are the forerunners of the formation of strictures); edematous folds, which occur either immediately inside of the meatus or at the junction of the bulbous and membranous portions of the urethra.

In about 50 percent of cases of chronic urethritis, stricture will be found to be the cause of their production. When the glands of Littré, on the floor of the urethra, are involved, they can readily be detected by passing a steel bougie into the canal and running the finger along the under surface of the urethra, when a number of small nodules about the size of a pin's head can be distinctly felt. By means of the endoscope the mouths of the ducts of these glands, when inflamed, can be plainly seen on the floor and roof of the urethra, presenting the appearance of tiny red spots, which are adherent to small tenacious plugs of mucus.

Symptoms of Chronic Anterior Urethritis.—In most instances there are no symptoms apparent beyond a mucopurulent or mucoid discharge, usually showing itself in the morning when the patient awakens, frequently gluing together the lips of the meatus. In some cases the urethra is unusually moist, with a slight watery discharge, the urine containing a few threads of epithelium, called *Tripperfaden*, or clap-threads. Should these threads be heavy and sink to the bottom of the glass, it is probable that they contain either pus-cells or gonococci, or both; they are formed at the site of the location of the chronic lesion in the urethra, and are made up of pus and epithelium held together by fibrin or mucus. Their peculiar thread-like shape is caused by the impinging of the urine against the edges of the moist scales, rolling them up into the characteristic shape. As the patient advances toward recovery the pus-cells disappear, the thread consisting of epithelium only. When the cure is finally effected, the epithelia likewise disappear, the urine becoming clear and transparent.

Symptoms of Chronic Posterior Urethritis.—There is an increased frequency of micturition,

with a feeling of discomfort either with the beginning or termination of the act, accompanied by a feeling of weight and pain in the perineum, often extending to the testicles. Nocturnal pollutions are common; occasionally the semen is tinged with blood, the ejaculations frequently being painful. As a rule, there is little or no discharge seen at the meatus. The severity of these symptoms is increased by alcoholic stimulation or sexual indulgence. Atonic impotence is not uncommon if the disease is persistent for any length of time, the patients frequently developing neurasthenia.

Treatment of Chronic Anterior Urethritis.—Primarily, the cause and position of the chronic lesion that has given rise to the discharge should be ascertained. If, on examination, the urine is found to be cloudy and full of threads, capsules containing the oil of sandalwood and salol will be found serviceable, together with a daily irrigation with a solution of 1:2000 potassium permanganate, or silver nitrate, beginning with a strength of 1:1000 and gradually reducing it to the strength of 1:7000. If congested patches exist, an irrigation with a hot solution of alum, 1:500, will often prove beneficial. An injection highly recommended at this stage of the disease consists of:

℞.	Mercuric chlorid,	gr. $\frac{1}{8}$
	Zinc phenolsulphonate,	ʒ ss
	Boric acid,	ʒ ij
	Carbolic acid,	gr. xv
	Boroglycerid (25 percent),	ʒ ij
	Water,	℥ vj.

Dilute if painful.

Should superficial ulcerations or erosions exist, the employment of the following powder by means of the urethral applicator will prove of great benefit:

℞.	Hydrastinin hydrochlorid,	gr. vj
	Bismuth subgallate, Boric acid, each,	ʒ ss.
℞.	Zinc stearate,	ʒ iij
	Boric acid,	℥ ij.

When the urine is clear, containing but a few threads, a mucoid drop alone being present in the morning, it becomes necessary to employ the steel bougie, which may be medicated with a salve composed of:

℞.	Iodin,		gr. v
	Olive oil,		ʒ j
	Potassium iodid,		ʒ ss
	Lanolin,	q. s.	ʒ j.

Or:

℞.	Silver nitrate,		gr. v
	Lanolin, Olive oil,	each,	ʒ ss.

When beginning this method of treatment, a small-sized bougie should be first employed and the instruments gradually increased in dimension until pain or slight hemorrhage, which is likely to follow their use, presents itself. This method is to be pursued until a full-sized instrument is reached. Blue ointment will frequently be found to be very serviceable.

Treatment of Chronic Posterior Urethritis.—In the more acute stages of the inflammation instillation is not to be repeated more frequently than every third day; it should be made with a silver nitrate solution, beginning with a strength of 1:8000 and gradually increasing until 1:500 is reached. When the desire for frequent urination begins to disappear, and the urine becomes less cloudy, a Jacques catheter (No. 18 F.) should be passed as far as the membranous urethra, and the bladder injected with a hot solution of potassium permanganate 1:2000, or of silver nitrate 1:10,000; the instrument should then be removed and the patient instructed to empty his bladder in the usual manner, thus flushing the entire canal with the medicament.

In congested and irritable conditions of the prostatic urethra, associated with pain and discomfort, with little or no frequency in passing urine, the urine being clear except for a few threads, benefit will be derived from the employment either of a bougie or the cooling sound.

Should the urine contain much pus, the desire to urinate being frequent, any of the antiblennorrhagic remedies may be employed. Often relief will be experienced from the administration of a capsule containing $\frac{1}{4}$ of a grain of codein sulphate combined with 5 grains of salol.

The following formula will be found serviceable:

℞.	Liquor potassæ,		ʒ v
	Tincture of nux vomica,		ʒ ij
	Fluidextract of pichi,		℥ ij
	Mixture of calisaya,	q. s.	ʒ iv.

A tablespoonful in hot water every 4 hours.

Or:

℞.	Fluidextract of pichi,	℥ ij
	Fluidextract hyoscyamus,	ʒ ij
	Syrup of ginger,	℥ ij.

A teaspoonful before each meal and at bedtime.

When the urine is alkaline and very cloudy, a combination that is frequently beneficial is:

℞.	Ammonium benzoate,		ʒ iij
	Fluidextract of cubebs, Tincture of eucalyptus,	each,	ʒ ij
	Fluidextract of glycyrrhiza,		℥ j
	Water, to make		℥ vj.

A tablespoonful in water after meals.

When the irritability of the bladder disappears to a great extent, the urine becoming clear, containing *Tripperfaden* alone, the balsamic remedies should be discontinued and a strong tonic administered.

When neurasthenia is impending, great benefit will be derived from Fowler's solution administered in water 3 times daily after meals. Patients should abstain from active exercise, alcoholic stimulation, and sexual excitement. The diet should be plain and nutritious; condiments and highly seasoned foods should be eschewed.

Vaccine Therapy.—"There is a considerable dif-

ference of opinion as regards the efficacy of *vaccines* in the treatment of acute and chronic urethritis of gonorrheal origin. A polyvalent stock vaccine of gonococci of proved immunizing powers may be even more efficient than an autogenous one, especially if the latter must be prepared from a strain that has been repeatedly subcultured in order to obtain the vaccine in a pure state, or from one that has lost its virulence from long residence in the infected urethra. Owing, therefore, to the difficulty of isolating and cultivating gonococci, stock vaccines have been generally employed. In subacute urethritis the initial dose may be 25,000,000; if complications threaten, less than this, and if no local reaction has followed more than this is given, the object being to secure a slight increase of the secretion, which should become more purulent, and a little constitutional disturbance, followed by lessening of local pain and tenderness" (Kolmer).

For **treatment of the complications** of gonorrhea see the various headings, BALANITIS, CHORDEE, CONJUNCTIVITIS, TESTICLE, URETHRA (Stricture), PENIS, etc.

For **gonorrhea in the female**, see VAGINITIS.

GONORRHEAL ARTHRITIS.—See JOINTS (Diseases).

GONORRHEAL CONJUNCTIVITIS.—See CONJUNCTIVITIS.

GOSSYPIUM PURIFICATUM (Purified Cotton).—Cotton. The hairs of the seed of *G. herbaceum*. Freed from impurities and deprived of fatty matter, it becomes the absorbent cotton of surgery. It is soluble in an ammoniacal solution of cupric oxid. The root is believed to possess emmenagog properties.

Preparation.—**G. Cortex.** Dose, 10 to 60 grains. **Oleum G. Seminis**, the fixed oil expressed from the seeds and purified. Is yellow, odorless, of bland taste and neutral reaction, soluble in ether, but slightly soluble in alcohol. Is introduced into the Pharmacopœia for the reason that it constitutes most of the "Olive Oil" sold in foreign-shaped bottles and under foreign-appearing labels. It is used in the official liniments of ammonia and camphor. Dose, 1 to 8 drams. **Pyroxylinum**, *Soluble Guncotton, Colloxylin*)—is official for the purpose of making collodium. It is prepared by macerating cotton in a mixture of sulphuric and nitric acids, washing, draining and drying. **Collodium**, made by dissolving pyroxylin 4, in ether 75 and alcohol 25. **Collodium Flexile**, collodion 92, canada turpentine 5, castor oil 3, mixed thoroughly. **Collodium Stypticum**, ether 25, alcohol 5, tannic acid 20, collodion to 100. **Collodium Cantharidatum** (*Blistering Collodion*), cantharides 60, flexible collodion 85, chloroform, q. s. to 100. See COTTON.

GOUT (Podagra). Definition.—A constitutional disease characterized by an excess of uric acid or alkaline urates, especially sodium urate, in the fluids of the body. Sodium urate is first deposited about the articular surfaces of the small joints, but in time the arteries, cardiac valves, and connective tissue of the kidneys may be involved. The metatarso-phalangeal joint of the great toe is, curiously, the favorite point of attack, and the helix of the ear is another favorite seat. Tophi form about the affected part. To diminished solubility of the urates, due to increased acidity of the blood; to increased formation of uric acid and failure in function of the kidneys; to persistent plethora of the digestive organs, is variously ascribed the cause of gout.

Varieties.—(1) Acute; (2) chronic; (3) irregular gout.

Etiology.—Heredity, male sex, middle or advanced life, excessive indulgence in wines or malt liquors, rich foods, and inactive life are the principal causes of gout.

Pathology.—An excess of uric acid is found in the blood, and around the fibrous structures of the small joints, especially the great toe, there occurs a deposition of sodium urate. The ankles, knees, and joints may be affected later in the progress of the disease. The deposit of urates may affect the fibrous structures or the cartilages, and may be seen in small opaque areas forming "chalk stones" (tophi), or the deposit may be distributed uniformly throughout the joint, causing immobility of the parts. Often in the matrix and cell capsule of the cartilages may be seen the needle-shaped crystals of sodium urate. The kidneys often show evidences of interstitial nephritis, the pyramids containing urates.

Symptoms and Clinical Course.—The onset may arise after attacks of inactivity of the liver or of indigestion, and is ushered in with sharp pains shooting through the joints, should an attempt be made to flex them. The patient suffers such agony that the temper becomes irritable, made so by the pain and discomfort set up by the inflammatory process. These symptoms seem to be worse in the early morning hours, and there is no position that would seem to be the most comfortable. The affected parts soon become reddened, swollen, edematous, and excessively tender to the touch. Toward the afternoon the symptoms may gradually improve, but recur the following morning. The temperature gradually rises to 101° to 103° F., and the pulse is increased in proportion.

The urine contains an excess of the "cayenne-pepper" crystals of uric acid and urates. The cuticle over the affected areas generally desquamates. These symptoms gradually improve, the inflammation subsides, with less tenderness on pressure, the joints grow more supple, the cuticle desquamates, the uric acid disappears from the urine, and convalescence ensues. Should the disease persist, the joints become filled with the chalky deposits; and the concretions become so excessive that the joints are deformed with immobility, this constitutes **chronic gout.** Irregular gout is more allied to LITHEMIA (*q. v.*).

Diagnosis.—Gout is sometimes mistaken for rheumatism:

GOUT.	RHEUMATISM.
1. Chiefly affects small joints, as of foot.	1. Affects larger joints as knee, elbow, shoulder.
2. More pain, redness, and edema.	2. Parts swollen but less painful.

Gout.	Rheumatism.
3. Moderate fever, 101° to 102°.	3. High fever, 104°.
4. Sweats not profuse.	4. Profuse sweats, acid in reaction.
5. Pain more periodic.	5. Pain continuous.
6. Cuticle desquamates.	6. Cuticle usually intact.
7. Often recurs at regular intervals.	7. Time of recurrence indefinite.

See Garrod's Thread Test.

Prognosis.—In the acute form the prognosis is good. The chronic form often gives rise to nephritis and to deformity of the joints affected.

Prophylactic Treatment.—The logical treatment is to remove those causes that bring on the attacks. The hereditary tendency may be strong, yet if alcoholic and malt liquors are omitted, the attacks will usually be neither so protracted nor so liable to return. Gout is a disease in which the emunctories of the body are inactive; therefore treatment should be eliminative, by stimulating the skin, the kidneys and the bowels. The stomach should never be overloaded with indigestible food.

Treatment of the Acute Attack.—*Colchicum* has long been recognized as a specific, to abort a paroxysm or to lessen severity of the symptoms when the attack has developed; ʒj of the wine often removes the severest pain in an hour or two, and soon the swelling and heat subside; it is especially useful in acute and rheumatic gout. *Colchicine Salicylate* is highly efficient in chronic gout.

Elimination is distinctly indicated, as may be learned by the etiology and pathology. If neglected, the irritants in the blood may cause such inflammation of the kidneys as to give rise to serious disease of these organs. Diuretics are therefore valuable. The stomach and bowels should be unloaded of all material, as far as possible, so as to restore the inactivity of the liver, and the following be given:

℞. Mild mercuric chlorid, gr. ij
Sodium bicarbonate, gr. xx.
Divide into 6 powders. One powder every hour and a half.

Should the bowels not move by the following morning, a half ounce of Rochelle or Epsom salts may be given.

Saline diuretics are beneficial, and should be used early:

℞. Lithium citrate, ʒ jss
Potassium citrate, ʒ j
Aromatic elixir, ʒ iij
Water, q. s.
Two teaspoonfuls every 3 or 4 hours.

Or:

℞. Lithium citrate, ʒ jss
Wine of colchicum seed, ʒ ijss
Simple elixir, ʒ iij
Water, q. s. ad ʒ iij.
Two teaspoonfuls every 3 or 4 hours.

℞. Lithium citrate, ʒ jss
Wine of colchicum seed, ʒ ijss
Sweet spirit of niter, ʒ jv
Elixir of curacoa, ʒ iij
Water enough to make ʒ iij.
Two teaspoonfuls every 3 or 4 hours.

The most recent "remedy" is atophan (phenyequinolin-carboxylic acid). It is said to lessen the pain in the acute attack, and to increase the amount of uric acid which is excreted. See Atophan.

Local Treatment.—The parts must be placed at absolute rest, and should be on the same level with the body. Local applications are very soothing and often mitigate the inflammatory process. Probably for this purpose there is nothing better than lead-water and laudanum.

℞. Tincture of opium, ʒ iv
Solution of lead subacetate, ʒ iijss.
One teaspoonful to a pint of water, and keep constantly applied on flannel.

For the first few days this application may be made almost constantly while the patient is in bed. The whole foot may be enveloped in flannel and kept moist with lead-water and laudanum. Afterward the parts may be enveloped in lamb's-wool and a light bandage. A mixture of equal parts of ichthyol and vaselin may be rubbed over the inflamed area to keep the skin in a lax condition.

The Diet.—Futcher states that "the regulation of the food is undoubtedly the most important factor in the treatment. Meat is the article supposed to possess the most baneful influence, and over which there has been the most discussion. The red meats have for a long time been considered much more injurious than the white meats and fish. But there is very little difference between the two so far as the purin content is concerned. The protein foods considered particularly injurious, are those rich in cell nuclei and, consequently, containing an abundance of purin bodies. These comprise the thymus, pancreas, liver, kidney, and brain. The meat extracts are to be avoided, owing to their richness in nitrogenous extractives and salt. Fresh fish may be permitted in moderation. Salt fish should be avoided. Fish roe and caviar should be forbidden, owing to their richness in nuclein, although in the latter it is in the form of paranuclein. Eggs constitute the most valuable protein food for gout patients, in that they are free from purin bodies. Milk, for the same reason, is also most useful. Starchy foods may be freely allowed. An exclusive starch and vegetable diet has its advocates still, but their number is gradually diminishing. Bread, rice, potatoes and other garden vegetables, may form a liberal portion of the dietary. Cucumbers and tomatoes had better be avoided. Until recent years the prevailing belief has been that fruits were harmful. The best opinion at the present day favors the free use of fruits. The experience in any individual case is the best teacher in this regard, for certain fruits, such as bananas and strawberries, particularly the latter, may excite joint pains, and cause pharyngeal

symptoms. Fats, in the form of butter particularly, may be allowed with freedom; and butter in large quantities was advocated by Ebstein. All highly seasoned foods should be forbidden. Pepper, paprika, and mustard should not be permitted in dressings. Their only injurious effect is through impairment of the digestive functions. The majority of gout patients are better off without any alcoholic beverages. The general advice is that tea and coffee should be eliminated from the diet owing to the methylxanthins they contain. The gout patient should be induced to drink freely of water, particularly on an empty stomach early in the morning and before the various meals."

Treatment of Chronic and Irregular Gout.—The diet should be corrected; and alcoholic drinks, tea, coffee, and tobacco interdicted. The condition of the skin should be active, and hot baths 2 or 3 times a week may be advised. It is perhaps best to have the baths given in the middle of the day, followed by thorough massage.

Bier's Method in Gout.—Marked benefit has been derived from the induction of passive hyperemia both in acute and chronic gout, the pain being relieved almost immediately.

GRAFTING.—See Plastic Surgery.

GRANATUM.—Pomegranate. The bark of the stem and root of *Punica granatum* contains a mixture of alkaloids, *pelletierin*, one of the most efficient anthelmintics against tape-worm, rarely failing to bring away the whole worm. **Fluidextractum G.** Dose, 10 to 60 minims.

Pelletierinæ Tannas is a mixture of the tannates of four alkaloids (punicin, iso-punicin, methyl-punicin, and pseudo-punicin), obtained from *Punica granatum.* Dose, 3 to 8 grains, in powder, taken fasting and followed after 20 minutes by a full dose of castor oil.

GRANULAR LIDS.—See Trachoma.

GRANULOMA.—A term used by Virchow to include a neoplasm that does not advance beyond the stage of granulation tissue. See Tumors.

GRAVEL.—See Bladder (Stone), Kidney, Cystitis, Urine, etc.

GRAVES' DISEASE.—See Exophthalmic Goiter.

GRINDELIA.—The leaves and flowering tops of *G. robusta*, or *G. squarrosa*, wild sunflower, or gum-plant, found in California; an antispasmodic and motor depressant, in large doses producing mydriasis. It is valuable in asthma, bronchitis, and whooping cough. Dose of the fluidextract, 10 minims to 1 dram; of the alcoholic extract, 3 grains. Locally, it is used with advantage as a lotion for the dressing of burns and blisters, in vaginitis and uterine catarrh, and to allay the pain of herpes zoster. In the proportion of 1 part of the fluidextract to 9 of water, as a sedative lotion, it is a very efficient application for the cutaneous irritation due to poison-oak or ivy, also in skin diseases attended with itching and burning sensations.

GRIP.—See Influenza.

GRIPE.—See Colic.

GROWING PAINS.—A term applied to neuralgic or rheumatic pains in the limbs occurring during youth, and apparently of varied origin and character. The condition is sometimes known as "growing fever," and occurs usually in children from 7 to 15 years of age. It is characterized by pain in the regions of the epiphyseal lines, rapid growth, and sometimes fever, with considerable constitutional disturbance. The symptoms usually pass off without any bad results, although osteomyelitis is sometimes set up, and exostoses are developed along the epiphyseal lines.

GRUTUM.—See Milium.

GUAIAC (Guaiacum).—The resin of the wood of *Guaiacum officinale.* It is diaphoretic, expectorant and alterative; also laxative and purgative, according to the dose administered. Its taste is acrid and very disagreeable. Internally it is a local stimulant, producing salivation, an acrid sensation in the throat, warmth in the epigastrium, increase of the gastric and intestinal secretions and the flow of bile, and reflex stimulation of the heart. Its continued use causes gastric catarrh, and in large doses it is a gastrointestinal irritant, causing vomiting, purging and severe congestive headache. It has considerable reputatation in tonsillitis, neuralgic dysmenorrhea, amenorrhea, chronic rheumatism, gout, lumbago and sciatica. The ammoniated tincture in water makes a cleanly and not very disagreeable gargle. The reputation of guaiac in many chronic and obscure complaints is due, partly to its purgative property and partly to its nastiness, a quality which is highly appreciated by many patients.

Tinctura G.—20 percent. Dose, 30 to 90 minims, in mucilage or syrups, as the resin is precipitated by water. **Tinctura G. Ammoniata,** has of guaiac 20, aromatic spirit of ammonia to 100. Dose, 10 to 60 minims.

GUAIACOL.—One of the chief constituents of creosote, is prepared synthetically from catechol. It occurs as a colorless solid or liquid, of agreeable and aromatic odor, soluble in alcohol, ether, acetic acid and glycerin. Dose, 5 to 15 minims in capsule, pill, or whisky.

G. Carbonas (Duotal),—occurs as an almost tasteless and odorless, white, crystalline powder insoluble in water. Dose, 5 to 20 grains or more, gradually increased to a maximum of 90 grains per day. It is said to be a powerful local anesthetic.

Guaiacol, applied to the skin, appears in the urine 15 minutes after. In the treatment of phthisis, fetid bronchitis, or bronchiectasis, while diminishing the cough, perspiration, and fever, guaiacol rarely effects a cure. It is often better borne by the stomach than creosote. The drug may also be given by inhalation or subcutaneously. In the form of **guaiacol carbonate** (Duotal) it is still more acceptable.

℞. Guaiacol, ℥ j
Glycerin, ℥ ss
Spirit of orange, q. s. ℥ iij.
A teaspoonful to a dessertspoonful in water after meals.

Guaiacol Salve.—Salicylate of guaiacol. It has the same actions as its constituents. Dose, 15

grains. Inunctions are highly extolled, especially for children, in pulmonary tuberculosis and tuberculous glands and nontuberculous glandular enlargement.

GUARANA.—A dried paste consisting chiefly of the crushed seeds of *Paullinia cupana*. It occurs in brown cakes or sticks, having an odor of chocolate, and a bitter, astringent taste: partly soluble in water and in alcohol. It contains caffein and theobromin, also tannic acid, gum, albumin, starch, and a fixed oil. The specimens found in commerce are untrustworthy, unequal in quality and expensive (Squibb). Dose, 15 to 45 grains. **Fluidextractum G.**, made with diluted alcohol. Dose, 15 to 45 minims. Guarana is chiefly employed in the treatment of nervous sick-headache (migraine) administered in half-dram doses of the fluidextract when the attack is developing. It has been used in the diarrhea of phthisis, in convalescence from acute diseases, and generally in conditions requiring tonic treatment.

GUINEA-WORM DISEASE (Dracontiasis, Dranunculosis, Medina Worm Disease).—Infection with the *filaria* or *dranunculus medinensis*, the Guinea-worm, a parasite common in tropical and subtropical Asia and Africa. It has reached South America. It is believed to enter man free or enclosed in certain minute arthropods (cyclops) through drinking of infected water. It is suggested that probably a male and female larva enter the host, the male dying later and being absorbed while the female continues to develop. The adult worm is about 30 inches long and 1/10 of an inch thick. Whether the embryo enters ordinarily through drinking water; or through the bites of mosquitoes, flies, or other insects; or whether it penetrates the skin is a moot question. The fact that its usual habitat is the subcutaneous tissue of the lower extremities lends support to the transdermal theory. Usually but one worm is found in one host, though frequently the infection is multiple. Maturation of the embryo requires about a year. Locomotion may be impossible.

The symptoms are inflammatory, localized at the place where the matured worm attempts to reach the surface of the body in order to discharge her embryos and leave the host. If the worm be broken during its exit, suppuration and symptoms of sepsis may appear. After removal of the worm, symptoms vanish.

Prophylaxis consists in boiling all water used in preparing food or for drinking, refraining from bathing in infected water, and the wearing of shoes.

Treatment is directed to the safe extraction of the worm and antiseptic dressing of the lesion. The natives generally moisten the ulcerated surface, and when the head projects fasten it round a stick which is gradually twisted from day to day until the entire worm is extruded. Surgeons now inject with a hypodermic needle into the head of the worm or into the adjacent tissue a solution of mercury bichlorid. This kills the worm and its embryos and the dead worm is readily removed the next day.

GUM-BOIL.—An inflammation about the apex of a tooth-root, usually developing into an abscess, inclosed in a sac a little distance from the end of the root. There is always some inflammation of the neighboring periosteum or bone. Pus often evacuates through the pulp-canals or eats through the alveolar plate, and appears on the surface of the gum. The cause is usually the escape of the products of decomposition of the pulp. The pain is proportionate to the degree of confinement of the inflammatory products.

The tooth should be opened freely and syringed out, so as to enable the pus to escape. The gum should be lanced freely, to allay inflammation; and healing ensues most rapidly when there are exits through the gum as well as through the root-canals. Creosote or other powerful antiseptic may be pumped through the tooth. The root-canals and the cavity of decay should be solidly filled after the inflammation has passed off, or the abscess will recur. Left to itself, relief is afforded in time by the escape of the pus, but a permanent fistula results, and the tooth eventually loosens. When the roots reach beyond the reflection of the mucous membrane of the gum, the abscess may burst on the cheek. When this threatens, a free opening through the tooth and support of the cheek by collodion should be attempted. A poultice should never be applied externally. Tincture of iodin may be used to paint the gums. Tincture of aconite may be mixed with the iodin, or used alone, when the inflammation is slight.

GUMMA.—A soft, elastic tumor resulting from a peculiar kind of caseation of tertiary syphilitic inflammatory deposits. See SYPHILIS.

GUMS, AFFECTIONS.—The chief ailments of the gums are gingivitis or acute inflammation, sponginess, tendency to bleed, tumors, and the associated conditions of mercurialization and plumbism.

Gingivitis is very common in teething infants, and is discussed under DENTITION (*q. v.*).

A spongy condition of the gums is seen in those who neglect the care of the teeth, or who are in feeble health, or under such constitutional drains as lactation. The excessive administration of mercury causes a well-defined red line along the margin of the gum before sponginess appears, while a blue line along the gums just below the teeth results from plumbism. In true scurvy the gums are swollen and livid from submucous extravasations of blood, and bleeding occurs from the slightest touch. In advanced cases the gums are black and extremely offensive. Bleeding from healthy gums is a common symptom of the hemorrhagic diathesis.

The tumors of the gums are epulis, papilloma, epithelioma, and polypus myeloid growths. Hypertrophy of the gums and a nevoid condition may occur as a congenital affection. A vascular, noncongenital tumor of the gums may originate from irritation of the teeth, especially in the region of the incisors. It may be treated with caustics, but if large, it should be removed, and the surface from which it grows touched with the actual cautery.

Treatment.—When a spongy condition of the gums exists, the general health must be improved,

and the tooth-brush used carefully with some astringent mouth-wash. In scurvy the most severe cases yield to the administration of vegetables and fresh fruit. Lime-juice is useful. Bleeding from the gums may be checked by pressure or astringent washes or by the administration of various preparations of iron and the mineral acids. Nothing less than cutting away the portion of the alveolus from which it springs or inducing its exfoliation by the application of the actual cautery can be relied on for the cure of epulis. A tooth on each side must usually be sacrificed for this, and the whole growth occasionally comes away in the removal of the teeth. Tumors are usually completely removed. For ulceration of the gums, 20 grains of silver nitrate in solution may be applied upon a swab, followed by an antiseptic and astringent mouth-wash.

In the treatment of polypus of the gums the removal of the tartar or decayed teeth and the use of astringent washes is sufficient for most cases; or the growth may be snipped off with scissors, or, if sessile, cut off and cauterized with the Paquelin cautery. Vascular outgrowths may be treated with caustics when small, but when large, they should be removed and the surface touched with the actual cautery. The only successful treatment for epithelioma of the gums is removal of the whole thickness of the jaw well beyond the disease, and excision of glands in the neighborhood and in the neck connecting with the site of the disease.

Tincture of myrrh, 2 to 4 drams, in 4 ounces of water, or the infusion of cinchona, is highly serviceable as a gargle or mouth-wash for spongy and ulcerated gums; alum is also useful. A piece of catechu, dissolved slowly in the mouth, is often of service in similar conditions. In teething, 2 grains of potassium chlorate may be given every 4 hours to a child of 1 year. The glycerite of tannin is serviceable for spongy and bleeding gums. The carbolate of iodin, or the tincture of benzoin, or the bark of pomegranate in solution is an efficient application when fetor exists. Carbolic acid, 3 grains to 1 ounce of water, is useful as a lotion. Potassium iodid in 10-grain doses, given thrice daily, is indicated in periostitis of the alveolar process, when looseness of the teeth and pain and swelling of the gums exist. Powdered rhatany is used as a dentifrice. See JAWS, MOUTH, PYORRHEA ALVEOLARIS.

The following is a useful mouth-wash:

℞.	Alum,	ʒ ss
	Tincture of myrrh,	ʒ j
	Tincture of cinchona,	ʒ iv
	Honey of rose,	ʒ j
	Alcohol,	ʒ viij.

GUNPOWDER STAINS, REMOVAL.—Gunpowder stains are best removed by picking out each grain with a sharp-pointed tenotome. Irritating ointments followed by poulticing may be used with the hope that the grains will be discharged by suppuration. The application of equal parts of ammonium iodid and distilled water has been recommended; the spots gradually turn red, and the red marks are faded by the application of dilute hydrochloric acid. Electrolysis and caustics cause permanent scarring. When the stains are quite superficial, the upper layer of the skin may be shaved off, and the raw surface covered with a Thiersch graft (Stewart). (See PLASTIC SURGERY.)

GUNSHOT WOUNDS.—Two important causes are destined to bring about a radical change in the treatment of gunshot wounds as practised in the past, and as will be taught and advised in the future: (1) The modifications which the weapon and projectile have undergone; (2) the introduction into general practice of aseptic and antiseptic surgery. The diminution in the caliber of the bullet, the metallic jacket, the substitution of smokeless for black powder, the greater velocity and power of penetration of the missile, are conditions and influences which must necessarily modify the character of wounds inflicted with the modern weapon. From a practical standpoint there remains no doubt as to the following facts, which will be confirmed by experience in the treatment of gunshot injuries inflicted with the small-caliber bullet: (1) Few bullets will be found lodged in the body; (2) wounds will be incised rather than contused; (3) range will have more influence in changing the character of the wound; (4) diminished risk of infection; (5) dangerous primary hemorrhage will be more, secondary hemorrhage less, frequent; (6) more difficult extraction of the bullet. As to the relative number of dead and wounded, and the tendency of the jacketed bullet to become encysted—these are subjects on which it is only possible to theorize and conjecture; subjects which can only be definitely settled by an extensive experience. It is less difficult to predict the influence wrought by the recent discoveries and advancements in surgery on the treatment of gunshot wounds and on the fate of the wounded. The antiseptic treatment of wounds and asepsis are destined to minimize the remote dangers of gunshot wounds and other open injuries inflicted on the battle-field. We may safely repeat with the late Professor von Nussbaum, "The fate of the wounded rests in the hands of the one who applies the first dressing." This is the motto that every military surgeon must adopt and carry into effect. To this may be added, "Never probe a bullet wound on the battle-field." The experience of the past has taught the wisdom of adopting such a universal rule.

First-aid Dressing.—The idea of rendering first aid to the wounded immediately upon receipt of injury in modern warfare must be abandoned. Alarming hemorrhage from a large vessel of any of the extremities will in many instances be arrested by the patient himself or his nearest comrade by the use of some sort of circular constriction, but the legitimate function of the hospital corps men will begin after the engagement. Desirable as it may appear, attempts at disinfection of the wound or wounds will prove impracticable and useless on the battle-field. Time alone is an important element in contraindicating such a course. Hundreds and thousands may demand attention, to say nothing of the limited facilities

for procuring for the wound and its vicinity an aseptic condition. The wisest and safest course to pursue under such circumstances is to make an intelligent use of the first-aid dressing package, which should be found upon the person of every soldier—officers and men. The average first-aid package—the one devised by von Esmarch included—is too cumbersome. A first-aid package, to meet the indications for which it is employed, should include: (1) An efficient antiseptic powder; (2) a sufficient quantity of a hygroscopic material to absorb the primary wound secretions and to serve as a filter for the wound; (3) a handkerchief or bandage with which to retain the dressing; and, in case of necessity, to be used in constructing a Spanish windlass; (4) safety-pins.

Senn's package contains about a teaspoonful of a powder composed of 4 parts of boric acid and 1 part of salicylic acid; about 1 dram of absorbent cotton; a piece of sterile gauze 40 inches square; and a number of safety-pins. The powder is lodged in the center of the cotton compress, and is to be applied directly to the wound when the package is used. The package, when compressed, is small and is wrapped in gutta-percha. The piece of gauze can be readily transformed into a Mayor triangular bandage, and serves as an excellent substitute for Esmarch's bandage, which is heavier and requires much more space. The figures printed on Esmarch's bandage are useful for instruction, but absolutely without value on the battle-field. In rendering first aid the injured part should be divested of clothing with as little disturbance of the wound as possible. Instead of removing the clothing, it is much better to make free use of scissors and knife in gaining access to the wound. If two wounds are found, both must receive the same attention and care in protecting them against infection. In the absence of grave symptoms, such as hemorrhage, the dressing should not be disturbed until the patient reaches the field-hospital, and in many cases healing of the wound will take place without further interference. The immobilization of the injured part, particularly in cases of compound fracture of the extremities, constitutes an important part of the manifest duties of those who render first aid to the wounded. In all large engagements the supply of mechanic supports carried by the men of the hospital corps will be exhausted long before all the wounded have received attention. Splints must be improvised. Rifles, sabers, bayonets, bark, branches of trees, shrubs, etc., the chest, in fractures of the upper extremity, the opposite limb, in fractures of the thigh or leg, will have to be utilized in procuring rest for the injured limb in transporting patients from the line of battle to the first dressing station. It is here that the surgeons will supplement or improve the work done by the litter-bearers and hospital corps. It is for the purpose of doing away with the necessity of using splints that a German military surgeon has recently devised a litter on the plan of a double inclined plane for the lower extremities. In the absence of a litter of such special construction the same object is attained by securing the same position for the injured limb by a roll made of a blanket, clothing, knapsack, drum, straw, etc. The transportation of a wounded man suffering from a fracture of the lower extremity can be done with less pain and with greater security against additional injuries if the fractured limb is placed in a flexed position.

Arrest of Hemorrhage on the Field.—Lives are placed in jeopardy and deaths occur more frequently from internal than from external hemorrhage; in the treatment of the former little can be done on the field. Ligation of arteries on the field proves impracticable in most instances. The company-bearers and hospital corps men should be fully instructed in the details of the various hemostatic resources applicable in emergency work. Elevation of the injured part, hyperflexion, digital compression, and antiseptic tamponade are some of the measures employed that may be intrusted to intelligent and well-instructed laymen for arresting hemorrhage. Some form of circular constriction is, however, most frequently relied upon in arresting hemorrhage complicating gunshot wounds of the extremities. The advantages and dangers attending this method of arresting hemorrhage must be made a prominent feature in giving instructions on first aid. The technic of the procedure, whether it consists in the use of the typical Esmarch's elastic constrictor, a pair of suspenders, or the Spanish windlass, should be fully explained and demonstrated on the living subject. The fact must be impressed that it is of great importance to render the limb that is to be constricted comparatively bloodless by elevation before the constrictor is applied. The next most important step to be carried into effect in the use of circular constriction is to constrict quickly and with sufficient firmness to interrupt at once and completely both the arterial and the venous circulation. A question of immense and far-reaching importance, and one that has not as yet been definitely answered, is: How long is it safe to continue the constriction? There must be, and there is, a limit as to the length of time it is safe to exclude blood supply from living tissues. Although cases have been reported in which elastic constriction was continued for from 3 to 12 hours without any serious immediate or remote consequences, yet the consensus of opinion among surgeons at the present time is opposed to excluding the blood supply from an entire limb, the seat of a gunshot injury, for a longer time than 3 or 4 hours. The danger of gangrene is always greater in constricting an injured than a healthy limb.

Locating, Finding, and Extracting Bullets.—The new rifles minimize the surgeon's work in locating, finding, and removing bullets. In the vast majority of cases requiring surgical treatment two wounds will be found—the wound of entrance and that of exit—marking the location and direction of the tubular wound made by the bullet. The cases in which the jacketed bullet will be found in the body, indicated by the existence of only one wound, will be exceptional. The search for bullets should be reserved until the patient has reached the field-hospital, when the surgeons have at their disposal the necessary instruments for making an accurate diagnosis and the essential facilities

for performing operations under the strictest aseptic and antiseptic precautions. Before using the finger or probe in exploration for a bullet, the wound and the surface for a considerable distance around it should be thoroughly disinfected, to guard against all possibility of infecting the wound during the examination or during attempts at removal of the bullet, should such a course be deemed advisable after the completion of the examination. One of the most important rules to be followed in locating a bullet in the body is to place the patient and the part injured as nearly as possible in the same position as at the moment the injury was received.

The metal-clad bullet has, to a certain extent, rendered the famous Nélaton probe obsolete. However, leaden bullets will be used to a greater or less extent by certain branches of the military force, and the porcelain tip will occasionally prove of service. The great objection to Nélaton's bullet-probe is the size of the porcelain tip. The end of the probe should correspond approximately in size to the caliber of the tubular wound. By using an instrument constructed on this principle the danger of making false passages is greatly reduced. In parts of the body composed of deep muscular planes and layers of fascia it is often found impossible to follow the track of the bullet with any kind of probe. It is in such cases, when it is deemed prudent, from the symptoms presented and the probable location of the bullet, to explore the track, that the surgeon should take advantage of the use of the knife in dilating the track, using the probe, step for step, as a guide. The use of the X-ray will prove of the greatest value in all attempts to locate bullets. In order to locate the bullet with sufficient accuracy to enable the surgeon to determine the propriety of an operation for its removal, and to guide him safely in his work, photographs from at least two directions must be taken. Every field- and general hospital should be supplied with an X-ray apparatus, and in all difficult cases this should be made use of before undertaking an operation, and in preference to repeated recourse to the probe. The famous old-fashioned American bullet forceps has lost its distinction in military surgery through the introduction of the metal-clad bullet.

Gunshot Wounds of the Extremities.—Besides the ordinary treatment of gunshot wounds, regardless of the anatomic location of the injury, bullet wounds of the extremities, when complicated by fracture or joint injury, present to the surgeon special clinical features of great importance. Under modern treatment injuries of soft tissues not implicating important vessels and nerves should heal in a short time under the first dressing, with little or no functional impairment. The existence of a gunshot fracture, regardless of the extent of bone injury, no longer furnishes a legitimate indication for a primary amputation. Such injuries, under appropriate aseptic and mechanic treatment, heal satisfactorily in the course of time. The ingenuity of the surgeon is taxed in applying and maintaining the necessary mechanic support until the fracture heals by bony consolidation, with the limb in a satisfactory useful position. In gunshot fractures of the femur extension and immobilization constitute the generally accepted treatment. A determined, strong protest must be made against the unnecessary removal of detached and partly detached fragments of bone. If the wound remains aseptic, the loose fragments of bone will not only retain their vitality, but will take an important part in the restoration of the continuity of the bone, and will add materially to the functional result. *Débridement*, more or less extensive, only becomes necessary, and should be performed, in case the wound becomes infected. In such an event the loose infected fragments of bone should be promptly removed, free tubular drainage established, and the wound throughout subjected to thorough disinfection. If the ordinary measures fail, continued irrigation with a saturated solution of acetate of aluminum will very often bring about the desired results and obviate the necessity for an amputation. Fixation and suspension in such cases will not only procure comfort for the patient, but will serve an excellent purpose in securing and maintaining coaptations and in facilitating drainage and irrigation. As soon as the fracture has united with sufficient firmness to render extension superfluous, the limb should be immobilized in a circular plaster-of-Paris splint, extending from the base of the toes to the groin, and in high fractures including the pelvis, after which the patient may be permitted to walk about with the aid of crutches. In gunshot fractures of the leg early immobilization in a circular plastic splint is to be advised, and yields the most gratifying results. Watchful control of patients suffering from such injuries, and treated by the use of plaster-of-Paris bandage, is essential in guarding against disastrous complications and in obtaining satisfactory functional results. Gunshot injuries of any of the large joints are now within the range of successful conservative treatment. The indications for primary amputation of a limb or part of a limb should be restricted to cases in which the nutrition is suspended or seriously threatened by the coexistence of vascular lesions incompatible with the vitality of the tissues at and below the seat of injury. In doubtful cases the soldier is entitled to the benefit of the doubt, and the conservative treatment should be carried to its ultimate limits until the appearance of complications demonstrates its futility and dictates the propriety of resorting to a mutilating operation. It is always more creditable to the surgeon to save a limb than to remove it, and the plan of the military surgeon of the future should and will be to limit more and more the indications for amputations.

The few cases of penetrating gunshot wounds of the skull that come under the observation of the military surgeon invariably require operative interference, provided it holds out any encouragement whatever of saving life. In case a bullet has passed through the skull and its contents, the entire scalp should be thoroughly shaved and disinfected. The wound of entrance must be enlarged sufficiently to expose the perforation freely, which is then enlarged with chisel, De Vilbiss, or

rongeur forceps sufficiently to enable the surgeon to remove the loose spicules of bone, which are frequently embedded some distance in the brain. With a long-eyed probe a strip of iodoform gauze large enough to pack loosely the tubular visceral wound should be inserted from the wound of entrance to the wound of exit, and the rough gauze drain made to project a few inches beyond the surface of each wound. Thorough capillary drainage of this kind will prevent accumulation of primary wound secretion in the interior of the skull, and will be of value in arresting capillary hemorrhage. A large hygroscopic dressing enveloping the entire scalp, and covering both wounds, should be applied, and held in place by a few turns of a plaster-of-Paris bandage. The drain must be allowed to remain until the danger of infection is passed, when it is to be removed gradually by shortening it every day or two. In case the bullet should be found lodged in the interior of the skull, the wound of entrance must be treated in the same manner, and the bullet located by the careful use of Fluhrer's aluminium probe. A counter-opening may become necessary in removing the bullet if it has reached the opposite side of the skull, or when it has become deflected or arrested in its course near the surface of the brain, in case the locality in which it has become lodged warrants operative intervention. In all visceral injuries of the contents of the skull resulting from gunshot wounds, capillary or tubular drainage or a combination of the two is indicated, and should be continued until there is no further danger of infection, hemorrhage, or accumulation of wound products, when the drain is to be gradually removed. The value of the X-ray in locating bullets in the interior of the cranium has not, as yet, been definitely determined.

Gunshot Wounds of the Chest.—Penetrating gunshot wounds of the chest are attended by an enormous mortality, owing to the physiologic importance of the organs that it contains. Visceral wounds of the heart and large blood-vessels usually result in death in a few moments from acute anemia. Hemorrhage into the pleural cavity and into the large bronchial tubes interferes mechanically with the respiratory functions, and frequently proves fatal in a short time; and if the patient recovers from its immediate effects, life is placed in danger by complications often caused by hemothorax. The accumulation of a large quantity of blood in the pleural cavity is not incompatible with a speedy recovery, as when the blood is aseptic, its removal by absorption is accomplished in a short time.

Experience during the War of the Rebellion proved that in gunshot wounds of the chest the chances for life were much better if the bullet passed through the chest than if it remained lodged in the body. Little progress has been made in the treatment of penetrating wounds of the chest. Direct operative treatment of visceral wounds of the heart and lungs is always attended by imminent risk to life from pulmonary collapse. This source of danger stands in the way of direct treatment of visceral wounds of the chest. Hemorrhage from wounds of the lung is often corrected spontaneously by the accumulation of blood in the cavity of the chest, causing temporary pulmonary collapse, and by tamponade of the tubular visceral wound by the formation of a blood-clot. Free incision of the chest-wall has been strongly advocated by several French surgeons in cases of penetrating gunshot wounds of the chest, with a view to arresting hemorrhage by ligation, tamponade, or the use of the cautery; but the profession on the whole is opposed to such heroic treatment. Unless the source of hemorrhage is one of the intercostal arteries or of the internal mammary artery, it is advisable to rely on nature's resources for arresting the bleeding. Hemorrhage from the intercostal arteries can be effectually checked by tamponade, using for this purpose an hour-glass-shaped tampon of iodoform gauze. Rest in the recumbent position, with the chest slightly elevated, is essential in aiding spontaneous arrest of hemorrhage and in the prevention of complications. A rise in the temperature during the first 48 hours is no indication of the existence of sepsis, as, with few exceptions, it indicates a febrile disturbance caused by the absorption of fibrin ferment—the so-called fermentation fever. Should later symptoms develop, suggestive of septic infection, aspiration should be promptly resorted to; and if not followed by speedy improvement, no time should be lost in subjecting the patient to the same medical treatment as that advised and practised for empyema—that is, rib resection, free incision, and drainage. The production of an artificial pneumothorax or hydrothorax by the introduction into the pleural cavity on the injured side of a nontoxic gas, filtered atmospheric air, sterilized water, or nontoxic antiseptic solutions, has not proved satisfactory in the treatment of intrathoracic traumatic hemorrhage. From what has been said it is clear that the best treatment in penetrating gunshot wounds of the chest consists in hermetically sealing the wound of entrance and that of exit, if such exists, under strict aseptic precautions, and in watching for and treating subsequent complications as they present themselves.

Gunshot Wounds of the Abdomen.—The penetrating wounds of the abdomen that come under the observation of the military surgeon are, with few exceptions, wounds inflicted with the modern small-caliber projectile. The visceral wounds and the wounds of entrance and exit will be small—too small for digital exploration. A penetrating wound of the abdomen should never be probed either for diagnostic or therapeutic purposes. If any doubt exists as to whether or not the bullet has entered the abdominal cavity, it is far better and safer to dilate the track by the use of the knife, relying on the probe as a guide, than to work in the dark with the probe, thus increasing the possibilities of infecting the peritoneal cavity. Quite recently the assertion has been made by several prominent surgeons that celiotomy should be performed in all cases in which it can be shown that penetration has occurred. It must, however, be admitted that, in the absence of serious visceral lesions, penetrating wounds of the abdomen are

injuries from which the patients are very likely to recover without operative treatment, and that when such patients are subjected to celiotomy, death may occur solely in consequence of the operation. It is undoubtedly true that in most cases of spontaneous recovery after penetrating gunshot wound of the abdomen the favorable termination has been due to the absence of serious visceral lesions, which some hold to be invariably present in such cases. During the Græco-Turkish war, several cases of gunshot wound of the abdomen recovered under a conservative plan of treatment. In nearly all these cases the bullet entered the abdomen above the umbilicus—the most favorable location for the escape of intestines from the missile—the patient being in a standing position.

In 2 out of 16 cases of penetrating gunshot wounds of the abdomen observed, the absence of visceral injuries of the gastrointestinal canal was demonstrated by the use of the hydrogen gas-test, and both of these patients recovered without resort to celiotomy. Clinical experience and the result of experiment show conclusively that this operation should not be performed simply because a bullet has entered the abdominal cavity, but that its performance should be limited to the treatment of intraabdominal lesions that, without operative interference, would tend to destroy life. A bullet that passes through the lower part of the abdomen from side to side or obliquely is almost sure to produce from 4 to 14 perforations of the intestines, while absence of dangerous visceral complications may be inferred with some degree of probability if it crosses the abdominal cavity in an anteroposterior direction at, or a little above, the umbilical level.

The general symptoms in cases of penetrating gunshot wounds of the abdomen, with the exception of those due to profuse hemorrhage, furnish very little information in reference to the existence or absence of visceral complications. Severe shock may attend a single nonpenetrating wound, or it may be absent, or at least slight, in cases of multiple perforation of the intestines. It is not an uncommon occurrence for a patient with a number of intestinal perforations to walk several blocks, or even a number of miles, without a great deal of suffering and without showing any symptoms of shock. Vomiting occurs as frequently in parietal wounds and in simple penetrating wounds as when the viscera have been injured. Vomiting of blood points to the existence of a wound of the stomach.

Pallor is present soon after the receipt of the injury in all penetrating wounds of the abdomen, and it is only more pronounced when produced, at least in part, by sudden and severe hemorrhage. Pain is a very unreliable and often a misleading symptom, as it may be moderate or almost completely absent soon after the injury has been inflicted, even when multiple perforations are present. The pulse at first is slow and compressible in all cases, and nothing characteristic in its qualities is observed even when the stomach or intestines have been wounded. Hemorrhage caused by wounds of any of the large organs, as the spleen, liver, or kidneys, gives rise to progressive acute anemia, small rapid pulse, cold clammy perspiration, dilated pupils, yawning, vomiting, and, in extreme cases, syncope and convulsions. The local symptoms are of no more value in determining the existence of visceral injuries in penetrating wounds of the abdomen than are the general symptoms enumerated. External hemorrhage is slight or entirely absent, unless an artery or vein in the abdominal wall has been injured. The bleeding from visceral wounds gives rise to accumulations of blood in the peritoneal cavity—occult or internal hemorrhage; this can be recognized by physical signs denoting the presence of fluid in the free abdominal cavity and by general symptoms indicating progressive anemia—increasing pallor of the face and of the visible mucous membranes, small feeble pulse, superficial sighing, respiration, and dilated pupils. Wounds of the stomach often occasion hemorrhage into this organ and hematemesis. Blood in the stools seldom follows hemorrhage into the bowels from intestinal wounds sufficiently early to be of any diagnostic value.

Circumscribed emphysema in the tissues about the track made by a bullet has been regarded as an important sign of the existence of intestinal perforation. This symptom is misleading and is absolutely devoid of diagnostic value, as this condition has frequently been observed in nonpenetrating wounds of the abdominal wall, resulting from the entrance of air into the loose connective tissue, or later by gas formation as one of the results of putrefactive infection. The accumulation of any considerable quantity of gas in the peritoneal cavity can sometimes be recognized by the disappearance of the normal liver dulness, caused by the presence of gas between the surface of the liver and the chest-wall. This condition has been sought as a diagnostic sign in cases of perforating wounds of the abdomen, and if found, has been taken as a positive indication of the existence of visceral wounds of the gastrointestinal canal. This is not, however, always the case. Adhesions between the surface of the liver and the chest-wall may have existed before the injury was received, or the amount of gas present may be insufficient to give rise to this sign. The escape of the contents of the wounded stomach or intestines through the external wound is a rare occurrence, and is possible only when the external wound is sufficiently large and straight, and when it corresponds with the location of the visceral wound, or in the event of preexisting adhesions between the abdominal wall and the injured portion of the gastrointestinal canal. External extravasation occurs more frequently in wounds of the large than of the small intestine. When this symptom is present, it is conclusive proof of the existence of a visceral wound of the gastrointestinal canal, and the character of the extravasation will furnish reliable information as to the anatomic location of the visceral injury. With the exception of the last-mentioned symptom and the indications pointing to the necessity for arresting internal hemorrhage, there is nothing about the local or general symptoms in cases of penetrating gunshot wounds of the abdomen that would enable the surgeon to decide with any

degree of certainty soon after the injury was received whether or not visceral injuries existed, and, consequently, whether celiotomy should or should not be performed.

Diagnosis.—If a gunshot wound has penetrated the abdominal cavity and the general symptoms and local signs point to the existence of dangerous internal hemorrhage, no time should be lost in further efforts to make an accurate anatomic diagnosis, as sufficient evidence has been obtained to warrant a celiotomy for the purpose of preventing death from hemorrhage by the direct surgical treatment of the visceral injuries. If no such urgent indication presents itself, it is desirable that the existence of visceral lesions demanding surgical treatment should be ascertained before the patient is subjected to the additional risk incident to the operation. Since a simple penetrating wound of the abdomen is an injury from which the majority of patients recover without operative treatment, and since visceral wounds of the gastrointestinal canal are attended by so frightful a mortality without surgical interference, the practical value and importance of a correct diagnosis before deciding upon a definite plan of treatment become obvious. It is apparent that if some reliable diagnostic test could be applied in cases of penetrating wounds of the abdomen that would indicate to the surgeon the presence or absence of visceral lesions of the gastrointestinal canal, the indications for aggressive or conservative treatment would become clear. It has been shown by experiments on animals and clinical experience in the treatment of a number of cases of gunshot wounds of the abdomen, that **rectal insufflations of hydrogen gas** may be relied upon in demonstrating the existence of perforations of the gastrointestinal canal before opening the abdomen. It has been proved that if the abdominal muscles are completely relaxed under the influence of a general anesthetic, hydrogen gas or filtered air can, under safe pressure, be forced from the anus to the mouth if no perforations exist; and if such are present, the gas will escape into the peritoneal cavity, where its presence can be readily detected by the physical signs characteristic of a free tympanites or by its escape through the external opening.

Hydrogen gas is a nontoxic substance, endowed with valuable inhibitory antiseptic properties, and is absorbed from all the larger serous cavities and connective tissues within a few hours. Pure zinc and sulphuric acid should be used in generating the gas, which is collected in a rubber balloon holding at least 4 gallons. The rubber balloon used for this purpose is square in shape and is connected with the rectal tip by means of a rubber tube 6 feet in length and supplied with a stop-cock near its proximal end. In applying the test an assistant presses the margin of the anus against the rectal tip, so as to prevent the escape of the gas, while another assistant forces the gas along the intestinal tube by pressing or sitting on the rubber balloon. The gas passes through the ileocecal valve under a pressure of 2 1/2 pounds to the square inch, and is announced by a distinct gurgling sound, which can always be distinctly heard by applying the ear or stethoscope over that region. If the rectum or colon has been perforated, the gas will not reach the small intestine, but will escape into the peritoneal cavity under less pressure than is required in rendering the ileocecal valve incompetent. As soon as the gas reaches a perforation large enough to permit its escape, it will enter the peritoneal cavity and escape through the external wound, if this has been freely laid open down to the peritoneum. If the external wound is in a location that points to injury of the stomach, this organ should be insufflated through a rubber stomach-tube; and if this test proves negative, it is to be followed by rectal insufflation. It is impossible to inflate the intestines to any extent from the stomach.

Treatment.—The propriety of surgical interference in cases of penetrating gunshot wounds of the abdomen will depend upon one of three things:

1. General condition of the patient.
2. Dangerous internal hemorrhage.
3. Wounds of the stomach or intestines large enough to permit extravasation.

If the patient is pulseless and presents other indications of approaching death, operation is unjustifiable, as it would only hasten the end. Dangerous internal hemorrhage coming to the notice of military surgeons in gunshot wounds of the abdomen will be the cases in which the vascular organs of the abdomen, the liver and spleen, or some of the larger vessels of the mesentery or omentum have been injured. Delay in such cases is dangerous. The abdomen should be opened and the hemorrhage arrested. The symptoms are likely to be unusually severe if the hemorrhage is sudden; progressive, if the loss of blood is gradual. In the latter case it may be prudent to await more pressing indications, as spontaneous arrest of hemorrhage may occur and large quantities of aseptic blood are removed from the peritoneal cavity in a short time. Visceral lesions of the gastrointestinal canal large enough to permit extravasation are, with very few exceptions, mortal wounds, justifying prompt abdominal section as the only chance to save life.

Preparation of Patient.—A patient suffering from a penetrating gunshot wound of the abdomen should be properly prepared before he is subjected to celiotomy. If the stomach is filled with food, a salt-water emetic should be given for the purpose of emptying its contents, or, better still, this can be done by the use of the stomach siphon-tube. The rectum and colon must be emptied by a copious enema of warm water, to which may be added a tablespoonful of common salt. The unloading of the gastrointestinal canal will not only facilitate the operation, but will have a favorable influence in securing rest for the injured part. A hypodermic injection of 1/4 of a grain of morphin and 1/30 of a grain of strychnin should be given shortly before the anesthetic is administered, as these remedies, in the doses specified, assist the action of the anesthetic, secure rest for the intestines, and sustain the action of the heart. If the patient is much prostrated, 2 ounces of whisky diluted with 4 ounces of warm water should be given by the rectum. The whole abdomen should be thor-

oughly disinfected. Before and during the operation the use of external dry heat will do much to prevent shock and to aid the peripheral circulation. Compresses, towels, and several gallons of warm normal solution of salt must be provided. The operator should do the work with as little assistance and as few instruments as possible, as the danger of infection in emergency work is likely to be proportional to the number of assistants employed and the number of instruments used. Hands, instruments, suturing material, in fact everything that is to be brought in contact with the wound, must be sterilized. In military surgery silk has the preference over catgut. A hospital tent with a floor will be an admirable operating-room in all semitropic climates. Anesthesia should be commenced with chloroform until the patient is under its full influence, when it should be continued with ether.

Incision.—In the majority of cases the median incision should be made, as it affords advantages which give it the preference. It should always be selected in cases of gunshot wounds of the stomach, and when the wound of entrance is located near the median line. A median incision affords most ready access in the treatment of wounds of the small intestine. If the insufflation test is used, it will sometimes prove of value in deciding upon the location of the incision. In gunshot wounds of the upper portion of the abdomen, if direct inflation of the stomach through an elastic tube reveals the existence of perforation of this organ, the median incision should be selected. If rectal insufflation yields a positive result before the gas has passed the ileocecal valve, the incision should be made over the wounded portion of the colon, which is usually indicated by the course of the bullet. A wound in the transverse colon can be found and dealt with most effectually through a high median incision; perforation of the cecum or of the ascending colon calls for a lateral incision directly over the wounded organ; while a lateral incision on the left side is indicated if, from the direction of the bullet, it is evident or probable that the colon below the splenic flexure is the seat of the visceral injury. Celiotomy performed for the arrest of hemorrhage should always be done by making a long median incision, which will afford the most direct access to the different sources of hemorrhage. Very often it will be advisable to make the incision in the line of the wound of entrance, especially in those cases where a lateral incision is indicated.

Arrest of Hemorrhage.—In opening the abdomen in the treatment of internal hemorrhage the surgeon undertakes a task of which it is impossible to foretell the result. To do the work quietly and well he must be perfectly familiar with the anatomy of the abdominal organs, their source of blood supply, and must have full knowledge of all hemostatic resources, the indication for their selection and details of application. Profuse intraabdominal hemorrhage resulting from penetrating gunshot wounds of the abdomen is more frequently of parenchymatous and venous than of arterial origin. Wounds of the liver, spleen, kidneys, and mesentery give rise to profuse and often fatal hemorrhage. After opening the peritoneal cavity it is commonly very difficult to find the bleeding points, as the blood accumulates as rapidly as it is sponged out, and it becomes necessary to resort to special means in order to arrest profuse bleeding sufficiently to find the source of hemorrhage. One of two means should be employed: (1) Intraabdominal digital compression of the aorta; (2) packing the abdominal cavity with a number of large sponges or gauze compresses. Intraabdominal compression of the aorta below the diaphragm can readily be made by an assistant introducing his hand through the abdominal incision, which, in such a case, must be larger than under ordinary circumstances. Compression made in this manner will promptly arrest hemorrhage from any of the abdominal organs for a sufficient length of time to enable the surgeon to find the source of hemorrhage and to carry out the necessary treatment for its permanent arrest.

Hemorrhage from a perforated kidney may demand nephrectomy, if it does not yield to tamponade. If the tampon is used, an incision in the lumbar region must be made for the removal of the tampon, and the parietal peritoneum should be sutured, so as to exclude the peritoneal cavity from the renal wounds. Wounds of the liver are sutured with catgut, cauterized with the actual cautery, or tamponaded with a long strip of iodoform or a typical Mikulicz tampon; in any case the gauze is to be brought out of the wound and utilized as a drain.

A wound of the spleen, if the hemorrhage does not yield to ligation, suturing, or tamponade, necessitates splenectomy. Very troublesome hemorrhage occurs in wounds of the mesentery. When multiple wounds of the mesentery and visceral wounds of the stomach or intestines are the cause of hemorrhage, it is a good plan to pack the abdominal cavity with a number of large sponges, napkins, or compresses of gauze, to each of which a long strip of gauze is securely tied; these strips are allowed to hang out of the wound in order that none of the sponges or compresses may be left in the abdominal cavity after the completion of the operation. The sponges or compresses make sufficient pressure to arrest parenchymatous oozing as well as venous hemorrhage, if they are placed at different points against the mesentery and between the intestinal coils. The sponges are removed one by one, from below upward, and the bleeding points secured as fast as they are uncovered. The ligation of mesenteric and omental vessels, both arteries and veins, should be done by applying the ligature *en masse*. A round needle or Thornton's curved hemostatic forceps are the most useful instruments for this purpose. Catgut, as a rule, should not be relied upon in tying a mesenteric vessel, as for this purpose it is inferior to fine silk.

If hemorrhage is profuse, it should be checked before binding and suturing the visceral wounds. Troublesome hemorrhage from a large visceral wound of the stomach or intestines is best controlled by hemming the margin of the wound with

catgut or fine silk. In hemorrhage from localities not accessible to ligation and not amenable to tamponade, pressure forceps are applied and allowed to remain for 24 or 48 hours. When used in this manner, the instrument must be long enough to be brought out of the wound, and is then incorporated in the dressing. For the purpose of facilitating the binding and removal of the instrument, a strip of gauze is tied to the handle.

Search for Perforations.—A number of cases have been recorded in which celiotomy was performed, one or more perforations sutured, and the postmortem showed that a perforation was overlooked, death resulting from extravasation and diffuse septic peritonitis. Such experiences are by no means limited to the practice of novices. The handling of the entire length of the gastrointestinal canal in search for perforations requires time, adds to the shock of the injury and operation, and, even if done by experts and with the utmost care, a perforation may escape the attention of the operator and become the sole cause of death. If the surgeon adopts this plan of detecting the perforations, the work should be done systematically. The ileocecal region is the best landmark in beginning the search. From here the small intestine is traced in an upward direction, examining loop after loop, and returning the intestine as soon as examined so as to avoid extensive eventration, which adds greatly to the danger of the operation. The large intestine is traced from the ileocecal region downward. Perforation of the rectum has been found low down in the pelvis, and would have been overlooked had the inflation test not been used. If the air- or gas-test is employed with a positive result before the abdomen is opened, there will be no difficulty experienced in finding the first opening. If the stomach is inflated directly through an elastic tube, and the test shows the presence of a perforation, a median incision is made from the tip of the ensiform cartilage to the umbilicus, and the stomach is drawn forward into the wound. If no perforation is found in the anterior wall, the insufflation is repeated, and the escaping air or gas will direct the surgeon to the perforation. Through this perforation the stomach should again be inflated in search of a second, and possibly a third, perforation. In searching for intestinal wounds by the aid of inflation, further inflation should be suspended as soon as the lowest perforation has been found. If possible, the perforated portion of the intestine should now be brought forward into the wound, and after emptying the intestine below the perforation of its contents as far as possible, including the gas or air, the bowel is compressed below the perforation by an assistant, and the intestine higher up is inflated through the wound. As a matter of course, a perfectly aseptic glass tube should be inserted into the rubber tube in place of the rectal tip. The inflation is now carried as far as the second opening, when the first perforation is sutured; and after disinfection and emptying the intervening portion of its gas, the intestine is replaced in the abdominal cavity. Further inflation is now made through the second opening, and if a third one is found, the second is sutured, and so on until the entire intestinal canal has been thoroughly subjected to the test. By following this plan extensive eventration is rendered superfluous and the overlooking of a perforation is made impossible.

Suturing the Perforations.—The materials for suturing are an ordinary sewing-needle and fine aseptic silk. Catgut should not be used in intestinal work. Trimming the margins of the visceral wounds is not only superfluous, but absolutely harmful, as it requires a useless expenditure of time and may become an additional source of hemorrhage. The same can be said of the Czerny-Lembert suture. All that is necessary in the treatment of a visceral wound of the stomach and intestines is to turn the margins of the wound inward and bring into apposition healthy serous surfaces by the continuous or by interrupted seromuscular sutures, which should always be made to include fibers of Halsted's submucosa. From 4 to 6 stitches to an inch will suffice. If possible, wounds of the stomach should be sutured in the direction of the blood-vessels, and transverse suturing of the intestine is necessary for the purpose of preventing constriction of the lumen. Defects 1 1/2 inches in length, on the convex side, can be closed in this manner without fear of causing intestinal obstruction, while much smaller wounds on the mesenteric side usually necessitate a resection, not only because the vascular supply in the corresponding portion of the intestine would be inadequate, but also because a sufficiently sharp flexion might be produced at the seat of suturing, to become the immediate mechanic cause of intestinal obstruction.

Enterectomy.—Enterectomy is often indicated in cases of double perforation and in marginal wounds of the mesenteric border. If in cases of multiple perforations it should become necessary to make a double enterectomy, and the intervening portion of the small intestine is not more than 2 or 3 feet in length, it is well to leave it, as the immediate effect of the single operation will be less severe than that of a double resection with a corresponding double enterorrhaphy. After resection the continuity of the intestinal canal should always be restored by a circular enterorrhaphy, using for this purpose the Czerny-Lembert suture. Strips of sterile gauze are preferable to clamps in preventing extravasation during the operation. The gauze strip is passed through a small buttonhole made with hemostatic forceps in the mesentery near the intestine, and tied with sufficient firmness to prevent escape of intestinal contents.

Irrigation of the Abdominal Cavity.—This is necessary only when fecal extravasation or escape of stomach-contents has taken place, an accident that, if it has not occurred before the abdomen was opened, should be carefully avoided during the manipulation of the wounded intestines. Flushing the peritoneal cavity with warm sterilized water or normal salt solution not only clears it of infectious material, but acts at the same time as a stimulant to the flagging circulation. The current must be sufficiently strong not only to fill the peritoneal cavity quickly, but to flush it out.

After completion of the irrigation the patient is placed on his side, and in this position the fluid contents of the abdominal cavity are evacuated. The cavity is then rapidly dried with large sponges wrung out of a weak sublimate solution (1:10,000) or Thiersch's solution. Some surgeons have practically abandoned flushing of the abdominal cavity, and rely almost exclusively on sponging in removing pus and extravasated fecal material; others are partial to leaving the physiologic solutions of salt in the cavity, paying no attention to the peritoneal toilet practised with conscientious care by all surgeons only a few years ago.

Drainage.—Whether or not to drain is the all-absorbing question among surgeons whose time and attention are largely engaged in abdominal work. In gunshot wounds of the abdomen complicated by visceral injury the probability that infection has occurred must not be lost sight of, and the only safe course to pursue under such circumstances is to drain when in doubt. Cases that require irrigation should always be drained. Other indications for drainage are visceral wounds of the liver and pancreas, and the existence of parenchymatous hemorrhage, which cannot be remedied by any of the different hemostatic measures. A glass drain reaching to the bottom of the pelvis, loosely packed with a strip of iodoform gauze, is advisable. Occasionally, multiple drains are indicated. The Mikulicz drain is to be depended upon in arresting troublesome surface oozing. Drainage must be suspended with the cessation of the primary wound secretion.

Suturing of External Incisions.–Incisions through the median line are rapidly closed by a row of silk or silkworm-gut sutures which are placed close together, and include all the tissues of the margins of the wound. Incisions made in any other place are to be closed by buried catgut sutures uniting the peritoneum and muscular layer separately, and by a superficial row of silkworm-gut sutures including all the tissues except the peritoneum. A large hygroscopic compress composed of sterile gauze and absorbent cotton, held in place by broad strips of adhesive plaster, constitutes the proper dressing. The sutures are removed at the end of the second week, and the patient must not be allowed to leave the bed before the expiration of the fourth week. Four weeks in bed and the wearing of a well-fitting abdominal support for from 3 to 6 months are the most reliable precautions against the occurrence of a postoperative ventral hernia. The drainage opening should be closed with secondary sutures, inserted at the time of operation as soon as the drain is closed; otherwise a ventral hernia will be almost sure to develop in the scar at the former site of the drainage-tube.

After-treatment.—Absolute rest must be strictly enforced. Opiates should be given in doses sufficiently large to quiet the peristaltic action of the intestines. Stimulants must be used to counteract the effect of shock and to restore the vigor of the enfeebled peripheral circulation. No food is to be allowed for at least 48 hours. During this time a mixture of brandy and ice-water, in small doses frequently repeated, or iced champagne, is agreeable to the patient, as it quenches thirst, relieves nausea, and exerts a favorable influence upon the circulation. If more active stimulation is called for to overcome shock and the effects of hemorrhage, whisky, strychnin, ether, musk, or camphor may be injected subcutaneously or by the rectum, while the peripheral circulation is restored by applying dry heat to the extremities and trunk. The subcutaneous infusion of 1 or 2 pints of normal salt solution is an excellent restorative, and is of special therapeutic efficiency in cases in which the vital forces are depressed and life is in danger from the effects of hemorrhage.

Should symptoms of peritonitis set in, a brisk saline cathartic should be given at the end of 48 hours, as at this time the intestinal wounds will become sufficiently united to resist the peristalsis provoked by the cathartic, while the removal of the intestinal contents and the absorption of septic material from the peritoneal cavity thus attained are not only the most efficient means of averting a fatal disease, but also of placing the wounds in the most favorable condition for rapid repair. Reopening of the wound and secondary flushing have done little to arrest or limit septic peritonitis. If the case progresses favorably, liquid food by the stomach may be allowed at the end of the second day, and light solid food at the end of the first week. Under ordinary circumstances no effort is made to move the bowels until the end of the third or fourth day. If early feeding becomes necessary in marasmic or exsanguine patients, this may be effected by rectal alimentation.

Conclusions.—The following conclusions may be formulated:

1. In theory and in practice military surgery is equivalent in every respect to emergency practice in civil life.

2. The wounded soldier is entitled to the same precautions against infection as persons in civil life suffering from similar injuries.

3. The fate of the wounded rests in the hands of the one who applies the first dressing.

4. The first dressing should be as simple as possible, including an antiseptic powder (composed of boric acid 4 parts, salicylic acid 1 part), a small compress of cotton, safety-pins, and a piece of gauze 40 inches square.

5. Any attempt to disinfect a wound on the battle-field is impracticable.

6. The first-dressing stations and the field-hospitals are the legitimate places where the work of the hospital corps and company-bearers is to be revised and supplemented. All formal operations must be performed in the field-hospitals, where the wounded can receive the full benefits of aseptic and antiseptic precautions.

7. Probing for bullets on the battle-field must be absolutely prohibited.

8. Elastic constriction for the arrest of hemorrhage must not be continued for more than 4 or 6 hours, for fear of causing gangrene.

9. The X-ray will prove a more valuable diagnostic resource than the probe in locating bullets lodged in the body.

10. Gunshot wounds of the extremities must be

treated upon the most conservative plan, the indications for primary amputation being limited to cases in which injury of the soft parts, vessels, and nerves suspends or seriously threatens the nutrition of the limb below the seat of injury.

11. Operative interference is indicated in all penetrating gunshot wounds of the skull.

12. Gunshot wounds of the chest should be treated by hermetically sealing the wounds under the strictest aseptic precautions.

13. Celiotomy in penetrating gunshot wounds of the abdomen is indicated in all cases when life is threatened by hemorrhage of visceral wounds, and when the general condition of the patient is such as to sustain the expectation that he will survive the immediate effects of the operation.

And see WOUNDS, for the Carrel-Dakin method.

GYNECOLOGIC EXAMINATION.—Bimanual examination is the most useful of the methods of gynecologic examination. By it are determined the position, size, and consistency of the uterus; the condition of the tubes and ovaries, and pelvic tumors of any variety. It is performed in the following manner: One or two fingers of either hand are introduced into the vagina, and the position and direction of the cervix is noted; the ulnar edge and the tips of the fingers of the other hand are then placed upon the abdomen just above the symphysis, and firmly pressed downward and backward. The uterus, tubes, ovaries, or any morbid growth may in this manner be palpated between the two hands.

The genupectoral or knee-chest position is useful for inspection of the vagina, cervix, rectum, and bladder; also for the replacement of a retrodisplaced uterus. In this position the intestines gravitate out of the pelvis, and if the perineum is retracted or if the urethra or bladder is opened, the vagina, the bladder, and the rectum become distended with air, permitting free inspection of their walls. In assuming this position the patient should rest the knees upon the table; the chest and side of the face thrown forward upon a pillow. The thighs should be vertical and the back straight.

The Sims or lateroabdominal position is a convenient one for inspecting the cervix and vaginal vaults; for making applications to the uterine cavity, cervical canal, cervix, and vagina; and for some minor operations. The patient is placed upon her left side with the left arm thrown back and the left side of the face resting upon a pillow. The thighs are flexed at a right angle to the body; the right knee is thrown a little forward so as to touch the table in front of the left knee. When the perineum is retracted with a Sims speculum, the vagina becomes distended with air, the intestines gravitate out of the pelvis, and a perfect view of the cervix and vaginal vaults is obtained.

Trendelenburg Position.—The patient lies in the dorsal position with the hips greatly elevated, the body making an angle with the horizon of about 45°. The legs and feet hang over the foot of the table, forming a right angle with the thighs. This position is a very useful one in pelvic surgery, since it allows the intestines to gravitate out of the pelvis, and thus exposes to view the pelvic organs.

For the various positions, see the following TABLE OF POSTURES AND POSITIONS.

TABLE OF POSTURES AND POSITIONS

VARIETY.	DESCRIPTION.	WHEN EMPLOYED.
Back posture	See Dorsal recumbent.	
Dorsal elevated	Patient on back, with head and shoulders elevated at an angle of 30° or more.	1. Digital exploration of the genitalia. 2. Bimanual examination.
Dorsal recumbent	Patient on back, with the extremities moderately flexed and rotated outward.	1. Application of obstetric forceps. 2. Repair of lesions following parturition. 3. Vaginal examination. 4. Bimanual palpation.
Dorsosacral or lithotomy position.	Patient flat on back, with legs flexed on thighs and thighs on abdomen. The thighs are abducted.	1. Plastic operations on the genital tract. 2. Vaginal hysterectomy. 3. Diagnosis and treatment of diseases of the urethra and bladder.
Edebohls' posture	Same as Simon's position.	
English position	See Left lateral recumbent.	
Erect position	The occiput and heels on a line; also the nose, groins, and great toes are in the same vertical plane.	1. In the practice of ballottement. 2. In differentiation of tumors, cystic, solid, and hernial. 3. In diagnosing loosening of pelvic joints.
Exaggerated lithotomy	See Simon's position.	
Fowler's position	The head of the bed is elevated 24 to 30 inches, so that the patient is in the semi-erect position.	In abdominal surgery (after peritonitis) to allow the intraperitoneal fluids to gravitate away from the diaphragm (where absorption is rapid) and into the pelvis (where absorption is relatively slow).

TABLE OF POSTURES AND POSITIONS

Variety.	Description.	When Employed.
Genucubital or knee-elbow posture.	Patient upon the knees, with the thighs upright, and the body resting upon the elbows, the head down upon the hands.	When not possible to employ the classic knee-chest position.
Genupectoral or knee-chest position.	Patient upon the knees, with the thighs upright; the head and upper part of the chest resting upon the table; the arms crossed above the head.	1. Replacement of prolapsed funis. 2. Dislodgement of an impacted head. 3. Management of transverse presentations. 4. Replacement of a retroverted uterus or prolapsed ovary. 5. Flushing of the intestinal canal.
High pelvic posture.....	See Trendelenburg's position.	
Horizontal abdominal posture.	Patient flat on the belly, with the feet extended.	Examination of the back and spinal column.
Horizontal position.....	Patient supine on the back, with the feet extended.	1. For employment of palpation. 2. Auscultation of the fetal heart. 3. The position for operative procedures.
"Jack-knife" posture.....	Patient reclining on the back with the shoulders elevated, legs flexed on thighs, and thighs at right angles to abdomen.	For passing the urethral sound.
Knee-chest posture.....	See Genupectoral.	
Knee-elbow posture.....	See Genucubital.	
Kneeling-squatting position.	Patient stooping, with knees pressed upon the abdomen, trunk erect.	Childbirth in difficult cases and in uncivilized nations.
Lateroprone.....	Same as Semiprone.	
Laterosemiprone.....	Same as Semiprone.	
Left lateral recumbent, English, or obstetric position.	Patient on left side, with the right knee and thigh drawn up.	Childbirth.
Lithotomy.....	Same as Dorsosacral.	
Obstetric.....	See Left lateral recumbent.	
Reclining posture.....	Same as "Jack-knife" posture.	
Semiprone or Sims' position, or side posture.	Patient on left side, with right knee and thigh drawn well up above the left; left arm back of patient and hanging over the edge of the table; chest inclined forward so that the patient rests upon it.	1. Curettage of uterus. 2. Intrauterine irrigation after labor. 3. Tamponade of vagina. 4. Rectal exploration. 5. Operations upon the cervix.
Side posture.....	See Semiprone.	
Simon's position, or exaggerated lithotomy position.	Patient flat on back, with legs flexed on thighs and thighs on abdomen, and hips somewhat elevated. The thighs are strongly abducted.	Operations upon the vagina.
Sims'.....	See Semiprone.	
Trendelenburg's position.....	Patient in dorsal position, with body elevated at an angle of about 45°, feet and legs hanging over the end of the table.	In abdominal surgery to favor gravitation upward of the abdominal viscera.
Walcher's position.....	A dorsal posture, with the sacrum at the edge of the table, and lower extremities hanging.	1. In pelvic deformity. 2. To increase the conjugate diameter 1/4 to 1/2 inch. 3. To facilitate bimanual examinations. 4. For version or forceps.

H

HABIT SPASM.—Habit chorea; convulsive tic; Gilles de la Tourette's disease. A choreic disease characterized by simply localized spasmodic movements, or by such movements combined with explosive utterances and psychic symptoms (*convulsive tic*). *Habit spasm* is confined chiefly to young girls, and is marked mainly by spasmodic action of the facial muscles or of the head. *Convulsive tic,* or *Gilles de la Tourette's disease,* is a psychosis allied to hysteria, and occurring usually in children of a neurotic tendency. It is marked by involuntary muscular movements, usually affecting the facial or brachial muscles, and by explosive utterances that may resemble a bark or an inarticulate cry. A word heard may be mimicked at once, and repeated over and over again, usually with the involuntary movements. To this the term *echolalia* has been applied. *Coprolalia,* or the use of obscene language, is another symptom, and occasionally actions are mimicked (*echokinesis*). These may also be associated with curious mental disturbances, the patient becoming the subject of a form of obsession or a fixed idea. See CHOREA, HYSTERIA.

HAIR, FALLING.—See ALOPECIA.

HAIR, GRAYNESS.—See CANITIES.

HAIR, SUPERFLUOUS.—See HYPERTRICHOSIS, ELECTROLYSIS.

HALLUCINATION.—The highest degree of subjective sensation, dependent alone upon morbid stimulation of the sensory cortical centers. There is the perception of nonexistent objects or impressions, creations of the imagination. Hallucinations are variously classed as hypochondriac, hypnagogic, motor, negative, pseudosensorial, unilateral, visual, auditory, gustatory, olfactory, tactile, hemiopic, epileptoid, etc. See INSANITY, DELUSION.

HALLUX RIGIDUS (H. flexus).—An arthritis of the metatarsophalangeal articulation, the result of flat-foot, defective shoes, or injury, and terminating in ankylosis.

HALLUX VALGUS.—An outward deviation of the great toe produced by short, tight, or pointed shoes, occurring in a slight degree in most civilized people. The head of the first metatarsal often becomes enlarged as the result of chronic periostitis. A bursa may form in this situation (BUNION, *q. v.*) which may become inflamed.

HAMAMELIS (Witch-hazel).—The leaves of *H. virginiana,* with properties not fully known. It is thought to be tonic, astringent, styptic, and sedative, and appears to affect the circulation in a manner similar to aconite. It is recommended in hemorrhages from the nose, stomach, lungs, rectum and kidneys, in threatened abortion, and externally for sprains and bruises, foul ulcers, the pruritus of eczema, also in leukorrhea and gonorrhea. A preparation of this drug is sold under the name of "Pond's Extract." It is official in two forms, **H. Cortex,** Hamamelis bark; and **H. Folia,** the leaves; the dose of each is 10 to 45 grains.

Preparations.—Aqua H., *hamamelis water.* Dose, 1 to 3 drams. **Fluidextractum H. Foliorum,** *fluidextract of hamamelis leaves,* is made with glycerin, alcohol and water. Dose, 5 to 45 minims.

HAMMER-TOE.—A permanent hyperextension of the first, and flexion of the second and third phalanges. Slight cases give no trouble; in severe cases amputation may be demanded by the patient. See TALIPES.

HAND IN DIAGNOSIS. Color.—When inspecting the hand of a sick person, one naturally first notices the color of the skin. If the skin is pale, it indicates some form of anemia—some disease in which the blood is deteriorating in quality. If there is a waxy appearance as well as paleness, it is possible that chronic nephritis is present. A bluish tinge, especially blueness of the finger-nails, strongly indicates disease of the heart and in examining that organ we would expect to find some lesion which prevented the free return of venous blood from the extremities. Cyanosis with clubbing of the fingers is characteristic of emphysema and fibroid phthisis, and is usually marked in the later stages in all cases of pulmonary tuberculosis; there may be a mottled appearance on the backs of the hands—small brown spots which do not disappear on pressure. It is also stated by some authorities that in cases of jaundice stretching the skin on the back of the hand will often reveal the characteristic yellowing which is not shown elsewhere (Goodspeed).

Eruptions.—Various eruptions may appear on the hands, the palmar surfaces being, however, nearly always exempt. An itching eruption between the fingers on the backs of the hands may prove to be scabies. Eczema appears on the dorsal surface in preference to the palmar.

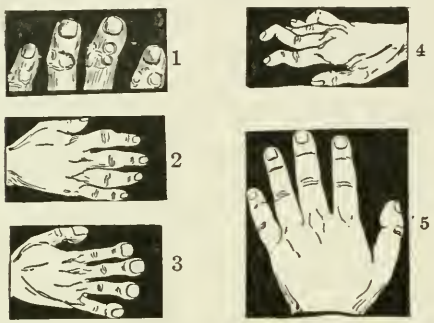
Edema of the hand, if bilateral, would indicate chronic nephritis, but if unilateral, it would point to some lymphatic or other injury in the region of the axilla. An aneurysm of the aorta might also produce an edematous condition in one hand, but the arm would also share in the swelling. Unilateral edema of the hand and arm is sometimes observed as a temporary symptom after cerebral hemorrhage or embolism.

In the later stages of Bright's disease puffiness on the backs of the hands is very prominent, and as the end approaches the edema gradually creeps up the arms. Swelling with redness would, of course, indicate some inflammatory condition—most likely erysipelas or acute rheumatism.

Change in Shape and Size.—Thickening and enlargement of the joints of the fingers are the result of rheumatism, rheumatoid arthritis, or gout. In

rheumatoid arthritis the tenderness is not so great as in rheumatism and gout, but the pain in these affections is more constant than in rheumatism. Besides, gout attacks the toes much more frequently than the fingers. There are further differences between these affections. The rheumatic finger is swollen, but soft and puffy, while in gout it is hard. Then, too, the hot and evidently inflamed condition is not present in arthritis and gout, as it is in rheumatism.

In rheumatoid arthritis the opposing surfaces of the joints become absorbed, and the joints are partially or wholly dislocated. In advanced stages of this disease the fingers will often be found bent and firmly ankylosed, sometimes backward and sometimes forward. Curiously enough, rheumatoid arthritis nearly always spares the thumbs.



1. Heberden's Nodes. 2. Syphilitic Dactylitis. 3. Clubbed Fingers. 4. Arthritis Deformans. 5. Spade Hand of Akromegaly.—(*Greene.*)

Tubercular dactylitis may at first sight closely simulate rheumatoid disease in children; but the spindle swelling is caused by bone expansion, and is accompanied by suppuration, in both of which points it differs essentially from the latter disease. The other group, the rarer diseases, are as follows:

In Paget's disease (ostitis deformans) the cranium and long bones are the parts usually affected; and, though the hands sometimes show changes, these are hardly diagnostic and are very rare.

In akromegaly the large size of the hands is due to the excessive development of all the tissues; there is no appreciable increase in length, only in width and thickness, earning for the hands the epithets "battledore" and "spadelike." The wrists are about normal; the nails are somewhat flattened, small, and longitudinally striated.

In hypertrophic pulmonary osteoarthropathy the carpometacarpus, the hand proper, is about normal in size, but the fingers are enormously enlarged, the bulbous terminal phalanges being especially prominent; the nails are curved and striated, reminding one of the beak of a parrot; there is great enlargement of the wrists.

Myxedematous hands may at first sight be mistaken for either akromegaly or hypertrophic pulmonary osteoarthropathy; but it will be seen that the skin of the other parts of the body is involved, and that it is adherent to the deeper structures.

Vasomotor paralysis of the extremities may somewhat resemble the foregoing; the presence of subcutaneous hemorrhages may clear up the diagnosis.

The hands may exhibit marked changes in rickets, which in rare cases may simulate some of the former diseases, but an examination of the rest of the body will generally readily afford the data for a diagnosis.

In leontiasis ossea (Virchow) the hands may be affected; but for diagnostic purposes, the changes are unimportant.

Nodosities of the fingers have been noted in connection with dilatation of the stomach.

Nails.—The white spots that are often seen on the finger-nails of children have no special clinical significance. Some authorities say they are due to slight injuries; others that they result from processes of growth and development.

The incurved nail associated with a clubbed finger-tip is a sign of chronic pulmonary or cardiac disease of the obstructive type, or an advanced pulmonary tuberculosis. Brittle, striated or split nails most frequently occur in connection with gout, peripheral neuritis, and prolonged exposure to the X-ray. Most important of all to the case-taker are the transverse ridges indicating a past severe illness; these are easily noted, last for a period of over 6 or 8 months, and by their proximity to the matrix indicate approximately the date of the illness.

If the finger-nails are very close and show evidence of being bitten off, the chances are that the subject is of a neurotic temperament, and hysteric manifestations might be expected.

Tremors of the hand may indicate paralysis agitans, general paresis, alcoholism, poisoning by lead or mercury hysteria, Graves' disease, spinal sclerosis, great weakness, as in typhoid fever, senility, and chorea.

In paralysis agitans the whole hand is affected, and usually both hands alike. The head, too, joins in the shaking process. The tremor is fine and rhythmic in character. It is always worse when attention is called to it, and in the early stages of the disease ceases during sleep. The fingers are generally semiextended and the thumb is drawn to the side of the hand, so that it constantly rubs against the forefinger.

The tremor of general paresis is rapid—8 to 10 a second—and is a very fine tremor. It is best felt when the patient's arm is extended and his fingers are resting on the hand of the physician.

In alcoholism the shaking is slow and not constant. It does not necessarily increase when attention is directed to it, and is worse in the morning.

The tremor of chronic mineral poisoning is not more marked in the hands than in other parts of the body. There is a general trembling and unsteadiness of muscular movement; then, too, in lead-poisoning we find the characteristic "drop-wrist," the extensor muscles being unable to hold up the hand. Partial anesthesia, or impaired sensibility to touch, is also a phenomenon of lead-poisoning, the affection being found equally distributed on the two sides of the body.

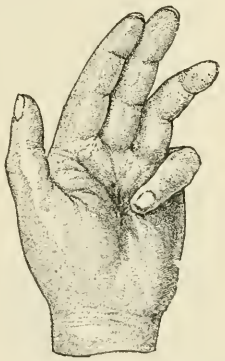
The tremor of Graves' disease is also fine, like that of general paresis, and is best observed when the arm is extended. This motion has been called the "railroad-bridge tremor," on account of its fineness and vibratory character. The fingers do not separately tremble, as in paralysis agitans.

In spinal sclerosis the amount of agitation increases when the subject attempts any muscular act, such as raising a glass of water to the lips (*intention-tremor*).

The movements of chorea are very irregular and arrhythmic, and only one hand or arm may be affected. When the choreic patient attempts any action with the affected hand or arm, the movement is likely to be counteracted by some other involuntary muscular contraction, and the resulting motion is widely different from that intended by the patient.

The trembling and carphology of typhoid fever denote great prostration, and are a sign of serious import, generally foreboding ill.

HAND, DUPUYTREN'S CONTRACTION.–The palmar fascia and its prolongations that run by the side of the fingers and are attached to the periosteum of the first phalanx not infrequently become the seat of a peculiarly obstinate form of contraction, tying the fingers rigidly down into the palm of the hand. It is more common in men than in women, generally begins in middle life, and frequently affects both hands. It has been attributed to heredity, gout and rheumatism, and to habits or occupations necessitating pressure in the palm, or flexion of the fingers, or to inoculation of the subcutaneous connective-tissue with a specific germ by a scratch of the palm by the finger-nail. The affection consists in a shortening of the prolongations of the fascia from the palm on to the sheath of the flexor tendons. The tendons themselves are not affected. The contraction generally begins in the fascia of the little or ring finger as a small rounded fibrous nodule, and later may affect that of the middle finger, and at times the forefinger and also the thumb. The affected fingers are drawn by tense bands toward the palm, and in severe cases may become fixed in contact with it. The skin being adherent to the fascia, is thrown thereby into transverse puckers. The affection may be distinguished from a contracted tendon by the latter forming a tight cord, which can be traced under the annular ligament, and by the skin in the case of the contracted tendon being free. In contraction of the fascia, moreover, two tense bands can generally be traced to the sides of the finger, whereas a contracted tendon is centrally placed. The last phalanx is not involved in the contraction of the fascia, but is often flexed by a contracted tendon.



Dupuytren's Contraction of the Palmar Fascia.—(*Spencer & Gask.*)

Treatment.—The progress of the contraction is checked by applying a splint at night to keep the fingers fully extended, by gentle passive movements and massage. In some cases injections of fibrolysin or thiosinamin have had a good result in causing the scar tissue to disappear. When the finger is already drawn down, the *contracted fascia may be excised* by making a V-shaped incision pointing upward through the skin, which becomes a triangular wound as the finger is straightened. Through it the fascia, with its prolongation forward to the sides of the phalanges laterally, is carefully dissected out. Then the triangular wound is sutured by drawing the edges together in the shape of a Y. There is less tendency to relapse after this than after the older method of subcutaneous division.

Subcutaneous division is done by making several punctures in the palm near the web and at the side of the proximal phalanx opposite the puckers in the skin, not in the creases, so that the punctures do not gape when the fascia is stretched. After the latter operation in particular, a splint must be worn at night for months to prevent recontraction. (Spencer and Gask.)

HAND, PALMAR ABSCESS.—This is a serious matter both on account of the danger of sepsis and because the hand may be left permanently crippled

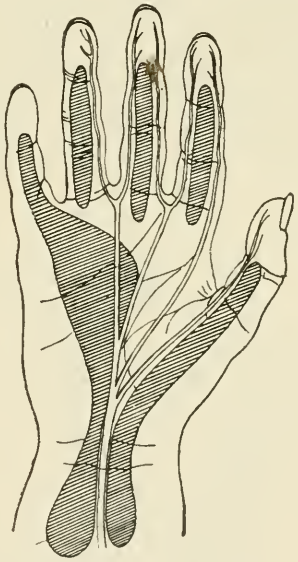


Diagram of Tendon Sheaths of the Hand.—(*Tillaux.*)

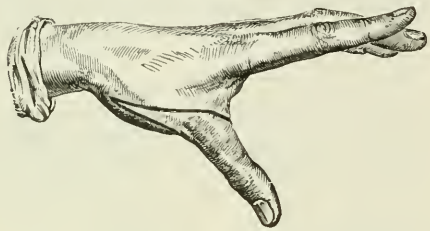
as a result of the destruction of tissue and inflammatory adhesions. Immediate evacuation of pus is imperative. If the pus is limited to the connective tissue of the palm, and has not reached the tendon sheaths, the incision should be made over and parallel with the interosseous space in the region of the greatest swelling. If the tendon sheaths are involved, the incision should be made in the long axis of the metacarpal bone. If a large abscess has formed a longitudinal incision should be made, the position of the palmar arches

being borne in mind. The incision is begun just below a line drawn across the palm from the web of the thumb and is made deep enough to go quite through the palmer fascia. A drainage-tube is inserted and the wound is dressed antiseptically (Sluss).

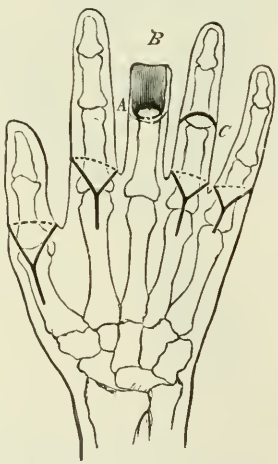
HAND AND FINGERS, AMPUTATIONS.—Amputation at the wrist may be performed by two short flaps, by a long palmar flap, or by an external flap taken from the thumb. In the double flap method the incision is commenced 1/2 of an inch above the styloid process of the radius or ulna. The flaps should be cut square, with rounded



Amputation of Metacarpal Bone of the Thumb.

angles, and about 2 inches in length. The joint should be opened on the dorsal aspect, and on the completion of the disarticulation the styloid processes of the radius and ulna should be sawed off.

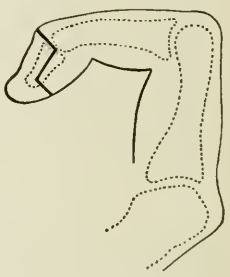
Amputation of the Metacarpal Bone of the Thumb.—By anterior flap operation: Hold the thumb out; insert the bistoury near the metacarpophalangeal joint; its point is thrust between the bone and the muscles of the ball of the thumb, and as close to the bone as possible, and brought



Outline Diagram for Amputation of the Thumb and Fingers.—(*Moullin.*)

out just above the articulation with the trapezium. The bistoury is then made to cut its way outward, and the point of the knife is carried from the upper end along the bone, and around the metacarpophalangeal joint, to meet the other incision. The bone is disarticulated by being forcibly abducted, and the ligaments on the inner side of the metacarpotrapezial joint are cut through first.

Amputation of the Fingers.—It must be remembered that, in all these joints, the bone that projects on the dorsal surface is the proximal one; and that, on the palmar surface, although the fold of the skin corresponds fairly well to the first interphalangeal joint, this is not the case either with the one above or the one below; the circle formed by the skin (when the fingers are flexed) is smaller than that formed by the bones, and consequently the distance between the folds is less than that between the joints; the nearest of the three is the thickness of the metacarpal bone below the articulation; the middle one corresponds to it, and the furthest is the thickness of the phalanx above.



(*After Binnie.*)

Amputation at the Metacarpophalangeal Joint.—A racket-shaped incision is the best, commencing on the neck of the metacarpal, running straight down on to the phalanx, and then winding round the finger below the web. It should divide the extensor tendon at once, and pass right down to the bones. Afterward, the lateral ligaments and a few other structures require division. In the case of the index- and little fingers, the incision should be made at the side, as it is less conspicuous. When strength is required, the head of the metacarpal should be left; but if it is wished to minimize the deformity at all cost, it may be removed obliquely with bone-forceps.

Dislocation of the Thumb Backward at the Metacarpophalangeal Joint.—(*After Agnew.*)

Interphalangeal Amputation.—This is usually performed with a single palmar flap; but single dorsal, lateral, or equal dorsal and palmar flaps may be selected instead.

When a long palmar flap is chosen, the finger is bent to a right angle, and the knife, which should be long and very narrow, is drawn across the front of the joint, so as to open it, dividing the extensor tendon at one sweep. The lateral ligaments are then divided, and the knife is insinuated behind the distal phalanx, and, following its palmar surface, made to cut a long, square-shaped flap from the under portion.

It is usually recommended not to amputate through the proximal phalangeal joint or through the proximal phalanx itself; but, as Jacobson points out, this rule should not be followed in the case of the index- or the little finger, when all the

fingers are amputated, or when the patient prefers to have one left. If the flexor tendons are stitched to the theca, to the periosteum, or even to the skin, the stump follows all the movements of the other fingers.

HAND AND FINGERS, DISLOCATIONS.—Dislocations of the carpal and metacarpal bones are very rare. Their diagnosis is usually obvious. See also Wrist.

The phalanges of the fingers may be dislocated backward or forward. Reduction is easily affected by extension and manipulation.

Dislocation of the metacarpal bone of the thumb from the trapezium may occur in a backward or forward direction, and is easily reduced by extension or pressure.

Dislocation of the first phalanx of the thumb from the metacarpal bone is of more importance. The phalanx is nearly always displaced backward; the shortening of the thumb and the projections of the base of the phalanx and head of the metacarpal bone serve for diagnosis. Reduction is often very difficult; this is usually ascribed to the head of the metacarpal bone being forced between the two insertions of the flexor brevis pollicis, by which its neck is tightly embraced. Humphry has shown, however, that the hindrance to reduction depends upon the fact that the sesamoid bones and the ligaments connecting them are carried back with the phalanx, and being held there by the flexor brevis, and intervening between the metacarpal bone and the phalanx, prevent the articular surfaces of the bones being brought into contact.

Treatment.—Press the metacarpal bone well into the palm of the hand to relax the flexor brevis pollicis, and bend back the first phalanx on the metacarpal bone until the extremity of the thumb points toward the wrist, thus forcing the base of the phalanx wedgewise between the two insertions of the short flexor. Next flex the phalanx, while an assistant, by placing the thumb behind its base, prevents its slipping back. The head of the metacarpal bone will now probably slide into its place between the two insertions of the flexor brevis pollicis, which are forced apart by the wedge-like action of the base of the phalanx. Reduction may sometimes be accomplished by extension: *e. g.*, by the clove-hitch, or, if at hand, by the Indian puzzle-toy or the forceps. These means not proving successful, it is usually advised that the insertion of the flexor brevis pollicis should be subcutaneously divided. Humphry recommends an incision over the sesamoid bones and the introduction of a hook to hitch the sesamoid bones over the head of the metacarpal. In this way, he says, the reduction is immediately effected. As a last resort, the joint may be cut down upon, the bands resisting reduction, divided and the bone replaced; or the joint may be excised, or, perhaps better, left alone, as very fair movement will, as a rule, in time be gained.

HAND AND FINGERS, FRACTURES.—**The carpal bones** are rarely fractured, and then nearly always as a result of direct violence that contuses and lacerates the overlying soft parts at the same time. The seriousness of the lesion will depend upon the extent and course of these complicating injuries. See Carpal Bones (fracture).

The metacarpal bones are fractured usually from direct blows upon the back of the hand. Crepitation and abnormal mobility, together with the marked pain at the site of fracture, give the clue. Displacement seldom occurs.

Frequently a circular bandage, with a pad and protection of the hand for a few days, suffices for treatment. Sometimes an unruly fragment or unusual pain may demand the application of a simple splint. Massage and exercise of the fingers are useful.

The phalanges, from their freely exposed and unsupported position, are frequently fractured; usually from direct force, occasionally from a force acting in the direction of their long axes.

The diagnosis of fracture of bones of the hand or fingers is very simple, and the treatment is simple, consisting of a small padded splint.

HANDKERCHIEF-DRESSING.—A form of temporary dressing for wounds and fractures made of handkerchiefs. There are two varieties: viz., *cravats*, in which the handkerchiefs are folded into rolls like cravats; and *triangles*, the handkerchiefs being folded diagonally in the form of triangles.

The most important **cravats** are the following: **C., Abdominoinguinal.** Two handkerchiefs are folded into cravats and their ends tied together. The body of one is placed beneath the thigh, close up to the nates; the ends are brought to the front, crossed over the groin, then carried around the opposite sides of the body and tied together on one side rather than behind, so that the knot shall not press injuriously upon the back. **C., Axilloacromial.** See C., Parietoaxillaris. **C., Axillocervical.** The body of the cravat is placed in the axilla, the ends are crossed over the shoulder and tied on the opposite sides of the neck. **C., Cervical.** A handkerchief is formed into a cravat, the body placed on the front, back, or sides of the neck, according to the part to be dressed, the ends are carried around, crossed on the opposite side and returned, and fastened with pins. **C., Compound Bisaxillary.** For this two handkerchiefs in cravat form are required. One is tied as an axilloacromial cravat through one axilla, while the body of the other is placed in the opposite axilla, and its ends, being brought across the chest, one in front and the other behind, are passed through the loop of the first and tied in front of the breast. **C., Compound Bisaxilloscapulary.** Form two handkerchiefs into cravats. The one as a loose ring, or form the axilloacromial cravat of one side, and, placing the body of the other in front of the opposite shoulder, bring the ends back, one over the shoulder and the other through the axilla; then form these into a single knot, and complete the dressing by passing the ends through the ring or loop of the other cravat and tying them into a knot. **C., Frontooccipitolabialis.** The handkerchief is formed into a cravat and the middle portion is placed upon the forehead; the ends are carried back, crossed upon the posterior part of the neck, brought forward under the ears, and crossed over

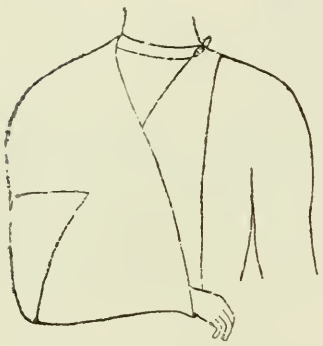
the upper lip. This is used to approximate lip wounds. **C., Ilioinguinal.** A double cravat, also called the *sacrobicrural cravat of Mayor.* The body of a long cravat is placed over the body of the sacrum; the two extremities are brought around the body, down in front of each groin and around the thighs, to be fastened on the opposite side of the body. **C., Ilioinguinal,** or the *cruropelvic cravat of Mayor.* The body of a large cravat is placed over the inguinal region; the upper extremity is carried around the body, the lower extremity around the thigh, and the two ends knotted in front. **C., Metatarsomalleolar.** Place the body of the cravat obliquely across the dorsum of the foot; carry one end under the foot and up in front of the ankle, and the other around the leg above the malleoli, fastening them together in front of the joint. **C., Parietoaxillaris.** One handkerchief is formed into a cravat and its body is placed in the axilla; the ends are tied over the shoulder, forming the *axilloacromial cravat.* A second handkerchief is made into a triangle, and its body placed over the side of the head, and its ends tied into the first over the shoulder. It is used to approximate wounds on the side of the neck and to prevent contraction after burns. **C., Simple Bisaxillary.** Place the body of the cravat in the axilla, cross the ends over the shoulder, and, after carrying one across the back and the other across the breast, tie them together at the anterior border of the axilla of the opposite side. **C., Simple Bisaxilloscapulary.** This is a posterior figure-of-eight, and is best formed with a strip of muslin 3 inches wide and 10 yards long. Place the center of the strip in front of the shoulder and the axilla; bring one end back over the top of the shoulder and the other through the axilla; cross them between the scapulas, carrying the axillary end over the shoulder of the opposite side and back through the axilla, and the humeral end forward through the axilla, the two overlapping each other; then fasten their ends front and back. This is an extemporaneous dressing for fracture of the clavicle. **C., Tarsopatellar.** This requires three handkerchiefs, all in cravat form.

Bitemporal Triangle.

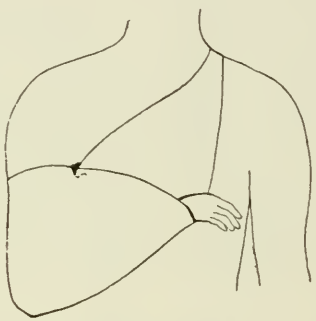
Frontooccipital Triangle.

Auriculooccipital Triangle.

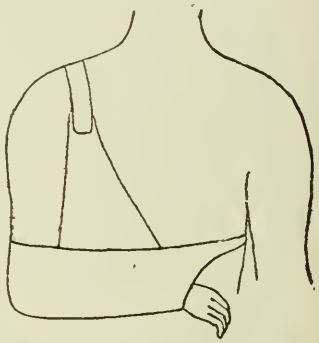
Triangular, or Hunter's Cap of the Head.



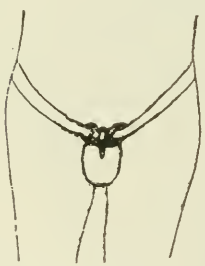
Brachiocervical Triangle.



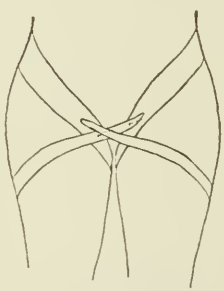
Oblique Triangle of the Arm and Chest.



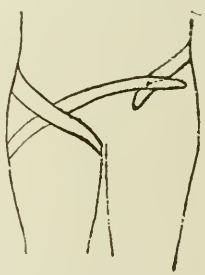
Mayor's Bandage for Fractured Clavicle.



Scrotolumbar Triangle.
(Suspensory bandage of the scrotum.)



Ilioinguinal Cravat (Double).
(The sacrobicrural cravat of Mayor.)



Ilioinguinal Cravat.
(The cruropelvic cravat of Mayor.)

One is placed about the knee as a figure-of-eight; a second round the foot in front of the ankle; the third is passed through the loop of the latter, the ends being carried on each side through the figure-of-eight of the knee, and pinned or tied as they are turned downward. **C., Tibial.** Place the body of a handkerchief, folded into a cravat, obliquely across the posterior surface of the leg, and carry the extremities around the limb, the one below the knee and the other above the malleoli. **Mayor's Bandage for Fractured Clavicle.** The arm is flexed at a right angle and confined to the side of the chest by a triangular handkerchief, the base being placed above the forearm and the two extremities fastened on the back, the apex hanging down in front. The two folds forming the apex are carried up between the arm and the body, and the under one is passed to the sound shoulder, while the upper one is carried to the affected shoulder. A broad piece of bandage is fastened to one apex and carried beneath the handkerchief at the back, and is then brought up and fastened to the other apex on the opposite shoulder.

The most important **triangles** are the following: **T., Auriculooccipital.** A variety of handkerchief-dressing for the head, used in keeping an application to the ear in proper place. The base of the handkerchief is placed in front of the ear to be covered, and the apex directed backward. The lower end is next carried under the jaw and up over the face in front of the ear on the sound side, where it is made to meet the upper end, the two being tied together. **T., Bitemporal.** A form of handkerchief head-dressing, the base being placed over the temporal region upon one side and the apex over the other. The ends are carried round to the opposite temple, crossed, brought back, and secured with pins, and the summit or apex is turned up and pinned above the temporal ridge. **T., Frontooccipital.** A variety of handkerchief-dressing in which the base is placed over the forehead, while the summit is allowed to hang down over the occiput. The ends are next carried backward along the sides of the head, above the ears, and either tied behind the occipital protuberance or crossed, brought forward, and pinned at each side. The apex is then turned forward and pinned to the body of the handkerchief. **T., Malleolophalangeal.** Form the handkerchief into a triangle; place the base under the foot, opposite to the instep; fold the summit back over the toes and the dorsum of the foot, and carry the ends round the malleoli, making them fast in front. Tie the ends in front, or cross them over the dorsum and tie under the sole of the foot. **T., Mammary.** Fold a handkerchief into a triangle; place its base under the breast and its apex over the corresponding shoulder; then carry one end under the axilla and the other over the opposite side of the neck, tying the two behind the scapula of the affected side, and pin to these the summit. **T., Oblique, of the Arm and Chest.** The base of the triangle is placed under the wrist, the apex being allowed to project beyond the elbow. The extremity that is next to the chest is carried over the opposite shoulder, the other extremity being passed through the axilla of the injured side and tied with the first extremity over the sound shoulder. The apex is folded backward around the elbow and fastened. **T., Occipitofrontal.** The same as the *frontooccipital*, only that the handkerchief is reversed, the base being placed over the occiput. **T., Occipitosternal.** One handkerchief is formed into a triangle and another into a cravat. The latter is tied around the chest, forming the sternodorsal cravat. The body of the former is placed over the occiput and its apex over the forehead The ends are brought down on each side of the face and fastened to the cravat about the chest. The apex is turned backward over the vertex and pinned. **T., Palmar.** The base of the handkerchief is placed across the back or the front of the wrist, according as it is desired to dress the palm or dorsum of the hand; the summit is folded back upon the wrist, and secured there by carrying the ends around the same. **T., Scrotolumbar.** See T., Suspensory. **T., Simple Brachiocervical.** The arm being flexed at a right angle, the base of the triangle is placed under the wrist, and the two extremities are tied around the neck, the knot being thrown to one side. The apex is brought around the elbow and pinned in front. **T., Suspensory.** See Scrotolumbar Triangle. Fold one handkerchief into a cravat and tie it around the loins; form another into a triangle, the base of which should be placed under the scrotum, and the extremities brought up, passed beneath the circular cravat, and tied in front. The apex is next carried up, passed beneath the abdominal cravat, and turned down in front, where it may be fastened with a pin. **T., Verticomental.** A form of handkerchief head-dressing in which the body of the handkerchief is placed over the vertex, the ends brought down over the ears and crossed under the chin, carried upward and pinned to the descending portion of the handkerchief. The apex is brought round one side of the head and secured with a pin. **The Triangular, or Hunter's Cap of the Head.** A piece of material is secured, with the side sufficiently long to pass over the head and fasten under the chin. First hold it transversely across until one side is within an inch of the opposite side; the short side is then placed beneath; the two corners of the folded edge are turned inward, forming a triangle. The two extremities of the triangle are taken one in each hand, and while kept tense are twisted and rolled up to the extent of 2 inches. Lifting the bandage and approximating the hands cause the two sides to separate. It is placed on the head with the thin edge over the forehead and the rolled edge around the back of the neck. The ends are brought under the chin and tied.

HANGING.—Death by suspension of the body from the neck, by a rope provided with a slip noose. The immediate cause of death may be asphyxia, cerebral hemorrhage (from strangulation), or dislocation or fracture of the cervical vertebræ. When from a long drop, the method now employed in judicial hanging, where the knot is usually under the chin, death is mostly due to fracture of the vertebræ or injury of the medulla oblongata. When death is not instantaneous, convulsive

movements may continue for some time after suspension, and the heart may continue to beat for a considerable period. The proof that death by hanging has occurred depends upon the position of the body when found, the presence of certain external marks on the neck and of the signs of asphyxia in the internal organs, and the absence of any other possible cause of death. The external signs vary according to the length of time the body has been left hanging and the nature of the cord used. The mark on the neck is generally a hard, dry, yellowish, horny furrow, running obliquely. Similar appearances usually result if the body is suspended immediately after death.

The face is usually turgid, with blood-stained froth about the mouth and nostrils; the tongue is swollen and semiprotruding. In men the penis is often erect, and an escape of prostatic or seminal (?) fluid has taken place. In women the genital organs may be turgid or blood-stained.

Internally, the right side of the heart and lungs will be distended with venous blood. The left side may be empty. Fracture or dislocation of the cartilages of the larynx or of the hyoid bone may be found, and sometimes the inner coats of the carotid artery are found to have been divided. As suicidal hanging is intentional, it is not necessary that complete suspension in the air exist for a fatal termination to ensue.

Opportunity for treatment seldom presents itself. A free supply of air after the body is cut down, and constricting clothing undone or removed, and artificial respiration are the means to restore suspended animation. Bleeding is sometimes useful to relieve cerebral congestion. See Asphyxia, Artificial Respiration, Neck (Injuries).

HARELIP.—A congenital malformation in which the upper lip is vertically cleft on one or both sides of the median line. It is produced by failure of union of the frontonasal process which forms the median portion of the lip, with the superior maxillary processes which form the lateral portions. It is frequently a mere notch, but more usually it extends through the substance of the lip into the nostril above. Single harelip is most common. Cleft palate is often an accompaniment, and malformations in other parts of the body, such as club-foot, etc., are not uncommon.

Mumford notes that no two cases of harelip are alike. They vary as much as do the faces which they deform; and so, from the simple notch in the border, to the double harelip with complete cleft palate, each case must be treated on its own merits.

With all the varieties of deformity, however, there are two main divisions for surgical purposes: those lips which are backed by a sound jaw, and those which are continuous with the nostril and a palatal cleft. In the former class the mortality is *nil*, so far as the lip is concerned, whether treated or not. In the second class the mortality is high when untreated—by some writers placed as high as 30 percent; when treated, the mortality ranges from 2 to 15 percent, according to Fritsche. These deaths are ascribed in all cases to malnutrition, hemorrhage, or bronchitis. Harelip babies are vigorous, puny, well nourished, and rachitic. Most of these babies are well enough at birth, and their subsequent condition depends largely upon the care and intelligence used in their feeding. If care is used the average infant can be brought comfortably up to the sixth or eight week—the proper time for a harelip operation. Operations done earlier must be hurried, and are ineffectual for cosmetic purposes; if done later, except in the simple cases, the advantages of an early molding of the nose and lateral pressure upon a cleft upper jaw are in a measure lost.

This highly important preparatory feeding of the patient is in itself an art, and if outside the experience of the surgeon, should be intrusted to some one skilled in infant feeding. In Mumford's experience its successful prosecution influences very largely the result of the subsequent operation, and its effects are felt even up to the period of dentition.

Ordinarily, there is no difficulty in giving the modified milk mixture prepared in the laboratories for infant feeding. Those mixtures with an alkalinity of 5 to 6 percent answer all practical purposes. When milk laboratories are not accessible, home modification may be done. In administering the milk there are a few practical hints which should be borne in mind. The food is best fed from a spoon; the various shields and patent nipples are needless and troublesome. The child should be placed on the bed in a half-reclining position during feeding, because when prone, the milk is more likely to run up into the nares. If there is a cleft palate, the most scrupulous care must be observed to keep the mouth and nares clean; for this a cotton stick dipped in a weak boric acid or borax and water solution is best. Plenty of clear water to drink should be give between feedings, as the mouth necessarily is very dry, and by the use of the water a proper action of the bowels is maintained. Stimulants should be given if there is pallor or a flabby skin—one or more drops of brandy with each feeding. The brandy should be increased for 2 days before operation, and on the day of the operation, in any case, a goodly measure should be allowed.

Most authorities are now agreed that chloroform is the best anesthetic for the operation, on account of its nonirritating action on the lungs.

In simple notched lips not extending to the nostril, it is well to wait until the child is 3 or 4 years old, as the wound is more easily managed and a most exact plastic operation can be done with the more mature tissues. In these cases, and, indeed, in all others, so far as ultimate beauty of result is concerned, the greatest attention must be paid to the finish of the vermilion border. For this purpose the Nélaton or Malgaigne operations are those to be used. The old-fashioned slashing cuts with scissors and the quick sewing up are bad surgery, and should never be used except when desperate hurry is demanded.

There is a large variety of other flap operations described by authors—Hagedorn's, Mirault-Langenbeck's, Simon's, Giradlès', and many more. They are all designed on the dovetail principle, their object being to fill in the cavity and provide a smooth, red lip border. They sometimes answer

admirably for older children and adults, but not for restless, crying babes. At best, they leave an irregular scar instead of a straight line, and there not infrequently results an ugly notch in the lip border. The intermaxillary bone can usually be forced into position and utilized. In very rare cases it must be sacrificed.

It has been claimed by some writers that double harelip operations should be postponed until the second or third year of life, but others prefer to do them within the first two months, if possible, because the same advantâges apply to the early operations in these cases as to those of single harelip. In all operations, except for a simple notch, the soft parts about the alveolar processes and nares should be dissected free from the upper jaw with blunt-pointed scissors. By clinging closely to the bone, no hemorrhage will result. When the flaps are being cut, the coronary arteries may be controlled easily by an assistant's fingers. Scissors should not be used in cutting the flaps. They are inaccurate, sometimes bruise the tissues, and do not leave so clean and broad a cut surface. A narrow-bladed knife is best.

The old-fashioned harelip pins have gone out of use, and very properly. Even when removed on the third day—the old rule—they leave a scar: and the third day is too early for the removal of deep sutures. In all operations, for both double and single harelip, one shotted stitch of silver wire is sufficient to anchor the parts. It is inserted in the fold behind the alæ, lies in that natural furrow, takes all the strain from the severed deep parts, holds in place the intermaxillary bone, and leaves no perceptible scar. When this stitch has been placed and the parts approximately brought into position, the question of passing the remaining stitches is one simply of time and patience. In all extensive operations, and always in the case of babies, Mumford has adopted the method of J. C. Warren. Working with a stout silk suture, threaded with a needle at each end, the stitch is entered close under the skin in the freshened lip border, is passed deeply through the underlying soft parts and buccal mucous membrane, and tied strongly to its fellow inside the mouth. Three or four of these heavy stitches suffice to hold the parts firmly in excellent apposition; when tied, the ends should be cut long. The slight gaping in the skin flaps of the external wound is closed with a few very fine intestinal sutures threaded in small embroidery needles, which are passed as closely as possible to the cut edges, the greatest care being taken not to draw them tight enough to invert the skin. The fine superficial sutures must be removed on the third day, and it will be found that no perceptible stitch scar results. The deep stitches are removed from the inside of the mouth on the fifth or sixth day, and the wire bridge on the seventh or eight day. By no means the least part of the operation is the application of a proper sustaining strap from cheek to cheek. The old-fashioned adhesive plaster is a wretched device, and should never be used. It is unclean, sweats the parts, and checks any discharges that may collect. The familiar crêpe-lisse "butterfly" is the best support. It is light, clean, sightly, and does not check discharges. Before applying it, it is well to paint the wound inside and outside the mouth with compound tincture of benzoin, to lay a soft absorbent pad across the external wound, and then firmly to secure the "butterfly" with flexible collodion.

Silkworm-gut is sometimes used for sutures. It is applicable only when tied outside the lip. When so used, it always leaves a scar. For older children and adults, excellent and satisfactory results have been obtained with buried catgut. Only by its use can an approach to an aseptic operation be made. The firm resisting tissues of an adult offer an excellent hold for the buried stitch, and if there remains a slight gaping of the skin, it can be closed with the fine intestinal sutures.

An absolutely aseptic program can never be carried out in any harelip operation, but some attempt should always be made to render the field approximately sterile. The constant use of boric acid washes, both before and after operation, should be maintained. At the time of the operation, the upper lip should be thoroughly wiped over, inside and out, with alcohol, which in its turn is to be washed off with water.

During convalescence, especially after the removal of the stitches, some spreading of the upper part of the wound should not discourage the surgeon. As a rule, if the vermilion border holds, the open cleft above will heal, by second intention, in 2 or 3 weeks. There is often a very anxious time about the end of the first week, but the holding of the border is a sure sign that all will yet go well. No one feature in the whole treatment of harelip is of more importance than that of the feeding of young infants during convalescence from the operation. As an immediate result of the operation there is almost always considerable gastrointestinal disorder. This is in part due to the anesthetic and in part to shock, but by far the most important factor is the blood which has been swallowed. No matter what the form of operation or the position in which the child is held, a very considerable amount of blood finds its way into the stomach. If this is vomited, so much the better; but usually it remains and makes trouble. There then follow several days of diarrhea, undigested stools, pain, colic, sometimes loss of appetite and occasionally vomiting. These symptoms may persist many days, and not infrequently most seriously threaten life. More often, however, they merely debilitate the patient, and seriously delay the healing of the wound. Sometimes there is a total lack of success in closing the lip, obviously due to a low vitality in the wound through malnutrition in an infant hitherto perfectly healthy and strong. Of the very greatest importance, therefore, is proper care during convalescence. The ordinary rules for the treatment of an acute mycotic diarrhea are here applicable. On the evening after the operation a brisk purge should be given—castor oil or calomel; and the child should be put on a weak cream mixture. Sometimes even this is not borne, and a thin barley-water mixture or weak, strained chicken soup

should be substituted for it. Meanwhile liberal doses of brandy should be given, and if diarrhea persists, bismuth subgallate, in 3-grain doses or more, should follow each feeding. Gradually the diet may be strengthened as convalescence progresses, until the normal mixtures have been reached. At the same time plenty of water to drink should be given—a precaution most often neglected by uninstructed nurses.

A résumé of the important points brought out by Mumford in the treatment of harelip includes the following considerations:

1. Harelip babies are not necessarily feeble at birth, and by proper feeding may be kept up to the normal standard.
2. Keep the field clean with aseptic washes before the operation.
3. Operate in the sixth to the eighth week.
4. Do not slash with scissors, but cut and trim carefully with a knife.
5. Free the upper lip thoroughly from the jaw.
6. Anchor the nares with shotted wire.
7. Use no pins or heavy outside sutures.
8. Use crêpe-lisse, not surgeon's plaster.
9. Leave the heavy inside stitches for 6 days.
10. Feed carefully and pay attention to the bowels.

HARRISON LAW.—This is a law relating to the production, importation, manufacture, compounding, sale, dispensing, or giving away of opium or coca leaves, their salts, derivatives, or preparations. We print such parts of it as refer to the physician, druggist and veterinarian. On account of the uncertainty of its meaning we decline to venture an opinion on its interpretation.

The Law.—By an act of Congress approved December 17, 1914, it is provided:

That on and after the first day of March, nineteen hundred and fifteen, every person who produces, imports, manufactures, compounds, deals in, dispenses, sells, distributes, or gives away opium or coca leaves or any compound, manufacture, salt, derivative, or preparation thereof, shall register with the collector of internal revenue of the district his name or style, place of business, and place or places where such business is to be carried on: *Provided*, That the office, or if none, then the residence of any person shall be considered for the purpose of this Act to be his place of business. At the time of such registry and on or before the first day of July, annually thereafter, every person who produces, imports, manufactures, compounds, deals in, dispenses, sells, distributes, or gives away any of the aforesaid drugs shall pay to the said collector a special tax at the rate of $1 per annum: *Provided*, That no employee of any person who produces, imports, manufactures, compounds, deals in, dispenses, sells, distributes, or gives away any of the aforesaid drugs, acting within the scope of his employment, shall be required to register or to pay the special tax provided by this section: *Provided further*, That the person who employs him shall have registered and paid the special tax as required by this section: *Provided further*, That officers of the United States Government who are lawfully engaged in making purchases of the above-named drugs for the various departments of the Army and Navy, the Public Health Service, and for Government hospitals and prisons, and officers of any State government, or of any county or municipality therein, who are lawfully engaged in making purchases of the above-named drugs for State, county, or municipal hospitals or prisons, and officials of any Territory or insular possession or the District of Columbia or of the United States who are lawfully engaged in making purchases of the above-named drugs for hospitals or prisons therein shall not be required to register and pay the special tax as herein required.

It shall be unlawful for any person required to register under the terms of this Act to produce, import, manufacture, compound, deal in, dispense, sell, distribute, or give away any of the aforesaid drugs without having registered and paid the special tax provided for in this section.

That the word "person" as used in this Act shall be construed to mean and include a partnership, association, company, or corporation, as well as a natural person; and all provisions of existing law relating to special taxes, so far as applicable, including the provisions of section thirty-two hundred and forty of the Revised Statutes of the United States are hereby extended to the special tax herein imposed.

That the Commissioner of Internal Revenues, with the approval of the Secretary of the Treasury, shall make all needful rules and regulations for carrying the provisions of this Act into effect.

SEC. 2.—That it shall be unlawful for any persons to sell, barter, exchange, or give away any of the aforesaid drugs except in pursuance of a written order of the person to whom such article is sold, bartered, exchanged, or given, on a form to be issued in blank for that purpose by the Commissioner of Internal Revenue. Every person who shall accept any such order, and in pursuance thereof shall sell, barter, exchange, or give away any of the aforesaid drugs, shall preserve such order for a period of two years in such a way as to be readily accessible to inspection by any officer, agent, or employee of the Treasury Department duly authorized for that purpose, and the State, Territorial, District, municipal, and insular officials named in section five of this Act. Every person who shall give an order as herein provided to any other person for any of the aforesaid drugs shall, at or before the time of giving such order, make or cause to be made a duplicate thereof on a form to be issued in blank for that purpose by the Commissioner of Internal Revenue, and in case of the acceptance of such order, shall preserve such duplicate for said period of two years in such a way as to be readily accessible to inspection by the officers, agents, employees, and officials hereinbefore mentioned. Nothing contained in this section shall apply—

(*a*) To the dispensing or distribution of any of the aforesaid drugs to a patient by a physician, dentist, or veterinary surgeon registered under this Act in the course of his professional practice

only: *Provided*, That such physician, dentist, or veterinary surgeon shall keep a record of all such drugs dispensed or distributed, showing the amount dispensed or distributed, the date, and the name and address of the patient to whom such drugs are dispensed or distributed, except such as may be dispensed or distributed to a patient upon whom such physician, dentist or veterinary surgeon shall personally attend; and such record shall be kept for a period of two years from the date of dispensing or distributing such drugs, subject to inspection, as provided in this Act.

(*b*) To the sale, dispensing, or distribution of any of the aforesaid drugs by a dealer to a consumer under and in pursuance of a written prescription issued by a physician, dentist, or veterinary surgeon registered under this Act: *Provided, however*, That such prescription shall be dated as of the day on which signed and shall be signed by the physician, dentist or veterinary surgeon who shall have issued the same: *And provided further*, That such dealer shall preserve such prescription for a period of two years from the day on which such prescription is filled in such a way as to be readily accessible to inspection by the officers, agents, employees, and officials hereinbefore mentioned.

(*c*) Omitted.

(*d*) To the sale, barter, exchange, or giving away of any of the aforesaid drugs to any officer of the United States Government or of any State, territorial, district, county, or municipal or insular government lawfully engaged in making purchases thereof for the various departments of the Army and Navy, the Public Health Service, and for Government, State, territorial district, county, or municipal or insular hospitals or prisons.

The Commissioner of Internal Revenue, with the approval of the Secretary of the Treasury shall cause suitable forms to be prepared for the purposes above mentioned, and shall cause the same to be distributed to collectors of internal revenue for sale by them to those persons who shall have registered and paid the special tax as required by section one of this Act in their districts, respectively, and no collector shall sell any of such forms to any persons other than a person who has registered and paid the special tax as required by section one of this Act in his district. The price at which such forms shall be sold by said collectors shall be fixed by the Commissioner of Internal Revenue, with the approval of the Secretary of the Treasury, but shall not exceed the sum of $1 per hundred. Every collector shall keep an account of the number of such forms sold by him, the names of the purchasers, and the number of such forms sold to each of such purchasers. Whenever any collector shall sell any of such forms, he shall cause the name of the purchaser thereof to be plainly written or stamped thereon before delivering the same; and no person other than such purchaser shall use any of said forms bearing the name of such purchaser for the purpose of procuring any of the aforesaid drugs, or furnish any of the forms bearing the name of such purchaser to any person with intent thereby to procure the shipment or delivery of any of the aforesaid drugs. It shall be unlawful for any person to obtain by means of said order forms any of the aforesaid drugs for any purpose other than the use, sale, or distribution thereof by him in the conduct of a lawful business in said drugs or in the legitimate practice of his profession.

The provisions of this Act shall apply to the United States, the District of Columbia, the Territory of Alaska, the Territory of Hawaii, the insular possessions of the United States, and the Canal Zone. In Porto Rico and the Philippine Islands the administration of this Act, the collection of the said special tax, and the issuance of the order forms specified in section two shall be performed by the appropriate internal-revenue officers of those governments and all revenues collected hereunder in Porto Rico and the Philippine Islands shall accrue intact to the general governments thereof, respectively. The courts of first instance in the Philippine Islands shall possess and exercise jurisdiction in all cases arising under this Act in said islands. The President is authorized and directed to issue such Executive orders as will carry into effect in the Canal Zone the intent and purpose of this Act by providing for the registration and the imposition of a special tax upon all persons in the Canal Zone who produce, import, compound, deal in, dispense, sell, distribute, or give away opium or coca leaves, their salts, derivatives, or preparations.

SEC. 3. That any person who shall be registered in any internal-revenue district under the provisions of section one of this Act shall, whenever required so to do by the collector of the district, render to the said collector a true and correct statement or return, verified by affidavit, setting forth the quantity of the aforesaid drugs received by him in said internal-revenue district during such period immediately preceding the demand of the collector, not exceeding three months, as the said collector may fix and determine; the names of the persons from whom the said drugs were received; the quantity in each instance received from each of such persons, and the date when received.

SEC. 4. That it shall be unlawful for any person who shall not have registered and paid the special tax as required by section one of this Act to send, ship, carry, or deliver any of the aforesaid drugs from any State or Territory or the District of Columbia, or any insular possession of the United States, to any person in any other State or Territory or the District of Columbia or any insular possession of the United States: *Provided*, That nothing contained in this section shall apply to common carriers engaged in transporting the aforesaid drugs, or to any employee acting within the scope of his employment, of any person who shall have registered and paid the special tax as required by section one of this Act, or to any person who shall deliver any such drug which has been prescribed or dispensed by a physician, dentist, or veterinarian required to register under the terms of this Act, who has been employed to prescribe for the particular patient receiving such drug, or to any

United States, State, county, municipal, District, Territorial, or insular officer or official acting within the scope of his official duties.

Sec. 5. That the duplicate-order forms and the prescriptions required to be preserved under the provisions of section two of this Act, and the statements or returns filed in the office of the collector of the district, under the provisions of section three of this Act, shall be open to inspection by officers, agents, and employees of the Treasury Department duly authorized for that purpose; and such official of any State or Territory, or of any organized municipality therein, or of the District of Columbia, or any insular possession of the United States, as shall be charged with the enforcement of any law or municipal ordinance regulating the sale, prescribing, dispensing, dealing in, or distribution of the aforesaid drugs. . . . .

Sec. 6. That the provisions of this Act shall not be construed to apply to the sale, distribution, giving away, dispensing, or possession of preparations and remedies which do not contain more than two grains of opium, or more than one-fourth of a grain of morphine, or more than one-eighth of a grain of heroin, or more than one grain of codeine, or any salt or derivative of any of them in one fluid ounce, or, if a solid or semisolid preparation, in one avoirdupois ounce; or to liniments, ointments, or other preparations which are prepared for external use only, except liniments, ointments, and other preparations which contain cocaine or any of its salts or alpha or beta eucaine or any of their salts or any synthetic substitute for them: *Provided*, That such remedies and preparations are sold, distributed, given away, dispensed, or possessed as medicines and not for the purpose of evading the intentions and provisions of this Act. The provisions of this Act shall not apply to decocainized coca leaves or preparations made therefrom, or to other preparations of coca leaves which do not contain cocaine.

Sec. 7. Omitted.

Sec. 8. That it shall be unlawful for any person not registered under the provisions of this Act, and who has not paid the special tax provided for by this Act, to have in his possession or under his control any of the aforesaid drugs; and such possession or control shall be presumptive evidence of a violation of this section, and also of a violation of the provisions of section one of this Act: *Provided*, That this section shall not apply to any employee of a registered person, or to a nurse under the supervision of a physician, dentist, or veterinary surgeon registered under this Act, having such possession or control by virtue of his employment or occupation and not on his own account; or to the possession of any of the aforesaid drugs which has or have been prescribed in good faith by a physician, dentist, or veterinary surgeon registered under this Act; . . . .

Sec. 9. That any person who violates or fails to comply with any of the requirements of this Act shall, on conviction, be fined not more than $2,000 or be imprisoned not more than five years, or both, in the discretion of the court.

Sec. 10. Omitted.

Sec. 11. Omitted.

Sec. 12. Omitted.

See Antinarcotic Legislation.

HARTSHORN.—A popular name formerly given to ammonia water. See Ammonium.

HASHISH.—See Cannabis.

HAY-FEVER. Synonyms.—Hay asthma; rose cold; pollen catarrh; autumnal catarrh.

Definition.—A hypersensitive condition of the upper air-passages, with intense catarrhal symptoms, mostly occurring in the autumn or spring, and probably due to the inhalation of irritating particles in the atmosphere, such as the pollen of plants.

Etiology.—Since the publication of Dunbar's work the accepted theory is that hay-fever is caused in predisposed individuals by the toxic action of pollen grains, which contain a proteid substance of the nature of a toxalbumin. In this country golden rod (*Solidago*) and ragweed (*Ambrosia*) are the chief sources of intoxication (autumnal catarrh); while the variety occurring during the spring (rose cold, June cold) is excited by the pollen of grasses and Indian corn. Among predisposing factors may be enumerated: Spring or autumn season; heredity; hypertrophy of the nasal mucous membrane; irritation of the sensitive areas in nostrils; deflection of the nasal septum; nasal polyps; neurotic constitution. Haig lays stress upon uric acid as an etiologic factor.

Pathology.—There is often hypertrophic rhinitis, nasal spurs, or deflection of nasal septum.

Symptoms.—The onset is quite sudden, frequently recurring at the same period of each month for successive years. The attack generally begins with sneezing, coryza, nasal stenosis, headache, burning or pricking sensation in nasal chambers, and an excessive secretion of clear or whitish mucus from the nostrils. There is often lacrimation, burning of eyeballs, conjunctivitis, obstinate hacking cough, asthmatic attacks, and depression.

Diagnosis.—The periodicity or season of the year and character of the attack generally distinguish the disease.

Prognosis.—For temporary relief the prognosis is good, but the disease is prone to recur.

General Treatment.—The system must be supported by proper regimen and the administration of general tonics, such as iron, strychnin, arsenic, phosphorus, or the hypophosphites. Elimination must be promoted by careful attention to the excretions and secretions—intestinal, renal and cutaneous. Patients should always be instructed to drink plenty of water. If constipation exists, it should be corrected at once. Any disturbance of digestion will require appropriate remedies. Frequent hot baths, massage, and electricity have been advocated.

It may be best to restrict animal foods, coffee, and tea to the minimum, and to use fruits and vegetables as the principal articles of diet. As a general tonic:

℞. Solution of potassium arsenite, ℥ j
Syrup of hypophosphites,
enough to make ℥ iv.

Two teaspoonfuls after meals.

The elixir of phosphates of iron, quinin, and strychnin (1 dram to 2 ounces), after meals, is a valuable tonic.

Internally may be given:

℞. Tincture of opium, ℥ j
Tincture of belladonna, ℥ ss
Camphor water, enough to make ℥ iij.

Tablespoonful every 4 hours.

Or:

℞. Extract of belladonna, } each, gr. j
Extract of cannabis indica, }
Camphor, gr. xv
Quinin, gr. xx.

Divide into 6 capsules; 1 capsule every 3 hours.

If the patient can afford it, a sea voyage or a trip to certain coast cities or to the mountains is of great benefit.

Diuretics containing lithium are advisable; also potassium iodid for a short period, followed by salicylate of sodium.

Local Treatment.—The acute symptoms render the patient miserable on account of the burning sensation in nares and pharynx. The excessive watery secretion is often so great as to cause stenosis of the nasal chambers, giving rise to mouth breathing.

Kyle determines the choice of local applications by the chemical reaction of the buccal and nasal secretions; whether the condition is alkaline, acid or neutral, whether it is due to the presence of ammonium salts, the sodium salt, or potassium salts, or whether there are present sulphocyanids, lactic acid or oxalic acid. The proper drug must be selected to counteract these conditions: alkalies such as the citrate, lactate or benzoate of sodium; sodium chlorid and the salicylates; or, on the other hand, boric acid, dilute hydrochloric acid and dilute nitric acid.

Hollopeter, who reports great success in treating this affection, says that the nares must be thoroughly cleansed and scrubbed carefully with Dobell's solution, followed by an application of some oily preparation. He says that simple douching and spraying are insufficient.

The patient may inhale:

℞. Menthol, gr. ij
Spirit of camphor, ℥ jss
Compound tincture of benzoin, enough to make ℥ j.

To this may be added every 2 hours a drop or two of chloroform. The latter, being more volatile than the other ingredients, evaporates more rapidly.

Some hay fever patients are relieved by local applications of suprarenal extract, either adrenalin chlorid sprayed into the nostrils or applied to the mucous membrane with a cotton swab, or in the form of a 10 percent suprarenalin ointment or snuff.

Considerable success has attended the use of Dunbar's serum patented under the name of "*Pollantin*" and marketed both in liquid and in powder form. It is used externally, not by hypodermic injection, and, unlike other serums, must be used daily during the hay fever season, as a single dose does not completely immunize against subsequent attacks. Pollantin is said to be perfectly harmless even in large doses, and repeated use neither lessens the effect nor creates a habit. Dunbar believes that the pollen toxin is identical in the various plants, and utilized for the preparation of his serum the pollen of Indian corn.

Liquid pollantin contains 1/4 percent phenol, which, however, is not sufficient to inhibit bacterial growth, if the preparation is contaminated by contact with the nasal mucous membrane or the eye.

Dosage and Administration.—In the manufacturers' directions for using *powdered pollantin* the patient is instructed to fill about one-fourth of the scoop inserted into the glass tube, hold the scoop under one nostril, and sniff the powder while keeping the other nostril closed. The same dose is then applied to the other nostril. The powder may also be used in treating the eyes, a few grains being introduced into the conjunctival sac with a camel's hair brush. The dose of *liquid pollantin* is 1 drop in each eye, and 4 or 5 drops in each nostril. It is stated that the substance is entirely harmless even in large doses. Pollantin should be used every morning and as often during the day as the symptoms seem to demand.

Hypertrophic rhinitis, nasal polyps, septal deformities and any other surgical conditions that may be present should always be corrected by operative means, in the hope of thus removing one of the causes of the malady (see RHINITIS, chronic).

HEAD, INJURIES.—For **injuries of the scalp,** see SCALP. For **injuries of the skull,** see SKULL. For **injuries of the brain,** see BRAIN. See also NOSE, FACE, EAR, etc.

HEADACHE (Cephalalgia).—Pain in the head. It may be due to organic cerebral disease, congestion or anemia of the brain, functional nervous disorders, toxemic conditions, Bright's disease, high arterial tension without kidney involvement, derangements of the stomach and liver, and reflex causes, such as eye-strain, nasal disease, etc. The character of the pain varies, being superficial or deep, constant or paroxysmal, general or local, dull and heavy, or throbbing and stabbing.

Ocular and Nasal Headaches.—The largest number of frontal, temporal, and so-called "sick" headaches are due to eye-strain, and even though there may be a number of underlying conditions at work to cause a headache, eye-strain of any kind, if present, may be a dominant factor in exciting the attack or in aggravating it, and the relief of this strain will often exert a most favorable influence. No study of headache is complete that does not reckon with the conditions that may exist in the eye; and when etiology is not perfectly clear, these should receive careful attention.

According to Gradle, the characteristics of the ocular and nasal headaches are (1) their location

and (2) their time relations. Their severity is a less reliable guide.

Location.—The most important question concerning the site of a headache is whether it is wholly or predominantly one-sided. One-sided headache is generally due to trouble on the same side of the head, either intracranial or in one of the organs of sense. An exception is that form of migraine which, though one-sided at the time, alternates regularly between right and left, for in this case the source is not one-sided, if it is peripheral at all. Conversely, however, one-sided lesions may in some instances cause headache not limited to the same side. This is sometimes true of unilateral errors of refraction, as well as of affections of one ethmoid or sphenoid cavity. Apart from the side of the head, the location of a headache furnishes no positive indication as to its source. Although headaches are, as a rule, located in the vicinity of the organ in which the irritation exists, there are so many exceptions to this rule, especially in neurotic subjects, that it has but little diagnostic value.

Time Relations.—From the point of view of their time relations, headaches may be classified as: (1) Paroxysms recurring at (*a*) irregular or (*b*) regular intervals; (2) attacks following some specific act; (3) more or less continuous pain. In this connection, too, must be considered the date of suffering and its manner of onset (Gradle).

1. Paroxysms of headache of similar intensity and duration, and occurring at variable intervals, constitute the form called migraine. The experience of oculists is very definite regarding the ocular origin of many instances of migraine. If wholly or predominantly one-sided, migraine is surely dependent either on an error of refraction or, in a smaller proportion of cases, on some nasal disease. If there are eye symptoms, and especially if the migraine is on the side of the notably weaker eye, an ocular origin is very probable. Still, the absolute proof in a given case can only be furnished by the influence of glasses. The absence of eye symptoms does not preclude the existence of a moderate degree of astigmatism as the starting-point of the headache. The form of migraine preceded by scintillations and dim sight—the scotoma scintillans—is not always of ocular origin, although often the result of astigmatism.

In relatively rare instances migraine is induced by nasal disturbances. Grünwald quotes some convincing instances of ethmoid and sphenoid suppuration. Migraine of moderate severity and relative infrequency occurs in persons of apparently normal nervous system and good family history. But great frequency, great severity, or massing of separate paroxysms into a continuous spell indicate other factors exerting a depressing effect upon the nervous system besides a possible peripheral origin in the given case.

Paroxysms of headache with regular periodicity —recurring about the same hour daily—have usually been the result of sinus-disease. In most of these instances the pain should really be classified as a neuralgia. If, however, it is not strictly confined to a small area of nerve distribution, the patient may describe it as a headache. It has been seen in connection with acute or subacute inflammation of the various nasal accessory cavities. When starting from the frontal sinus, it appears as a supraorbital neuralgia which, however, may radiate into a diffuse one-sided headache. The diagnosis is not always easy, even on inspection, for suppuration of the frontal sinus of moderate intensity is sometimes almost latent, and often transient, though recurrent. But there is always the history of a preceding acute coryza. These attacks often yield to either quinin or antipyrin, even when there exists demonstrable sinus-disease. In ethmoid and sphenoid disease the pain is more often described as headache than as a circumscribed neuralgia—usually, but not unvariably, one-sided.

2. Of headaches following specific acts, the most characteristic is the pain brought on by the use of the eyes for near work. The more precise the coincidence of headache with eye work, the more probable is the origin in hypermetropia, hypermetropic astigmatism, myopia, myopic astigmatism, or muscular anomaly. The more neurotic the subject, the greater the probability of headache occurring at irregular occasions during the day, but these eye headaches are never present on rising, and never severe enough to prevent sleep. In any deviations from this rule other factors must be sought. In highly neurotic subjects these ocular anomalies may bring on headaches on using the eyes even for a distant fixation: as, for instance, in the theater, riding in the steam-cars, etc. Finally, there are rare instances, generally in anemic, sometimes in hysteric, patients, of headaches following strictly upon the use of the eyes when no ocular anomaly of any kind exists.

3. Headaches more or less persistent or with irregular intermission may result from optic anomalities, but only in run-down subjects. Very often other assisting factors can be demonstrated, such as stomach or intestinal disease, loss of sleep, and particularly insufficient outdoor exercise. In other instances the refraction may be perfect, but other ocular disease may be found. This is sometimes a pheripheral choroiditis. It has seemed rather characteristic, in such instances, that the pain begins at once on awaking. Continuous one-sided headache, if at all connected with the eye, is usually indicative of some serious inflammatory condition, especially if of recent date and rapid onset. Optic neuritis—especially the retrobulbar form—is to be thought of, even if dim sight is not specifically stated by the patient. The most serious condition that may lead to such symptoms is glaucoma; and the possibility of chronic glaucoma as the cause of severe and persistent one-sided headache should not be forgotten.

Among nasal diseases, the forms most likely to lead to persistent and unusually severe headache are the more intense suppurative inflammations of the sinuses, in which case nasal symptoms always exist. Nocturnal aggravations are not uncommon under these circumstances. Moderate

but very persistent headache is occasionally complained of in nasal stenosis of any kind, but only by distinctly neurotic subjects. It is less generally known that inflammatory conditions of the pharyngeal tonsil are sometimes the source of continuous headache, usually not very severe, in both children and adults; in fact, the existence of such transient inflammations in this region is not yet generally recognized. Persistent, diffuse one-sided headache with irregular exacerbation sometimes may be traced to carious teeth, and ceases promptly after their extraction.

Nervous Headaches.—The head pain is usually of the nature of migraine, and it occurs in hysteric, high-strung, sensitive, and emotional people, especially precocious girls, and may resist every form of treatment. A neuralgic element often exists. A vertical headache often occurs in hysteric women, usually of a boring character, or such as might result from driving a nail into the top of the head. This is the so-called "clavus hystericus." Uterine disease may produce such a headache as well as occipital pain.

In nervous exhaustion, particularly from prolonged worry, headache is common.

Anemic headache is usually frontal; and congestive states of the brain from heart-disease, asthma, and other forms of dyspnea give rise to it. It is usually, in these latter cases, throbbing and is increased by stooping, coughing, or a condition increasing the congestion.

Toxemic Headaches.—A frontal and deep-seated headache is often toxemic from uremia, lithemic fevers, secondary syphilis, diabetes, or chronic alcoholism, and may be very severe. Uremic headache is overwhelming; the headache of secondary syphilis is neuralgic, limited to the temples, and recurs with great regularity at night; lithemic headache occurs in the morning. A heaviness or acutal pain in the head may result from breathing the air of an unventilated room or one overfilled with people, and a similar pain may occur before a thunderstorm. Headaches from hepatic and stomachic derangements are possibly of toxemic origin, and are usually occipital or vertical. The headache which is a feature in certain cases of chronic interstitial nephritis belongs in this group; it is usually, but not always, associated with high arterial tension and arteriosclerosis.

Syphilitic Headache.—Headache is an important stigma of cerebral syphilis. As before stated, it is present in three-fourths of the cases. Dangerous complications seldom occur without this prodromic symptom. This headache is intense, is generally referred to the depth of the brain—an encephalalgia. It is seldom diffuse, but is localized in a definite region. When seated in the parietofrontal region, it is either unilateral or predominates on one side. One of the special characteristics of this headache is the regular exacerbations, followed by remissions or intermissions, to which it is subject. Absent or quite supportable in the day-time, it reappears or becomes intensified in the early part of the night, and subsides gradually toward morning. Exceptionally, its maximum intensity is in the morning at the waking hour. Very seldom, indeed, does it persist night and day without any variation. This headache is often accompanied by an evident change in the mental condition of the patient. In mild cases there may be only slowness of thought and inaptitude for sustained mental effort. In more pronounced cases there are veritable mental torpor, amnesia and a noticeable change of character. These prodromes acquire a still more precise signification when there are added to them formication and numbness of the extremities with transient or enduring pains.

Headache of Arteriosclerosis.—The pain is persistent, of a throbbing character, often associated with tinnitus and vertigo. These headaches are often forerunners of apoplexy. They occur in chronic nephritis as a result of the concurrent arteriosclerosis.

Drug Headaches.—Quinin or salicylates may cause a dull throbbing headache associated with tinnitus.

Headache During Childhood.—In the very young headache is infrequent except in disease of the brain or meninges. In older children the etiology is similar to that in the adult.

1. *Eye-strain, or eye defects,* is the most frequent cause of headache in children. In all cases of headache the possibility of eye-strain or eye defects should first be eliminated by careful refraction and treatment by an efficient oculist before seeking further for the cause.

2. *Headache of Nasal, Pharyngeal, or Aural Origin.*—Adenoids, hypertrophic rhinitis or tonsillitis, nasal polypi, may be the cause. It is made worse by coughing and stooping. Local treatment is in these cases imperative.

3. *Headache of nervous origin* occurs in those of highly neurotic tendency or subject to hysteria or epilepsy, also in brain disease.

4. *Anemic headaches* due to impoverished blood and malnutrition occur generally in school girls from overstudy combined with more or less worrying.

5. *Toxic headaches* are usually due to autointoxication—from the absorption of toxins from the intestines. These are caused also by malaria, uremia, carbonic acid derived from impure ventilation. They are generally accompanied by digestive disorders and constipation.

6. *Gouty or rheumatic headaches* due to the inherited diathesis may be intense. These may be associated with neuralgias and pains in joints or muscles.

7. *Menstrual headaches* may occur in girls at puberty, due to amenorrhea or dysmenorrhea.

Treatment of Headache.—Eye-strain should be sought for and corrected, as well as any existing nasal disease. Toxemic states should be remedied by dietary and medicinal prescriptions. Anemia calls for preparations of iron. Uterine disease should be corrected. Cerebral syphilis demands mercurials and iodids. In other words, to be effective, the treatment must be directed to the cause.

Palliative treatment consists in local applications of cold, evaporating lotions, menthol, thymol.

Various pungent and aromatic spirits are useful for inhalation.

Eau sédative:

℞. Sodium chlorid, ʒ j
Camphorated spirit of wine, ʒ jss
Ammonia water, ʒ j
Water, O j.
Apply locally.

For migraine:

℞. Monobromated camphor, gr. xviij
Citrated caffein, gr. xviij
Acetphenetidin, gr. xxxvj
Sugar, gr. xviij.
Make into 20 powders. One every hour until relieved.

℞. Sodium arsenate, gr. j
Extract of cannabis indica, gr. ij
Extract of belladonna, gr. iv.
Make into 12 pills. Take 1 pill twice daily.

For bilious headache:

℞. Calomel, Compound rhubarb pill, each, gr. iv
Extract of hyoscyamus, gr. ij.
Make 2 pills. One at night.

For uremic headaches:

℞. Potassium acetate, ʒ vj
Infusion of digitalis, ʒ vj.
A tablespoonful every third hour.

For nervous headaches:

℞. Zinc phosphid, gr. iiij
Extract of nux vomica, gr. x
Confection of rose, q. s.
Divide into 30 pills.

HEARING, DRUGS AFFECTING.—Hearing is affected by many drugs. Strychnin and morphin increase the excitability of either the auditory nerve or the center for hearing in the superior temporosphenoidal convolution, making that faculty much more acute. Quinin, antipyrin and salicylates produce hyperemia of the auditory apparatus, causing subjective noises, as humming, buzzing, or ringing, which are very unpleasant. Hydrobromic acid and the bromids, also ergot, will diminish the congestion and thus neutralize or prevent these noises to a great extent. Quinin in large doses is believed by some to have produced permanent injury of the sight and the hearing, but authentic cases of such action are extremely rare, if indeed they can be found at all. Temporary deafness is often caused by quinin but it usually disappears soon after the administration of the drug is stopped.

HEARING, TESTS.—See Ear (Examination).

HEART, EXAMINATION.—In making a physical examination of the heart five methods of diagnosis are employed, namely, (1) Inspection; (2) palpation; (3) mensuration; (4) percussion; (5) auscultation.

These methods are best employed when the patient is in a quiet room with a good light, and in a sitting posture during inspection; in the recumbent posture during percussion, and compared in both positions during auscultation.

Inspection

Precordia.—The precordia is that region of the chest that immediately overlies the heart.

By inspection we note certain appearances: (1) Prominence in this area; (2) the size of the interspaces; (3) the color of the skin; (4) the position of the apex-beat; and (5) the strength and extent of the cardiac impulse.

The Apex-beat.—The apex is that portion of the heart that touches the chest-wall at each pulsation synchronously with the first sound of the heart. The apex-beat is also spoken of as the "cardiac impulse," when it is felt by the hand over the precordia.

The position of the apex-beat in health is between the fifth and sixth ribs, or in the fifth interspace, 1/2 of an inch within the midclavicular line. The apex-beat in health is movable. In distention of the stomach by gas it may be carried upward. In deep inspiration it is carried downward by the expanded lung. In children the apex-beat is usually in the fourth interspace, and nearer the nipple line.

Displacement of the Apex-beat.—

- Upward:
  - (*a*) High position of diaphragm.
  - (*b*) Tympanites.
  - (*c*) Ascites.
  - (*d*) Abdominal growths.
  - (*e*) Pericarditis with effusion.
- Upward and to left:
  - Effusion into right pleural sac.
    - (*a*) Liquid.
    - (*b*) Gaseous.
- Downward:
  - (*a*) Aortic aneurysm.
  - (*b*) Mediastinal tumor.
  - (*c*) Senility.
  - (*d*) Hypertrophy of left ventricle.
  - (*e*) Collapse of abdominal viscera.
- To right or left:
  - (*a*) Hypertrophy and dilatation.
  - (*b*) Effusion of gas or liquid into pleural sac—*i. e.*, pneumothorax, hydrothorax, etc.
  - (*c*) Unilateral emphysema.
  - (*d*) Pleural adhesion and retracted lung.
  - (*e*) Marked solid enlargements of lung or of the left lobe of the liver.
- Apex-beat may be invisible by reason of:
  - (*a*) Interposition of rib.
  - (*b*) Fat chest-wall.
  - (*c*) Feeble heart.
  - (*d*) Emphysema.
  - (*e*) Edema of chest-wall.
  - (*f*) Pericardial effusion (marked).
  - (*g*) Pleural effusion.
  - (*h*) Transposition of the viscera (is present on right side).
- Its area and apparent force may be increased because of:
  - (*a*) Nervous excitement.
  - (*b*) Hypertrophy or dilatation.
  - (*c*) Retraction of lung.

Diminished force of the apex-beat may be due to: (1) Fatty degeneration of the heart; (2) emphysema; (3) left-sided pleural effusion; (4) pericardial effusion.

Palpation

By this physical method of diagnosis we determine: (1) Force of the cardiac impulse; (2) frequency of the heart's action; (3) regularity of its movements (rhythm); (4) thrill.

Increase of the cardiac impulse may be due to: (1) Hypertrophy of the heart; (2) early stages of endocarditis; (3) fevers due to inflammation.

Decrease of the cardiac impulse may be due to: (1) Fatty degeneration of the heart; (2) emphysema; (3) pericardial effusion; (4) dilatation of the heart.

Increased frequency of the action of the heart may be caused by: (1) Excitement; (2) shock; (3) fatty degeneration; (4) goiter; (5) all fevers. See TACHYCARDIA.

Decreased frequency of the action of the heart may be done to: (1) Constipation; (2) atheroma; (3) lithemia; (4) nephritis; (5) chronic myocarditis; (6) Stokes-Adams' disease (30 to 40 beats per minute); (7) it is physiologic in old people. See BRADYCARDIA.

Thrill.—This means a vibratory sensation perceptible to the hand when placed over the precordia. A presystolic thrill is almost pathognomonic of mitral stenosis; hypertrophy of heart with dilatation often produces a thrill over the precordial area.

Mensuration.

By this physical method of diagnosis we determine the circular measurement of the chest and compare the two sides. A good instrument for the purpose is a steel tape-measure, or long strips of lead bent around the chest on each side, or Quain's stethometer may be used.

The points of measurement are the spinous process of a vertebra behind and the median line in front. The two sides are then compared. The average circular measurement of a healthy chest is 32 1/2 inches. Normally, the right side of the chest is slightly increased in right-handed individuals. In disease it is often much increased on the left side in certain forms of congenital heart-disease when hypertrophy supervenes. The position of the apex-beat is sometimes indicated by its distance from the middle line of the sternum, which in normal adults is 9 to 10 centimeters or about 4 inches.

Percussion.

By this physical method of diagnosis we determine the shape and area of cardiac dulness. There is, normally, (1) superficial cardiac dulness and (2) deep cardiac dulness.

The normal area of superficial cardiac dulness is studied best by *light* percussion. It is an approximately quadrangular area extending from the fourth costosternal junction to the apex-beat; from the apex-beat to the junction of the xiphoid cartilage with the sternum; thence up the left border of the sternum.

The normal area of deep cardiac dulness is studied best by *deep* percussion. The dull area has a somewhat triangular shape and extends from the third left costosternal junction to the apex-beat; from the apex-beat to the junction of the xiphoid cartilage with the sternum; thence up the right border of the sternum to the third rib.

The area of cardiac dulness may be (1) increased or (2) diminished.

The area of cardiac dulness is increased in (1) pericardial effusion; (2) retraction of left lung; (3) hypertrophy with dilatation.

The area of cardiac dulness is decreased in (1) emphysema; (2) pneumothorax; (3) gaseous distention of stomach; (4) aneurysm of aorta.

Auscultation.

The posture of the patient should be recumbent when examination is first begun; then the patient should assume the sitting posture, and the examiner should compare the variations, if any. At times the patient should hold the breath.

By auscultation we determine: (1) Quality; (2) intensity; (3) rhythm; (4) murmurs. When the ear or stethoscope is placed over the apex-beat of the heart, two sounds are heard, called the *first* and *second* heart-sounds; these sounds may be represented by the words, "lūbb," "tŭp."

The first sound of the heart occurs during *systole*, and is heard when the apex of the heart impinges against the chest-wall, producing a low-pitch sound, "lūbb," and is caused by the contraction of the ventricle, tension of the auriculoventricular valves, and the impact of the heart against the chest-wall. The first sound of the heart is synchronous with the apex-beat and pulse of carotids. It precedes the pulse in the radial arteries.

The second sound of the heart is heard shortly after the first sound. It is termed the second or diastolic heart sound. It is short and high-pitched, "tŭp." It is caused by the closure of the aortic and pulmonary valves.

Quality of the Heart-sounds.—The first sound of the heart (lūbb) is softer in quality, lower in pitch, and more prolonged than the second (tŭp) sound.

Accentuation of Both Heart-sounds.—Both sounds are accentuated in: (1) Hypertrophy of the heart; (2) pneumonia; (3) anemia; (4) excitement; (5) thin chest-walls.

Accentuation of the first heart-sound is present in hypertrophy of heart.

Accentuation of the second sound (aortic) is present in: (1) Hypertrophy of left ventricle; (2) arteriosclerosis; (3) aneurysm of aorta.

Accentuation of the second sound (pulmonary) is present in: (1) Pulmonary obstruction; (2) hypertrophy of the right ventricle; (3) mitral regurgitation; (4) mitral stenosis.

Weakness of both sounds is present in: (1) Emphysema; (2) fatty degeneration; (3) pericardial effusions; (4) debility; (5) obesity.

Weakness or absence of the second aortic sound is a feature of aortic insufficiency and aortic steno-

sis; **weakness of the second pulmonic** indicates dilatation of the right ventricle and impending cardiac failure.

Rhythm of Heart-sounds.—The acts which constitute a complete cardiac pulsation are: (1) Contraction (*systole*); (2) pause; (3) dilatation (*diastole*); and (4) *rest* of each of its cavities.

This complete heart action, from the ending of one systole to the beginning of the next, may be called its *cycle.* The periods of rest and the periods of action should follow each other in regular time. This is called the **rhythm** of the heart.

The normal **cardiac cycle** is made up as follows: (1) Systolic or first sound; (2) a brief interval of silence; (3) diastolic or second sound; (4) long silence. This is most important to remember, for if these regular intervals of rest are disturbed, the rhythm will be altered, indicating cardiac disease.

Irregular rhythm of the heart-sounds is observed in both functional and organic disease of the heart.

Irregular rhythm from functional diseases of the heart is due to: (1) Irritation of the heart muscle by toxic substances such as tobacco, caffein and the like, or by the products of disturbed metabolism, as in gout and various forms of indigestion; (2) reflex irritation, as from the stomach, liver, hysteria, or disturbance of uterine functions.

Irregular rhythm from organic diseases of the heart is due to: (1) Fatty degeneration; (2) angina pectoris; (3) myocarditis, including disease of the auriculoventricular bundle; (4) mitral regurgitation and mitral stenosis. See HEART-BLOCK.

Heart Murmurs.—By a murmur we mean an abnormal heart-sound. Cardiac murmurs are produced either within the heart (endocardial murmur) or upon its surface (pericardial murmur). Heart murmurs are also divided into (1) organic and (2) inorganic. For the different varieties, see HEART-DISEASE (Organic).

HEART, INJURIES.—Contusions, wounds, and rupture of the pericardium may at times be produced by a severe crush of the chest-walls; but are more often due to the penetration of a fragment of a broken rib or to a stab or gunshot. In the last two instances the heart is generally also involved. The signs are severe shock, hemorrhage, the position and direction of the wound, and subsequently symptoms of pericarditis. The prognosis is always very serious, death occurring either from the effused blood impeding the heart's action, or from pericarditis.

The treatment consists in absolute rest, the local application of cold, and, if inflammation threatens, of leeches. Should the heart's action become seriously impeded by effused blood, serum, or pus, aspiration or free incision and drainage may be required. When there is an external wound, it should be dressed antiseptically.

Wounds of the heart, especially when they penetrate one of its cavities, and particularly an auricle, are generally instantaneously fatal from shock or hemorrhage. Remarkable exceptions occur, however, and patients have been known to linger for a few hours or a few days, or even to recover. When not at once fatal, a wound of the heart is attended with great collapse, syncope, a fluttering pulse, and dyspnea, and later with symptoms of pericarditis. The treatment is the same as that for a wound of the pericardium.

Rupture of the heart, though rare, occasionally occurs as the result of great external violence to the chest-walls, or of some sudden exertion on the part of a patient suffering from disease of the heart's substance. Death is, as a rule, almost instantaneous.

The following case of cardiac injury is particularly interesting, and serves to illustrate the mode of operative procedure (Rehn):

A man 22 years of age sustained the following injury: A wound 1.5 cm. broad was found in the fourth intercostal space, on the left side. He was not bleeding externally when examined, but on account of the facts that his clothing was covered with blood, his state of collapse, his paleness, dyspnea, and an increase of dulness over the region of the heart, and even over the whole pleural cavity, the necessity for operative interference became imperative.

Operation.—After temporary resection of the fifth left rib, near the mammillary line, and emptying the copious collection of blood from the thorax, a small opening was discovered in the pericardium. Through this opening venous blood was found to be escaping. Free incision into the pericardium was then made and the pericardium lifted by clamps applied at the wound. This brought the heart up into full view. Its action could be seen perfectly. The diastole seemed to last longer than the systole. A wound 1.5 cm. long which was bleeding freely was discovered in the middle of the right ventricle. This wound was closed by three interrupted silk sutures, and the bleeding immediately stopped. It was especially to be observed that the finger could be pressed upon the wound without interfering to any considerable degree with the action of the heart.

The principles of operation on pericardiac and cardiac wounds are summarized by Binne as follows: (1) Cleanse; (2) enlarge the external wound; (3) freely expose the injured pericardium by excision of portions of the ribs and sternum; (4) attend to hemostasis; (5) open the pericardium and remove effused blood; (6) attend to cardiac wounds if present; (7) close the wounds in pericardium and in pleura if such be present; (8) close external wound with or without drainage.

HEART, PAIN.—Pain in the region of the heart is due either to functional or organic changes in adjoining organs or structures or to disease of the heart itself, and the probability that it is organic is slight if the patient is young, and decided if he is old.

A large proportion of the patients suffer from **neuralgia of the intercostal nerves,** which is increased by exertion or deep breathing. Often it is so severe as to make the patient catch his breath, or, more commonly, he unconsciously breathes in a superficial manner, and so gradually impairs his respiratory activity to such an extent that he feels oppressed and dyspneic, a condition that greatly increases his distress, as he regards this symptom as confirmatory of his own diagnosis

of heart-lesion. The darting character of the pain and its superficial position, the fact that spots of superficial tenderness can often be found over its course by slight or deep pressure, and that a tender spot can be found at the origin of the nerve in the back, will aid in clearing up the diagnosis and in relieving the mind of physician and patient, particularly if the heart-sounds are normal and arterial sclerosis is not discovered.

In another so-called cardiac pain the difficulty is due to an **accumulation of gas under the heart** in the angle where the transverse colon turns to form the descending colon. As a result of this not only pain, but cardiac palpitation and arrhythmia are produced by reflex causes, even when the abdominal wall may not seem to be very tympanitic. This pain occurs in women with relaxed and pendulous abdomens, who take little exercise, often overfeed themselves with foods productive of gas, and have actual syncopal attacks from this cause. These syncopal attacks may be the most alarming part of the ailment, and give rise to the belief that degenerative changes are present in the myocardium or coronary vessels. During the attack the irregular action of the heart, its feebleness, and its distant sounds may, if the physician is seeing the patient for the first time, make a differential diagnosis almost impossible. Sometimes the distention of the abdomen is not sufficient to account for the symptoms, yet percussion of the lower ribs on the left, in the area of Traube's semilunar space, will reveal marked tympany. According to Hare, an important point in diagnosis is that between the attacks the heart-sounds will be normal and the pulse-tension healthy, whereas in true angina pectoris, there will always be found high tension, with exaggerations of the tension during the attack. Similar attacks due to identical causes may occur in men who are high livers, but are more rarely met.

Closely associated with these forms of cardiac pain, without a marked lesion, is that found in persons who use **tobacco** to excess, and it is to be remembered that the excess of one man is not the excess of another. The pain complained of may be caused by an intercostal neuralgia due to tobacco, plus cardiac palpitation due to the same cause. **Coffee**, even in moderate quantity, produces similar effects in many susceptible individuals, especially in women with a tendency to hyperthyroidism. Cardiac pain of this type is usually not severe, but persistent, and associated with palpitation. It is readily distinguished from angina pectoris.

There seems to be also a form of cardiac pain due to **gastric disorder**, which reflexly disturbs the cardiac branches of the vagus as well. It may exist side by side that just described, or may follow an attack of indigestion due to imprudence in food or drink.

Among forms of nonorganic cardiac pain we must also consider **false angina pectoris.** This is most frequently seen in hysteric, neurotic women or girls, is associated with pallor, a gasping cry, and more or less complete syncope. The pain is rarely excessively severe, and is described as if the heart were being overdistended, whereas that due to true angina is described as if the heart were crushed in a vise. In the cases that Hare has seen the pain in the arm has not been marked, unless suggested to the patient. The facts that the patient is a young female, that the arterial walls are not sclerotic, that there is evidently a neurotic tendency, and, finally, that true angina pectoris is comparatively rare in women, are to be recalled. Thus, true angina pectoris occurred in only 47 women out of 227 cases quoted by Huchard; and, according to Quain, the disease occurs in 80 percent of the cases after 50 years of age. It is true that false angina also occurs in a severe form at the menopause, but here again the character of the pain, the history of the case, and the absence of vascular disease exclude true angina. However, it is not to be forgotten that marked vasomotor disturbances accompany this state. The hands are often very cold and clammy and the skin is generally relaxed. Further, if the aortic sound is normal and not accentuated, the tension low, and the kidneys normal, true angina is to be excluded. The patient may be flushed instead of pale, restless and frightened, or moaning, markedly nervous, while absolute immobility, with an expression of agony and anxiety, is the state in true angina pectoris. Finally, the pain often lasts for some hours, whereas in the true form it is fleeting, as a rule.

Lastly, in connection with these forms of cardiac pain, independent of true cardiac lesions, we must recall the so-called **vasomotor angina** that attacks susceptible persons on exposure to cold, producing a vascular spasm, an increased resistance to the heart, and syncope. The cyanosis and pallor, the contracted arteries and small pulse, all indicate true angina, but no heart-lesions or chronic vascular lesions can be found.

The pain of **mitral stenosis** is not recognized with sufficient frequency. This is because emphasis is not laid upon the constancy of this symptom of valvular disease, and secondary mitral stenosis is a valvular lesion often overlooked; first, because it is not sought so carefully as the more common lesions; second, because it is not so readily heard or differentiated as the others; and, finally—and this fact is very important—the period in which the pain develops is often that of advanced cardiac breakdown, when the action of the heart is so irregular that its sounds are not readily separated, but are confused, and when the auricle is so dilated and feeble that it cannot force the blood through the obstructed orifice with sufficient power to produce a murmur loud enough to be heard above the confused sound, or gallop rhythm, of the heart.

Aortitis is rarely acute; but if so, the pain is exceedingly severe. In the chronic forms it is also somewhat constant and severe, and is characterized by paroxysms. How far these attacks depend upon alterations in the blood supply of the coronary arteries and how far upon a neurosis it is difficult to determine. Such attacks, however,

must be separated from those of true angina pectoris, if possible. This is accomplished in some cases by the presence of more or less constant pain in the aortic area, by the discovery of a constant aortic systolic murmur, indicating aortic roughening, and by the paroxysms involving the upper part of the chest rather than the heart itself.

In **aortic regurgitation** pain may be an early symptom and may actually stimulate angina. Sometimes the pain is mild and constant; in other cases it is paroxysmal; and it often radiates down the arms, particularly the left, as do all severe cardiac pains.

General cardiac dilatation also causes cardiac pain, probably by pressure on surrounding tissues. The diagnosis of this cause of pain is readily made on a physical examination and in association with an injury.

Fatty degeneration of the heart is rarely associated with true pain, the condition being more one of discomfort. So, too, in fibroid heart anginal attacks are not rare.

Angina pectoris is emphatically a disease of the well-to-do, or at least of the class that does not perform manual labor for a living, and it seems peculiarly a disease of professional life, chiefly in medicine and law, or in those persons who are subjected to periods of great nervous strain: as, for example, in financiers. In the lower classes equally marked arterial degeneration ensues, but for some reason high arterial spasm is not so common as in the upper classes, thereby emphasizing the nervous element in these cases. Great caution should be used in making the diagnosis of true angina pectoris. Only when the pain is severe, the patient advanced in years, and the signs of degenerative arterial change are present, should this decision in a given case be reached, and then only after all other causes of cardiac or thoracic pain have been excluded. On the other hand, it is important to recall the fact that the pain of true angina may not be typically cardiac, and may appear to be felt most severely in the epigastrium; and marked gastric disturbance, with belching and vomiting, may be present as a result, in all probability, of a general nerve storm in the pneumogastric filaments; and if such gastric symptoms occur in a woman, a suspicion of hysteria should always be entertained.

The mental anguish, the fixed expression of the face, the slow and feeble pulse, the shallow expectant respirations, the ashy skin and cold sweat, are the symptoms which make the symptom complex of this disease.

Aside from the cardiac pains already named one must recall that of **aortic aneurysm, pericarditis, and pleurisy.** The last of these is readily recognized; the aneurysm is often overlooked because it is not sought, or because, being deeply seated, it cannot be found without the aid of Roentgenography. The pain of aneurysm is often paroxymal, radiates in directions like that of true angina, and the pressure of the growth paralyzes or benumbs nerve-trunks and produces hyperesthetic areas in the skin of the chest.

Further consideration of the symptoms, diagnosis, and treatment of the various causes of cardiac pain is given under the separate headings. See Angina Pectoris, Aorta (Aneurysm), Heart-disease, etc.

HEART-BLOCK.—A form of cardiac arrhythmia characterized by partial or complete *dissociation of the auricular and ventricular systole.* The relation between auricular and ventricular beats may be 2 to 1, 3 to 1, or 4 to 1; or the two cavities may pulsate quite independently of each other. Clinically the condition, which is known as *Stokes-Adams disease* or *syndrome,* manifests itself in *bradycardia* and *periodic syncopal attacks,* with or without convulsions. Secondary symptoms are disturbances of digestion, nausea and vomiting, or both, and of respiration, dyspnea on exertion and, sometimes, Cheyne-Stokes breathing. The pulse rate falls as low as 40 or 30 to the minute, and is not influenced by active movements or change of position; simultaneous jugular and radial tracings show partial or complete dissociation of the auricular and ventricular systole. The syncopal attacks are probably due to cerebral anemia; sometimes the attacks are apoplectiform or epileptiform (cerebral congestion), and an epigastric aura occasionally occurs.

The cause of heart-block is believed by the followers of the myogenic theory of the rhythmic activity of the heart to be a destructive lesion of the *bundle of His,* also known as *Gaskell's bridge,* a bundle of muscular tissue, 18 mm. long, 2.5 mm. broad, and 1.5 mm. thick, extending from the right side of the interauricular septum to the interventricular septum, immediately below the membranous portion. It is the pathway by which the impulse initiating the contraction of the heart is conveyed from the auricle to the ventricle. Others authorities seek the cause of heart-block in a lesion of the pons or medulla, affecting the respiratory and cardioinhibitory centers. Among the pathologic findings in cases of heart-block may be mentioned: gumma; syphilitic ulcer or scar; arteriosclerosis with calcareous nodule compressing the bundle; anemic necrosis; abscess and ulcer of pyogenic origin; tumors and infarcts.

According to the *myogenic theory* the contractions of the heart are originated and maintained by the muscle fibers themselves, as opposed to the neurogenic theory that the heart contracts only in response to stimulation by the cardiac ganglia and the central nervous system. The heart muscle is endowed with the functions of (1) stimulus production; (2) excitability or irritability; (3) conductivity; (4) contractility; and (5) tonicity. Normally the stimulus originates at the *sinoauricular node,* a small bundle of tissue representing the remains of the primitive cardiac tube near the mouth of the superior vena cava, and the term *sinus rhythm* is accordingly used to designate the normal rhythm of the heart, in which auricular and ventricular contractions follow one another in rhythmical sequence. The rhythm may be disturbed, without being altogether abolished, by the occurrence of *extrasystoles, i. e.,* premature contractions of the auricle or ventricle or both, which are

responsible for the ordinary forms of irregularity and especially intermittence. The irregular stimulus initiating the extrasystole usually arises in the *auriculoventricular node* or in the auriculoventricular bundle (bundle of His) and its ramifications, but may arise in other portions of the musculature of either auricle or ventricle; the fundamental sinus rhythm of the heart is, however, maintained. In certain forms of arrhythmia, associated with advanced myocardial degeneration in which the prognosis is grave, ventricular systole precedes, or is synchronous with, the contraction of the auricle, and in such cases it is believed that the impulse originates in the *auriculoventricular node* or *node of Tawara*, an enlargement of the remains of primitive cardiac tissue in the wall of the right auricle, from which the bundle of His arises. This form of cardiac irregularity is called *nodal arrhythmia* or *nodal rhythm*. It has recently been suggested that the term *arrhythmia* be restricted to this type of cardiac irregularity, and that all others be described as *allorrhythmias*.

Treatment should be directed toward the associated conditions. In partial heart-block atropin is said to be of service. In cases of syphilitic origin antisyphilitic treatment should be instituted; and in doubtful cases a Wassermann test should be made.

See Bradycardia.

HEART-BURN.—See Pyrosis.

HEART-DISEASE, FUNCTIONAL (Arrhythmia; Irregular Heart-beat and Pulse-beat).—This subject admits of consideration under a variety of heads. Thus, the cases of arrhythmia, considered in relation to their course, may be (1) *temporary* or (2) *habitual*. In the latter the heart's action may manifest marked irregularity during a period of many years without apparent impairment of the general health. On the other hand, when it is dependent upon obvious organic lesions (mitral affections, cardiac dilatation), it has a graver significance.

Temporary arrhythmia is due to the action of a great variety of causes. It may be evoked by toxic substances, by mechanic embarrassment of the heart's action, by emotional disturbances, and by various reflex causes. Temporary irregularity is, on the whole, more common than the permanent or habitual form of the disorder, and in many cases the irregularity vanishes with the successful removal of the exciting cause or causes. A second classification—more acceptable, because it facilitates an appreciation of the essential elements that enter into the clinical manifestations—is based principally upon irregularity (1) in volume and force as well as wave intervals or (2) in time. The former is spoken of as "*irregularity*," and the latter as "*intermittence*," and the familiar clinical observation that these are often found in association is to be kept in remembrance.

It is further important to remember that there is an irregularity of the heart and another of the pulse; also that trivial irregularities may be shown to exist temporarily in healthy subjects; they are not always appreciable, however, by the ordinary methods of examination, but are readily revealed by the sphygmograph. "Strictly speaking, no pulse is regular, as a time line at the foot of the sphygmographic tracing will prove; if not otherwise influenced, the respiration at any rate disturbs the order, as does muscular effort, even the slightest, especially in nervous or otherwise unstable systems" (Allbutt).

Irregularity in the Volume and Force of the Pulse.—In this variety the pauses between two beats are equal, but the fulness and strength of the beats are unequal. It sometimes happens that a pulse of good volume and strength regularly alternates with one of smaller volume and lesser force—the so-called *pulsus alternans* of Traube. This is a comparatively rare form of arrhythmia, and there is a belief that it is not always a bad augury.

Irregularity in Time.—The simplest form is but an exaggerated degree of the previous variety and is represented by the so-called "**intermittence**," signifying a missed or dropped beat. In the majority of instances this occurs at irregular intervals. On the other hand, there is sometimes noted a regular intermittence, or cyclic irregularity (**allorrhythmia**): *e. g.*, every second, fourth, sixth, or eighth beat being lost. Rhythmic intermittence has been observed in persons with fatty overgrowth associated with more or less fatty degeneration of the heart-muscle, and also in persons taking large doses of digitalis. Moreover, cases are occasionally met in which this form of disorder is purely functional. It is to be noted that intermissions of the pulse may occur when the heart-beats continue in regular succession. This is due to the fact that the cardiac contractions are at times too feeble to propel the blood to the radial artery.

Twin Pulse (Coupled Beat).—The coupled heart-beat is evidenced at the wrist either as a bigeminal pulse or as a false intermission (Claytor). When two beats follow each other quickly (the diastole being shortened), followed by a pause (the diastole being lengthened), we have produced the **pulsus bigeminus.** The first and second beat of each couplet may be of equal volume and strength, but in many cases the second is comparatively feeble. When the second contraction of the ventricle is too feeble to drive the blood-stream to the radials, there is a pseudointermission of the pulse. To distinguish this from true intermittence of the heart-action, direct auscultation of the heart is necessary. The pulsus bigeminus is frequently observed in mitral disease, particularly after compensation is lost. It happens that the heart-beats equal twice the rate of the radial pulse, when every alternate systole of the ventricle fails to produce a radial pulse. With respect to the diastole, the approximated pulsations may be in blocks of three (**pulsus trigeminus**), or even of four (**pulsus quadrigeminus**). Like others, this form of arrhythmia may be unperceived by the patient; it is clear that it often partakes of the nature of the following variety.

Combined Irregularity in Time and Volume.—It would be desirable to distinguish the different

forms of irregularity from one another, but this is not always practicable, particularly in the last stages of valvular affections and in the acute infectious diseases. Symptoms are dependent upon advanced degenerative processes of the heart-muscle and ganglia and the previous forms of arrhythmia are variously combined in different cases. Marked polysarcia may coexist, in which some degree of fatty degeneration of the heart-muscle is also present.

When the pulse becomes feeble, more rapid as well as irregular in volume, strength, and time, instead of stronger with each act of inspiration, it is spoken of as the **pulsus paradox** (Kussmaul). Ordinarily, the heart-beats are stronger during inspiration than during expiration, while in the case of the paradoxic pulse this relationship is reversed. Paradoxic pulse occurs in chronic adhesive pericarditis, in cases of pressure upon the root of the aorta by bands, in pleuropericarditis, and in a very weak heart from any cause.

Delirium Cordis.—When the arrhythmia is extreme and combined with marked rapidity so that the heart falls into a state of absolute disorder, there is said to be *delirium cordis* (Whittaker). The ventricular systole may be so rapid as to be evidenced by mere vibrations (*tremor cordis*). These forms are commonly seen in extreme dilatation of the heart and in advanced exophthalmic goiter.

Embryocardia, or Fetal Heart-rhythm.—The diastole is here shortened, while the first sound of the heart simulates closely that of the second, as in the fetal heart. It is a common concomitant in dilatation of the heart, and it also attends the advanced stages of grave fevers and lobar pneumonia. In the latter disease it is ominous, since it usually indicates oncoming dilatation of the right ventricle

Cantering or Galloping Rhythm (Bruit de Galop).—The sounds are triple, like the footfall of a horse at canter. There is an interpolated second sound, which may be brief and sudden, or it may be dull, and it may occur at any period of the diastole. This interpolated (third) sound, when dull, is generally due to a doubling of the second sound, though rarely it is the first that is duplicated.

Among numerous morbid conditions in which this phenomenon is encountered are: (1) Hypertrophy of the heart, especially hypertrophy of the left ventricle, associated with Bright's disease; (2) dilatation of the heart; (3) these conditions combined, especially when there is adherent pericardium; (4) typhoid fever and some zymotic affections in which myocarditis occurs; (5) some cases of profound anemia and cachexia.

In the instances in which the third or interpolated sound resembles the normal heart-sounds —*i. e.*, brief and sudden—it is probable that, as Potain and others have pointed out, it occurs principally in the absence of pathologic lesions (physiologic reduplication). If one listens to the heart of a patient with an irregular pulse, he will hear either one sound with an intermission or two sounds immediately following the two normal heart-sounds. Wenckebach states that these extra heart-sounds can be considered only as evidence of a systole taking place at an unusual time. If the **extrasystole** occurs in the early portion of diastole, the contraction will be so ineffectual that it will produce but one slight first sound, and will not cause the expulsion of a sufficient amount of blood to give rise to the valvular second tone. If it occurs later, it will be a strong contraction, and will result in two healthy tones. A brief supernumerary sound will also be audible in the course of chronic interstitial nephritis associated with hypertrophy of the heart and general arteriosclerosis. On the other hand, cases have been recorded in which the first as well as the second sound was duplicated (double duplication of the heart-sounds) under conditions of structural disease—*e. g.*, exophthalmic goiter—and rarely in the so-called tobacco heart.

Etiology.—The following is a modification of the etiologic classification of Baumgarten:

Central (Cerebral) Causes.—In organic disease the centers of the pneumogastric and accelerator nerves may be either directly or indirectly (due to pressure) implicated; in which instances the arrhythmia may be temporary or habitual, according to the precise nature of the lesion in different cases; thus, brain tumors, chronic meningitis, abscesses, and the like, may give rise to persistent irregularity of the cardiac rhythm. On the other hand, concussion of the brain, hemorrhage, and even apoplexy may produce a temporary arrhythmia. More commonly, however, arrhythmia is due to psychic influences, although it is to be remembered that emotional disturbances produce, in the majority of cases, occasional or temporary arrhythmia. In melancholia and hypochondriasis it may, however, be of protracted duration. Various other neuroses, including particularly chorea—which may be a choreiform affection of the myocardium—may cause arrhythmia.

Reflex influences, such as produce cardiac irregularity, in dyspepsia and diseases of the liver, lungs, and kidneys. Clinical experience suggests that affections of the gastrointestinal tract furnish the greatest relative proportion of this category, and it is often associated, under these circumstances, with attacks of palpitation. Here may be mentioned the effect of sudden, severe surgical shock. Again, pain—*e. g.*, in hepatic colic—may be so intense as to arrest the action of the heart.

Toxic Influences.—These fall naturally under three groups, the first comprising coffee, tea, alcohol, and tobacco. It is, as a rule, the abuse of these otherwise benign agents that excites arrhythmia. and these poisonings in their more pronouneed forms have been observed to follow excessive indulgence in smoking and in drink. The cause is frequently a composite one, which has to be carefully analyzed. Liebermeister noted that the use of a single cigar, or at most 2 a day, would keep up arrhythmia which had resulted from excessive indulgence. Arrhythmia excited from smoking to excess is usually associated with marked palpitation.

The toxins of the severer forms of acute infec-

tious diseases act poisonously upon the heart-muscle and nerves, inducing arrhythmia (cerebrospinal meningitis, typhus fever, diphtheria, typhoid fever, pneumonia, influenza, etc.). In these affections arrhythmia may arise either during the period of the tachycardia of the acme or during convalescence, and it is of grave significance when associated with feeble cardiac action. It is the characteristic manifestation of tuberculous meningitis in children.

Changes in the Heart Itself.—(1) In the cardiac ganglia: Fatty, pigmentary, and sclerotic changes have been described in cases of arrhythmia, and these may have an important influence in producing disturbances in the rhythm, but as yet we do not know their exact significance. They may be present in cases that have not presented arrhythmia. (2) Mural changes are common in conditions of this kind. Simple dilatation, fatty degeneration, and sclerosis are most commonly present, the latter usually associated with sclerosis of the coronary arteries.

Arrhythmia may occur in the **various dyscrasias** (obesity, gout, syphilis, migraine).

Concerning arrhythmia of the heart in children, Comby and Huebner (whose conclusions are strikingly similar) state that, of whatever origin it may be, the final step in the production is either the action of a toxin on the heart-muscle or nerves, or a reflex disturbance of the innervation.

Symptoms.—In many cases slight, and rarely marked, arrhythmia is discovered accidentally, for the reason that there are no associated symptoms centering about the heart. This is true of certain functional forms and of cases of reflex origin. Arrhythmia is often combined with palpitation, and the presence or history of this serves to excite the attention of the physician, and should lead to a physical examination. It is a matter of common observation, also, that intermittences and irregularities of really serious import often pass unperceived by the patient. Conversely, harmless arrhythmia often attracts the patient's attention and excites great alarm. The feeble heart-action of the acute infections is apt to arrest attention on account of the associated symptom-group.

Physical Signs.—Intermittences and special forms of irregularity are usually detected by combined palpation of the pulse and auscultation. Inspection of the heart may reveal an irregular pulse, but does not, as a rule, give any clue to the precise form of arrhythmia. The results obtainable by palpation of the apex region are sometimes of greater diagnostic importance. Both intermittence and irregularity are evidenced by an alteration of the radial pulse. The examiner should carefully distinguish between irregularity of time only and irregularity of the volume and force of the beat. A good plan is to note first the rate and any irregularity of time (intermittence). This may be the only abnormality, although frequently alteration of the time and irregularity of volume coexist. In the next place one should attempt to estimate carefully the time and degree of deviation from the normal volume and force of the pulse that may be present. To obtain accurate results, sphygmographic and cardiographic tracings are sometimes necessary. Combined auscultation of the heart and palpation of the pulse should never be neglected, since it permits us to differentiate true from false intermittence.

Associated Physical Signs.—These vary within the widest limits, and in given cases the special cause or causes will be found to govern their character. For example, in lobar pneumonia the strength of the right ventricle may become exhausted when there arise the signs of dilatation of this chamber: *i. e.*, of relative tricuspid incompetency. This condition and arrhythmia are often found together. In simple dilatation associated with chronic valvular disease and in fatty degeneration with ensuing dilatation the physical signs may be those of bilateral or unilateral enlargement of the ventricles.

Prognosis.—To estimate the prognostic significance of arrhythmia is sometimes exceedingly difficult. A gentleman with whom Anders was well acquainted was rejected by a leading life insurance company 22 years ago on account of occasional intermittence and irregularity of the heart, although he is still in active business life and manifests great vigor both of mind and body. Osler, in his text-book of medicine, relates that the late Chancellor Ferrier, of McGill University, who died at the age of 87, had an extremely irregular pulse for almost 50 years of his life. Such instances are by no means rare, and, whether temporary or habitual, are to be looked upon as physiologic; but it is one of the most difficult problems in practical medicine to determine the line of demarcation between these and the more numerous cases that have a pathologic basis.

There are cases of mild character, due to gastric disturbances, to constipation attended with flatulence, to mental excitement, and not uncommonly occurring in neurotic subjects, that are not of unfavorable prognosis. In mitral regurgitation irregularity may arise early, and is not incompatible with fair compensation and apparent good health for many years. In mitral stenosis, on the other hand, the existence of marked arrhythmia adds to the gravity of the prognosis. Moreover, an arrhythmia that disappears upon exertion or cardiac stimulation is a not unfavorable sign. On the other hand, one that is aggravated by these agencies is to a like extent unfavorable.

Experience teaches that many forms of arrhythmia are often connected with grave diseases of the heart and other organs, as pointed out under the etiology.

While **prognostic conclusions** are not warranted from the particular forms of arrhythmia, it is found that the delirium cordis is usually met in the advanced stages of dilatation associated with valvular lesions, and hence is of the gravest significance. Embryocardia points to cardiac dilatation, while the pulsus bigeminus and pulsus trigeminus are most often encountered in mitral disease, particularly as an evidence of heart failure. When the myocardium becomes involved (no matter

what the particular complaint), either secondarily to chronic valvular or coronary disease or in association with acute infectious disease, the prospect is gloomy. In general terms, if we except organic lesions of the brain and Bright's disease of the kidneys, the outlook is more favorable when it is due to causes outside of the heart itself. Contrary to what has been stated with reference to arrhythmia in typhoid fever, when this symptom develops after the period of convalescence in diphtheria, it almost invariably heralds a fatal termination. The arrhythmia that not uncommonly occurs in influenza may at times be due to myocarditis, and at others to neuritis; it may lead to a sudden, fatal termination. Again, the irregularity that springs from coronary sclerosis may end life suddenly.

Finally, temporary arrhythmia is, on the whole, a symptom of less danger than the habitual form.

Treatment.—Physiologic arrhythmia, the symptom, without associated symptoms or morbid conditions, requires no treatment apart from methodic, physical training to improve the general systemic development. When due to psychic and reflex influences, and to such toxic substances as tea, alcohol, tobacco, as well as certain drugs, it may be relieved, and even cured, by a removal of the special cause. In purely functional cases in which there is a preponderating neurotic element the subjoined formula has been found useful:

℞.	Iron valerate, Zinc valerate, each,	gr. xxx
	Strychnin sulphate,	gr. j
	Powdered digitalis,	gr. viij.

Make 30 capsules; take 1 after meal-time.

Again, the various neuroses and chronic affections—as gout, Bright's disease—including saturnine poisoning, are to be assailed by the usual measures when arrhythmia develops in their course. The arrhythmia that is dependent upon myocarditis, whether in the acute infectious diseases or in chronic ailments, calls for the use of cardiac stimulants and tonics, while meeting the indications presented by the causative affection.

Among the special stimulants to be mentioned are digitalis, strychnin, strophanthus, nitroglycerin and caffein. The effect of digitalis, particularly when arrhythmia is secondary to chronic valvular disease or the acute infections, is sometimes striking. In a small proportion of cases strophanthus is to be preferred, on account of its happier influence. In either case the remedy employed is to be discontinued when the symptom has vanished. As is stated elsewhere, many cases of marked arrhythmia will not yield to either of these remedies when but one is given; in such, Anders has occasionally obtained good results from digitalis and strophanthus in combination. Evidences of fatty degeneration and atheroma are not contraindications to the use of digitalis and strophanthus, but are signals for the observance of extreme reserve and caution in their use. Anders has frequently proved the therapeutic efficiency of nitroglycerin in cases in which arteriosclerosis was associated. By widening the blood-pass, this remedy tends to diminish the work of the heart.

In extreme cases—often met in the course of acute infectious diseases—time is a paramount element; hence the remedies should be administered hypodermically, and strychnin, in full doses, is the best single agent; it may also be combined with digitalis. Camphor and caffein enjoy an enviable reputation in similar cases. Atropin is said to be useful when the conductivity of the heart fibers is depressed, as in disease of the bundle of His. Brilliant results have followed in arrhythmia after hemorrhage in typhoid fever from the use of intravenous and subcutaneous injection of normal saline solution.

In the lighter chronic forms of the complaint systematic and carefully graduated exercise often serves to strengthen the heart-muscle, and, as a consequence, to overcome the irregularity. In many cases of mild character much can be accomplished also by measures, both hygienic and medicinal, that benefit the general health.

HEART-DISEASE, ORGANIC.

General Remarks on Diagnosis

In order to reach a correct diagnosis in heart affections, etiologic factors, symptoms, and the physical examination must necessarily be taken into account. A knowledge of etiologic conditions is of particular value in acute myocarditis and endocarditis and in chronic affections of the myocardium, for without this aid it might be impossible to differentiate, for example, between a fibroid, a fatty, or a hypertrophic heart. A history of rheumatism or chorea, the presence of an infective disease—such as acute rheumatism, pneumonia, septic pyemia, scarlatina, diphtheria, typhoid, measles, tuberculosis, or gonorrhea—might lead us to suspect an acute lesion. Syphilis, arterial sclerosis, physical and mental overwork, over-indulgence in food or alcohol, would suggest a chronic myocardial, or perhaps a valvular, affection.

Symptoms such as palpitation, precordial distress, dyspnea, general weakness, giddiness, and faintness are common to most cardiac conditions, and consequently are of little value for differential diagnosis, since a serious lesion may exist with but few symptoms, while the most distressing complaints may be present in a mere neurosis. Fainting fits and marked giddiness are, however, more common in aortic insufficiency and mitral stenosis, in consequence of the associated cerebral anemia. Severe precordial pain—one form of angina pectoris—is likely to occur in disease of the coronary vessels and the aortic valves. By far the most valuable information, however, is to be derived from a careful physical examination; educated eyes, fingers and ears are our best assistants.

The points to be looked into are the general facies, the pulse, the shape of the thorax, the position of the apex-beat, abnormal or excessive pulsations, valvular shocks, and the presence of thrills, the area of cardiac dulness, the heart-sounds, associated murmurs, and various complications.

Excessive or persistent **pallor** always calls for an examination of the heart; the face often is dusky and subicteric in hue, or there may be alternate flushings and palings.

Each valvular lesion has a **pulse** peculiar to the pathologic condition present. In mitral leakage the pulse is usually well filled, without peculiarity; in mitral stenosis it is small, badly filled, often irregular and intermittent. The pulsus bigeminus may occur. In aortic regurgitation the pulse is full and bounding, with sudden collapse (water-hammer pulse); in aortic stenosis very slow, thready, and badly filled. A positive (presystolic-systolic) pulsation in the external jugular vein denotes tricuspid insufficiency; a negative one is of no special significance. An arterial pulsation in the liver is sometimes present in aortic regurgitation; a venous one is pathognomonic of tricuspid leakage. Such pulsations should be carefully distinguished from communicated pulsation.

In children, or when the disease has begun in childhood, the **precordium** may be prominent and the intercostal spaces widened, due to hypertrophy.

The apex-beat is more or less dislocated in all cardiac affections, but may be difficult to make out; in such cases if the patient bends forward, it may become palpable. The apical impulse is powerful and heaving in pure hypertrophy and aortic regurgitation; weak in extreme dilatation; diffuse in mitral insufficiency; punctate in mitral stenosis. An increased area of cardiac pulsation is often present in hypertrophy, and if most prominent at the ensiform cartilage and epigastrium, is due to a powerfully acting right ventricle.

Palpation.—In mitral stenosis particularly the closure of the pulmonary valves may be felt as a distinct snap on palpation over the pulmonary cartilage. Palpable thrills are valuable signs of obstructive valvular lesions, but must not be confused with pericardial frictions.

Percussion.—The area of cardiac dulness is increased in pericardial effusions, hypertrophy and dilatation, aneurysms, mediastinal tumors, and retraction of the lung; it is lessened in emphysema and pigeon-breast. The dulness in effusion is usually pear-shaped, with the apex upward, and reaches to the right of the sternum in the fifth interspace. In such a case the apex is dislocated upward and outward, and is within the line of dulness, the heart-sounds being muffled, while the pulse is relatively strong. In dilatation the dull area has rarely a triangular shape, nor does it reach so high without marked pulsation, while the heart-sounds are at first short and snappy. Retraction of the lung, as in fibroid phthisis, may be recognized from other signs of lung involvement. Aneurysms or mediastinal tumors may be excluded from the absence of other distinctive features.

Auscultation.—The heart-sounds may be pure or impure, and may be accompanied or replaced by murmurs. An accentuated aortic second sound is present in high arterial tension from any cause. An accentuated pulmonary sound is due to a hypertrophied right heart. A reduplicated second sound sometimes occurs in mitral stenosis or insufficiency, but it should be remembered that it also occurs normally in children at the end of deep inspiration.

When murmurs are present, one should note the time, the point of greatest intensity, and the line of transmission. It is important, though not always possible, to distinguish a functional (accidental) from an organic murmur. A functional murmur—*e. g.*, in anemia—is heard usually at the pulmonary cartilage, but often at the apex; it is soft, low-pitched and whiffing; systolic; and rarely transmitted so far as an organic one. Differentiation may be impossible, but an unaccentuated pulmonary second sound and a right ventricle of normal size are in favor of functional origin; moreover, the condition is transient. Organic murmurs, as a rule, are loud, blowing, often accompanied by thrills; hypertrophy and dilatation are present and the condition is permanent.

It is often necessary to decide whether a murmur is due to valvular disease or to dilatation of a chamber. If the patient has been under observation this is easy, but later on may be impossible.

Murmurs are systolic, diastolic, or presystolic according to their position in the cardiac cycle. A pericardial friction is of a to-and-fro rubbing character, superficial, inconstant, increases on pressure, not perfectly synchronous with systole and diastole, and eventually disappears; it should not be confounded with an endocardial murmur. It should be observed that in walking the patient up and down a murmur may sometimes be brought out that was previously inaudible. The complications may be general anasarca, effusion into serous sacs, passive congestion of various organs, hemoptysis, albuminuria, or embolism.

Acute Affections of the Heart

These are myocarditis, endocarditis and pericarditis. Etiologically and symptomatically they have much in common. Diagnosis is in general difficult.

Acute Myocarditis.—This is merely an incident in the course of an infective disease, such as acute rheumatism, pneumonia, septicemia, tuberculosis, or typhoid. It is also an almost constant accompaniment of acute pericarditis and endocarditis. Subjective symptoms are generally absent. The condition may be suspected when the heart begins rapidly to dilate, when the pulse becomes more rapid, thready, and irregular, or when the temperature suddenly rises. In rheumatic cases restlessness and delirium may be marked; yet the pulse may run up to 200 and the patient's mind be quite clear. A systolic murmur may be heard at the apex. The condition is more often than not overlooked.

Acute Endocarditis.—The causes and physical signs are those just mentioned; there may be no symptoms. The disease is due to the action of microorganisms, and all grades exist, from a mild inflammation to the so-called "malignant" form. In half the cases the mitral valve is affected, less often the aortic, rarely the tricuspid. The condition may be grafted on a chronic valvular lesion. The pulse is small, rapid, and irregular, and mur-

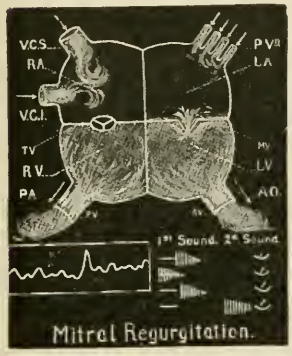
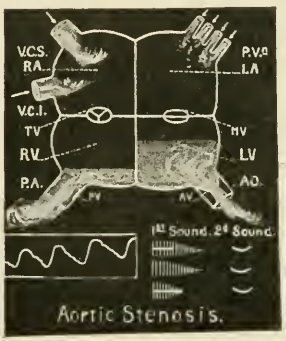
Mitral and Tricuspid Regurgitation.—(*Greene.*)
Heart in systole. Mitral and tricuspid valves both incompetent. *Result.*—Double systolic murmur, enlargement of both right and left chambers, pulsating jugulars, general venous congestion, edema, anasarca, etc.

Mitral Regurgitation. —(*Sansom.*)
Maximum intensity and transmission.



Mitral Regurgitation.—(*Greene.*)
Four varieties of the murmur of mitral regurgitation are shown graphically. The heart in systole, mitral leakage evident. The contracting ventricles are forcing the blood through the open aortic and pulmonary valves; the tricuspid, tightly closed, prevents regurgitation into right auricle. The leaky mitral allows back-flow into the left auricle already filling from the pulmonary veins above. *Results.*—A systolic murmur, dilatation of left auricle, pulmonary congestion, and consequent enlargement of right ventricle.



Aortic Stenosis.—(*Greene.*)
Three varieties of the aortic systolic murmur are represented graphically. Diagrammatic representation of the heart in systole, stenosis of the aortic valve being present; the mitral and tricuspid valves have closed; the right ventricle is nearly empty; the left ventricle is still more than half full of blood, because of the obstruction present at the aortic orifice. *Results.*—A systolic murmur in the aortic area; enlargement of left ventricle, etc.

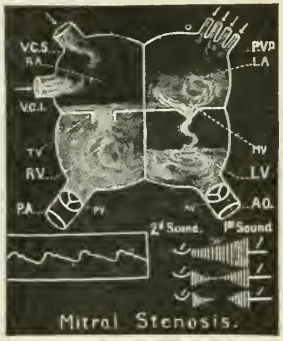
Aortic Stenosis.— (*Greene.*)
Transmission.

Pulmonary Stenosis in Adults.—(*Sansom.*)
Shaded area represents field of maximum intensity.

Pulmonary Stenosis.— (*Greene.*)
Maximum point and direction of transmission.

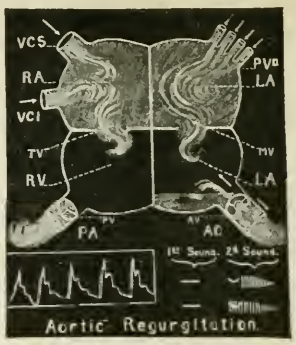
Mitral Stenosis.— (*Sansom-Bramwell.*)
Point of maximum intensity and transmission.

Mitral Stenosis.— (*Sansom.*)
Upper shading, area of audibility of simulated doubling of second sound. Lower shading, area of murmur transmission.



Graphic represention of three varieties of the murmur of mitral obstruction. Heart at moment of auricular contraction immediately before systole (presystole); mitral obstruction evident; aortic and pulmonary valves closed; tricuspid freely opened; *right* auricle nearly empty; right ventricle filled; *left auricle but partly emptied*; *left ventricle barely half full. Result.*—Presystolic or diastolic murmur, dilatation of left auricle, congestion of lungs, consecutive enlargement of right heart.—(*Greene.*)

Aortic Regurgitation. —(*Greene.*) Maximum intensity direction of transmission.



Graphic representation of murmur. Two varieties of aortic diastolic murmur shown graphically. The heart is shown in diastole, aortic leakage being evident. The blood has just been projected into the aorta and pulmonary artery by the ventricular contraction. The pulmonary valve tightly closed maintains the blood column, but through the leaky aortic valve a regurgitant current meets the stream descending from above through the open mitral valve. *Results.*—A diastolic murmur, dilatation, and hypertrophy of left ventricle, a slapping, low-tension pulse.—(*Greene.*)

murs are usually present. **Malignant endocarditis** is particularly likely to occur in pneumonia, erysipelas, and infected wounds, and is of two main types: the typhoidal and the septic. The first is marked by grave prostration, erratic pyrexia, delirium or coma, sweating, diarrhea, and skin eruptions. In cases of doubt the blood should be tested for Widal's reaction. The second often sets in with a rigor, followed by high fever. Some cases run a subchronic course, and may simulate a quotidian or a tertian ague. The plasmodium malariæ should then be sought. Other cases simulate cerebral or cerebrospinal meningitis. Cases may be overlooked, as the heart may be negative on examination. Recovery in malignant cases is rare. Emboli may first give the clue to the diagnosis.

Acute Pericarditis.—The etiology is the same as that of acute myocarditis. The inflammation may be primary or secondary. Usually it follows some general infection. It may result from extension of inflammation from a neighboring structure. The resulting changes are similar to inflammation in other serous membranes. These changes present themselves as acute plastic or dry pericarditis or pericarditis with a serofibrinous, hemorrhagic, or purulent effusion. Varying grades of myocardial inflammation are encountered in combination with pericarditis. The disease is characterized by slight fever, precordial distress and pain, disturbed cardiac action and circulation, dry cough and dyspnea. If the effusion becomes purulent, there will be the additional symptoms of sepsis—chills, pallor, irregular fever, sweats, marked leukocytosis. During the first stage of acute pericarditis auscultation reveals excited heart action and usually a rough to-and-fro friction sound, synchronous with the cardiac sounds, uninfluenced by respiration but often increased by pressure with the stethoscope, heard best at the fourth left interspace. Later as the effusion forms, the cardiac sounds are feeble and deep-seated, especially at the apex. As absorption progresses, the friction sound returns, being replaced shortly by the normal heart-sounds. During the effusion stage, the impulse is feeble or absent and when present is considerably displaced. The precordium may bulge. The dulness assumes a triangular shape with the apex upward and base on a line with the sixth or seventh rib. A characteristic sign is dulness in the fifth right interspace (Rotch's sign). Sometimes an area of dulness is found posteriorly below the ninth rib.

Differential Diagnosis.—A loud, persistent murmur, particularly if diastolic or presystolic, is in favor of endocarditis. An unaccentuated pulmonary second sound, while not absolute, is in favor of myocarditis. If endocarditis is present, it is necessary to know whether it is recurrent. If a chronic lesion exists, hypertrophy is of high degree, while in purely acute cases the increase of cardiac dulness is due to dilatation and is never extreme. The harsh friction murmur and signs of effusion are characteristic of pericarditis.

Chronic Affections of the Heart

Those affecting the myocardium are chronic myocarditis, fatty heart, and idiopathic heart

hypertrophy; those affecting the endocardium are chronic endocarditis and atheroma.

Chronic Myocarditis.—More correctly styled "interstitial fibrosis of the myocardium." It rarely supervenes upon a previous acute myocarditis, but generally upon sclerosis of the coronary arteries. This may go on to obliteration of their lumen, and, if sudden, may bring about softening of the heart wall, with aneurysm or rupture. If gradual, formation of scar tissue throughout the organ, with compensatory hypertrophy of the muscle, is the result.

As in other organs, there is considerable reserve power in the heart, and the patient may for years suffer no inconvenience. Symptoms come on insidiously. Upon exertion, dyspnea or palpitation is complained of, and precordial distress, often with weakness and anemia. These may disappear for a time, only to return in greater intensity. The pulse, at first full and powerful, becomes weak, rapid, and irregular; but cases are known in which it only beats 50 or 60 to the minute. It may be bigeminal. As the heart dilates, the area of dulness increases, unless emphysema coexists. A murmur at the apex, if present at all, is due to ventricular dilatation (relative insufficiency). The pulmonary second sound is accentuated if the right heart is hypertrophied. Urgent dyspnea may be present and anginal attacks may be frequent. Vomiting or maniacal fits are not uncommon. The prognosis is always grave.

Chronic Pericarditis.—Adhesive pericarditis is always secondary to an acute attack. The pericardium may bulge and the impulse is more diffused or displaced. Sometimes there is a systolic retraction of the chest-wall. This may be followed by a diastolic collapse of the cervical veins—Friedreich's sign. Broadbent's sign—retraction posteriorly between the eleventh and twelfth ribs—has recently been discredited. Sometimes there is present the pulsus paradoxus (*q. v.*).

Fatty Heart.—This may be due to fatty infiltration or degeneration. The latter occurs in all wasting diseases, Bright's disease, diabetes, and pernicious anemia. The former is a constant accompaniment of general obesity. For years the heart may be adequate and no symptoms be present; eventually all the signs of a chronic myocardial affection set in, and sudden death may occur from syncope or heart rupture. The area of cardiac dulness is increased.

Idiopathic Heart Hypertrophy.—Hypertrophy is often secondary to arteriosclerosis, nephritis, arterial hypoplasia, emphysema, and the like. There is, however, a class of cases—"idiopathic" or primary—where the condition results from overwork, mental anxiety, abuse of alcohol, tea, coffee, or baths. Increased arterial tension is probably the cause in every case. The so-called Munich heart, or "beer-heart," is a type of this condition. The symptoms at first are merely dyspnea and palpitation, but later all signs of cardiac insufficiency set in. The heart-sounds are weak and the apex-beat is weak or absent. The heart dulness may be very extensive.

All the lesions above mentioned are characterized by the same symptoms and physical signs. Differential diagnosis may be difficult or impossible.

Differential Diagnosis.—The points in favor of interstitial fibrosis are arteriosclerosis or late lues, anginal attacks, an unaccentuated pulmonary second sound, and the absence of general obesity.

In favor of fatty heart are presence of wasting diseases; cancer; pernicious anemia; certain poisons, as phosphorus; general obesity.

In favor of simple hypertrophy are abuse of food or alcohol, excess of work or mental strain, increased cardiac dulness, a powerful heaving pulsation, loud heart-sounds, an accentuated aortic second sound, a full pulse, excessive blood-pressure, throbbing carotids, flashes of light, humming in the ears. If the right heart is mainly affected, the pulmonary second sound is accentuated.

In all cases we must exclude a valvular lesion; this is done by a due consideration of the murmurs present. A diastolic murmur is sure evidence of a valvular lesion.

When the cardiac dulness is increased, we must exclude pericardial effusion, aneurysm, mediastinal tumors, sacculated pleuritic exudates, and retraction of the lung. The chief point is in the position and force of the apex. In hypertrophy it is forcibly acting, and corresponds with the outer line of dulness. The history and repeated examinations will, as a rule, differentiate.

Chronic Valvular Lesions

The conditions are *leakage* (*insufficiency*) or *obstruction* (*stenosis*). These are due to sclerotic changes in the valve cusps, resultant from previous inflammatory processes, which lead to loss of substance, fusion of the cusps, stiffness, or puckering, and are often associated with deposition of calcareous material; more rarely the condition is due to atheroma resulting from alcoholism, muscular strain, or syphilis. Aortic insufficiency is especially likely to be of this nature. Such conditions react upon the heart-muscle, bringing about hypertrophy and dilatation of the various chambers. Hypertrophy is compensatory, enabling the heart to meet the increased strain, and while it is in excess, the heart works quite well and compensation is said to be intact.

When dilatation predominates, we get, consequently, lowered arterial pressure, increased venous pressure, with diminished interchange of the body fluids and lessened metabolism. This leads to dyspnea, cyanosis, passive congestion, anasarca, effusions into serous sacs, cough, headache, vertigo, gastrointestinal catarrh, and diminution of urine. Compensation is then said to be ruptured. See below, **Compensation and Incompensation.**

As to the distribution of the lesions, the mitral valve is affected in 58 percent of the cases, the aortic in 36 percent, the tricuspid in 4.33 percent, the pulmonary in 1.66 percent. In old age valvular lesions are more likely to result from degenerative processes, as atheroma.

Mitral Insufficiency.—In these cases blood regurgitates into the left auricle, which consequently

dilates and hypertrophies. An increased amount of blood is forced into the left ventricle, and it also dilates and hypertrophies; eventually all the chambers suffer.

There is diffuse pulsation over the pericardium, and the cardiac dulness is increased both ways. The apical impulse is downward and outward. At the apex can be heard a loud, blowing systolic murmur, either wholly or partially obliterating the first sound, and transmitted well into the axilla, or even into the back. Occasionally, it is quite circumscribed. The pulmonary second sound is accentuated. A systolic thrill at the apex is rare. While compensation is good the pulse is regular, full, and of low tension; later, irregular and small.

Regurgitation without valvular lesion may result from weakening of the heart muscle and loss of the normal sphincter action of the circular fibers around the orifice. This form of regurgitation is temporary and occurs after great muscular fatigue, excitement, or exhaustion. It is to be distinguished from *relative insufficiency*, a condition due to stretching of the orifice along with dilatation of the left ventricle. Relative insufficiency is seen in myocarditis and especially in aortic regurgitation.

The diagnosis of mitral regurgitation is easy, but care must be taken to exclude accidental murmurs due to anemia of simple dilatation.

Mitral Stenosis.—This lesion is generally combined with insufficiency. The cardiac dulness is moderately increased, mainly to the right. The left ventricle, as a rule, is small, and the apex is only moderately dislocated to the left. Epigastric pulsation may be marked. Palpation reveals a presystolic thrill at the apex. This is pathognomonic. The second pulmonic sound is greatly accentuated. At the apex may be heard a rough grating murmur; this is presystolic, increasing rapidly in intensity, to be suddenly cut off at the onset of systole. Rarely the murmur is diastolic. Occasionally, at the onset of diastole may be heard a murmur, then a pause, and finally a short presystolic murmur (Fräntzel's murmur). In the later stages the diastolic sound is sometimes reduplicated—Sansom's double-shock sound. The apical shock is forcible. Gallop rhythm may be present. The pulse is small, badly filled, and irregular. Extreme ascites is not common. Hemoptysis is a common feature. The presystolic murmur alone is not pathognomonic, as it has been heard in cases where at autopsy no mitral lesion was found. When insufficiency is present, a blowing systolic murmur at the apex is heard as well.

Aortic Insufficiency.—Leakage may be due to atheroma, ulceration, or rupture of the cusps. *Cor bovinum* often results, and the condition is sometimes called the "athlete's heart." The cardiac impulse is diffuse; the apical impulse is forcible and heaving, downward and outward. The cardiac dulness is increased relatively more to the left. Pathognomonic is a diastolic murmur at the aortic cartilage or to the left of the sternum at the level of the fourth left costal cartilage (Cabot). This is a long-drawn-out bruit, propagated downward toward the xiphoid or the apex. Generally accompanying it is a systolic murmur. *This rarely indicates aortic stenosis*, since very slight roughening of the valves or the dilatation of the aortic arch, which is usually present, will produce it. Occasionally, at the apex can be heard a rumbling murmur of limited area; sometimes, but not invariably, presystolic (Flint's murmur). The aortic second sound is feeble or absent. The pulse is full and forcible, suddenly falling in tension (collapsing or water-hammer pulse). Capillary pulsation is seen in the nails, and the spleen and liver occasionally pulsate. On drawing the thumb-nail across the forehead, the alternate flushing and paling can be demonstrated readily. On auscultation over the larger peripheral arteries, especially the femoral, a short, sharp systolic sound—the "pistol shot sound" and often a systolic murmur may be heard. Occasionally a diastolic murmur —Duroziez's sign—may also be present. The condition may be unsuspected, and sudden death may occur. Insanity is sometimes associated with this lesion.

Aortic Stenosis.—The rarest, uncomplicated, valvular lesion of the left side of the heart. There exists marked hypertrophy of the left ventricle and the apex is downward and outward. The pulse is slow, hard, and of small volume. At the aortic cartilage is a loud, grating, whistling, or musical murmur, systolic and transmitted up the vessels of the neck. The second aortic sound is absent or greatly diminished—an essential diagnostic sign. At the same region may be felt an intense grating thrill, felt also in the episternal notch. The diagnosis should not be made on the murmur alone, but only when the thrill is present, as a slight roughening of the valves, or dilatation of the arch without stenosis, may cause a loud, rough murmur. When insufficiency is also present, diagnosis may be impossible.

Tricuspid insufficiency is nearly always due to passive dilatation of the right ventricle. The physical signs are characteristic. The cardiac dulness is markedly increased to the right. To the right of the sternum, in the fourth or fifth interspace, is a systolic murmur, transmitted well to the right, together with a systolic thrill in the same region. In the neck is a positive venous pulse; the liver may also pulsate; this must be distinguished from communicated shock. The pulmonary second sound is weak.

Tricuspid stenosis is very rare, generally congenital; cyanosis is marked and the pulse is small. At the pulmonary cartilage is a presystolic or diastolic murmur, and the pulmonary second sound is weak.

Pulmonary insufficiency is rare. Dilatation and hypertrophy of the right ventricle are marked. There is a diastolic murmur at the pulmonary area transmitted down the sternum and a diastolic thrill. There is an interruption of the vesicular breath-sounds during inspiration.

Pulmonary stenosis is congenital. The right heart is hypertrophied; a systolic murmur is heard at the pulmonary cartilage, accompanied by a

systolic thrill. The second pulmonary sound is weak. Tuberculosis of the lungs is likely to occur.

Compensation and Incompensation

The importance of this subject is well expressed by Greene, as follows:

"A clear understanding of these two factors as affecting diagnosis, prognosis, and treatment is absolutely essential, and a lack of it leads to sins of commission no less than omission. Owing to the wonderful interaction of the regulating mechanisms controlling the blood-vessels and the heart, almost every form of heart defect may be so compensated for varying periods as to equalize the circulation and minimize symptoms. A clinician recognizes three distinct phases in the course of any heart lesion: (1) *good compensation*, (2) *impaired compensation*, (3) *lost compensation*. As regards the four chief varieties of valvular lesions, namely, mitral regurgitation or stenosis, and aortic regurgitation or stenosis, *the first stage* may show nothing more than the peculiar murmurs, the characteristic change in the cardiac outline, which indeed may be slight for a long period, and certain characteristics in connection with the pulse or general peripheral circulation. This statement is equally true of certain forms of myocarditis with intermittent *relative valvular* insufficiency and indeed applies to a greater or less extent to all lesions. Sins of commission occur in connection with this stage and consist of meddlesome interference in the way of treatment and the creation of unnecessary alarm through irrational and terrifying statements as to prognosis. *Such hearts need little or no treatment, but do need watching from time to time.*

"(2) **Impaired Compensation.**—This stage is the one most commonly encountered and the sins committed in connection with it are chiefly those of omission due to a failure to recognize and interpret obscure manifestations of the condition.

"In many lesions these symptoms are actually obtrusive; for example, the victim of *aortic regurgitation* complains of dull pain and oppression in the precordium or sharper neuralgic pains radiating to the neck, left shoulder and down the left arm, or he has some subjective or objective dyspnea, attacks of *pronounced* angina pectoris, vertigo, headache, insomnia, probably an increase of the nervous irritability so common in these cases, or signs of secondary mitral lesions may appear.

"*In mitral stenosis* the dyspnea may be marked, especially on exertion, the pulse becomes rapid more markedly irregular and unequal, pulmonary congestion and blood-streaked sputum may be evident, and this may even be reflected in the condition of the kidney, *stomach*, liver and spleen.

"*In mitral regurgitation* much the same symptoms are evident, and if the right heart is markedly weakened or *tricuspid regurgitation* established there is marked diminution of the pulmonary second sound, direct pulsation of the distended jugulars, pulmonary congestion, enlargement of the spleen and liver, indigestion, flatulence and, in short, general, visceral, passive congestion.

"*These symptoms are sufficiently striking and to them are added in any case an extension of the cardiac borders due to a dilatation which may be manifested by the substitution of a weakened heart impulse for that of hypertrophy, and oftentimes by a change in the quality of the murmur.*

"*Edema.*—In *aortic lesions* edema is likely to be absent or slight so long as the mitral holds fast.

Hopeless Incompensation.—(*Greene.*)
Attitude frequently assumed. Triangular area represents superficial cardiac dulness.

In *mitral lesions* edema of the lower extremities *may* be present with even slight degrees of incompensation. In the later stages general anasarca may appear.

"*These are plain, straightforward symptoms, each with its clear meaning, but it is quite otherwise when one deals with the slighter forms of such incompensation* and still more so in relation to the dilatation and slight incompensation associated with *chronic myocarditis;* cases which frequently present no murmur until rest and cardiac stimulants have renewed the tonus of the heart muscle and narrowed the valvular ring.

"**The nervous system** is peculiarly affected in many cases of slight incompensation. *Some of the most typical cases of neurasthenia ever seen by the author have been associated with a silent or almost silent leakage or stenosis of the mitral or aortic valve, and indeed several were associated with unrecognized aortic aneurysm.*

"Nothing is commoner in these cases than nervous irritability, drowsiness or insomnia, lack of concentration and ability to perform sustained mental or physical work, while numbness and tingling of the extremities are frequent. Again and again these cases have been associated with only slight increase of the cardiac area, enfeebled or somewhat fetal heart sounds, and most often, *markedly diminished or absent mitral first sound.*

"**The skin** may be the seat of persistent pruritus or eczema and very often a very slight grade of edema may be present, limited usually to the lower extremities, bilateral and often most marked over the surface of the tibia.

"**The Lungs.**—Persistent dry cough, slight or even marked congestion of the bases, asthmatic seizures, diffuse bronchitis, moderate grades of

emphysema and persistent pharyngitis and laryngitis may divert attention from an underlying incompensation, which is either causative, or a factor in the severity and continuance of pulmonary symptoms.

"**The Gastrointestinal Tract.**—Indigestion and persistent constipation together with recurrent attacks of acute gastric and hepatic disturbance and hemorrhoids are frequently associated with inefficient heart action.

"The author firmly believes that many of the results obtained by the rest cure in neurasthenia may be attributed to the good effect upon the *stomach and heart with the resulting improvement in nutrition.* Certainly under mental and physical rest all of the symptoms described promptly disappear in all minor degrees of incompensation.

"(3) **Complete Incompensation.**—*This term should be applied to those cases in which the heart muscle has completely lost its recuperative quality* as is seen in the terminal stages of all chronic heart affections that terminate gradually, or by sudden though not immediately fatal rupture of compensation. The best examples are seen in terminal cases of coronary sclerosis, fatty heart and chronic myocarditis in general. So also in mitral lesions there comes a time when the heart that has alone or with assistance again and again recovered itself finally yields and resists all therapeutic measures. In such terminal and *irrecoverable* cases the orthopneic patient often rolls the head aimlessly from side to side and wears a peculiarly listless yet distressed and hopeless expression. The term is frequently erroneously applied to cases of very marked and extreme cardiac weakness and especially to that of mitral regurgitation or stenosis associated with secondary tricuspid leakage and general anasarca.

"*In mitral regurgitation especially, the assumption of terminal incompensation is seldom justified as a primary assumption, for there is no cardiac lesion in which proper treatment can do so much, however extreme may be the manifestations.* Indeed in the case of all heart lesions it is only after trying and failing that surrender is justifiable on the part of the physician.

"**Relative Insufficiencies.**—The secondary dilatation of the valvular rings, such as occurs in the tricuspid following prolonged mitral lesion or as a result of myocarditis and severe physical strain, or in the mitral as secondary to aortic lesions, chronic myocarditis or the terminal stage of an interstitial nephritis the prognosis is variable. In such cases under proper treatment the tricuspid usually recovers its function in whole or in part, as does the mitral to a less degree and with less constancy. *The left heart cases associated with sudden rupture* of compensation *through severe strain do badly if the myocardium is not sound, and often terminate quickly and fatally.* So also the mitral insufficiency so often encountered in chronic interstitial nephritis will not respond to treatment with anything like the promptness usually noted in connection with this valvular lesion, and, moreover, the patients of this type are often irritable, restless, difficult to control and quite unlike the ordinary phlegmatic, cheerful mitral-regurgitant patient."

Prognosis of Valvular Lesions.—While compensation is maintained and the patient can and will live quietly, life may be of long lease. In children the outlook is usually bad. Pregnancy has not the prejudicial effect upon the heart-lesion that has usually been taught. Aortic stenosis is the most favorable; next, mitral insufficiency. Worst of all is aortic insufficiency. Stenosis, when accompanying mitral insufficiency, has a somewhat compensating effect.

The following factors make the prognosis more grave: (1) Early life, (2) female sex, (3) old age, (4) lost compensation (indicated by irregularity of pulse, dyspnea, etc.), (5) nephritis, (6) cirrhosis of the liver, (7) diseases of the lungs.

Sudden death from heart-disease is somewhat uncommon. The following conditions may produce it: (1) **Aortic regurgitation.** With this form of cardiac disease death is sure to result sooner or later. One writer has never seen any such patients improve much under any form of treatment, excepting those in whom the disease was dependent on syphilis. With this form of cardiac trouble the patient not only gradually grows worse, but he may drop dead at any moment, and the mode of this death has never been satisfactorily explained. The best explanation that can be given is that the left ventricle becomes more and more enlarged, until we get what is known as the *cor bovinum*, or ox heart, and in some of these cases there will be pressure on the coronary vessels that feed the heart; the patient then dies of anemia of the heart, very much as in angina pectoris. In fact, aortic regurgitation is not infrequently associated with attacks of angina, due to this pressure on the coronary vessels. (2) **Angina pectoris.** A patient with this affection may die in the first attack, or he may survive a dozen or more attacks. With the more recent methods of treatment, the mortality from this disease has been considerably reduced. (3) **Fatty heart,** or fatty metamorphosis of the muscular structures of the heart. This process may go on until the time comes when the heart simply ceases to beat. (4) **Cardiac aneurysm.** In these cases the ventricular wall becomes thinner and thinner until rupture and sudden death occur.

Treatment of Organic Heart-disease

The treatment of acute endocarditis and myocarditis practically resolves itself into the treatment of the primary systemic condition. The danger is not so much from the acute process as from the chronic changes that result and the effects of which are to be of concern in future time. When a rheumatic poison is present, it is questionable if the exhibition of salicylates will prevent endocarditis. It is probable, however, that if the rheumatic attack is cut short, the liability is diminished. In such cases salicylates should be given in 20-grain doses every 2 hours until 2 drams are given, and then gradually diminished until the patient is taking 1 dram a day. This should be kept up for from 2 to 3 weeks or longer. When convalescence

sets in, iron or arsenic is indicated. This treatment is usually very efficacious. Digitalis is rarely of use. Light diet and absolute rest in a recumbent position are imperative. It is of the utmost importance that the patient should not get up too soon, a fault which is liable to occur under the salicylate treatment, since the severe symptoms pass off so quickly. If endocarditis is present, too early a return to activity is extremely pernicious, and increases the subsequent trouble. Patients should usually be 6 weeks in bed, and should be regarded as invalids for at least 3 months longer. Many years may be added to life by adherence to this principle.

The treatment of malignant endocarditis is that of septicemia. If a clear streptococcus infection is made out, antistreptococcus serum may be employed and free stimulation.

The treatment of pericarditis should be prompt. Absolute rest in bed is imperative. It is well to give calomel. A large blister is especially valuable. Cold compresses or the ice-bag should be usually applied, though sometimes heat is more comforting. For the relief of pain, morphin (1/4 grain) with atropin (1/150 grain) should be administered hypodermically. Stimulants such as digitalis, alcohol, aromatic spirit of ammonia and strychnin, are indicated. If the effusion is large, the pericardium should be tapped in the fourth left interspace 1 inch from the sternum. In purulent effusion, free incision followed by drainage is indicated. The treatment of chronic pericarditis is largely symptomatic, tonics and stimulants being of great importance.

The treatment of the chronic affections, both myocardial and valvular, will vary according as compensation is perfect or ruptured.

During the compensation stage it is to be remembered at the onset that drugs are unnecessary, if not actually deleterious. A patient with a chronic lesion should obey rigidly all the laws of hygiene. Excesses in food, exercise, and mental and physical toil should be avoided; alcohol and tobacco should not be used. As such persons are very liable to "take cold," they should avoid extremes of temperature, getting wet, or sitting in drafts, and should always wear flannel next the skin. A morning cool or tepid bath is advisable. Plethoric or obese persons should take an occasional saline purge, and if arterial tension is high, an occasional course of potassium iodid is advisable. A sojourn in an equable climate during inclement seasons is to be recommended.

In recent years, owing to the influence of Schott, of Nauheim, massage, resisted movements, together with dieting and the use of carbonated saline baths, have come into prominence as curative agencies. The graduated walking exercises of Oertel are not now so frequently employed, but may be commended as a sequel to the Schott method. The so-called Swedish movements are somewhat similar to those of Schott, and were introduced by Zander in 1872.

After much debate it seems to be settled that within certain limits the mechanic treatment is a valuable adjunct to other methods; its use, like that of drugs, must be intelligent and guarded, and only applied to certain cases; otherwise much harm may result. The contraindications are: All acute conditions; advanced arteriosclerosis, especially if associated with intestinal nephritis; aneurysm and cardiac neuroses. It should be employed with care when there is any reason to suspect coronary changes and in early rupture of compensation. Gymnastics should be avoided for at least 6 months after an acute attack of endocarditis. Massage is particularly suitable for those convalescing from acute endocarditis,

DIFFERENTIAL DIAGNOSIS OF ORGANIC HEART-DISEASES

Disease.	Heart Dulness.	Heart-sounds.	Pulsation.	Apical Impulse.	Murmurs.	Thrills.	Pulse.	Arterial or Venous Phenomena.
Pericarditis...	Pyriform area of dulness.	May be distant.	.....	Within area of dulness; often weak or absent.	Friction rub at first; occasionally a presystolic murmur at apex.	.....	Strong in proportion to heart-sounds and impulse.	Venous congestion.
Acute myocarditis.	Increased.	Clean or with murmurs; pulmonary second sound often not increased.	.....	Weak.	When present often intermittent.	.....	Small, frequent, and arrhythmic.	.....
Chronic myocarditis.	Variable.	Weak; pulmonary second sound often not increased.	.....	Weak.	May be present; intermittent.	.....	Small, frequent, and arrhythmic; at first may be slow and full.	.....
Fatty heart...	Increased.	Weak, but clean; pulmonary second sound variable.	.....	Weak or absent.	.....	.....	Small, rapid, and arrhythmic.	Pseudo-apoplectic attacks.

DIFFERENTIAL DIAGNOSIS OF ORGANIC HEART-DISEASES

Disease.	Heart Dulness.	Heart-sounds.	Pulsation.	Apical Impulse.	Murmurs.	Thrills.	Pulse.	Arterial or Venous Phenomena.
Idiopathic hypertrophy of heart.	Increased.	Loud; aortic second sound increased; pulmonary second sound may be increased; gallop rhythm.	Often marked epigastric pulsation.	Powerful, diffuse, heaving.	.....	.....	Large and full.	Pulsation in carotids; flushings.
Acute endocarditis.	Slightly increased, due to dilatation.	Pulmonary second sound accentuated.	.....	Dislocated to left.	Systolic; rarely diastolic at apex; or diastolic—rarely a systolic—at aortic cartilage.	.....	Febrile.	.....
Mitral insufficiency.	Increased: at first, mainly to left; later to right.	Present or obscured; pulmonary second sound accentuated.	Diffuse pulsation over precordium.	Diffuse; apex down and out.	Blowing systolic murmur, loudest at apex; transmitted into axilla.	Often a systolic thrill at apex.	At first normal; later small and irregular.	.....
Mitral stenosis	Increased, mainly to right.	Pulmonary second sound accentuated, often reduplicated; first sound often loud.	Area of pulsation increased; epigastric pulsation.	A little dislocated to the left and punctate.	Presystolic at apex: harsh and grating; rarely diastolic and presystolic.	Presystolic thrill felt toward apex.	Very small, rapid, and irregular.	.....
Aortic insufficiency.	Increased, mainly to left at first.	Weak first sound at apex; second aortic feeble or absent.	Pulsation in left axillary line.	Heaving, forcible, well down and out.	A long blowing, diastolic murmur at aortic cartilage; seldom at apex; a systolic murmur may be present at base.	A diastolic thrill may be felt at base.	Quick, vigorous full, and collapsing capillary pulse.	Systolic shock heard in brachials, radials, and crurals, or to-and-fro murmurs; sometimes double shocks in vessels.
Aortic stenosis.	Marked increase to left.	Aortic second sound is weak, or absent.	.....	Downward and outward.	Systolic murmur at aortic region, loud, sustained, singing, or whistling; transmitted up vessels of neck	Systolic thrill in aortic region and in suprasternal notch.	Slow, badly filled; vessel hard.	Anemia in arterial tract.
Tr cuspid insufficiency.	Marked increase to right.	Pulmonary second sound not increased.	Epigastric.	.....	Systolic at right sternal border at 4th and 5th ribs; transmitted well to right.	Systolic thrill may be present in same region.	.....	Positive venous pulse in neck: pulsating liver.
Tricuspid stenosis.	Increased to right.	Pulmonary second sound weak.	.....	.....	Presystolic or diastolic over tricuspid region.	.....	Small.....	Negative venous pulse in neck.
Pulmonary insufficiency.	Increased to right.	.....	.....	Moderate dislocation to left.	Diastolic at second left intercostal space; not heard in neck.	Diastolic thrill at base.	.....	Interrupted inspiratory breath-sounds—Gerhardt's sign.
Pulmonary stenosis.	Increased to right.	Pulmonary second sound weak.	.....	.....	Systolic at second left intercostal space.	Systolic at base.	.....	Marked cyanosis; tendency to hemorrhages.

when there is a tendency to lividity, cold extremities, and local stases, or when the bodily weakness is extreme. Massage promotes the arterial flow, the venous return, and the interchange of lymph, thus stimulating metabolism and assisting absorption and circulation. It may be used as a preliminary to the more active treatment by the Schott or Oertel methods.

The Nauheim or Schott treatment consists in systematically exercising every set of muscles in the body by means of resistance exerted by attendants or by overcoming weights; every gradation in the power exerted can thus be obtained. These exercises are used alone or in conjunction with the use of saline baths saturated with carbon dioxid.

According to Schott, the periodic stimulation of the heart increases its action, and, as a consequence, the cardiac muscle regains some of its natural power, and its nutrition and tone are improved. He also thinks that dilatation is diminished, the pulse improved, and dyspnea alleviated, and that the effects of the baths and of mechanic treatment are very similar. They are supposed to produce their effect largely by a reflex stimulation of the cardiac centers.

It has been doubted by many—especially by Groedel, Guntz, and Leyden—that diminution of the cardiac dulness is a consequence of this treatment. Schott has exhibited a series of skiagraphs of the heart, taken before and after treatment, and it can scarcely now be doubted that his contention is correct; the evidence seems conclusive.

The effect, then, seems to be a more vigorous heart-action, a more complete systole, and a more rapid and perfect circulation, with consequent lessened tension upon the right side of the heart. In a measure the treatment also indicates the reserve power in the heart, and to what extent a return to ordinary habits of life may be permitted. The Schott treatment is of chief value in moderate degrees of fibroid heart, the idiopathic hypertrophy, or when there is fatty infiltration. For those who may not be able to afford a trip to Nauheim, a bath may be employed containing 2 percent of chlorid of sodium to which is added sodium bicarbonate and hydrochloric acid. It would seem that the presence of CO_2 is more important than the salt. See SCHOTT TREATMENT.

Oertel's method is more exacting. It consists, in brief, of a dry diet, avoidance of fats and starches, and graduating walking-exercises. Fluids are cut down to 36 ounces a day. The reduction in fluids tends to reduce the fat in the patient and to concentrate the blood. The diet should be highly nitrogenous. Walks should be taken on the level and then on slight inclines until considerable heights are climbed. The exercise may be slightly prolonged each day. It should be pursued short of extreme dyspnea and until a healthy action of the skin is induced. The effect is much the same as that of the Schott method. The advantage is that one gets the stimulating effects of outdoor exercise. Powell thinks that carefully regulated outdoor sports—as golf, cycling, tennis, fishing, and the like—may be advantageously substituted.

When compensation is on the verge of rupture, rest is indicated. Patients who present dyspnea with slight lividity and cough, with slight edema of ankles and a rapid and irregular pulse, should be confined to bed on a restricted diet. This alone in many cases will restore compensation. Sometimes iron, arsenic, or strychnin, with general tonic measures, may be advisable. The use of digitalis should, as a rule, be reserved for the severer cases of ruptured compensation. In cases of acute heart failure reliance should not be placed on digitalis, as it takes about 3 days to exert its action, and time is precious. Hypodermics of ether, alcohol, camphor, or strychnin must be relied on until the danger is over and the ordinary heart tonics can get time to act. Inhalations of oxygen are of great value.

When compensation is completely ruptured, either in myocardial or valvular affections, some one of the class of heart stimulants—digitalis, strophanthus, caffein—is to be employed. Spartein and convallarin are rarely of use. Of this group, digitalis is by far the most valuable. Its action is to slow the heart, producing more forcible and complete contraction, prolonging diastole, and later contracting the arterioles, thus raising blood-pressure. When there is a weak and irregular systole, with venous stasis and low tension pulse, precisely these qualities are called for; since the irregular beats are gathered up into more effective contractions, the interchange of fluids in the tissues is promoted, and more time is given for the due performance of function.

Strophanthus differs in that it has no effect upon the arterioles, and hence is indicated when vascular tension is high. It is difficult to get a satisfactory preparation. To relieve tension potassium iodid may be prescribed with digitalis.

Caffein causes more rapid action of the heart, and so may be of value in those cases of myocarditis in which the pulse is very slow and the use of digitalis risky.

In mitral stenosis the first weakness is on the side of the right heart, and this at first may be relieved by rest, exhibition of saline purges or diuretics, or even by blood-letting, with restricted diet. If the pulse remains weak and irregular, and other signs of venous stasis do not improve, digitalis is to be used.

In mitral regurgitations are all the conditions for the most advantageous effects of digitalis. In cases, however, of relative insufficiency of the mitral from arterial tension, the condition is compensatory, and digitalis would be of doubtful benefit. In aortic regurgitation it might be doubted whether digitalis would be indicated, since it lengthens diastole, and therefore, theoretically, should not be used. Practically, however, its use is advisable, though we cannot expect as beneficial results as in the case of mitral lesions.

When the breakdown is due to some temporary over-strain—as a dyspeptic, nervous, or gouty attack—attention should be directed to reducing tension by mercurials and salines or the nitrite group, digitalis being reserved until later. Digi-

talis in this condition prevents accumulation of residual blood in the ventricle, and promotes the effective closure of the mitral cusps, and thus is advantageous. It may be given as the tincture, 15 to 20 minims 3 times a day, gradually increased to 90 minims. Signs of saturation—as returning rapidity of pulse, vomiting, or green vision—should be watched for. It is often more effective as the infusion, of which an ounce, freshly made, may be given hot twice a day.

℞. Tincture of digitalis, Simple elixir, each, ʒ iv
Water, q. s. ℥ iij.

One teaspoonful every 4 hours.

℞. Strychnin sulphate, gr. j
Tincture of strophanthus, Elixir curacoa, each, ʒ iv
Water, q.s. ʒ iv.

One teaspoonful every 4 hours.

℞. Citrated caffein, ʒ j
Tincture of digitalis, ʒ ij
Aromatic elixir, ʒ iv
Water, q. s. ℥ iij.

Two teaspoonfuls every 4 hours.

℞. Citrated caffein, ʒ j
Tincture of strophanthus, ʒ jss
Elixir of curacoa, ʒ iij
Water, q. s. ℥ iij.

Two teaspoonfuls every 4 hours.

Anemia:

℞. Strychnin sulphate, gr. j
Reduced iron, ʒ j.

Make 30 pills; 1 pill after meals.

℞. Strychnin sulphate. gr. j
Tincture of iron chlorid, ʒ ij
Aromatic elixir, ʒ iv
Water, enough to make ʒ iv.

One teaspoonful after meals.

Dyspnea.—If hydrothorax is the cause, tap the chest. Morphin in other cases is of much value used freely; if arterial tension is high, nitroglycerin, beginning with 1 minim of a 1 percent solution. A back-rest should be used.

Dropsy.—This often disappears under the action of digitalis. If action is tardy, saline purges or diuretics are advisable. Of great value is the so-called Guy's pill (pulverized digitalis, 1 grain; pulverized scilla, 1 grain; and blue mass or calomel, 1 grain). This often has a miraculous power over effusions. Southey's tubes are occasionally useful.

The Matthew Hay plan is of value. This consists in a restriction of fluids, a dry diet, and the administration of 1/2 of an ounce of Epsom salts before breakfast. The compound jalap power (20 to 30 grains) may be given once or twice daily in place of the salts. Calomel (1/4 of a grain) may be given also until 4 or 5 doses have been taken, followed the next day by 1/2 of an ounce of Epsom salts.

Palpitation.—A Leiter's coil or ice bag over the heart is useful.

Vomiting.—If extreme, stop food and give ice, iced milk, or champagne.

Insomnia.—Spirit of chloroform or ether may be tried; paraldehyd, sulphonal, or trional, and, lastly, morphin.

Syncope.—The aromatic spirit of ammonia (30 drops) may be given every half hour for 2 or 3 doses. One or two drops of the 1 percent solution of nitroglycerin may also be given every 2 or 3 hours by the mouth or 1/100 of a grain hypodermically. Inhalations of nitrite of amyl or of ammonia often prove valuable.

The signs of improvement under digitalis are the steady and slowing of the pulse, diminution of dropsy and lividity, and increase in the flow of urine. It should not be expected that a return to a normal pulse condition will result, since it may be said that there is a certain pulse character to each kind of lesion, and if this character is restored, that is all that can be expected. As a rule, when once patients have taken digitalis, its use must be continued.

HEAT-STROKE. Synonyms.—Insolation; sunstroke; thermic fever; coup de soleil; heat-exhaustion.

Definition.—A depression of the vital powers, the result of exposure to excessive heat. The condition manifests itself as acute meningitis (rare), heat-exhaustion (common), and as true sunstroke.

Etiology.—Exposure to the prolonged influence of excessive heat, either to the direct rays of the sun, to artificial heat in confined quarters, or to diffused atmospheric heat without proper ventilation. Heat cases are most numerous after a protracted period of excessively hot weather.

Among the predisposing causes which act by lessening the power of the system to resist the heat are great bodily fatigue, overcrowding, intemperance, and humidity of the atmosphere.

Differential Diagnosis.—It is of great importance, therapeutically, to distinguish at once between attacks of *sunstroke* and *heat-exhaustion*. Sunstroke is to be differentiated from cerebral hemorrhage and alcoholic insensibility, for which purpose the clinical thermometer is indispensable. See Coma.

Heat-exhaustion develops with a rapid feeling of weakness and prostration; the surface is cool, the face pale, the voice weak, the pulse rapid and feeble; the respiration is increased, the vision grows dim and indistinct, noises develop in the ears; painful muscular spasms are common; the individual is overcome, and is partially or completely unconscious. In some cases the attack of prostration is sudden, the person falling unconscious, with perhaps convulsions or tremors, and shrunken features.

Sunstroke.—The symptoms, developing suddenly, with or without prodromes, are insensibility with or without delirium, or convulsions, or paralysis; the surface is flushed and hot, the conjunctivæ injected, the breathing either rapid and shallow or labored and stertorous, the pulse quick and either bounding or weak, and the temperature in the axilla ranges from 105° to 110°, with suppression of all glandular action. Death occurs as

the result of asphyxia, or from a slow failure of respiration and cardiac action.

Prognosis in attacks of heat-exhaustion, if properly and promptly treated, is favorable. In sunstroke or heat fever it is unfavorable in the majority of cases, death resulting in from half an hour to several hours. Unfavorable indications are excessive body-temperature, cardiac failure, convulsions, absent reflexes, followed by complete muscular relaxations. Favorable indications are decline in surface heat and axillary or rectal temperature, stronger pulse, increased depth of respirations, restored reflexes, and return of consciousness.

After-effects.—The most constant after-effect of sunstroke is a permanent inability to bear high temperatures. When the thermometer reaches as high as 80° F. in the shade, patients become very uneasy. More constant and more troublesome is the loss of the power of mental concentration and failure of the memory. Hot weather always makes such patients worse. Convulsions and mental disturbances are likely to develop. Peripheral neuritis has been recorded as an after-effect, and acute neuritis is also mentioned.

Treatment of Heat-exhaustion.—These cases are successfully treated by placing the patient in the recumbent position, with the head low, and the use of stimulants and external heat. If able to swallow, administer at once brandy (1/2 to 1 ounce) with deodorized tincture of opium (20 to 30 minims), to be repeated p. r. n.; if he is unable to swallow, the remedies may be thrown into the rectum, or whisky, strychnin, and tincture of digitalis may be used hypodermically. As convalescence occurs, tonic doses of quinin sulphate and strychnin sulphate should be prescribed.

Treatment of Sunstroke.—The indications for treatment are the reverse of the foregoing. The patient is in imminent danger from the extraordinary temperature, and measures to reduce it must at once be instituted. Of these, none give such excellent results as rubbing with ice, or by the cold bath or cold pack, and cold effusions, cold enemata, and the hypodermic use of quinin sulphate or antipyrin. The tendency to subsequent rise of temperature is met by wrapping the patient in a wet sheet, or by the repetition of the hypodermics mentioned if consciousness has not been regained; in which case the remedies may be given by the mouth. If convulsions and restlessness occur, the hypodermic use of morphin sulphate (1/4 to 1/2 of a grain), cautiously repeated, is successful. If symptoms of depression occur, the stomachic, rectal, or hypodermic administration of stimulants is indicated, and strychnin sulphate, 1/24 of a grain, repeated half hourly by the hypodermic method. For convalescence, use quinin sulphate, strychnin sulphate, or iron.

HECTIC FEVER.—This is a common accompaniment of prolonged suppuration, from whatever cause, when the wound cannot be kept aseptic and efficiently drained. It has been ascribed to the drain on the system owing to the formation of large quantities of pus; but this is certainly not the only cause, as a chronic abscess may attain a very large size, and exist for years unattended by hectic fever, so long as it remains unopened; nor after opening does it occur if the pus can be prevented from undergoing fermentative or putrefactive changes, and the cavity can be well drained. It would, therefore, appear to be due to chronic blood-poisoning, consequent upon the absorption of the products of fermentation or putrefaction in small quantities at a time.

Symptoms.—Hectic fever is characterized by profuse sweating, rapid wasting, nocturnal rises of temperature with morning remissions, and generally by diarrhea and deposits of urates in the urine. The face is pale and pinched, the cheeks flushed, the eyes bright, the pupils dilated, the tongue red and dry at the edges, and the pulse rapid, small, and weak. The appetite gradually fails, the patient becomes weaker and weaker, and dies, exhausted, of diarrhea, lardaceous disease, etc.

Treatment.—The cause of the suppuration should be removed, or, if this is impossible, the absorption of septic products, so far as practicable, should be controlled by establishing a free drain to the suppurating cavity and by preventing, by the use of antiseptics, the putrefaction of the discharges. At the same time the system must be supported by nourishing diet and stimulants, the sweating combated by dilute sulphuric acid or atropin, and the diarrhea by opium, catechu, or other astringents. See SUPPURATION, TUBERCULOSIS.

HEDEOMA.—The dried leaves and flowering tops of *Hedeoma pulegioides*, Pennyroyal. Dose 1 to 3 drams. Hedeoma is a stimulant aromatic, also somewhat carminative and emmenagogue. Its odor is extremely repulsive to insects, especially fleas and mosquitos. In warm infusion it is a popular remedy for amenorrhea and flatulent colic. It may be used as a corrective with other medicines, and the spirit is well employed on the hands and face to keep away mosquitos. Death by narcosis has been known to result from an overdose of the oil taken to produce abortion.

Oleum H., *oil of pennyroyal*, is the volatile oil, readily soluble in alcohol. Dose, 1 to 5 minims.

HEDONAL.—A urethane having a more pronounced hypnotic action than ethyl carbamate. It is considered safer than most of its class and leaves no after-effects. Dose, 15 to 30 grains.

HELIOTHERAPY.—See BURNS, LUPUS VULGARIS, PHOTOTHERAPY.

HELMITOL.—The methylene-citronate of urotropin. A urinary antiseptic and germicide. It is said to act more rapidly and energetically than urotropin. Dose, 10 to 15 grains.

HEMATEMESIS.—Hemorrhage from the stomach.

Etiology.—(1) Traumatism; (2) mechanic obstruction, as in cirrhosis of the liver; (3) cardiac disease; (4) pulmonary disease; (5) vicarious menstruation; (6) rupture of an aneurysm; (7) ulcer of the stomach; (8) cancer of the stomach; (9) irritant poisons; (10) hysteria.

Diagnosis.—It is to be distinguished from hemorrhage from the respiratory passages. See HEMOPTYSIS.

Treatment requires absolute rest in bed; rectal alimentation, as advised for ulcer of stomach; an ice-bag or ice-cloths to the epigastric region; and hypodermics of ergotol (20 minims) with morphin (1/4 of a grain). Medicines by the mouth should be avoided for several days. The transfusion of blood may be tried in severe cases. See STOMACH.

HEMATICS.—Medicines which augment the quantity of hematin in the blood by enriching its red corpuscles. They consist chiefly of iron and manganese and their compounds.

HEMATIDROSIS.—Bloody sweat caused by the extravasation of blood into the coils and ducts of the sweat-glands, whence it is carried to the surface, mixed with sweat. See SWEAT-GLANDS.

HEMATOCELE.—A swelling occasioned by effusion of blood into the pelvis or into the sac of the tunica vaginalis, or into a cyst connected with the testicle, or into the spermatic cord.

Pelvic hematocele may be intraperitoneal or extraperitoneal. It differs from hematoma in that the bleeding is into the connective tissue, while in hematocele it is effused into the pelvic cavity. An intraperitoneal effusion of blood usually gravitates into Douglas' pouch, and is spoken of as retrouterine hematocele. It may arise from rupture of a vein in the broad ligament, which is rare, and there are no definite symptoms preceding the rupture whence its cause may be inferred. Inflammation of any serous membrane may result in hematocele, or the rupture of an ovary may cause it. It may be due to rupture of a Fallopian tube, or it may follow bleeding from the tubes, as a result of fever, phosphorus poisoning, scurvy, atrophy of the liver, and yellow fever. It may follow abortion or delivery, more often the latter; or it may result from menstrual retention from atresia, stenosis, hypertrophy, or flexions of the cervix, or closure of the tubes at their uterine ends.

The usual course of pelvic hematocele, when reaction from the immediate shock of hemorrhage ensues, is to complete recovery by absorption of the effused blood, and no treatment other than expectant is to be given. Rest in bed, while there is any pain or fever; tonics, if the appetite fails; and laxatives, to prevent the passage of hard scybala, are indicated. A case is very seldom seen while the hemorrhage is going on, because the patient dies or the hemorrhage stops before medical aid can arrive. If hemorrhage can be seen, it is proper to open the abdomen and check it by mechanic and surgical means. If a slight hematocele is followed by signs of increase, the abdomen should be opened. If serious trouble results from the size of the tumor, such as retention of urine or obstruction of the bowel, or if febrile symptoms come on, abdominal section is preferable to tapping.

Hematocele of the tunica vaginalis, cord, or testicle may occur in a healthy state of the parts, or may succeed or be combined with hydrocele. Blows, violent efforts at straining, or accidental wounding of a vessel are causes. A hematocele may be distinguished from a hydrocele by the absence of transparency, the obscure character of the fluctuation, the heavy feeling of the tumor when balanced in the hand, and the sudden mode of its occurrence. An effusion of blood into an encysted hydrocele of the testicle causes an encysted hematocele of the testicle, while extravasation of blood into the substance of the testicle causes what is known as parenchymatous hematocele. See HYDROCELE, TESTICLE (Tumors).

Treatment.—If the patient is seen early, an attempt must be made to limit the extravasation by means of cold, rest, and pressure. Afterward, when there is no fear of further hemorrhage, the size of the swelling should be reduced by tapping, and strapping applied, in the hope of causing absorption of the more solid portion. If this fails, or if the patient is not seen until the disease has already lasted some time, an exploratory incision should be carefully made into the front of the swelling (the position of the vas deferens will usually give a clue to the relation the sac bears to the testis), the contents turned out, and all the fibrin dissected off. As this operation is a very tedious one, likely to be followed by extensive sloughing (the vitality of the sac and of the layers that line it is very low), and as it exposes the testis to considerable danger, the question arises, as in the case of old hydroceles, whether castration is not better for the patient.

HEMATOCOLPOS.—See HEMATOMETRA.

HEMATOMA.—A collection of extravasated blood that has undergone certain changes, and is observed more especially in connection with the ear, the vagina, the scalp, and the meninges. A hematoma acts as an irritant, and arouses inflammation around it until it is encapsulated by embryonic tissue. This tissue, by organizing into fibrous tissue, forms a blood cyst, and gradually absorbs the fluid blood, while the contents of the cyst thicken until a mere fibrous scar remains. When not absorbed, hematoidin forms, and the fluid becomes clear. Suppuration may ensue, an abscess forming.

The means used to combat an acute inflammation may be employed early in the treatment of a hematoma. Rest, elevation and compression, cold, lead-water and laudanum, and tincture of iodin are advisable. When the injury is very severe, heat and stimulation may be used. Massage and ichthyol are serviceable when the swelling is subsiding.

Hematoma auris occurs mostly in the insane, and consists of an effusion of blood or bloody serum between the cartilage and the perichondrium. Protection from injury is usually sufficient, and opening should not be allowed. Aspiration rapidly empties the cavity, but it speedily fills again. The treatment by pressure is very painful and yields no good results.

Pelvic hematoma is an effusion of blood into the cellular tissue of the pelvis. It is rare except as a result of direct violence, or in hemophilia, purpura, or scurvy. The treatment requires the maintenance of the recumbent posture, the relief of pain, and prevention of inflammation by an evaporating lotion: *e. g.*, solution of lead subacetate, 1/2 of an ounce; rectified spirit of wine, 1/2 of an ounce; and rosewater enough to make a pint. Absorption will usually take place under this treatment. Should

labor ensue, it may be necessary to incise the tumor, or it may burst. In either event the cavity should be emptied, washed out with an antiseptic solution (corrosive sublimate, 1:2000), and drainage established. Daily antiseptic washings with an unirritating antiseptic, such as boric acid in saturated solution, should be practised. The recumbent position should be maintained until near complete filling of the cavity.

HEMATOMETRA.—Distention of the uterus with menstrual blood. If the retained fluid is largely mucous or watery in character, the condition is known as **hydrometra**; if suppuration has occurred, it is **pyometra.**

The cause of these conditions is some obstruction to the cervical or vaginal canals. This may be a congenital atresia or it may be acquired as the result of operation or inflammation.

Symptoms.—In case of congenital atresia the symptoms do not develop until after puberty. At this time all the phenomena of menstruation appear except the discharge of blood. There may be excessive pain and a feeling of distention in the pelvis. Examination will reveal the obstruction, and also an enlarged, probably cystic, uterus.

If the obstruction is situated low down in the vaginal canal, the upper part of the vagina will be distended with blood. This condition is known as hematocolpos.

Treatment consists in relieving the obstruction by incision or puncture and in maintaining a patulous condition of the vaginal and cervical canals.

HEMATOXYLON (Logwood).—The heart-wood of *Hæmatoxylon campechianum*, a tree of tropical America. It occurs in chips or powder of a dark, brown-red color, often with a greenish luster, and colors the saliva a dark pink when chewed. It contains tannic acid and a sweet, crystalline coloring principle, which is colorless when pure, but turns red on exposure to light.

The dose of the hematoxylon extract is 5 to 20 grains.

Being devoid of irritating qualities, it is well adapted for use in diarrheas and hemorrhages in young children. It is mildly astringent, its properties depending on the tannin. It does not produce constipation nor disorder the bowels, but colors the stools and the urine blood-red. It has been used as a hemostatic in bleeding of the lungs and in hemorrhages from the uterus and intestines, and as an astringent in leukorrhea.

In chronic diarrhea:

℞. Extract of hematoxylon, ʒ ss
Tincture of opium, ♏ v
Water, ʒ ij.
Two teaspoonfuls 3 times daily.

℞. Extract of hematoxylon, gr. x
Chalk-mixture, } each, ʒ vj.
Cinnamon water, }
Take as a drink two or three times daily.

HEMATURIA.—In the strict sense of the term, hematuria should not include hemorrhage from the walls of the urinary passages, following or preceding micturition; but, for the sake of convenience, they are always considered together, and the blood may come either from the kidney, bladder, or urethra.

The color depends partly upon the amount, partly upon the time it has been mixed with the urine. If the hemorrhage is recent and profuse, as in a villous tumor of the bladder or in rupture of the kidney, the color is simply that of unaltered blood; when it is poured out slowly in the tubules or allowed to collect in the bladder, it gradually becomes more dusky, until the tint is a characteristic smoky brown.

Tests.—The presence of blood in the urine may be recognized:

By the color, red or smoky, carbolic acid gives urine a brownish hue, and certain drugs (such as senna and rhubarb) and articles of diet (beet-root, sorrel, etc.) in quantity turn it red, but they can easily be distinguished. In hemoglobinuria the color is, of course, the same as in hematuria.

By the Spectroscope.—There is a broad, dark band between D and E, which, on dilution, gradually separates into two. Sometimes there is a band between C and D, near the former (acid hematin), or midway between the two (methemoglobin).

By the Microscope.—Blood-corpuscles retain their appearance for some time in acid urine; when it is alkaline, the coloring-matter soon dissolves out. In hemoglobinuria they are absent. Hemin crystals may be obtained in the ordinary way.

By Chemic Reaction.—A dram of tincture of guaiacum is placed in a test-tube, a drop of the urine added, and then some ethereal solution of peroxid of hydrogen floated upon the top. A blue ring develops at the junction if blood is present, but the same effect is produced by many other substances.

The source may be conjectured from the color, reaction, the presence of clots or of casts, the uniformity of the mixture, and the presence of other symptoms, such as renal colic, suprapubic pain, etc. See URINE (Examination).

Renal Hematuria.—The urine may be bright red, but usually it is smoky, and it is always uniformly diffused. The reaction is acid, unless the quantity is very large or there is a profuse secretion of pus; tube-casts may be present and they are of themselves distinctive; a long, worm-like coagulum may come down from the ureter, and the attack may be accompanied by severe pain in the loins, renal colic, or retraction of the testicle. Blood-corpuscles often cannot be detected.

Vesical Hematuria.—The color is usually bright red, unless the urine has been retained some time in the bladder, and the mixture is rarely uniform; the last drops, as a rule, contain most blood, whether the hemorrhage is still going on or whether it has ceased and the sediment has gravitated to the bottom. The reaction may be acid or alkaline; irregular, shapeless clots may be present (they are best seen floated out in water), but too much reliance must not be placed upon this, for the blood may have poured down from the kidney and coagulate in the bladder.

Urethral hemorrhage is always bright red, the blood either preceding or following urination.

Causes.—Hematuria is due either to a morbid condition of the blood (purpura, scurvy, etc.) or to local affections, and these may be occasioned by injury, inflammation, or new growths.

Renal hematuria may be caused by blows upon the loins and renal calculus; all forms of nephritis (even granular kidney) and hyperemia, whether active or passive; carcinoma, sarcoma, and tubercle.

Vesical hematuria may follow wounds—*e. g.*, rupture of the bladder—and contusions caused by calculi, catheters, etc.; cystitis in all its forms and ulceration of the mucous membrane; carcinoma, villous tumors, and tubercle.

Urethral hemorrhage may be due to injury, such as impacted calculus or the passage of a catheter, inflammation, as in gonorrhea; or new growths; such as tubercle.

Treatment.—Perfect rest and opium (unless there is nephritis or renal congestion) are most important. Cold may be applied by Leiter's coils to the loins, the suprapubic region, or the penis and perineum, according to the seat of hemorrhage. Vesical hematuria may be checked by washing out the bladder with water of the temperature of 120° F., or, if the points can be seen, by touching them with a styptic. In urethral bleeding a catheter may be passed and the penis gently compressed around it with a bandage; or, if the hemorrhage is in the region of the bulb, Otis' crutch may be employed. Tincture of hamamelis is said to check vesical hemorrhage when injected into the bladder. Infusion of matico has been used in the same way. Gallic and sulphuric acids, acetate of lead, and ergot may be given internally; but if the hemorrhage comes from a vessel of large size, they are of little service. Coagula occasionally give rise to severe pain, and, if the urine is septic and the bladder atonic, may require speedy removal, for fear of decomposition and septic absorption. This may be done most easily by means of a soft catheter and a lithotrity evacuator, the clots gradually being broken up and sucked away.

HEMERALOPIA (Night-blindness).—It may be a disease of itself, due to overstimulation or to lack of proper nourishment, or it may be a symptom of retinitis pigmentosa or similar degenerative disease of the retina, alone or with disease of the choroid. It is sometimes noticed among people the subject of extreme denutrition from climatic and social influences, such as the lower classes of the Russians; the disease is common in some parts of Russia after the religious fasts during Lent.

Treatment consists in rest from bright light by protective glasses, and in improvement of the general health and the administration of tonics, cod-liver oil, etc.

HEMIANOPSIA.—A term used to indicate obliteration of half the visual field in both eyes. It may be complete, but is usually incomplete. There is generally a bending out of the hemianopsic line at the point of fixation, indicating that the fovea is supplied by fibers from both optic tracts, whereas the remainder of the retina is supplied by the tract on either side: that is, the right optic tract supplies the right half of each retina, and the left supplies the left half.

Varieties.—When the obliterated half is on the same side in both eyes, it is called **homonymous hemianopsia.** Such a condition is indicative of disease or pressure behind the chiasm, before the fibers have crossed. In left-sided hemianopsia there is some lesion of the right optic tract or of its connection with the cerebral cortex, and the reverse of this in right-sided hemianopsia. In **heteronymous** or **crossed hemianopsia**—that is, in both temporal or both nasal halves—there is probably a lesion at some part of the chiasm which includes the decussating fibers of both tracts. **Vertical hemianopsia** is due to lesion in front of the decussation.

In homonymous hemianopsia we have additional aid in locating a tumor or lesion by the pupillary reflex to light. The pupillary centers are near the corpora quadrigemina; if we carefully direct rays of light upon the blind side of a retina in a case of homonymous hemianopsia, and yet get pupillary reaction, we know that the pupillary centers and all the region in front in the path of pupillary reaction are intact; hence the lesion is posterior to the corpora quadrigemina; conversely, if pupillary reaction is destroyed, we have reason to believe that the lesion is between the corpora quadrigemina and the chiasm. This test is known as **Wernicke's sign.**

Causes.—Hemianopsia is usually due to hemorrhage, embolus, traumatism, or tumor.

The clinical significance of hemianopsia depends on the amount and form of the obliterated field and on the associate symptoms, such as hemiplegia, hemianesthesia, aphasia, etc.

Transient hemianopsia is a sign of some cortical disturbance and is probably the result of spasm of the superficial cerebral arteries. It is often associated with unilateral headache, vertigo, aphasia, amnesia, and other symptoms referable to a cerebral origin. In a number of the patients there is a family history of epileptiform seizures. See FIELD OF VISION.

HEMIC MURMURS.—See HEART-DISEASE (Organic).

HEMICRANIA.—See MIGRAINE.

HEMIPLEGIA.—Paralysis of one side of the body, due usually to a lesion of some part of the corpus striatum and internal capsule, of the crus cerebri, or of the cortex or subcortex of the opposite side of the brain. Alternate or crossed hemiplegia is the name given to paralysis of the facial muscles upon one side, with paralysis of the trunk and extremities upon the opposite side of the body. Spastic hemiplegia is a form occurring in infants, in which the affected extremities are subject to convulsive twitching. Spinal hemiplegia is due to disease of the spinal cord, and consists of paralysis of one side or of the whole body, with loss of sensation of the opposite side. See BRAIN (Hemorrhage), PARALYSIS.

HEMLOCK.—See CONIUM.

HEMOGALLOL.—This is hemoglobin deoxidized by pyrogallol. It occurs as a reddish-brown powder, insoluble in water and in alcohol. It is

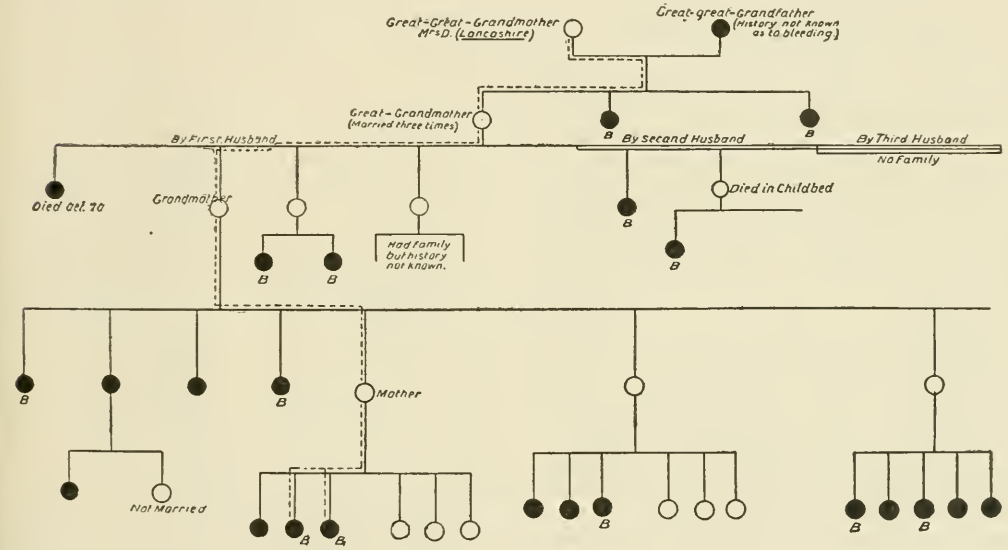
claimed to be the nearest to blood iron of any of the organic iron preparations, and to be readily assimilated without disagreeable effects of any kind. Dose, 4 to 8 grains thrice daily, half hour before meals.

HEMOGLOBIN (Hematoglobin; Hemocrystallin).—A doubly refractive, pleochromatic colloid or crystalline matter, existing in the corpuscles of the blood, and to which their red color is due. In man the amount is 13.77 percent; in woman, 12.59 percent, reduced by pregnancy to from 9 to 12 percent. It is an oxygen carrier or respiratory pigment. The crystals of hemoglobin have a dark-red appearance, with a strong purple or bluish tint; they are very soluble in water. It is the most important pigment in the body, forming 90 percent of the red blood-corpuscles when dried, and from which it may be extracted by water, ether, chloroform, or the bile salts. It is of an extremely complex nature, and is regarded as a compound of a proteid substance, globin, and of a colored body, hematin, which contains all the iron of the molecule. Its most important property is its affinity for oxygen. In some manner this gas forms a loose combination with hemoglobin in the lungs, forming oxyhemoglobin, and is then conveyed by the red corpuscles throughout the body, separating again from its conveyer in the tissues. Hemoglobin deprived of its oxygen is called reduced hemoglobin, and is of purplish color, while the oxyhemoglobin is scarlet. It is thus that the difference between the arterial and venous blood is mainly to be accounted for. The spectra of these two kinds of blood are different. Methemoglobin is another compound of hemoglobin with oxygen, in which the gas is much more closely combined. A still more stable association takes place between hemoglobin and carbonic oxid, which thus produces its rapidly fatal effect by preventing the oxygen-carrying power of the blood.

Certain variations of hemoglobin are recognized in disease: as, for instance, in anemia it is reduced often as much as one-half. See Blood (Examination).

HEMOGLOBINURIA.—A condition of the blood in which the hemoglobin is set free and is secreted in the urine. The etiology is as follows: (1) Specific infectious fevers, such as yellow fever, scarlet fever, diphtheria, malaria; (2) scurvy and purpura; (3) transfusion; (4) certain drugs or chemicals, as chlorate of potassium, sulphuretted hydrogen, carbon monoxid, carbolic acid; (5) certain stages of septicemia; (6) it may follow severe burns; (7) it may be paroxysmal without obvious cause (possibly related to cold and associated with Raynaud's disease).

To make a diagnosis, add a drop of acetic acid to a suspected specimen and boil; a red coagulum indicates hemoglobin. The prognosis depends upon the cause. Recovery usually occurs. Treatment is determined by the nature of the cause which occasions it. See Hematuria; Malarial Fever (Hemoglobinuria); Blood (Examination).



Genealogical Tree of a Hemophilic Family.

○ = Females. ● = Males (not bleeders). ●*B* = Males (bleeders). The dotted line shows the transmission of the disease to patients through four generations.—(*From Thomson and Miles' Surgery.*)

HEMOPHILIA.—The hemorrhagic diathesis; an abnormal tendency to hemorrhage, or ease of bleeding. It usually first appears at about the period of the second dentition. Heredity plays a prominent part in this affection, the disease being transmitted by females, though males are by far the most frequent sufferers.

The bleeding occurs spontaneously or after traumatism, and there are often obstinate swell-

ings of the joints. Men are far more liable than women, and fathers do not seem to transmit the disease to their sons. There is nothing about subjects of hemophilia to distinguish them, when not bleeding, from ordinary persons. The bleeding is nearly always capillary, and may prove fatal in a few hours or after some weeks. An anemic state, which may exist for months, follows the bleeding. Besides superficial bleedings, interstitial hemorrhages, ecchymoses, and blood tumors may be observed. The joints affected are the larger ones, commonly the knee, and most frequently after some injury. The joint becomes swollen and painful, and apparently filled with fluid.

The diagnosis is often easy. If from early infancy a child has suffered repeated bleedings, especially from traumatism and from joint affections, the diagnosis is plain.

The prognosis is not so serious as regards life as was formerly believed.

The treatment of hemophilia includes almost the whole subject of the treatment of hemorrhage. Ligation of arteries is contraindicated, since the hemorrhage is capillary. Ergot, for the same reason, proves of little service. Treatment should be directed to bringing about an increase in coagulation and in the firmness of the clot. Transfusion of a normal salt solution may be necessary. Lime salts may prove useful, and the administration of aromatic substances, such as camphor and turpentine, is advised. Pilocarpin is said to increase the number of circulating white corpuscles. Nuclein, alone or with tissue-fibrinogen, increases the number of white corpuscles in the blood. It is available in the form of yeast, sweetbreads, lamb's fry, and kidneys. It is questionable whether these cell substances do not lose their efficacy by boiling.

Calcium chlorid (15 grains) every few hours, and continued for 3 days, is supposed to favor clot-formation, but it is to be remembered that after the loss of large quantities of blood the coagulability is normally increased. Tablets of bone-marrow have been reported as beneficial.

When bleeding has occurred, very firm pressure and styptics may be tried. Absolute rest in bed is essential, and iron, lead, turpentine, ergot, alum, tannic acid, creosote, and digitalis may be tried. Hemorrhage from a tooth-socket may be checked by cotton-wool soaked in the strongest solution of the perchlorid of iron available, and a pad of wool may be placed over the depression and the jaws firmly bandaged. Epistaxis may be treated by plugging the nares. The actual or galvanocautery may be tried.

Vaccination, tooth extraction, and other minor operations should be performed with caution, and puncture should be as superficial as possible. The patient should be urged to inform the physician of the diathesis in future consultations.

For the joint affections, absolute rest and cold applications, followed by dry heat, are indicated. Splints may be necessary to insure thorough immobility. See HEMORRHAGE.

HEMOPTYSIS.—Blood-spitting. It is usually applied to expectoration of blood from lungs or from air-passages below the epiglottis.

Etiology.—(1) It may occur without obvious cause; (2) traumatism; (3) phthisis; (4) pneumonia; (5) pleurisy; (6) rupture of an aneurysm; (7) venous stasis, as in heart- or liver-disease; (8) purpura; (9) malignant fevers; (10) vicarious menstruation.

Symptoms and Clinical Course.—The onset is usually sudden, accompanied by a sense of heaviness in the chest; subsequently by a warm, saltish taste, frequently occurring just after the act of coughing. The blood is bright red in color if in large amount, but if the quantity is small, it is intimately mixed with frothy mucus and has an alkaline reaction. It may be swallowed and subsequently vomited; an acid reaction then occurs. If the hemorrhage is great, phthisis or rupture of an aneurysm may be suspected. In most cases of hemoptysis the face is pale, the pulse rapid and feeble, and the patient is bathed in a cold perspiration. The paroxysms may occur at intervals of several days, gradually becoming less in amount, or they may be profuse, causing sudden death. In phthisis intercurrent hemorrhages are common. Auscultation of the chest detects mucous râles during inspiration or expiration.

Diagnosis.—It must be distinguished from hemorrhage from the alimentary tract or nasal chambers:

Hemoptysis.	Hematemesis.
1. History of disease of lung, heart, or liver.	1. History of disease of abdominal organs.
2. Hemorrhage preceded by saltish taste in mouth and tickling of esophagus. Blood is ejected by coughing; collapse is great.	2. Hematemesis preceded by sense of heaviness in stomach or by nausea. Blood is ejected by vomiting; collapse not so frequent.
3. Blood is bright red and not coagulated.	3. Blood is dark or blackish, often containing clots.
4. Blood mixed with frothy mucus.	4. Blood mixed with food.
5. Blood alkaline in reaction.	5. Blood acid in reaction.
6. Blood gradually disappears from sputum.	6. Blood may all be discharged at one paroxysm.
7. Blood usually absent from stools.	7. Stools may be black from contained blood.
8. Mucous râles over lungs.	8. Auscultation negative.

The prognosis depends upon the cause. If the hemorrhage is due to rupture of an aneurysm, death usually occurs suddenly. If due to phthisis, the symptom is not necessarily fatal.

Treatment requires absolute rest in bed, guarding against everything which might cause excitement. The head and thorax should be elevated slightly, and to the external surface of the chest ice-bags may be applied. Most patients suffer from a fear of impending death, and morphin (1/4

of a grain) should be given at once. Hypodermic injections of ergotol (10 to 15 minims) may also be given every 3 hours until 3 or 4 doses have been administered. The fluidextract of ergot (20 minims) is also recommended, but is likely to cause severe irritation at the point of insertion of the needle. Gallic acid (20 grains) is also used to check hemorrhage, though not so reliable as ergotol. It may be given every half hour until 4 or 5 doses are used. Alcohol and other stimulants are distinctly contraindicated. Allowing small pellets of ice to be dissolved in the mouth may be of distinct advantage. The hemorrhage is slightly controlled by tying a ligature firmly around each lower extremity, to impede the flow of blood to the lungs. Transfusion or intravenous infusion are last resorts.

HEMORRHAGE.—Hemorrhage is arterial, venous, or capillary.

Arterial hemorrhage is known by its bright crimson or vermilion tint, and by its issuing from the divided vessels in jets, synchronously with the contraction of the left ventricle.

In **venous hemorrhage** the blood is of a dark blue tint, and flows from the divided vessel in a continuous stream.

In **capillary hemorrhage** the blood is of a reddish tint, and exudes from the tissues: in other words, there is a welling up.

Subcutaneous hemorrhage, also called diffused aneurysm, exists when there is no external flow of blood, either from want of parallelism of the wound in the vessel and the open wound in the tissue, or from the rupture of a vessel by a blow, or otherwise, subcutaneously.

Effects of Hemorrhage.—When large vessels or a large number of small ones are divided, death may take place at once. Usually the patient is seized with syncope, after the wound has been bleeding for some time, when the heart's action becomes more depressed, and, the blood becoming more coagulated, nature is given an opportunity to form a clot within and around the artery. After a time reaction takes place, when there is danger or a recurrence of the bleeding, followed by death.

Treatment of Primary Hemorrhage.—Put the finger over each divided extremity of the vessel or apply a provisional tourniquet; place the patient in the recumbent posture, with the head lower than the body. Compress both axillary and both femoral arteries, to divert the flow of blood to the brain. Apply external heat, by means of bottles of hot water, warm blankets, etc.

Stimulate the heart's action by a hypodermic of morphin, 1/4 gr., atropin, 1/100 gr., or of digitalis or ether. As soon as reaction takes place, resort to means to effect a permanent arrest of hemorrhage.

The reaction which follows upon a copious loss of blood is generally attended by the following symptoms: The pulse frequent, soft, and jerky; the heart fluttering and tremulous; the eyes suffused; the skin hot and dry; the countenance flushed; headache, nausea, and possibly vomiting, accompanied by wandering of the mind. The proper treatment of this condition is rest, exclusion of light, and every 4 hours 1/6 gr. of morphin; neutral mixture, (mixture of citrate of potassium, U. S. P. 1880) 1/2 of an ounce. Ice-bags should be applied to the head; the surface sponged with an evaporating lotion. Beef-extract, koumiss, and brandy and milk in small quantities should be given and at regular intervals.

When there is collapse from the loss of blood, a saline injection (1 dram of common salt to 1 pint of water) introduced under the skin in the region of the outside of the thigh or the buttock, by means of an aspirator, has frequently saved life. See TRANSFUSION, INFUSION.

When the hemorrhage takes place in a cavity, in consequence of bleeding from one of the abdominal viscera or from the lungs, the patient should be given, every 4 hours, either 3 grains of gallic acid or 2 grains of acetate of lead, with 1 grain each of powdered digitalis and ergotin, together with 1/2 of a grain of opium. These remedies sustain the action of the heart, produce contraction of the blood-vessels, and render the blood more plastic; hence they are of great utility when the blood-vessels cannot be reached. See ABDOMEN, LIVER, KIDNEY, etc.

Consecutive or recurrent hemorrhage comes on in about 24 hours after an operation; it is generally due to a faulty application of the ligature; including a nerve in the ligature, to the application of Esmarch's bandage, or to reaction that takes place after a shock. The proper treatment is to elevate the stump and compress the main artery; if hemorrhage continues, the wound should be opened, evacuated, washed with warm bichlorid solution, and the bleeding vessels tied. If there is much oozing, the part should be elevated and broad compresses applied. Sponging with warm water and exposure to air for some time is advisable.

Secondary hemorrhage comes on 24 hours from the time of the operation, but more generally about the time of the separation of the ligature. The mode of procedure is to remove the dressings; if there is merely oozing, proceed as directed in Consecutive Hemorrhage; but if the dressings are saturated with blood, the parts swollen and painful, and there are other evidences of profuse loss of blood, reopen the wound, turn out the clots, search for the bleeding vessels, and ligate them. Secondary hemorrhage may take place at the time of the separation of the ligature, and it generally comes from the distal end of the artery. This should be frustrated by compression; but if the hemorrhage continues or recurs, it is proper to cut down upon the artery and ligate it. Secondary hemorrhage may occur from *sloughing* or *ulceration* of an artery, or from imperfect closure of an artery when a ligature separates, either through a diseased state of the artery or of the constitution. In this case it is necessary to cut down upon and secure the bleeding orifice; if this cannot be done, carefully graduated pressure and styptics may be tried. A small button of lint, saturated with perchlorid of iron, may be put into the bleeding point, over which large compresses are placed and firm pressure applied. The bleeding surface may be touched with a hot iron (not

white heat), which will sometimes be more efficacious than any other styptic. Should these measures fail, the artery must be tied above the point of hemorrhage, and, finally, amputation may be necessary. See HEMOSTATICS.

When there is bleeding from arteries, the following rules are to be observed:

Should there be bleeding from an open wound, cut down, and tie the artery at the site of the wound, no matter what its condition; if the artery is brittle, resort to acupressure. If an artery has been wounded, and there is no bleeding when the surgeon first sees the case, is should be let alone, because hemorrhage may not recur; but a provisional tourniquet should be placed over the situation of the main trunk, so that it may be tightened should the slightest appearance of blood make it necessary. The exceptions to this rule are when a patient is to be transported some distance, when he is a hard-drinking man, when the vessel lies directly in the wound, so that it can be seen; in these cases the wounded artery should be secured at once.

If the artery is partially or wholly divided, cast a ligature around each end. In applying a ligature, if a branch is given off near the wounded artery, include it in the grasp of the ligature or secure it separately. If the branch of a main artery is wounded near the trunk, treat it as though it were a wound of the main trunk. On cutting down on a divided artery, if the distal end is so far retracted that it cannot be found, tie the cardiac end and place plugs of iodoform gauze in the wounded or distal side, keeping it in place by successive layers of gauze and a bandage from the distal extremity of the limb to the site of the wound. See ARTERIES (Ligation), ARTERIES (Suture).

For **orificial hemorrhages**, see HEMOPTYSIS, HEMATEMESIS, HEMATURIA, EPISTAXIS, POSTPARTUM HEMORRHAGE, VAGINA.

HEMORRHAGE, POSTPARTUM.—See POSTPARTUM HEMORRHAGE.

HEMORRHOIDS (Piles).—An enlarged and varicose condition of the vessels in the tissues around the anus, sometimes associated with eversion of the rectal mucous membrane.

To treat hemorrhoids successfully, the physician must understand:

1. That all things complained of about the rectum are not hemorrhoids.

2. That all hemorrhoids are not alike, either in pathology, etiology, or symptoms, and therefore cannot be prescribed for or treated in the same way.

3. That a "pile remedy" is no remedy at all, in that every case of this kind is an individual one.

4. That some cases of hemorrhoids may be relieved, perhaps, by palliative measures, but that a pronounced case of piles can be remedied and cured much better and quicker by a surgical operation than by palliative means.

External Hemorrhoids.

External hemorrhoids are divided into two classes: (1) *cutaneous* and (2) *thrombotic.*

Cutaneous Hemorrhoids.—This variety is simply a tag of skin in a state of inflammation, or there may be a proliferation of skin evenly extending around the outside of the anus. This condition, of course, favors an inflammatory attack. Even so simple a cause as friction of wearing apparel may induce it.

Causes.—Constipation, by inducing hardened stools felt at the anal orifice, may cause this form of piles; or the use of heavy, common, printed paper as a detergent may have the same effect. An attack of diarrhea or dysentery, a foul discharge from either the rectum or vagina, scratching with the finger-nails—indeed, any irritation—may, of course, influence these external tags, thereby causing them to enlarge, constituting an external hemorrhoid of the first variety.

Thrombotic Hemorrhoids.—This class is caused by the presence of a blood-clot, caused by the breaking of the vein-wall, which allows the blood to escape and coagulate in the tissues, or by blood coagulating in the vein itself. The location of the thrombotic pile is just at the verge of the anus, and is covered by both mucous membrane and true skin. No attempt should be made to "push them back," as is so often done. The thrombotic pile is less irritable than the cutaneous variety.

Causes.—Any force or exertion which would cause the vein-wall to give way may be a cause. Hence, straining at stool is perhaps the most frequent cause. Men suffering from enlarged prostate or from a stricture in the urethra are very liable to an attack. The heavy uterus of the female—as during pregnancy—a case of cystitis, stone in the bladder, an attack of gonorrhea, or a fissure of the anus may induce the condition.

The symptoms of both cutaneous and thrombotic piles are very much the same: viz., a heavy weight at the lower part of the rectum; an aching pain over the sacrum and down the thighs. These are increased by walking or by the act of defecation; the pain may be very acute or of a dull and heavy nature. An examination will reveal the nature of the trouble.

Treatment of External Hemorrhoids.—It depends upon circumstances whether the treatment should be *palliative* or *operative* from the onset. If the patient is able, at the time the physician is consulted, to attend to his business, it is, of course, best to palliate what distress he has. Fortunately, the majority of attacks of external piles do not compel the patient to go to bed. If, however, the external piles are very large, operation saves time and prevents return. Sometimes, however, circumstances will not permit of an operation.

Palliative treatment is simply that of a local inflammation. Heat or cold, whichever is borne best, should be used. Moist heat is to be preferred to dry. Hot applications can, therefore, be applied by using hot cloths or surgeons' cotton dipped in very hot water and held frequently to the parts. Poultices may also be used to advantage. A sitz-bath is advisable, especially if the action of the bladder is interfered with. The hot-water bag placed against the parts affords much relief.

If cold water is preferred, it can be applied by means of cloths or cotton, or finely cracked ice in rubber or cloth, laid up against the parts. Next

to heat and cold, ointments are to be considered. The following may be beneficial: equal parts of ointment of belladonna and ointment of galls; or the former 1 part, the latter 2 parts and stramonium ointment 1 part. Relief may be obtained by painting the part with liquor ferri subsulphatis (Monsel's solution). Applications of collodion dropped on a bit of cotton wool are recommended. The best local astringent is adrenalin. Warmed suppositories of hamamelis, or of lead and opium may be used.

In the thrombotic hemorrhoid, when some surface of the mucous membrane is exposed, the following will be found serviceable:

℞.	Cocain hydrochlorid,	gr. xij
	White vaselin,	ʒ j.

Apply frequently.

If there is much itching of the parts, the following:

℞.	Menthol,	gr. xij
	Lanolin,	ʒ j.

A favorite formula is:

℞.	Calomel,	gr. xl
	Chloral hydrate,	gr. xxx
	Vaselin,	ʒ j.

The bowels should be kept freely open with an aperient water. See Constipation. Absolute rest, if possible, should be enjoined.

Operative Treatment.—The operative treatment for external hemorrhoids is very simple. *All external piles should be cut off.* Held taut with a tenaculum, each tag should be cut off near its base with a sharp pair of serrated scissors. Any bleeding can be stopped either by torsion, hot water, or the compress. The parts should then be dusted with iodoform, a compress of cotton and a bandage applied, and left on for two days. When it is removed, the parts should be thoroughly cleansed with carbolized hot water, and redressed in the same manner. This should be done each succeeding day until the parts have healed. The thrombotic pile should either be slit open with a sharp bistoury and the clot released, or, what is better, it should be clipped off in its entirety, and dressed in the same manner as in the cutaneous variety.

The question of giving an anesthetic is to be left with the patient and the operator. The subcutaneous injection of cocain around the anus is not advisable.

Internal Hemorrhoids

Internal hemorrhoids are much more serious in their nature and complications than the external variety. Life is frequently endangered. Cases could be cited in which from 1/2 to 1 gallon of blood was lost at one sitting from an internal pile, and that, too, when no operation had been performed.

The hemorrhoid may be as large as a child's fist. By the erect posture alone or by the least exertion this mass may protrude. By friction—coming out and being often pushed in—ulceration is excited, and actual pain is added to the discomfiture of protrusion. The first danger, then, in internal piles is from hemorrhage; the second, inconvenience from protrusion; the third, actual pain.

Varieties.—(1) arterial, (2) venous, (3) capillary. The small capillary pile may bleed so as to endanger life; the large pile never does. The large internal pile protrudes; the capillary pile does not. The small capillary pile can be cured without surgery; the large pile cannot.

Diagnosis.—Such a condition is usually confused with *polypus* and *prolapse* of the bowel. A polypus has a stem or pedicle, which can be traced to its attachment by the finger. A prolapse of the bowel is differentiated from protruding hemorrhoids by its velvety appearance, its soft, bladder-like feeling, and its uniformity in circumference. Protruding piles have no pedicles; they are distinctly separated and are of a tumor-like appearance.

Causes.—Internal hemorrhoids are veritable tumors, produced by the changes brought about by long-continued irritation and the inflammatory process. They are not simple varicosities of veins. It is very difficult, indeed, to assign a cause of this affection. Every case seems to be an individual one, and must be so treated. The drinking of alcoholic or malt liquors, womb displacements, or diarrhea and dysentery, may be the cause. Sometimes more than one cause is found. There is unquestionably a hereditary predisposition to this affection.

Prophylactic Treatment.—It would be well to warn the patient against them. The young should be taught early the necessity of a daily evacuation of the bowels, cleanliness of the parts, the use of soft material as a detergent, the eating of fruit, and the drinking of much pure water. Cold water should be used freely for drinking purposes, as a wash for the anus after every act of defecation, and occasionally injected into the rectum. The habit of taking copious injections of hot water into the rectum is conducive to the hemorrhoidal state, and should be deprecated.

Palliative Treatment.—If existing conditions prevent an operation, or the patient suffering with inflamed painful protruding piles strenuously opposes an operation, palliative treatment should be tried. No attempt should be made to return the protruding mass into the rectum, for it will be futile. Rest in bed is indicated. The best application is heat: hot fomentations—on sterilized material always—hot poultices, or hot vapor to the parts. The bowels should be cleansed at once by an aperient, and kept open. Sometimes the free application of resinol or vaselin with the heat does good. A good formula is:

℞.	Chloral hydrate,	gr. xl
	Extract of opium,	gr. xxx
	White vaselin,	ʒ j.

Ointments containing tannin irritate and cause great pain, and subserve no good. Rest, the application of heat, sometimes cold, keeping the bowels open, a cooling diet, is the best and only treatment required in a palliative way.

Operative Treatment.—Sometimes after the violent inflammatory action subsides atrophy takes place in the mass, and nearly an absolute cure results. Again, the hemorrhoidal mass may slough off, and a cure is effected. Of course, there is danger here of hemorrhage. But, ordinarily, the piles are left in the same condition as they were before the attack, and the patient is informed that the same causes will superinduce another attack. The patient could have been permanently cured by an operation. There are quite a number of operations proposed for the cure of internal piles. In this country the preference is about equally divided between the use of the clamp and cautery and the ligature. The ligature is commended as the safest and best method.

Ligature.—After having purged the patient the day before the operation, he is to have a warm bath the night before, and no breakfast the day that he is operated on. He is put on the table, under an anesthetic, and the parts involved are shaved if necessary and thoroughly washed with a bichlorid of mercury solution, 1 : 5000. Presuming that the field is aseptic, the patient is put in Sims' position, with the legs well drawn up toward the abdomen. A grooved speculum should now be introduced, and the sphincter thoroughly divided. The hemorrhoidal tumors will prolapse. If they do not do so in their entirety, by placing a four-pronged (Mathew's) forceps upon one of them at its base, the entire mass can be pulled into view. The tumors are now to be ligated. A stout, plaited silk thread is the best ligature. The small tumors are secured and tied without transfixing. While the rectum is distended, it should be irrigated with bichlorid solution 1 : 5000. The large tumors are caught well at their base, drawn slowly down, and the forceps held by an assistant. A curved needle threaded with the ligature is passed immediately through the base of the tumor. The needle is withdrawn, the thread is cut, and the ligature tied firmly, first on one side of the tumor, then on the opposite. The tumor is now excised with a pair of straight scissors. At least two-thirds of the pile should be removed. The stumps should be dusted with iodoform and returned into the rectum. If any superfluous skin-tags should exist around the anus, these must be removed during operation. The best plan is, when the tumor is pulled down, to carry the incision out around its base so as to include all such skin or tag, the ligature to be placed in this and cut and tied as directed. Mr. Allingham directs that the incision be made in "Hilton's white line" and the tag cut off separately. A piece of iodoform gauze should now be laid over the anus, some absorbent cotton over this, and a T-bandage applied somewhat firmly One fourth of a grain of morphin should be given hypodermically, and repeated in one hour if necessary. The bowels should be moved on the morning of the third day by an aperient. The ligatures will separate on the eighth or ninth day. The wound should be dressed every day after the bowels are moved until recovery is complete.

Clamp and Cautery.—A pile have been seized with the forceps, the clamp is applied to its base, the pile shaved off, and the raw surface cauterized.

If **crushing** is employed, the pile is drawn into the crusher, which is then screwed tightly home, the pile cut off, and the crusher removed after a minute or two.

Excision has of late been extensively employed by some surgeons. It consists in dissecting away the piles, tying any arteries that bleed, and bringing down the mucous membrane and securing it by suture to the anal margin.

Injections of Carbolic Acid.—The strength usually employed is 1/2 of a dram of the acid to 1 dram each of glycerin and water, 4 to 5 minims being thrown into the center of the pile by a hypodermic syringe. The process has to be repeated several times, and takes some weeks to effect a cure.

Nitric acid is used as an application for the sessile vascular pile, and should be applied with a glass rod through a speculum, and any excess of acid removed by a weak alkaline lotion.

HEMOSTATICS AND STYPTICS.—Agents that arrest hemorrhage when taken internally are called hemostatics. Agents that arrest hemorrhage when applied locally are called styptics. Some styptics act mechanically by promoting the formation of a clot in the mouths of bleeding vessels; others cause the vessels themselves to contract, checking the flow of blood.

The principal **styptics** are adrenalin, acids, alum, antipyrin, cautery, cold, collodion, cotarnin, hydrastinin, ferric chlorid, ferric sulphate, gelatin, lead acetate, matico, silver nitrate, tannic acid, vegetable astringents, zinc sulphate.

The principal **hemostatics** are adrenalin, cotarnin hydrastinin, ergot, digitalis, gallic acid, lead acetate, dilute sulphuric acid, ipecac, hamamelis, oil of turpentine.

Hot air and steam have been used recently with good result in checking hemorrhage, particularly in surgical operations.

HEMP, INDIAN.—See CANNABIS INDICA.

HEPATITIS.—See LIVER (Cirrhosis).

HEREDITARY ATAXIA (Hereditary Ataxic Paraplegia; Friedreich's Ataxia).—A family disease, not always hereditary, characterized by lesions in the posterior and lateral columns of the cord and symptoms similar to those of tabes dorsalis. The cause is unknown. It usually occurs between the second and twentieth years.

Symptoms.—These are essentially ataxia and paraplegia. Speech is scanning, movements of head and arms are jerky. There are nystagmus, loss of knee-jerks, lateral spinal curvature, deformities of the feet, generally extension of the big toe and talipes equinus or equinovarus.

Diagnosis is not difficult. Its characteristic symptoms distinguish it from **tabes dorsalis** in which there are sharp pains, Argyll-Robertson pupil, anesthesia. In **ataxic paraplegia** there is increased knee-jerk, as well as spasms and foot clonus. It is differentiated from **disseminated sclerosis** by loss of knee-jerk instead of exaggeration, and by absence of intention tremor.

Treatment is of no avail, though the remedies used in tabes dorsalis may be tried. The disease may last for years.

Cerebellar Hereditary Ataxia.—This form develops in the third decade. There are scanning speech, ataxia, heredity, nystagmus, but there is Argyll-Robertson pupil associated with ocular palsies, optic atrophy. Club-foot and scoliosis are lacking.

HEREDITY.—The principle or fact of the transmission of physical or mental qualities or tendencies from ancestor to off-spring.

As a single species preserves its physical characteristics by the principle of natural selection, so also must function follow the law dominated by structure. Under certain conditions of climate, altitude, mode of life, and certain other factors, the physical characteristics may be somewhat modified, yet the principle of heredity cannot be escaped. The mental development depends upon those characteristics possessed by the parents, and environment and education in many instances are insufficient to subdue the influences of heredity. Thus we inherit certain characteristics, as trait, type, disposition, temperament, and predisposition to certain employment, or even disease.

The principle of heredity seems most active when the parents are between the ages of 20 and 30. The principle of heredity is continuous. There are no wide gaps that permit of great differences in types. A healthy man and woman beget healthy offspring, and if there is a reversion, it is the exception and not the rule. As mental characteristics necessarily depend upon this principle, so, too, does the physical man.

It is true that by close confinement, overwork, mental activity, and sedentary habits the growing child becomes susceptible to many diseases. But if its parents are strong and healthy, it should also be strong and healthy. Of the different diseases—or the susceptibility to them—which may be transmitted, there may be mentioned syphilis, tuberculosis, cancer, gout, certain skin-diseases, insanity, various criminal tendencies, nervous diseases, such as epilepsy and hysteria.

HERMAPHRODITISM.—A hermaphrodite is an individual with the coexistence of completely developed ovaries and testicles, or of at least one of each gland. The condition is accompanied by some congenital malformation of the genital organs, such as epispadias, hypospadias, cleft of the scrotum, etc., that makes the determination of sex somewhat doubtful. True functionating human hermaphrodites do not exist. See MONSTROSITIES.

HERNIA.—Hernia may be defined as the protrusion of a viscus or part of a viscus through the walls of the body in such a manner that it is covered by some or all of the constituent parts of the walls. In other words, the escaping organ carries various layers of the parieties before it. The term, however, is usually applied to the protrusion of intestine or omentum, or both, through the abdominal walls. In the following discussion it will be limited to protrusions of the abdominal viscera.

Anatomic Parts.—A hernia is composed of its sac or peritoneal investment, its contents, and structures which cover it.

The sac is a portion of the peritoneum derived from the parietal layer of the abdomen. It is pressed down from the hernial contents, developing into a pouch varying greatly in size and shape. In congenital hernia it is due to faulty obliteration of the vaginal process of peritoneum, which normally closes after the descent of the testicle. In some such cases there is a free communication between peritoneal cavity and the scrotum. In other cases obliteration occurs below but not above, so that there is a channel extending from the abdominal cavity to the site of obliteration. This channel is called the funicular process and a prolapse of intestine into it is known as hernia into the funicular process.

The Contents of the Sac.—When the sac contains a loop of intestine, it has been designated an **enterocele**; when only omentum, an **epiplocele**; when both intestine and omentum, an **enteroepiplocele.**

The portion of the intestine found in the sac is usually a part of the ileum, but the large intestine, the bladder, the uterus and ovaries, and in fact any intraabdominal organ except the pancreas may be found in a hernia. It may vary in amount from only a small part of a single loop to that of several coils, even, in rare instances, the larger part of the small intestine. In old retained hernia the contents undergo many changes, developing fibrous bands, adhesions, etc. Intestinal obstruction may take place because of these secondary changes rather than from constriction at the neck of the sac. In old large hernia the neck of the sac is usually firm and inelastic, owing to its plicated folds having become intimately blended.

The coverings of a hernia consist of the skin, fascia, muscular structures, and the peritoneum. In an old strangulated hernia these are often greatly thinned from pressure, a fact to be borne in mind in making the dissection, in order that the imprisoned intestine may not be injured.

When the hernial contents can be restored to the abdominal cavity, the hernia is called **reducible**; when this cannot be effected, **irreducible**; when the function of the intestine is held in abeyance, **strangulated.**

The predisposing causes have already been, in the main, attributed to the imperfect closure of the internal ring, and to the existence of a depression in the peritoneal surface resulting from it.

The exciting causes are many and various: *e. g.*, muscular weakness of the abdominal wall, violent exertion, etc. That these are only exciting causes is evinced by the fact that gymnasts and contortionists are, as a class, remarkably free from hernia.

Sex.—From the anatomic reasons it is apparent that hernia should be more frequent in males than in females. The ratio, as given by many observers, is about that of 5 to 1.

Age.—During the first year of life congenital and acquired hernias are very common. In many of this class a spontaneous cure results. From the medical statistics of the War of the Rebellion,

it appears that the larger number of cases were found in men over 40 years of age.

Nativity.—From the same source it appears that there is a great difference in races: *e. g.*, over 50,000 of each, German and Irish, were examined, with a result of rejection of 82 in 1000 of the former, and 36 of the latter.

Comparative Frequency.—Of the different forms of hernia the inguinal is by far the most common. The estimate is: Inguinal, 75 percent; femoral, 10 percent; umbilical, 5 percent. Inguinal hernia is most common on the right side.

Symptoms of Hernia.—First, a swelling in the region affected: *e. g.*, the inguinal canal, groin, scrotum, or umbilicus. This tumor is usually painless, varies in size with the position of the body, and generally disappears in the recumbent posture. When the hand is placed over the tumor, upon coughing an impulse is usually felt. When the contents are intestinal, the tumor is elastic, resonant upon percussion, and its return within the abdominal cavity is evinced by a gurgling sound. These conditions are absent when only a portion of the omentum is in the sac.

Treatment.—The treatment of hernia consists of palliative and radical measures. The former method comprises the reduction of the hernial contents and their retention by a properly fitting truss. This should be done at the earliest possible moment, as no individual may be considered safe with dislocated abdominal organs.

Trusses are in great variety, and are often inexpertly fitted, even by physicians of experience.

A truss consists of a steel band adapted to about two-thirds of the body, a pad to compress the hernial opening, and a strap to secure the apparatus in position. The spring should be light and flexible, and is covered with leather or hard rubber. The pad varies in solidity: firm, as wood or hard rubber; elastic, as, *e. g.*, a water-pad. It should be so connected to the spring as to admit of a change of its bearing. A truss should be carefully adjusted in its bearing and of strength only sufficient to retain the parts in position. Undue pressure weakens the abdominal wall, and may injure the cord and testicle. After the truss is applied, to be certain that the hernial passage is secure, the patient may cough, bend forward and backward, stoop down with the limbs widely separated, and, finally, sit down with the limbs crossed.

Inguinal Hernia

This variety of hernia is so common that various authors estimate that from 8 to 15 percent of all males are subject to it. An *indirect* or *oblique* inguinal hernia is one which comes out through the internal abdominal ring; a *direct* inguinal hernia is one which comes out through Hesselbach's triangle, a space bounded externally by the deep epigastric artery, internally by the outer border of the rectus muscle and below by Poupart's ligament. The term *incomplete* hernia is applied to one which remains in the inguinal canal (this is also sometimes known as a *bubonocele*); whereas one which passes through the external abdominal ring is known as a *complete* hernia. In the oft-recurring cases of strangulation, when the integrity of an imprisoned loop of the intestine is endangered, life depends upon the prompt execution of wisely determined means of relief. It is the duty of every physician to become thoroughly familiar with the anatomy of the parts, since, of necessity, emergency may, at any time demand of him surgical intervention.

Normally, the inguinal canal traverses the abdominal wall so obliquely that the intraabdominal pressure holds its walls in even lateral coaptation, and any increase of this force only brings them into more firm compact. The vessels descend from above to join the vas deferens at the site of the internal ring. The ring is formed of connective-tissue fibers of the transversalis fascia, and this fascia is greatly thickened and reinforced, making, usually, a firm, strong, tendinous wall, which enters into and largely makes up the posterior border or boundary of the inguinal canal. This fascia was first carefully described by Sir Astley Cooper, and its importance was recognized for a long period by designating it as the *fascia Cooperi.*

Not seldom muscular fibers of the transversalis may be traced about and below the border of the internal ring, in which condition the internal ring may be considered as an opening through the transversalis muscle.

The formation of the internal ring and the inguinal canal is best made clear by tracing the descent of the testicle from the abdomen to the scrotum.

As the testicle passes through the abdominal wall it carries in front of it a layer from each of the muscular or fascial planes which it perforates. Thus, as it comes out of the abdomen at the spot known as the internal ring, it carries a portion of transversalis fascia along, drawing it down like a cone or funnel. Hence the application of the term infundibuliform fascia to this portion of the transversalis fascia. From the next stratum of the belly wall, the internal oblique muscle, it takes up a covering known as the cremaster, and as it passes through the succeeding layer, the aponeurosis of the external oblique muscle, it pushes a fascial investment called the external spermatic fascia in front of it, which is identical with the intercolumnar fascia.

The spermatic cord occupies and fills up the channel thus made by the testicle in the substance of the abdominal wall. This channel is the inguinal canal. It extends from the internal to the external abdominal ring, and in the adult is about an inch and a half long. It is bounded anteriorly by the aponeurosis of the external oblique muscle and in its outer third by the internal oblique posteriorly by the transversalis fascia, superiorly by the arched fibers of the internal oblique and transversalis muscles, and inferiorly by Poupart's ligament.

The external abdominal ring likewise is not a ring in the true sense of the word. It is a cleft in the aponeurosis of the external oblique muscle, situated just above and external to the spine of the pubes, having its base below and its apex above.

The coverings of an indirect hernia are derived

from the various layers of the abdominal parietes, just as are the coverings of the spermatic cord. From within outward they are peritoneum, preperitoneal fat, infundibuliform fascia, cremaster muscle or fascia, intercolumnar fascia, superficial fascia, and skin.

The coverings of a direct hernia are, from within outward, peritoneum, preperitoneal fat, transversalis fascia, intercolumnar fascia, superficial fascia, and skin. The conjoined tendon is usually enumerated among the coverings of a direct hernia, but recent studies, notably those made by Blake of New York and Bonney of Philadelphia, have shown that the conjoined tendon does not exist as a well developed structure in more than one-fifth or one-fourth of all cases. The tendon, when well developed, is firmly fixed to the crest of the pubis and iliopectinal line and above is continuous with the substance of the internal oblique and transversalis muscles, so it is not at all probable that it could be pushed forward by a hernia.

The abdominal peritoneum is delicately interwoven as an investment membrane over the vessels and the vas deferens at their point of separation. It is interesting to note that in the normally developed adult the peritoneum lies as a smooth covering over the internal ring, and that a dimple is formed in it only by traction from without upon the cord. As the result of many years of observation, it is believed that the so-called infundibular process of the peritoneum, described by anatomists as a normal condition, is due to a primarily defective development, and is essentially pathologic, although the subject himself may have escaped a hernial deformity. This is owing to the fact that the imperfect closure of the inguinal ring after the descent of the testicle is common. It was first pointed out by the celebrated Cloquet, of Paris, who found it so common that he considered it the rule rather than the exception. It must be remembered that as a special student he dissected over 500 hernial subjects. By pulling upon the cord a dimpled depression of the peritoneum should take place. The infundibular process, when at all pronounced, is pathologic and not normal.

When we consider the physiologic process by which the testicle escapes from the abdominal cavity, we wonder that the inguinal canal is not more often imperfectly closed. The most frequent cause of inguinal hernia in the male is undoubtedly the imperfect development of the structures that enter into the formation of the internal ring. Almost without exception this is due to the weakening of the lower border of the ring, which causes the opening to lose its valvular character. In this condition the pathologic infundibular process becomes a depression in the abdominal wall and permits at once of a wedge-like hydrostatic pressure to be brought to bear upon the surrounding parts. This is the reason that the disability of hernia is so common; its importance cannot be overestimated, since means for the permanent cure of hernia must be dependent upon a divergence of the ever-constant intraabdominal pressure from the direction of its axis.

Given a depression of the lower border of the internal ring sufficient to permit the internal abdominal strain to act in the line of its opening, and it is only a question of time multiplied into power to produce an inguinal hernia.

These forces may act for years before the structures ultimately give way, and then the processes go on to make every varying degree of disability, from a slight opening, easily closed by the pressure-pad of a light truss, to the enormous scrotal hernia containing many feet of intestine, with large masses of adherent deformed omentum.

Signs and Diagnosis of Inguinal Hernia.—There is a swelling in the inguinal region having the general characters of hernia already given. When *incomplete* the swelling will be in the groin, and has to be chiefly distinguished from enlarged inguinal glands, a femoral hernia, encysted hydrocele of the cord, testicle in the spermatic canal; abscess in the inguinal canal, and, in rare instances, from fatty and other tumors of the cord. When it is *complete, i. e.*, has passed into the scrotum, the diagnosis has to be made from hydrocele of the tunica vaginalis, hematocele, solid tumors of the testicle, and varicocele. (1) In *enlarged glands*, the canal is free, the glands are felt in front of it, and some cause is present to account for their enlargement. (2) In *femoral hernia* the swelling is external to the spine of the pubes, the neck of the hernia is below Poupart's ligament, the inguinal canal is free, but the hernia can be felt through its front wall, and to return it pressure must be made in a direction downward, backward, and then upward. In inguinal hernia, on the contrary, the swelling is internal to, or covers the spine of the pubes; the neck is above Poupart's ligament; the inguinal canal is occupied by it, and to return it pressure must be made upward and outward. (3) In *encysted hydrocele of the cord* the swelling is translucent, tense, oval, and well-defined, and it cannot be returned into the abdomen. There is no

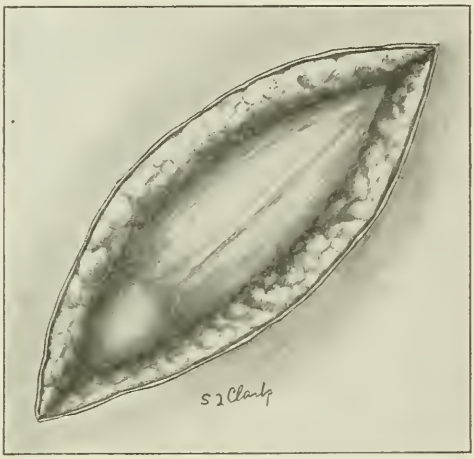
C. Cord. S. Sac. T. Testicle. V. Tunica vaginalis.—(*Stewart.*)

expansile impulse on cough. (4) When the *testicle is retained* in the spermatic canal that organ is absent from the scrotum; there is no impulse on cough; testicular sensation can be obtained by pressure on the swelling; and the swelling cannot



Showing the hernia presenting at the external abdominal ring after the skin and fascia have been divided and the aponeurosis of the external oblique muscle exposed.—(*Bonney and Rodman.*)

be returned into the abdomen. If the testicle is inflamed or the cord is twisted vomiting may be present, but it has not the gushing character of the vomiting of hernia, and constipation, if also present, is not complete. There may, how-

The inguinal canal is about to be opened by an incision made in the groove of a director which has been passed through the external abdominal ring. The structure to be divided is the aponeurosis of the external oblique muscle.—(*Rodman and Bonney.*)

ever, be a strangulated hernia in addition to an inflamed testicle. If in doubt an exploratory incision should be made over the tumor. (5) The swelling in a hernia begins above, in the inguinal canal, and descends into the scrotum. The swelling in a hydrocele begins below, in the tunica vaginalis, and extends upward. The testis

in a complete hernia is forced to the bottom of the scrotum. In hydrocele it is situated posteriorly and at the junction of the lower and middle thirds

Showing Bassini's method of radical cure. The lower margin of the internal oblique muscle, together with some of the transversalis, has been sutured to the shelving margin of Poupart's ligament. The spermatic cord will be placed upon the new floor thus formed.—(*Rodman and Bonney.*)

of the scrotum. A hernia gives a distinct impulse on coughing; a hydrocele gives no impulse. A hernia is opaque to light; a hydrocele is more or less translucent, though in a hydrocele with a

thick sac there may be little or no translucency. A hernia gives no fluctuation; a hydrocele does give fluctuation. The tumor in a hernia descends well into the scrotum and hangs down straight

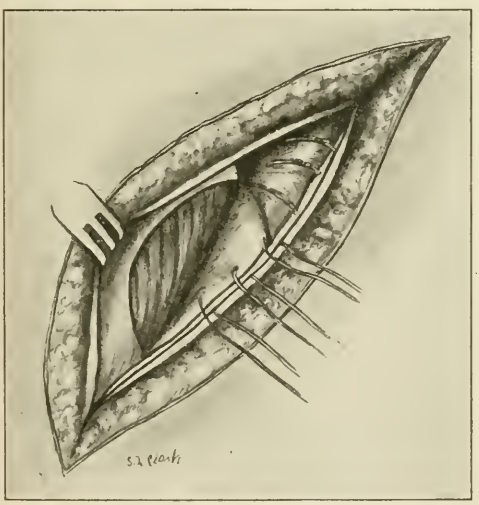
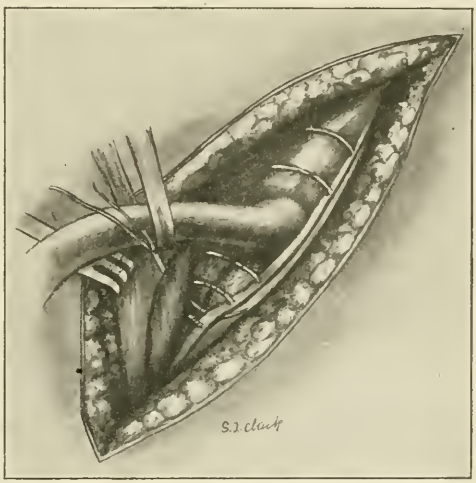
between the legs. A hydrocele is pyriform in shape and stands out more or less from the body. (6) In hematocele there is a history of injury and rapid subsequent formation of a tumor with discoloration of the part. (7) The absence of



Transplantation of the sheath of the rectus muscle.—(*Rodman and Bonney.*)

impulse on coughing together with a history of gonorrhea, tuberculosis, syphilis, or an old injury should prevent one from mistaking an enlarged testicle for a hernia. Acute disease of the testicle or epididymis should never be mistaken for hernia. (8) Hernia is more common on the right side, varicocele on the left. Both disappear when the patient is recumbent unless the hernia be irreducible, in which case there will be no liability of mistaking it for varicocele. Both give a distinct impulse on coughing, but the impulse is different. A more or less solid substance causes the impact against the finger in hernia, whereas varicocele is recognized by the soft purring made by the blood which is forced through the vessels against the finger. Then again, the descent of a hernia can be prevented when the patient is erect by pressing the finger over the internal ring and making pressure. The return of the varicocele, however, cannot thus be prevented.

Of the different procedures for the radical cure of inguinal hernia the one introduced by Bassini, in 1889, has been generally accepted and is believed



Showing a method of transplanting a portion of the rectus muscle as well as its sheath.—(*Bonney.*)

to be founded upon more correct principles and to give better results when correctly performed than any other method.

The principal features of this operation may be summarized as follows: separation of the spermatic cord, or in the female the round ligament, from the hernial sac; high ligation of the sac, which should always be made at least as high as the internal abdominal ring and a little above it when possible; removal of the sac; suture of the lower margin of the internal oblique and transversalis muscles to the shelving margin of Poupart's ligament; transplantation of the cord to the new floor of the inguinal canal thus made; and suture of the aponeurosis of the external oblique muscle over the cord to reform the roof of the canal.

This operation has been variously modified by different surgeons, and perhaps not always with good judgment. Of the useful steps which have been added to it may be mentioned transplantation of the sheath of the rectus muscle and overlapping the aponeurosis of the external oblique

muscle. The latter procedure, though usually thought to be of recent origin, was practised by Lucas-Championnière more than twenty years ago.

There are some surgeons who do not transplant the cord in every case, but we believe it is advisable to do so as a routine measure except in cases in which the hernia is associated with a retained testicle. In such cases the cord is already too short, and if an attempt be made to bring the testicle down into the scrotum, then a lower position can be obtained by suturing the muscles to Poupart's ligament with the cord *in situ*. In cases of this kind in which the hernia is large and the internal ring much dilated, greater assurance against recurrence will be conferred by removing the retained testicle. Some surgeons who transplant the cord in adults do not do it in young boys, believing that equally good results are obtained by omitting this step of the classical operation.

Obstructed Hernia.—By an obstructed hernia is meant one in which the intestinal contents have accumulated to such an extent as to block the fecal current. The term **incarcerated hernia** has also been applied to this condition, but it is an inaccurate one, as it does not convey the idea of the condition which actually exists. It occurs almost always in hernias of the large intestine, which have become irreducible as the result of inflammation. Intestine thus imprisoned loses its peristaltic power more or less, and this functional impairment, together with the mechanical conditions present, permit the occurrence of a gradual fecal obstruction.

Strangulated Hernia.—From a practical point of view the most important change which takes place in hernia is strangulation, by which is meant an occlusion of the lumen of the intestine together with arrest of its blood supply, produced by a constriction, which also renders the hernia irreducible if it was not already so before the said constriction occurred. As a result of strangulation the passage of both feces and gas is stopped and gangrene supervenes in the herniated bowel.

The effects differ, dependent upon the contents and the tightness of the constriction. The tumor usually becomes distended, tense, and tender to the touch. There is abdominal pain, often in the region of the umbilicus; a sense of constriction around the body, and the patient lies with the limbs drawn up in order to relax the abdominal walls. Vomiting early ensues. The pulse becomes feeble and rapid, the tongue dry, the countenance pinched; extreme prostration ensues, and is followed by death.

Diagnosis.—There is generally little difficulty in recognizing a case of strangulated hernia. This may not be true in some forms of partial inguinal hernia, when only a small part of the intestine is caught in the internal ring, and also when the neck of the sac has been returned, with the constricted portion of the intestine unreduced. The case may be considered one of colic, opium may be administered, and the real conditions overlooked until too late to save life.

Operation.—Modern surgical science reverses many of the old rules of practice. In the earlier days, when any opening into the peritoneal cavity was held to be attended with the gravest danger, naturally much emphasis was placed upon the importance of manipulative measures for the reduction of misplaced organs—so-called **taxis.** In the application of the reducing force, elevate the hips so as to reverse the position of the body to a considerable angle, and gently draw the contents of the hernial tumor downward, away from the line of the opening. The reduction is much more easily accomplished in this way than by direct upward pressure. If this fails, an anesthetic should be at once administered, and, if the displaced organs cannot be easily returned, the patient should be operated upon immediately. It is almost superfluous to say that this must be done with the utmost aseptic care.

Incision is freely made over the constricted parts in the direction of the canal, and the dissection carefully made, cutting from above downward until the constriction is reached. This is divided after all the parts have been brought clearly into view. The special probe-pointed knife, of varying curve, which for a century has been used, is now rarely required, since blind surgery is bad surgery, and the subsequent treatment of the parts demands a free open dissection. If the incarcerated intestine can be safely returned, this is done without delay. Oftentimes the judgment is greatly aided in this direction by watching the intestine and its returning circulation under hot irrigation. If necrosis of the intestine has occurred, it may be resected or otherwise dealt with, according to the judgment of the surgeon.

If, as is frequently the case, the patient is much reduced on account of prolonged vomiting, shock, and absorption of ptomains, so formidable a procedure as resection of the intestine and restoration of the continuity of the alimentary tract may be out of the question In such circumstances, the safety of the patient will probably be best subserved by an artificial anus (temporarily).

Masses of deformed omentum may be, and often are, wisely removed. If removed, hemorrhage from the stump is best controlled by double lines of continuous animal suture—double, since by it necrosis of the omentum is less likely to occur, because the constriction is more evenly applied, and with less force.

The peritoneal sac should be made tense by an assistant, dissected to its base, and closed at this point with a continuous suture in the line of the long axis of the wound. The resiliency of the peritoneum is such that no depression will be left upon its inner surface when thus sutured. The posterior wall of the inguinal canal is reformed by closing the aponeurotic structures from below upward upon the cord, thus reconstructing the internal ring and restoring the canal to its original length and normal obliquity.

It is usually wise to include in the suturing the posterior border of the conjoined tendon or lower margin of the internal oblique and transversalis muscles and Poupart's ligament, so as to strengthen the posterior wall of the canal. The suture material used should be absorbable. The tendon suture from the tail of the kangaroo is to be preferred.

The cord, which has been held out of the way by an assistant, is now replaced and the aponeurotic structures sutured over it in order to reconstruct the external wall of the canal, and its lower border is closed so as to form the external ring. These procedures are executed so as to restore the parts to their former normal conditions.

The skin is closed by a buried animal suture, and the wound sealed with iodoform collodion, without drainage.

The after-treatment of patients who have had strangulation is of the greatest importance. Vomiting has been so persistent that the thirst of such patients is well-nigh unquenchable. Therefore, water should be given in moderation as soon as the patient comes out of the anesthetic. Before he has done so, continuous enteroclysis should be begun. Not only is thirst relieved in this way, but the kidneys and skin are made more active, thereby eliminating poisonous products which have been absorbed. A little highly concentrated broth, albumin water, or milk may be given by the stomach as soon as they are likely to be retained.

The bowels should be allowed to act spontaneously, which they will usually do within twenty-four hours. Should such not be the case, an enema may be given. Purgatives by the mouth are dangerous, and should not be given, lest by their drastic action they cause damage to, or even perforation of, the bowel.

It is no longer a question of limiting operative measures for the cure of hernia to cases of strangulation. Little by little the opinions of surgeons have changed, until now it is considered advisable to operate for the cure of hernia in a large precentage of cases formerly condemned to the wearing of trusses.

In a recent exhaustive discussion of this subject Rodman and Bonney state that mechanical treatment should be used only when some good contraindication to operation exists, that the former is uncertain and possibly dangerous, while the latter is practically free from danger and almost invariably successful.

The operation for the cure of hernia, no matter how slight, differs only in degree from the method above described. In most cases the hernial sac is probably empty, but it should always be opened, ligated at or above the internal ring and cut away. In separating the sac care should be taken not to injure the veins of the cord nor to wound the vas deferens. If the plane of cleavage between the sac and the cord be determined, the former can usually be easily stripped off with a piece of gauze wound round the index-finger. In cases of congenital scrotal hernia a tunica vaginalis may be made out of the lower portion of the sac in the manner shown in the illustration. In operations for direct hernia it is always advisable to transplant the anterior sheath of the rectus muscle in addition to performing the various steps advocated above in conformity with the principles set forth by Marcy and Bassini. Within the last few years many surgeons have ceased to transplant the spermatic cord and apparently have obtained satisfactory results. The omission of this step of the operation, however, is not advised except when there is a retained testicle associated with the hernia. If the muscles are much weakened it is advisable to overlap the aponeurosis of the external oblique muscle. In all cases, however, it is obligatory, in order to obtain cure, to reform the posterior wall of the inguinal canal and to reconstruct the internal ring. This is the *sine qua non* of cure. It is surprising to note the ease and rapidity of convalescence in children, and the safety of operative measures even in old age. Apparently, the only risks from operation lie in the possible complication of anesthesia and wound infection.

Marcy has epitomized the records of over 3000 cases of hernial operations in which there was less than a fraction of 1 percent mortality, and the deaths were all referable to extraneous causes.

Femoral Hernia

A femoral hernia is one in which a portion of the abdominal contents pushes its way into the femoral canal and escapes through the saphenous opening. The coverings of a femoral hernia are from within outward peritoneum, preperitoneal fat, septum, crurale, femoral sheath, cribriform fascia, skin.

A femoral hernia appears as a tense globular swelling at the upper and inner part of the thigh, just below Poupart's ligament internal to the femoral vessels, and external to the spine of the pubis. It is usually small, but may sometimes be as large as an orange, or even larger. It then extends upward and outward over Poupart's ligament toward the iliac spine, and appears as an elongated soft and yielding swelling with its long axis parallel to the ligament. Its neck, however, can always be traced below the ligament toward the femoral ring. This form of hernia, although next in frequency to that of inguinal hernia in the male, is by no means common, and occurs usually in the female. A loop of incarcerated intestine is in the greatest danger because of the sharp, unyielding edge of Ginebernat's ligament above and the falciform process below. Even a few hours' constriction may produce necrosis of the intestine. On this account prompt surgical measures are of the utmost importance.

The cure of this variety of hernia is even more satisfactory than that of inguinal hernia in the male, while for anatomic reasons the safe control of the opening by a truss is far less satisfactory. For this reason all cases of femoral hernia should be operated upon.

Cure of Femoral Hernia.—An incision is made over the hernia from above Poupart's ligament vertically downward about 3 inches. After the sac is freed, drawn down, opened, and its contents returned, the neck is cleansed with the finger passed up the femoral canal. It is transfixed by a ligature above the neck; the body of the sac is cut away and with the aid of long slightly curved needles the two ends of the ligature, which has been tied round the neck are passed up the femoral canal anterior to the peritoneum

and should emerge through the abdominal wall just above the round ligament in the female, about a quarter of an inch apart. The tying of the two ends of the ligature will draw the sac well behind the abdominal parietes. While the ligatures are being inserted the femoral vein, also the spermatic cord in the male, should be protected with the finger. Then the fascia and pectineus muscle are drawn up to Poupart's ligament by each end of a suture being passed through the muscle, then up through Poupart's ligament from behind forward, where it is firmly knotted. The saphenous opening can now be closed, taking care to avoid the vein. But the chief point in femoral hernia is to remove the sac and any funnel of peritoneum above.

Umbilical Hernia

Umbilical hernia is much more common in women, especially in multiparous women of excessive adipose development. This variety of hernia is found at or near the umbilical cord. It is extremely difficult of control by a truss: in part because of the extraordinary tendency to adhesions of its contents, especially the omentum. When the intestine is strangulated, the danger is very great, owing to the usually sharp, inelastic border of the hernial opening. If the abdominal wall is excessively fat, the sac old and of considerable size, the operation is by no means easy. Especially important is the care in disinfecting the parts previous to operation, on account of the deep folds usually found in the skin. The sac should be opened with the utmost caution and its contents reduced with great gentleness. Very commonly, deformed adherent omental masses must be removed. It is well to apply a gauze pad for the protection of the abdominal contents before the dissection of the sac. This must be extended to within the ring, and the external margin of the ring is dissected free. The margin of the ring is split laterally to the distance of fully 1/4 of an inch through its entire circumference. The pad is then removed, the peritoneum is evenly sutured upon the median line, and the superabundant sac is resected. The sutures are then applied so that the split margins of the ring may be everted and brought in contact. This can hardly be done with the ordinary interrupted suture, may be effected by the mattress suture taken so as to be tied upon opposite sides, but is best closed by a double continuous suture (shoemaker's stitch). Tendon should be used and the suture should be of considerable size. Chromicized tendon is trustworthy and will remain about 3 months before absorption. The dimpled portion of skin making up the umbilical depression should be cleanly cut away, the skin closed with a buried animal suture, and the wound sealed with iodoform collodion, without drainage. When the abdomen is thick and heavy, a firm supporting bandage should be applied and worn for some weeks.

The Mayos' Operation.—1. *Transverse* elliptical incisions are made around the umbilicus and the hernia. These are deepened to the base of the hernial protrusion.

2. For an inch and a half in all directions from the neck of the sac the aponeurotic structures are carefully exposed.

3. The fibrous and peritoneal coverings of the hernia at the neck are divided in a circular manner and the hernial contents are exposed. If viscera are present the adhesions are separated and reduced. The contained omentum is ligated and removed with the entire sac of the hernia.

4. The margins of the ring are grasped with forceps and approximated. In whatever direction overlapping proves easiest, lies the proper direction for closure.

5. The aponeurotic and peritoneal structures of the ring are incised for a distance of 1 inch or more transversely to each side. The peritoneum is separated from the under surface of the upper of the two flaps thus formed.

6. Beginning 1 inch or more above the margin of the upper flap, three or four mattress sutures are introduced, the loop firmly grasping the upper margin of the lower flap. Sufficient traction is made on these sutures to permit of closure of the peritoneum with a continuous catgut suture. The mattress sutures are tied, the entire lower aponeurotic flap being pulled into the space between the peritoneum and aponeurosis above.

7. With catgut, the lower edge of the upper aponeurotic flap is sutured to the aponeurosis below and the superficial wound is closed.

Ventral Hernia

One of the rarer forms of ventral hernia is a small opening on the median line above, more commonly than below, the umbilicus. These openings occur in the linea alba, and surgically may be classed with those of the umbilicus. Owing to their rarity they are not infrequently overlooked, and by a lack of correct diagnosis a fatal issue may result.

For a great variety of reasons the abdominal cavity is now daily opened, more commonly because of diseases incident to the reproductive organs in woman and for appendicitis.

Septic wounds requiring drainage through the abdominal wall are not infrequently of necessity followed by hernia. It has been estimated that hernia supervenes in 10 percent of all celiotomies, although it certainly should be very much less. This class of hernias is often very troublesome, because of intestinal adhesions, and, as a rule, operation is advised.

The section should be made sufficiently free to permit a complete knowledge of the pathologic conditions. The resulting cure depends in large degree upon the independent suturing in layers of the component parts of the abdominal wall. The peritoneum should be separately closed, and usually 3 or 4 layers of continuous buried absorbable sutures are indispensable. Somewhat fine kangaroo tendon is to be preferred. The skin is closed by a running suture, parallel to the line of incision, as above described, and the wound sealed with iodoform collodion, without drainage.

HEROIN.—Diacetyl-morphin. An acetic ester of morphin, which appears as a white, crystal-

line, inodorous powder of faintly bitter taste. Investigation upon animals of the physiologic action of heroin has shown it to be almost identical with that of morphin. It is one of the most toxic of the morphin derivatives and the habit is readily formed. Being devoid of unpleasant after-effects, heroin, with its hydrochlorid, has been proposed as a substitute for the derivatives of opium. It is used in place of codein as a respiratory sedative. It is largely employed to relieve the cough of bronchitis. It is recommended in all catarrhal inflammations of the respiratory tract, and has been given with good results in pharyngitis, tracheitis, bronchial asthma, and phthisis. The dose is 1/24 to 1/6 of a grain, given in pill or powder or in aqueous solution with the addition of a few drops of diluted acetic acid.

HEROIN HABIT.—Heroin is an ingredient to many trade preparations widely advertised as cough syrups and remedies for asthma. The drug is considered more toxic than morphin and the habit is readily acquired. See DRUG ADDICTION, ANTINARCOTIC LEGISLATION. It has been claimed that the jungle plant—*Combretum sundiacum*—has effected a permanent cure of the habit.

HERPES SIMPLEX (Fever-blisters; "Cold-sore"). Definition.—Herpes simplex is an acute inflammatory disease of the skin, characterized by the formation of small groups of closely aggregated vesicles upon reddened bases.

Symptoms.—There are two chief varieties, according to localization: (1) *Herpes facialis* and (2) *herpes progenitalis.*

Herpes facialis (herpes febrilis, herpes labialis) has its favorite seat near the oral commissures, where it makes its appearance as closely aggregated pinhead-sized to pea-sized vesicles, which, through coalescence, often form bullæ. The lesions soon become pustular, rupture, and dry as yellowish or brownish crusts upon the skin. Vesicles sometimes develop upon the mucous membrane of the mouth, and are called by the laity "canker sores." Herpes runs its course in from 5 to 10 days. Burning and itching are usually present.

Etiology and Pathology.—Herpes facialis is extremely prone to accompany acute diseases, such as pneumonia, typhoid fever, malaria, coryza, and gastric and nervous disturbances. It is perhaps due to a mild toxic neuritis of the cutaneous nerve filaments.

Prognosis.—Favorable. Eruption disappears spontaneously in a week or ten days.

Treatment.—Mild sedative applications, such as oxid of zinc ointment, cold cream, saturated solution of boric acid, etc., suffice. In children painting with collodion protects the part from finger infection.

Herpes progenitalis (herpes præputialis) occurs both in the male and in the female. The groups of vesicles in the former are located upon the inner surface of the prepuce, glans penis, shaft of the penis, etc.; in the female upon the labia minora, labia majora, vestibulum, perineum, etc., In these locations they may, through subsequent infection, become the sites of chancres or chancroids.

Etiology.—A long, narrow prepuce seems to act as a predisposing cause. Unna found herpes progenitalis much more frequent in prostitutes than in the chaste.

Diagnosis.—It is important to differentiate herpes from the more serious genital sores. It must not be forgotten that the abrasion at the site of a herpetic patch offers any easy ingress for the chancroidal or syphilitic virus. See CHANCROID.

Prognosis.—Favorable as to immediate attack. Recurrences are extremely common.

Treatment.—Cleanliness must be strictly enjoined. Astringent lotions, such as equal parts of lotio nigra and lime-water, saturated solution of boric acid, and spirit of camphor, or dusting-powders, such as aristol, calomel, or acetanilid, may be employed. Patients with long prepuces who are subject to frequent attacks should be circumcised. The long-continued administration of arsenic has been advised.

HERPES ZOSTER (Shingles). Synonyms.—Zoster; zona; cingulum.

Definition.—Herpes zoster is an affection characterized by the formation of grouped vesicles along the line of a cutaneous nerve, and accompanied by neuralgic pains.

Symptoms.—After prodromal neuralgic pains, more or less severe in character, there appear in crops irregular groups of pinhead-sized to pea-sized vesicles, which follow in an interrupted manner the distribution of the nerve or nerves affected. When seen early, macules, papules, or vesicopapules may sometimes be distinguished. The vesicles rest upon a highly inflammatory base. The eruption is distinctly unilateral, bilateral cases being of great rarity.

In the course of 1 or 2 weeks, the vesicles, which do not tend to spontaneous rupture, dry upon the skin as yellowish-brown crusts and fall off. As a rule, no permanent trace is left, although in some cases there may be considerable scarring. The vesicles may become pustular, hemorrhagic, or even gangrenous.

The regions most frequently affected are those supplied by the intercostal, lumbar, and trifacial nerves, although any portion of the cutaneous surface may be involved. In *herpes zoster ophthalmicus,* severe destructive inflammation of the cornea, iris, and, indeed, of the entire eye, may occur.

Pain is nearly always present. It may be slight or so severe as to prevent sleep. It is variously described as of a darting, burning, drawing, or tugging character. It may persist indefinitely after the disappearance of the eruption, and may prove most refractory to treatment.

In severe cases febrile disturbance may be present. Herpes zoster seldom occurs twice in the same individual.

Etiology.—It is probably an acute specific disease of the nervous system. It is sometimes seen during a prolonged course of arsenical medication.

Pathology.—Zoster is due to an irritative or inflammatory condition of the central, spinal, or peripheral nerve apparatus. The process is usually an interstitial descending neuritis of one of

the spinal ganglia. There may, however, be merely a simple inflammation of a peripheral nerve.

Diagnosis.—A unilateral eruption, consisting of groups of large vesicles upon an erythematous base, following the course of a cutaneous nerve and accompanied by neuritic pains, is characteristic of herpes zoster. The vesicles of zoster differ from those of eczema in being larger and in showing no tendency to rupture spontaneously.

Prognosis.—Favorable. Spontaneous cure in 1 to 3 weeks is the rule. It should not be forgotten that some cases are followed by persistent neuralgia, and that others may lead to scarring or, in the ophthalmic form, to serious impairment or loss of vision.

Treatment.—**Local treatment** is concerned merely in protecting the parts from injury and infection, and, to a certain extent, in the relief of pain. Ordinary dusting-powders, such as oxid of zinc, starch, talcum, etc., may be employed, or, if there is much pain, morphin and camphor may be added:

℞.	Morphin sulphate,	gr. v
	Pulverized camphor,	gr. xx
	Pulverized zinc oxid,	ʒ j.

Dust on the affected area, cover with cotton, and bandage.

The calamin lotion is often a grateful application.

An excellent method is to paint flexible collodion (containing morphin, if necessary) upon the areas affected.

℞.	Morphin sulphate,	gr. x
	Flexible collodion,	ʒ j.

The galvanic current applied along the nerve often gives marked relief from the pain.

Internal Treatment.—The pain is often so severe as to require the use of an anodyne. The following capsule will be found of service:

℞.	Morphin sulphate,	gr. 1/8
	Phenacetin,	gr. ij
	Quinin sulphate,	gr. j.

One capsule every 4 hours or oftener.

Phosphid of zinc in doses of 1/10 to 1/3 of a grain, every 3 hours is warmly advocated by some. In the neuralgia persisting after the disappearance of the eruption antipyrin, quinin, iron, strychnin, arsenic, and the galvanic current are of value.

HETEROPHORIA.—A tending of the visual lines in some other way than that of parallelism. It may be **esophoria**, a tending of the lines inward; or **exophoria**, outward; or **hyperphoria**, a tending of the right or left visual line in a direction above its fellow; **hyperesophoria**, a tending of the visual lines upward and inward; **hyperexophoria**, upward and outward. See EYE-MUSCLES.

HEXAMETHYLENAMIN.—See UROTROPIN.

HICCUP (Singultus).—A sudden spasmodic descent of the diaphragm accompanied by a spasmodic closure of the glottis, the characteristic noise being caused by the incoming column of air striking against the partially closed glottis. It is a reflex act met in many forms of nervous and gastric disorders, uremia, peritonitis, etc. Undue distention of the stomach by food or drink, or an accumulation of gas due to faulty digestion are the most common causes. It is more frequent in children. It is found in carcinoma of the stomach, in cholera during convalescence, and in typhoid fever (when it is an indication of perforation or of the onset of general peritonitis), and as a true neurosis in gastric and abdominal disturbance. It may accompany hydrocephalus, meningitis, hysteria, or modified epilepsy.

Treatment.—Holding the breath is a popular and frequently efficacious method of arresting it. Attempts to count fifty without taking in a breath may be tried, the act necessitating a violent descent of the diaphragm. In severe cases an emetic or a stimulant to increase natural peristaltic action will give relief. Warm applications or counterirritation to the diaphragmatic region or over the cervical spine will occasionally relieve. Pressure upon the trunk of the phrenic nerve by means of the finger applied over the scalenus anticus muscle has given relief. Chloroform—administered internally, alone or with opium—camphor, belladonna, valerate of zinc, potassium bromid, musk, antacids, and, in severe cases, morphin administered hypodermically have been used. Rapidly eating ice-cream or swallowing quantities of cracked ice has been suggested. Hypnotism has proved successful in obstinate cases.

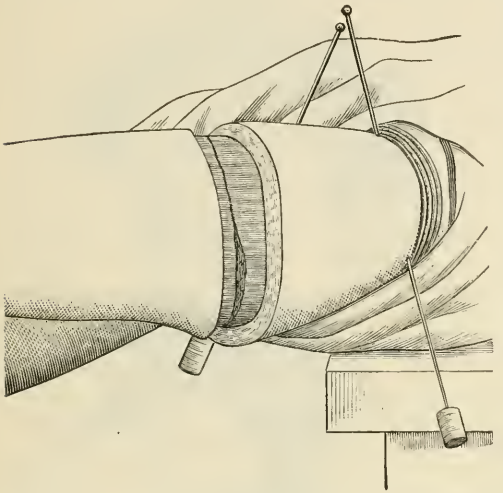
A woman presented herself at the Hôtel Dieu, of Lyons, for a rebellious hiccup, which had resisted all treatment for 4 days. She was asked to show the tongue, and it was noticed that with the putting out of the tongue the hiccup ceased. The same thing has since been tried, and with success, in other cases. All that is necessary apparently is to push the tongue strongly out of the mouth and hold it so for a minute or two. It is also suggested to try the same measure in suffocative cough, such as in whooping-cough, and choking by irrespirable gases.

HIDE-BOUND DISEASE.—See SCLERODERMA.

HIP-JOINT, AMPUTATIONS.—**Wyeth's Bloodless method.**—Bring the hip well over the edge of the table, and apply Esmarch's bandage as high as possible; then take a steel mattress needle at least a foot long, or, if preferred, a needle may be made for the purpose, and, starting at a point 1 1/2 inches below and slightly to the inner side of the anterior superior spinous process of the ilium, pass the needle through the tissues about half way between the trochanter major and the iliac spine, external to the neck of the femur, so that the point will emerge just back of the trochanter. Pass a second needle an inch below the crotch and internal to the saphenous opening, so that the point will come out about 1 1/2 inches in front of the tuber ischii; protect the points of the needles with cork; then pass a long piece of black pure rubber tubing, 1/2 of an inch in diameter, tightly around the limb, above the needles, tying or clamping it. Remove the Esmarch bandage, and examine the femoral artery to ascertain if the circulation has ceased; if it has not, tighten

the india-rubber tube sufficiently to have it under complete control.

Five inches below the pins make a circular incision down to the deep fascia, and reflect back the skin and fascia to the level of the trochanter minor; at this point make a circular sweep with the knife, dividing the muscles to the bone at a much lower level than the trochanter minor, which gives the operator a handle wherewith the subse-

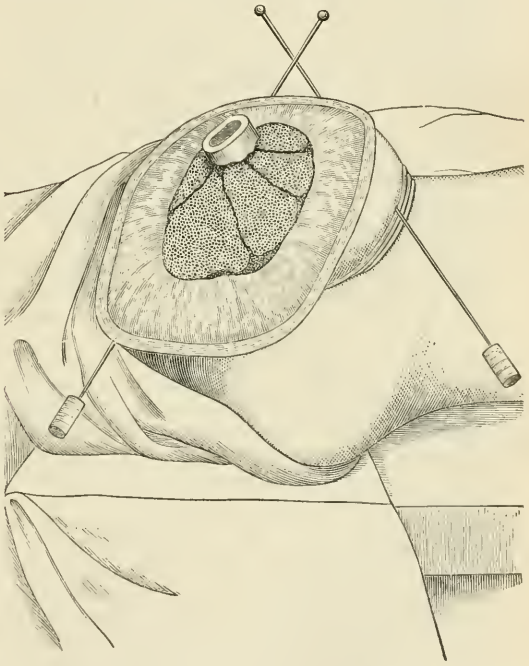


Amputation at Hip-joint, Showing Position of Pins.—(*Wyeth.*)

quent resection of the bone is rendered more simple. Secure all visible vessels, loosen the rubber band, tie all bleeding points. Then open the capsule and disarticulate the bone; this is facilitated by carrying the bone directly upward, forward, and inward, causing luxation to occur, when the ligamentum teres can be readily divided. Control all hemorrhage in the usual manner, bring the flaps in apposition by means of sutures, place the drain externally, and seal the inner end of the wound with iodoform and collodion, in order to prevent infection from urine and feces.

Senn's Bloodless Amputation.—The external incision is made about 8 inches in length, parallel to the long axis of the femur, directly over the center of the great trochanter, extending 3 inches above its upper border. When the knife reaches the trochanter from above downward, its point should be kept in contact with the bone the whole length of the remaining part of the incision. The margins of the wound are now retracted, and any spurting vessels, such as the circumflex arteries, are secured by pressure forceps. The trochanteric muscular attachments are now severed close to the bone with a stout scalpel. The thigh is then flexed, strongly adducted, and rotated inward, when the capsular ligament is divided transversely at its upper and posterior aspect. The remaining portion of the capsular ligament is severed while the thigh is brought back to a position of slight flexion. After complete division of the capsular ligament the thigh is rotated outward, and, if possible, the ligamentum teres is divided; if this cannot be readily done, the head of the bone is forcibly dislocated upon the dorsum of the ilium by flexion, adduction, and rotation inward of the thigh. After dislocation has been effected, the trochanter minor and upper part of the shaft of the femur are cleared by using alternately scalpel and periosteal elevator. By pushing the femur through the opening, as much of the shaft can be cleared as may be desired for the purpose of making a low amputation.

Elastic constriction applied as here indicated will prevent further loss of blood. Bring the limb down in a straight line with the body; flex the thigh slightly; insert long, stout, hemostatic forceps into the wound behind the femur and on a level with the trochanter minor; push the instrument inward and downward in a direction about 2 inches below the ramus of the ischium and just behind the adductor muscle. When its point is felt under the skin, make an incision about 2 inches in length, through which the instrument is made to emerge. Enlarge the tunnel with the forceps; then with that instrument draw along the tunnel a piece of aseptic rubber tubing, 3/4 of an inch in



Amputation at Hip-joint.—(*Wyeth.*)

diameter, and about 3 or 4 feet in length, withdrawing the forceps. The tubing having been grasped in its middle by the forceps, it is cut in two at that point. The anterior segment of the thigh is to be constricted sufficiently to completely interrupt both the arterial and venous circulation. Prior to constriction the limb is rendered bloodless by elastic compression and by keeping it in a vertical position for a few minutes. After having secured the necessary constriction, the elastic

tubes are caught and held in a pair of strong forceps at a point where they cross each other. The posterior segment of the thigh is constricted by the remaining rubber tube, which is drawn tightly behind.

Muscular flaps should be avoided in this amputation; if the conditions for which the amputation is made permit, a long oval anterior and short superior skin flaps should be made, which are best adapted for a useful stump and efficient drainage. In making the anterior flap the incision is commenced at the lower terminus of the straight incision; dividing the tissues down to the muscles, it is carried downward in a gentle curve across the anterior aspect of the thigh, embracing two-thirds of its circumference; it is then carried upward to a point on the inner side just below the opening of the skin occupied by the constrictors. The posterior flap is made in a similar manner, but about one-third shorter. The flaps, including the deep fascia, are reflected to the point where the muscles are to be divided; they are to be held out of the way while the amputation is being completed. The incision through the muscles should be slightly conic, the apex of the cone pointing upward. The sciatic nerve is to be resected to the extent of an inch, and the arteries are tied with catgut in the usual manner. The femoral artery and vein are now isolated and a second catgut ligature, including both of the vessels, is applied 1/2 of an inch higher up. The vein is thus ligated, and the artery is secured by a double ligature.

During the operation the body of the patient is drawn down so that the pelvis rests upon the lower edge of the table, that the position of the thigh can be conveniently changed by the assistant who is intrusted with this work.

HIP-JOINT, DISLOCATIONS. — Dislocations may be congenital, pathologic or traumatic.

Congenital Dislocation

Congenital dislocation of the hip is usually due presumably to arrested development. It may be inherited. It occurs more frequently in females. It is seldom apparent until the child begins to walk. Rarely it occurs during birth due to cramped position of the child *in utero*. The dislocation results in atrophy of the acetabulum, the cavity becoming more and more shallow, and of the head of the femur which rests behind the acetabulum on the dorsum of the ilium. The neck of the femur and the thigh muscles are shortened. The capsule is stretched, an hourglass constriction sometimes being found between the head and the pelvic bone. In unilateral dislocation there is scoliosis and limping; in bilateral, there is a waddling gait and lordosis.

Diagnosis.—Congenital dislocation is distinguished from *pathologic dislocation*, from tuberculosis, and from *traumatic dislocation* by being freely movable and painless. Trendelenburg's sign (dropping of the pelvis on the opposite side, which normally would be raised, when the patient stands on the affected limb) is present as it is in *coxa vara*, also the waddling gait and presence of the trochanter above Nélaton's line, but it differs from the latter condition in that the head of the femur is not in the acetabulum and there is free up-and-down movement. The X-rays should be used in every case.

Treatment.—If recognized early, the length of the limb may be restored by continuous traction for six months to a year, with the limb abducted and pressure made over the great trochanter.

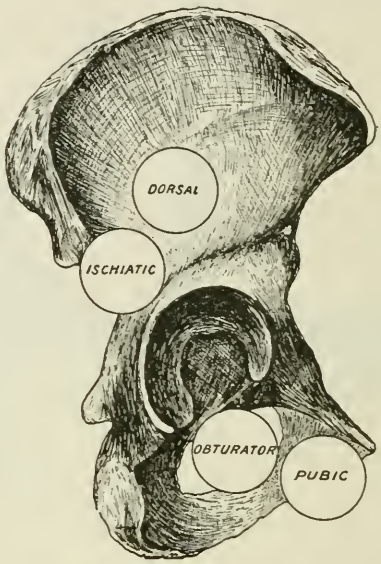


DIAGRAM OF THE MOST COMMON DISLOCATION OF THE HIP.—(*Thomson and Miles' Manual of Surgery.*)

Hibb's Method.—This is based primarily upon the fact that by flexing the thigh upon the abdomen and extending the leg, the head of the bone can be forced downward behind the acetabulum to a point below it. This has been confirmed by means of the X-ray in cases up to the fifteenth year. By this procedure, namely, flexing the thigh in extreme adduction and extending the leg, the muscles, chiefly the adductors and hamstring group, are made to exert in some measure the same pressure in forcing the head downward that they exert in holding it upward when the limb is in full extension parallel with its fellow, so that in this way the muscles which heretofore have furnished the chief difficulty to the reduction of the dislocation become a most important aid in its accomplishment. And what is of equal importance, the greater extension put upon the muscles by the increase in the length of the limb after reduction, makes them contribute largely to the stability of the reduction, and obviates the necessity of wearing plaster so long. Such resistance as the capsule and the Y-ligment may offer will not be increased but may be diminished, and in either case may be ignored. The problem, therefore, becomes one of adopting some means by which in bringing the leg back from the adducted and flexed position by abduction and extension, the head may be forced to travel upward by a more anterior route into the

acetabulum. The two conditions necessary to this end are, first, absolute control of the pelvis, and second, a trochanteric pad so shaped and held against the trochanter that it will force the head upward and forward. An instrument has been devised by Hibbs for this purpose. By means of straps, the pelvis is perfectly controlled, and by the use of a pad held against the trochanter, the head is forced forward into the acetabulum as the leg is brought down, through abduction and extension, from its adducted and flexed position. The reduction is accomplished without traumatism to any structure and as the integrity of the muscles is unimpaired the reduction is more secure, and it is only necessary to wear plaster for a short period of from three weeks to three months.

The Lorenz bloodless method may be used in children, up to seven years in bilateral cases, and about nine years in unilateral cases. Under anesthesia the shortened muscles are stretched by flexion, extension, and abduction of the thigh, during the last of which the adductor muscles are powerfully kneaded. The head of the bone is then drawn down to the level of the acetabulum by traction on the leg, and the thigh flexed on the abdomen, rotated internally, abducted, and finally rotated outward while pressure is made on the trochanter. With the limb in flexion, abduction, and eversion, a plaster-of-Paris cast is applied to the pelvis and thigh as far as the knee. The child is allowed to walk with the limb in this position in order to deepen the acetabulum. At the end of six months the cast is removed, the flexion and abduction lessened, and another cast put on for three more months.

For still older children Hoffa and Lorenz have each devised a *bloody method*. In the Hoffa operation the joint is opened by an incision similar to that of Langenbeck in resection of the hip, shortened muscle-fibers and fascia are cut, the acetabulum is deepened with a gouge, the dislocation is reduced, the limb is fixed in eversion and abduction for a few weeks, and finally the limb is straightened. The Lorenz operation is similar except that the joint is opened in front, the muscles are not severed unless it be found necessary in the case of the hamstrings.

Pathologic Dislocation

Pathologic dislocation may be the result of inflammatory effusion into the joint, as in osteoarthritis, tuberculosis, or it may occur during fevers due to distention when the thigh has been kept continuously flexed in bed, or in paralysis due to the action of unaffected muscles.

Traumatic Dislocations

Traumatic Dislocations.—Dislocations of the hip are infrequent (about 2 percent of all dislocations), very great violence being required to displace the femur head from the deep acetabulum and to tear the strong capsule and accessory ligaments and overcome the firm muscular support.

Etiology.—Adult males from 25 to 50 are most affected, women being less exposed to the producing violence, and children and the aged usually sustaining fracture from a similar force. But it may occur as a purely traumatic injury at birth. Like other traumatic dislocations, these are due almost entirely to indirect force overstepping the range of mobility in the way of flexion, extension, rotation, abduction, and adduction.

Mechanic Production.—To understand this we must take into account the *length of the neck* of the femur, the *angle* at which it joins the shaft, the powerful Y-ligament arising from the anterior inferior spinous process and inserted with its two branches into the outer part of the intertrochanteric line and the internal portion of the same ridge; also the fact that the shallowest portion of the acetabular rim is below.

If excessive *inward rotation* is produced until the femur neck impinges aginst the acetabular rim in front, the head of the bone tends to be forced through the capsule posteriorly. On the other hand, if the rotation is *outward*, the head will be forced through the anterior portion of the capsule. *Hyperflexion* and *hyperextension* alone do not tend to make the bone-head more than simply rotate in its socket. *Abduction* alone would tend to make the bone-head escape from the acetabulum at its lowest and most defective portion. *Adduction* alone could scarcely be made to produce a dislocation so long as the Y-ligament remains intact. The tendency would rather be to force the bone-head through the floor of the acetabulum, producing, in conjunction with the direct inward application of force to the trochanter, the so-called *central* dislocation. If the force were sufficient to rupture the Y-ligament, adduction would, of course, favor the escape of the bone-head through the capsule in an upward direction. The *typical* dislocations are all associated with the preservation of the Y-ligament. When this is ruptured, the dislocation is *atypical*, the bone-head occupying an indifferent position, the symptoms not being characteristic, and the same hindrances to replacement not existing.

While hyperflexion and hyperextension alone, with the trochanter in its normal position between inward and outward rotation, would not tend directly to produce dislocation, when combined with inward and outward rotation, abduction, and adduction they become powerful factors. In throwing the bone-head out of the socket in amputation at the hip, for instance, after the lower part of the capsule has been severed, no method is so easy and certain as forcing the thigh diagonally up over the abdomen, in forced flexion and adduction. Most of the hip dislocations are therefore produced by combinations of forces acting in the various directions already indicated; they are rarely produced by a force acting in one direction only, as in infracotyloid dislocation, due to forced abduction alone.

It would seem probable that Allis' statement is correct, that the bone-head in all of these dislocations with an intact Y-ligament primarily escapes from the lower acetabular segment, its final resting-place being determined by the continued action of the displacing force upward or downward. In practically all dislocations the ligamentum teres

is lacerated. The dislocating force sometimes acts on the limb, the body being fixed; and sometimes on the body, the limb being fixed.

Backward dislocations are the most common, resulting most frequently from forced flexion, adduction, and inward rotation of the thigh. The joint capsule is usually ruptured at its posterior lower portion, and the ligamentum teres at its insertion into the femur head. When the head escapes above the tendon of the obturator internus muscle, it finally lies on the dorsum of the ilium, and the dislocation is termed **iliac**; when below the obturator internus tendon, it rests in the sacrosciatic notch, and is termed **sciatic**, or **ischiatic**.

The symptoms are almost the same in either case; the thigh is rotated inward, and is elastically fixed in flexion and adduction, more or less marked; the

BIGELOW'S METHOD OF REDUCING BACKWARD DISLOCATION OF HIP.

BIGELOW'S METHOD OF REDUCING FORWARD DISLOCATION OF HIP.

trochanter is prominent, more so in iliac than in sciatic dislocations; the limb is shortened, more in iliac dislocation, and with the two thighs placed in right-angled hip flexion; the trochanter lies above the Roser-Nélaton line; passive motion is possible over small arcs in the way of adduction and inward rotation, is very painful, is greater in the iliac than in the sciatic variety, the limb returning to its first position when the force ceases to be applied; attempts at abduction and outward rotation produce a characteristic elastic resistance, due mainly to tension of the iliofemoral ligament. The bone-head can sometimes be directly palpated, especially if the patient is anesthetized, which is usually necessary both for satisfactory examination as well as for the succeeding reduction. Frequently, however, the heavy pad of the overlying gluteal muscles, together with the swelling, completely masks the presence of the head in its abnormal position.

Backward dislocation, especially of the iliac variety, is sometimes confounded with fracture of the neck of the femur. Careful consideration of the cardinal points of the two conditions should always make the matter clear.

Treatment.—In order to effect reduction the patient is laid on his back on the floor on a thin, hard mattress or a folded blanket, and is thoroughly anesthetized; any movements which contemplate reduction must produce relaxation of the powerful iliofemoral ligament. This is accomplished by flexion. The thigh is therefore flexed upon the body, and the leg upon the thigh; one hand grasps the leg at the popliteal space, while the other grasps the ankle. With the limb in this position simple traction will sometimes bring the head into place if it has lodged close to the acetabular rim. Ordinarily, however, certain definite further movements must be made. After flexion the limb is adducted, carried across the abdomen to the sound side, and then slightly rotated outward; it is next swept across the abdomen outwardly in circumduction, and is finally brought down to a straight position beside its fellow. This manipulation usually succeeds in making the bone-head retrace its path through the torn capsule into the acetabulum. Great care and gentleness must be exercised in the movements. If the bone-head fails to enter the rent in the capsule, this maneuver will sometimes cause the head to pass around the acetabular rim to the front of the joint (circumduction). A similar secondary movement of the bone-head may take place at the time of dislocation, so that the position of the head is not always a clue to the location of the rent in the capsule.

If the first attempt fails, strong traction should be tried with the thigh at right angles to the body and strongly adducted; this failing, traction in the abducted position, with slight outward rotation, should be tried. Finally, all efforts may sometimes fail because of the lacerated capsule forming a true obstruction to reduction. In such event, incision and direct replacement become the only remaining resources.

Forward dislocation occurs less frequently than backward, but its subvarieties are more numerous; thus, we have **suprapubic** dislocations, the head resting in the inguinal region above the pubic bone; **pubic**, the bone-head resting on the pubic bone internal to the pubic eminence; **obturator**, or **thyroid**, the head lodging over the obturator foramen; **perineal** dislocation, which is very rare, and in which the head is dislocated as far as the ascending ramus of the ischium.

Symptoms.—Forward dislocations are the result usually of abduction and outward rotation combined with overextension, more rarely with flexion. The limb is held in marked abduction, outward rotation, and flexion, the latter varying with the kind of dislocation, being slight in suprapubic and more marked the further the bone passes inward and downward; abduction varies in the same way, but inward rotation is only possible when the bone-head has cleared the pubic bone and invaded the pelvis. In the suprapubic and pubic forms the head is readily palpable, and its rounded outline can sometimes even be seen; in the obturator and perineal forms it lies more deeply and can be palpated less surely. In the former the limb is shortened, while in the latter it is either lengthened or remains about normal. Some authors state it can also be shortened.

Diagnosis.—Confusion with fracture of the neck

of the femur offers here also the chief difficulty in diagnosis. The single, symptom of elastic fixation is enough to differentiate, but the X-ray will reveal the real condition.

Treatment.—The first step in the reduction of the suprapubic variety should be hyperextension and traction, so releasing the bone-head from its hooked position over the pubic bone, the patient being meanwhile conveniently placed on his back on a table; the thigh is then flexed and the patient put on his back on the floor. The movements should be carried out in such a way as to first relax the Y-ligament, and then bring the bone-head into the acetabulum; this is accomplished in general by flexion in the abducted position, and then inward rotation followed by adduction. Circumduction of the head is especially prone to occur in thyroid dislocation, and is controlled by simultaneous traction on the limb.

Downward dislocation of the hip is very rare, resulting from extreme abduction; the bone-head rests at the lower margin of the acetabulum or on the tuberosity of the ischium; the thigh is flexed, abducted, perhaps everted, the knee-joint being sharply flexed. Reduction is usually easily effected by traction in the flexed position, followed by outward rotation and extension.

Atypical dislocations, as already stated, result from concurrent rupture of the Y-ligament. In such cases the femur head may find a resting-place in any direction without producing characteristic symptoms. The **supracotyloid dislocation** may result primarily with rupture of this ligament, or secondarily from an iliac dislocation.

HIP-JOINT DISEASE.—Hip-joint disease is a tuberculous lesion of the hip-joint, originating as an ostitis or a synovitis, chronic or progressive in character, and tending toward recovery, ankylosis, or complete destruction of the joint. Many different terms have been proposed to describe this affection, the most common of which is coxalgia; but that used is satisfactory and practical.

In collecting statistics it has been found that, next to the spine, the hip-joint is the most frequently affected by tuberculosis, the reasons for which may be briefly stated as follows: (1) the age of the epiphyses at the time of the beginning of the disease; (2) the direction of the nutrient artery to this joint; (3) the effect of superincumbent weight upon this articulation; (4) the effect of heredity on this as well as other articulations; (5) the influence of traumatism or injury upon this joint, leading to the localization of tuberculous germs in the inguinal parts.

In regard to age it is found that the disease occurs most frequently under 14 years, the proportion being 84.5 percent. Boys are more frequently affected than girls.

The influence of heredity is traceable in about 75 percent of cases but like all predisposing factors, its importance in individual cases is only relative. It must be remembered that the disease may be acquired by a child without any hereditary factor, an injury to the joint permitting the tuberculous germs that have gained entrance to the blood to localize themselves in the joint.

Pathology.—In most instances of hip-disease the lesion is primarily osseous, the head of the femur being the point usually attacked. Occasionally, particularly in adults, synovitis becomes tubercular arthritis. More rarely infection occurs from injury to the round ligament, a condition described and illustrated by Coulson and Agnew. The tubercle bacilli, having located themselves, continue their destruction until circumscribed by reactive inflammation or by the destruction of the joint or the death of the patient. Occasionally the process becomes a necrotic one, the epiphysis being separated as a sequestrum. In very rare cases the inflammation runs its course without the formation of pus (*caries sicca*), the lesion corresponding to fibroid phthisis in the lungs. The cartilage covering the head of the bone may be lifted off by granulation tissue. This form is exceedingly painful, and calls for early incision or erasion. According to the location of the primary lesion, three varieties are recognized: (1) The femoral, (2) the acetabular, and (3) the arthritic.

Symptoms.—A certain group of symptoms that pursue a more or less typical course is observed in every case. These were formerly divided into three stages but there is no pathologic or clinical reason for preserving this classification in the hip-joint when it is not used in any other joint.

The early symptoms are limping, pain, hardening about the joint, deformity, muscular atrophy, and glandular swelling in the neighborhood of the joint.

Limp.—Limping is very important as an early sign, although it is not a constant one. It is very slight and is noticeable sometimes in the early morning and again later in the day. Limping is due to stiffness and pain in the joint, and becomes intensified by exertion.

Pain.—Another early symptom is pain, which is usually referred to the knee. In most cases it is periodic, coming on suddenly while the child is at play, often in the latter part of the day, and disappearing at night. Various theories have been offered to explain why this pain is referred to the knee, but the one now generally accepted is that it is reflex, occasioned by pressure on the obturator nerve, transmitted to the short saphenous nerve, through the communicating branch passing between the femoral and profunda femoris vessels.

Hardening.—Very little induration or enlargement of the joint is noticed early in the progress of the disease unless it is of the very acute type.

Deformity.—This is one of the earliest and most constant symptoms. There exists a reflex tetanic contraction of the muscles of the joint, apparently the result of an effort to fix the joint and to diminish the jar upon motion. This fixation and the consequent atrophy of the muscles constitute the most positive symptoms. The limb is held slightly flexed and often slightly abducted or adducted.

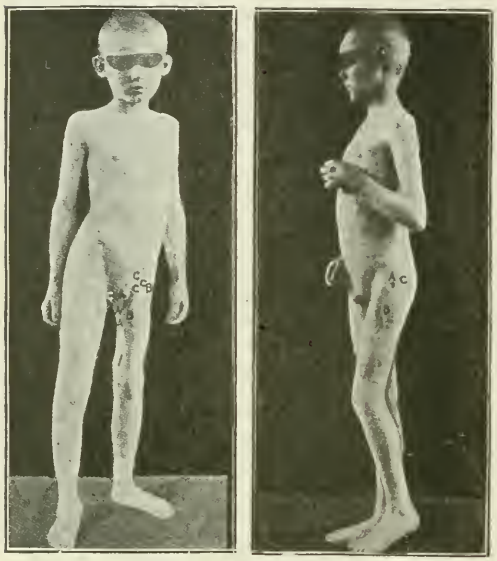
Under anesthesia the muscular spasm disappears entirely, thus showing the true nature of the rigidity.

Wasting.—Very early and most persistent is the

atrophy of the muscles of the thighs and buttocks. This has been noted as early as the eighth day and is due partly to disuse, partly to trophic disturbances, and partly to nerve irritation. The latter theory was deduced by Brown-Séquard from his experiments.

Glandular Swelling.—The enlargement and tenderness on palpation of the deep glands above Poupart's ligament may be frequently noted as an early sign.

General Condition.—Usually very little constitutional disturbance is exhibited at this period. The children may even increase in weight, and thus give a false idea of health.



Exit of Abscesses in Hip-Joint Disease.
A. Arthritic. *B*. Femoral. *C*. Acetabular.

Night-cries.—This distressing symptom happens early in the night, just as the child is falling asleep. The muscular relaxation, occurring as consciousness is lost, permits friction and pain within the inflamed joint, and the child awakens with a loud cry.

Abscesses.—Although there are some cases in which there is no suppuration—caries sicca—yet an abscess may occur early in the progress of the case. It is more commonly seen early if the joint itself has been involved.

The above illustrations indicate the location of the abscesses.

Grating.—A joint crepitation may be brought out by rubbing together the exposed cancellous tissue in the bone surfaces. The cartilage becomes eroded and grating ensues.

After the formation of abscesses the general health of the child is affected, as is shown by anorexia, pallor of the skin, fluctuations of temperature, irritability and diarrhea.

As the disease progresses, shortening, adduction, dislocation or ankylosis with recovery or suppuration, destruction of the joint, asthenic symptoms, and death from some visceral lesion may occur. Adduction, flexion, and shortening are characteristic of the position of the thigh. These changes are due at first to destruction of cartilage and ligaments, but later to real bone absorption and dislocation of the head of the femur.

As a consequence of the adduction and shortening, we have undue prominence of the buttock on the affected side, marked upward and backward tilting of the pelvis, lordosis, and a sometimes compensatory double lateral spinal curvature.

Tendency toward recovery is indicated by a gradual improvement of all the general and local symptoms—the sinuses close, the hardening and enlargement diminish, and the joint becomes ankylosed.

When the disease results fatally, it is due to exhaustion from continued suppuration, terminating in amyloid degeneration of the viscera. Tubercular meningitis is a not uncommon termination.

Lordosis of Lumbar Spine When Limb is Straight
P. Psoas muscle.—(*Walsham.*)

Diagnosis.—Hip-joint disease may usually be recognized if attention is paid to the cardinal symptoms.

These include:

1. Spasm.
2. Wasting.
3. Lameness, limp.
4. Deformity of limb—apparent and real.
5. Pain.
6. Swelling.

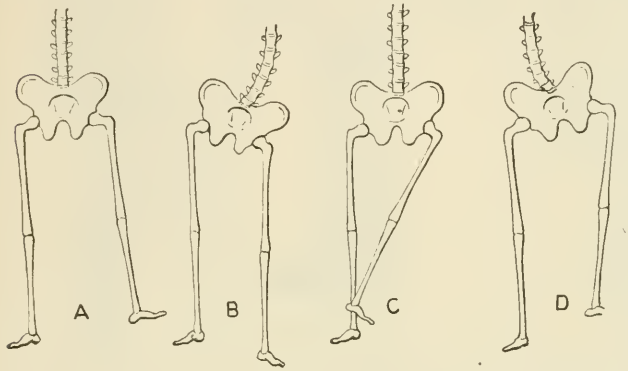
1. The deformity in the hip-joint is due to reflex tetanoid spasm, and is the most important symptom present. It is this spasm which produces the flexion, adduction, and abduction of the limb. The spasm can best be recognized by first examining the sound limb to ascertain the normal degree of motion. The spasm is most marked in the adductor muscles, and early adduction of the limb before the appearance of abscesses, and before the occurrence of much pain, is considered by the French authorities to be diagnostic of acetabular disease.

Disappearance of Lordosis When Limb is Flexed.
P. Psoas muscle.—(*Walsham.*)

2. The wasting of the limb in the early stage is directly due to spasm of the muscle. This is the second most important symptom. The disease of the limb later leads also to wasting.

3 and 4. The limp or lameness very early present is due first to the peculiar attitude of the limb, and later to the shortening that occurs from the absorption of the head of the bone.

As a diagnostic sign, limping is of little value. The attitude of the limb in the early stage is due to the spasm of the muscles, as before alluded to, producing flexion, *abduction*, and *adduction* of the limb. The body adapts itself to the changed position of the thigh, and this, with some atrophy of the gluteal muscles, produces the changes in the position of the gluteal folds, or *flattening of the buttock*, formerly considered so characteristic of hip-joint disease. At the present time the changes in the gluteal folds are not considered of great diagnostic importance. The changes that occur in the position of the limb from muscular spasm lead to "apparent elongation of the limb." This is determined by measuring from the umbilicus to the internal malleolus on the sound side, and also on the affected side taking care that both limbs are in same relative position. Later, the attitude of the limb is also affected by the absorption of the head of the bone, leading to what is known as "real shortening of the limb." This is determined by measuring from the anterior superior spinous process on the sound side to the internal malleolus on the same side, and comparing this with a similar measurement on the affected side.



Effects of abduction (*A*) and adduction, (*C*) in causing apparent lengthening (*B*) and apparent shortening (*D*) of the limb in hip-disease, when the limbs are parallel. Note effect on lumbar spine. In *C* and *D* foot should be inverted.—(*Walsham.*)

The position of adduction of the limb produces "apparent shortening" while abduction causes "apparent lengthening."

5. The pain, which may be absent in hip-disease, is referred to the inner side of the thigh above the knee to a space as large as can be covered by the hand. The pain varies in the different forms of the disease. In the femoral form it is often intermittent. In the arthritic it is acute, constant, and accompanied by a feeling of tenderness and fulness about the joint. In the acetabular form the pain is more marked on motion or jarring, but the pressing of the joint surfaces together or striking or jarring the limb to elicit pain should be discouraged, as pain thus elicited is untrustworthy as a diagnostic sign.

6. Swelling of the hip-joint is most marked in the femoral form, being confined to the front and back of the joint. The swelling is usually accompanied by induration or hardening about the great trochanter. This is best determined by grasping with the thumb and forefinger the trochanter on each side. The trochanter of the affected side will be found much thicker.

The most important diagnostic signs of hip-joint disease are limitation of motion, wasting, attitude of limb, and pain and induration.

Differential Diagnosis.—Hip-joint disease is frequently mistaken for other diseases through failure to recognize the cardinal symptoms. Rheumatism of the hip is so rare in childhood, and the positive symptoms are so easily recognized, that it is surprising to find how frequently hip-joint disease is mistaken and treated as rheumatism. Contusions and sprains of the hip are frequently mistaken for hip-disease, and this is not strange, considering that acute synovitis of the hip-joint from injury not infrequently becomes chronic tuberculosis of the hip. The pain in the hip-joint, the perfect movement of the joint in every direction, and the absence of the cardinal symptoms of spasm, atrophy, deformity, and induration would render the diagnosis positive. From periarthritis, congenital dislocation, infantile spinal paralysis, and sacroiliac disease, attention to the positive symptoms of hip-joint disease will readily distinguish this affection. From psoas contraction in lumbar Pott's disease, hip disease is readily distinguished by the free function of the joint when the leg is still further flexed upon the abdomen. There are two conditions, however, from which it is difficult to distinguish hip-joint disease. These are hysteric affection of the hip and chronic synovitis of the hip-joint. From the hysteric affections of the hip true hip-disease may be distinguished by the absence of an inherited or acquired neurotic diathesis, the presence of hyperesthesia and paresthesia, the readiness with which the spasm may be overcome, and the effect of antineurotic medication upon the patient. The use of anesthesia is an important aid in determining the absence of the positive symptoms of hip-disease. From chronic synovitis, a differential diagnosis is at times impossible, but generally if the case recovers within six months it is not tubercular. As the treatment of the two is identical, the differentiation is not so essential.

Prognosis.—The tendency of hip-joint disease is toward recovery. The progress is directly influenced by the age of the individual, type of the disease, the presence or absence of complications, and the efficiency of mechanic treatment. The influence of traction methods of treatment upon the progress and prognosis must be recorded, since the use of traction in the treatment of these cases appears to result in a more speedy cure and in fewer abscesses. Perfect recovery occurs in the arthritic form of the disease in a certain proportion of cases, but in the other forms there is always more or less

deformity. Death usually occurs from amyloid changes in the liver, kidney, or spleen, from excessive suppuration, or from tubercular meningitis. This last condition is sometimes the termination in the mild attacks of the disease. The occurrence of albuminuria is not now considered a fatal symptom, but one calling for operative interference.

Treatment.—The treatment of hip-joint disease should include the employment of constitutional remedies, together with efficient local measures. Improved hygiene, abundance of sleep, and liberal diet, should be included in the general management of the case. Constitutional medication includes the use of tonics, especially iron and hypophosphites, alteratives, such as cod-liver oil, iodin and its salts. A change of climate is sometimes recommended, but with discretion, the seashore being best suited to the late suppurative stages, and the mountains for the same type of phthisical cases that are improved by an increased altitude—viz., during the first stage or in nonsuppurative cases.

Local medication is of no value. A hot-water bag may give temporary relief to pain but efficient mechanical treatment is more to be relied upon. Bier's congestion treatment, while difficult of application to this part, is always indicated in this form of disease.

Special Treatment.—The special treatment of hip-joint disease may be divided as follows:

A. Mechanic Treatment.
1. Recumbency.
2. Fixation.
3. Traction.

B. Treatment of Complications.
1. Abscesses.
2. Deformity.

C. Surgical Treatment.
1. Aspiration.
2. Incision.
3. Erasion.
4. Excision.

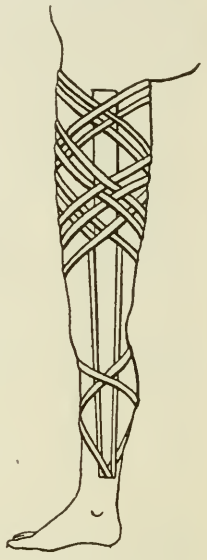
Mechanic Treatment.—Recumbency as a mode of treatment is employed by all orthopedic surgeons, the only difference of opinion being as to the length of time during which patients should be confined to bed. The appearance of complications—*i. e.*, abscesses or deformity—is an indication for bed treatment; but in the absence of these, two or three weeks are often sufficient, especially if a traction splint is applied while the patient is in the recumbent position. Fixation of the joints by means of splints is recognized as an important principle in the treatment of this disease, but almost all surgeons agree on the superior advantage of traction, with or without fixation. The expectant plan of treatment, without the use of apparatus, has now become obsolete, and science and humanity both demand that, as soon as a correct diagnosis is made, expectant methods should be abandoned, and that fixation or traction, or both, should be employed. Traction methods are undoubtedly preferable. The advantages of the traction methods are threefold: (1) A shorter time for cure; (2) a diminished number of abscesses; (3) a perfect recovery.

1. A shorter time will be required if traction methods are continuously employed from the beginning to the end of the treatment, because of the earlier relief, the less frequent relapses, and the smaller number of abscesses and other complications.

2. Comparison of the methods employed abroad with our own shows a much larger number of abscesses in Europe.

3. When continuous traction methods are employed, perfect recovery may be more confidently expected in a large numbr of cases. Different types of disease must be recognized, and the arthritic variety is more amenable to treatment than either of the others; but notwithstanding this, the most favorable variety will be conducted to the better termination, more quickly, and with a greater hope of a perfect result by the use of traction methods.

Adhesive Plaster Cut for Extension.



Extension Adhesive Plaster Applied.

Cases in which perfect motion has been obtained, with a fraction of an inch of shortening, and without deformity—ideal results—have been frequently reported.

Continuous traction can best be accomplished by dividing the treatment into 4 parts:

(1) Bed traction; (2) the traction splint with crutches; (3) the traction splint alone; (4) the traction splint as a protective apparatus.

1. Traction may be employed while the patient is in bed by using the ordinary Buck's method for fracture of the femur; applied by means of Z-O plaster; or the Sayre extension may be used, made of heavy adhesive plaster (manufactured by Maws, of London, or Shivers, of Philadelphia). The plaster is so cut that there are 5 pieces or tails, radiating from the narrow end, to which the buckles are attached. It is applied by lacing and crossing these ends over one another up the limb, and is secured with a muslin bandage. By means of a short leather strap, from 3 to 6 pounds extension is made. Bed extension is only employed during acute exacerbation, and only for a limited period—for 1 or 2 weeks or until the acute symptoms have subsided.

2. The traction splint is adjusted, as described in all systematic works, by securing the waist-band, buckling the perineal straps, attaching the straps of the foot-piece to the leg extension, and, by means of the ratchet and key, making extension until a comfortable amount of traction has been made. Motion should be restricted at the pelvic joint, and the apparatus must be applied and traction made in the direction of the axis of deformity. If the case has been treated thoroughly and efficiently from the commencement of the attack, deformity

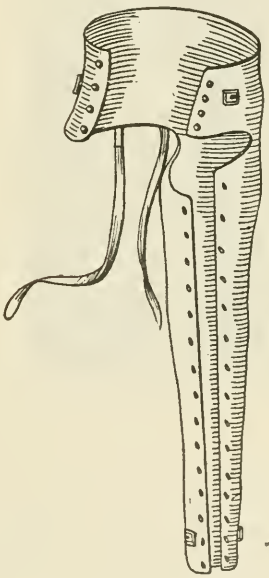
Traction Splint Applied as in Third Part of the Plan of Treatment.

will be avoided, or if an acute attack occurs, with pain, flexion, and adduction of the limb, the patient should be at once placed in the recumbent position until it has subsided. The foot-piece should extend sufficiently below the shoe on the diseased side to allow the foot to swing clear, and a high shoe should be worn on the sound limb, sufficiently high to allow the brace to swing clear (about 3 inches) when the child walks on crutches. The brace-crutch treatment is employed until all evidence of acute disease has disappeared, or for from 6 to 8 months.

3. At the end of this period the crutches are discarded and a shoe about 1 1/2 inches high is worn on the sound side to equalize the length of the limbs, and the child walks on the traction splint.

4. After a variable period, ranging from 1 to 2 years, the high shoe is altogether discarded, and the foot-piece is fitted close to the shoe of the affected side, the perineal straps are loosened, but are still worn, and the patient continues the use of the traction splint, as a protective brace only. This should be worn for at least a year after the cure has been established, to prevent relapse. The treatment by the plaster spica with a high shoe on the sound side and crutches is all that is needed in many cases and will be found to secure as brilliant results as any other method in proper cases. The "weight-bearing" method of the European surgeons is likewise efficient in those cases where the tendency to breaking down is absent but there is no doubt that this method promiscuously applied is more destructive and more frequently followed by abscesses than those of fixation and traction.

Treatment of Complications.—In regard to the treatment of abscesses much difference of opinion exists among orthopedic authorities, some incising all abscesses early, and others permitting spontaneous absorption or rupture in all cases. The preferable course seems to be a middle one, the abscesses being incised when they increase rapidly in size or when they exhibit a tendency to burrow to great distances, or when they interfere with the health of the patient. Even in adopting this plan of treatment, most abscesses will require incision. Before incising an abscess connected with the hip-joint, permission should be obtained to proceed with whatever operation may be necessary. Great care should be taken to avoid pressure upon the abscess, unless an attempt is to be made to entirely remove the diseased parts; since the tuberculous germs may be disseminated throughout the body, and general tuberculosis or tubercular meningitis result. The cavity of the abscess should be washed with bichlorid solution 1 : 4000, or, if large, with a boric solution or sterile



Modified Plaster Cast Traction Splint.

Modified Traction Splint Applied.

water, 1 to 2 drams of sterilized iodoform oil, 5 to 10 percent, and the dressing to be completed with a sterile compress and bandage. The whole treatment will extend over a period of from 2 to 4 years.

For general use by practitioners who are unable to have special apparatus manufactured to suit each case, a simple and efficient plan of traction may readily be devised by means of a modified plaster cast. The adhesive plaster strips are first applied. The entire limb on the affected

side should be thoroughly padded with cotton batting, secured by a roller from the malleoli to the waist. This is best applied in the vertical position, with the patient standing on a chair and the limb swinging clear, or, better, resting on an inverted basin or dressing-stool, with the buttocks close to the edge of the bed and an assistant making firm traction. Before completing the cast, 6 buckles are incorporated in the dressing: 2 front and 2 back, each over the spinous processes, and 1 about 3 inches above each malleolus. These may be attached to strips of tin, leather, or webbing. The cast may be strengthened by strips of tin or by a wood bandage. It is then trimmed out around the perineum, and may be made removable by splitting down the front, binding, and adding eyelet hooks. Two perineal strips are attached to the buckles above and the extension strips are secured below, and by these means any amount of extension may be made. A cheap wooden patten on the sound foot and a pair of crutches complete an outfit with which hip-joint disease may be treated scientifically.

Excision of the Hip by Lateral Incision.

Same, Showing Degree of Motion.

The deformity of the thigh incidental to the disease may be overcome in the early stages by bed treatment with extension. In the later stages, when ankylosis, either fibrous or bony, is present, operative procedures will be necessary, and these may best be determined by skiagraphy. If the ankylosis is of the fibrous or false variety, it can be overcome by tenotomy, myotomy, or forcible correction; but none of these operations should be performed until the sinuses, if present, have been closed for one year. When true or bony ankylosis is present, the deformity can only be overcome by osteotomy or osteoclasis, the former operation being recommended. Several methods of osteotomy have been proposed, but the only one now in general use is the division of the femur below the trochanters, subcutaneously, with a saw, or what is known as Gant's operation, or by means of a chisel, as modified by Maunder. The operation of Adams through the neck of the bone is not suitable, and the operation of Barton between the trochanters does not give so good results as the one already recommended. After all operations for correction of bony ankylosis it must be remembered that the limb will remain fixed in the corrected position, and motion at the hip-joint must not be expected.

Surgical Treatment.—Aspiration of the abscess is not satisfactory, because the contents of the joint are not always sufficiently fluid to be removed in this manner. When the distention of the capsule is great in acute cases, aspiraton will occasionally arrest the disease, and always relieves the acute symptoms. It should always be performed under the strictest antiseptic precautions, and the wound should be hermetically sealed with iodoform collodion. The injection of iodoform oil in this joint has not been satisfactory, since it causes irritation and usually requires incision for its removal.

Simple incision of the joint is sometimes employed instead of aspiration, but has no particular advantage over the latter, except when the joint contents are thick. By far the best operation upon the hip-joint is that proposed and performed by De Forest Willard. It consists of an exploratory incision over the most dependent portion of the abscess, the removal with a heavy curet of "every particle of diseased tissue that can be reached," the insertion of rubber drainage-tubes, and the application of a large antiseptic dressing. This operation is as far in advance of formal excision to-day as excision was formerly in advance of amputation.

When the exploratory incision reveals too extensive areas of disease to remove by erasion, formal excision of the hip-joint will be required. The indications for this, at the present time, formidable operation are long-continued suppuration, extensive disease of the bone, and myeloid disease of the kidneys, as evidenced by albuminuria. The latter condition, it will be observed, is considered, at the present time, an indication for operation, and not a contraindication. X-ray photography is of considerable importance in deciding between erasion and excision. In considering the operation of incision it must not be forgotten that it is at least as fatal as the corresponding amputation. After this operation, and in performing it, every necessity for the comfort and safety of the patient must be at hand. After this operation motion is usually obtained.

HIPPOCRATIC FACIES.—See Face in Diagnosis.

HIPPOCRATIC OATH.—A solemn engagement entered into in ancient times by young men about beginning the practice of medicine, and especially by the Asclepiads. The formula itself has been ascribed to Hippocrates, and is certainly

very ancient. It was as follows: "I swear by Apollo the physician, by Æsculapius, by Hygeia, Panacea, and all the gods and goddesses, that, according to my ability and judgment, I will keep this oath and stipulation: to reckon him who teaches me this art equally dear to me with my parents; to share my substance with him, and relieve his necessities if required; to look upon his offspring upon the same footing as my own brothers, and to teach them this art, if they shall wish to learn it, without fee or stipulation; and that by precept, lecture, and every other mode of instruction I will impart a knowledge of this art to my own sons, to those of my teachers, and to disciples bound by a stipulation and oath according to the law of medicine, but to no others. I will follow that system of regimen which, according to my best judgment, I consider best for my patients, and abstain from whatever is injurious. I will give no deadly medicine to any one if asked, nor suggest any such counsel. Furthermore, I will not give to a woman an instrument to procure abortion. With purity and holiness will I pass my life and practise my art. I will not cut a person who is suffering with stone, but will leave this to be done by those who are practitioners of such work. Into whatever house I enter I will go for the advantage of the sick, and will abstain from every voluntary act of mischief and corruption, and, further, from the seduction of females or males, bond or free. Whatever in connection with my professional practice, or not in connection with it, I may see or hear, I will not divulge, holding that all such things should be kept secret. While I continue to keep this oath inviolate, may it be granted me to enjoy life and the practice of my art, respected always by all men; but should I break through and violate this oath, may the reverse be my lot."

This oath has not always been administered to practitioners in modern times (though something equivalent to it was used in the Middle Ages, and especially in the school of Salerno); but every honorable and right-minded physician governs his private and professional life by its noble principles. It is the oldest and one of the best of the codes of medical ethics.

HIPPUS.—Spasmodic pupillary movement. See PUPIL.

HIRSCHSPRUNG'S DISEASE (Idiopathic Dilatation of the Colon).—This may occur at any period of life, but it is usually of congenital origin and is most frequent in male infants. Although mild cases may remain stationary, the disease generally progresses and terminates, in from a few weeks to many years, in death from peritonitis, toxemia, or pneumonia. The whole colon, or only a part, usually the sigmoid, may be involved. The bowel is greatly dilated, hypertrophied, sometimes elongated, often kinked, and frequently contains stercoral ulcers, which on healing may lead to stenosis.

Symptoms are obstinate constipation (the bowels may not move for weeks), sometimes alternating with diarrhea; emaciation; possibly convulsions or tetany; ballooning of the abdomen; visible, audible, and palpable peristalsis; foreshortening of the thorax; flaring of the costal margins; and interference with the action of the heart and lungs from pressure

Treatment is at first medical, viz., liquid diet, tonics, strychnin, colonic lavage, electricity locally, and abdominal massage. If these measures fail appendicostomy and daily irrigations of the colon, short circuiting of the colon by ileosigmoidostomy, or excision of the colon or its most affected part may be performed. In desperate cases right inguinal colostomy is indicated, more radical measures being adopted after improvement has occurred (Stewart).

HIRSUTIES.—Hypertrichosis; hypertrichiasis; polytrichia; trichauxis. That condition in which the hairs of the body are increased in number or size, or grow in unusual situations, or in normal situations in unusual length or number. See HYPERTRICHOSIS.

HIVES.—A name loosely applied to almost any papular eruption of the skin. In Great Britain the term is applied to croup, laryngitis, and to chicken-pox; in the United States it is limited to a transitory form of URTICARIA (*q. v.*).

HOARHOUND.—See MARRUBIUM.

HOARSENESS.—Harshness of the voice depending on some abnormal condition of the larynx or throat.—See DYSPHONIA, LARYNGITIS.

HODGKIN'S DISEASE.—See LYMPHADENOMA.

HOLADIN.—An extract of the entire pancreas, capable of digesting starch and proteids and splitting up fats. It is recommended in the treatment of indigestion. Dose, one capsule (containing 3 grains).

HOLOCAIN.—An efficient local anesthetic and germicide. Many observers report that it is superior to cocain in nearly all operations upon the eye. It has apparently little or no effect on the conjunctival vessels, iris, or ciliary muscle. The hydrochlorid is used in 1 percent solutions. Hotz says that it is more painful and irritating to the conjunctiva than cocain. Its antiseptic properties are greatly in its favor. It has been used with success in the treatment of suppurative keratitis.

HOMATROPIN.—Hydrobromid of homatropin, a derivative of atropin, has of late years been extensively used as a means of suspending the accommodation. (Note that *homatropin slows* the heart; *atropin quickens* it.) It is likely, to a great extent, to supplant all other mydriatics in ordinary refraction work, as, while equally efficient when used correctly, its effects last less than one-fourth as long as those of atropin, and about half as long as those of duboisin, and there is little danger of inconvenience from constitutional poisoning. Conjunctival hyperemia and a slight burning sensation usually follow its use, but are much less marked now than at the time of its first introduction, probably on account of improvement in the process of manufacture. Again, these can, in a great degree, be offset by the use of cocain. Homatropin, as a mydriatic and cycloplegic, is especially serviceable in office practice, in which it is often desirable that the

paralysis of accommodation shall not extend over 1 or 2 days. In such cases it should be prescribed:

℞.	Homatropin hydrobromid,	gr. j
	Cocain hydrochlorid,	gr. ss
	Distilled water,	℥ j.

Before refraction, 1 drop of this solution should be used in each of the eyes, 5 or 6 times, at intervals of 10 minutes. The accommodation usually returns by the end of the second day.

HOMESICKNESS.—See NOSTALGIA.

HONEY.—See MEL.

HOOK-WORM DISEASE.—Hook-worm disease is the most common of all of the serious maladies of the South. It occurs in the majority of people in many localities, while in others it is scarcely found at all. Associated almost always in its severest forms with poverty, it is peculiarly a malady to which the poor mountaineers and the equally poverty-stricken inhabitants of other portions are particularly susceptible. As might be expected from its African origin, the disease is

HOOK-WORM, NATURAL SIZE. The smaller is the male.

most common where the negro has been most numerous. Through ages of infection the black man has acquired an almost perfect racial immunity from the effects of the parasite, but this in no way interfered with the fact that he frequently harbors a considerable number of the worms. The negro coming in contact particularly with the poorer class of white persons, the disease was quickly transferred to the latter, and the parasite, sapping the life and vitality of its new host, for the most part prevented normal, mental and physical development, and precluded in many cases the possibility of further advance in life. As a consequence of this, particularly in extreme southern Georgia, and in the lower portions of neighboring southern states, there are up to this day communities of "dirt-eaters," who present the very lowest type of the white race in America. In such communities it is safe to say that practically the entire population is hook-worm diseased. A few miles away the large planter is probably himself entirely free from the infection; his bare-foot children may harbor a greater or less number of the parasites but are rarely or never badly infected, and subsequent to their adoption of shoes—no re-infection taking place, and the worms already in their intestinal tracts dying off—become entirely normal in a few years. So also is it true that in the village not far away the children, owing to the general use of the toilet, are but little infected. It is thus that we have in the same locality communities in which the percentage of hook-worm subjects would run well up into the nineties, and others where the disease practically does not exist. As Dr. Stiles has shown, very soon after the poor whites commence work in the cotton mills they begin to improve, and in a few years practically lose their hook-worm infection. Therefore, in the south, child-labor in mills is the greatest possible existing boon to this class, and instead of being condemned it should be encouraged in every possible way.

History.—As has so often been found where parasites of this class are concerned, members of the genus were first discovered in the lower animals. Goeze, in 1792, first described the parasite his observations having been made on the particular species of hook-worm that inhabits the intestinal tract of the common badger. Seven years later Froelich discovered a somewhat similar worm in the intestinal tract of a fox. He named the parasite "Haakenwurm," or "hook-worm." He it was also who originated the name "Uncinaria" the same being the zoological name for the genus in which this worm, along with many other allied species, is still included by most writers.

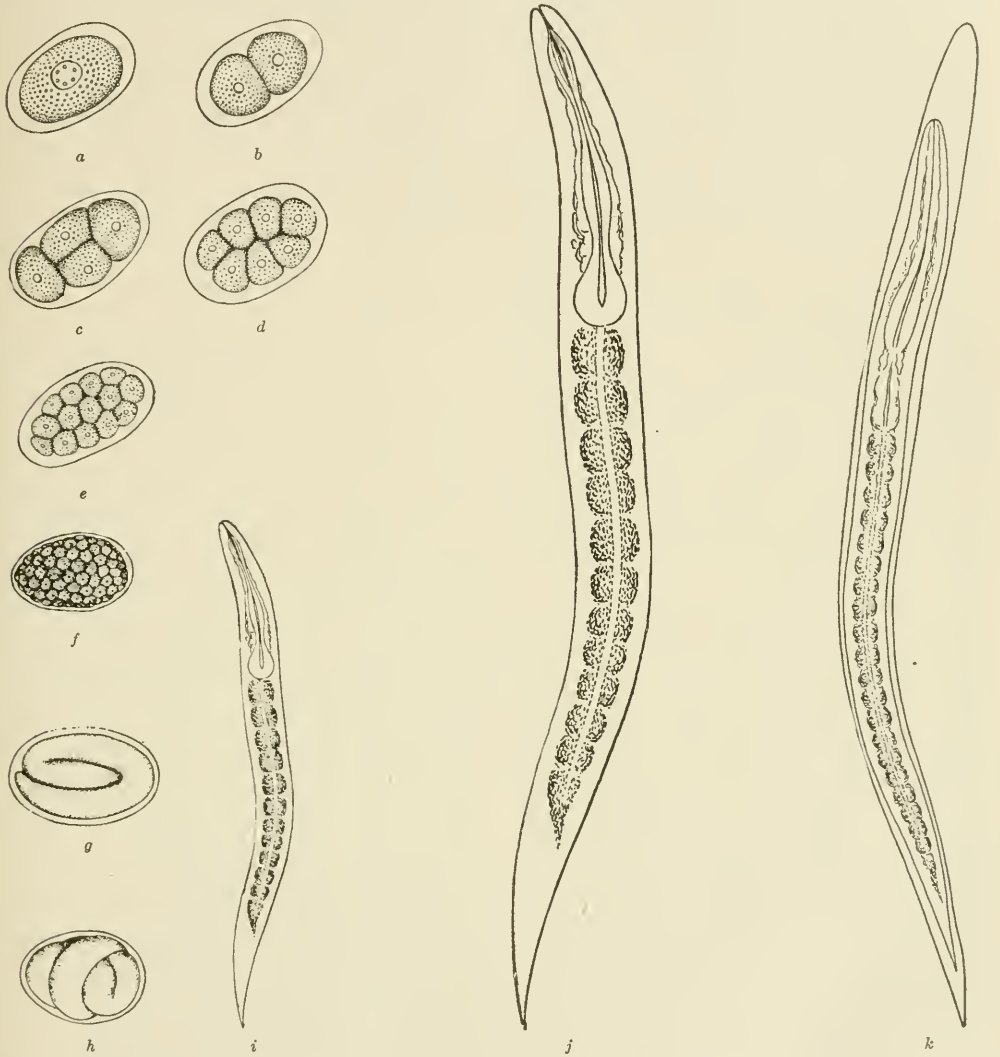
This worm was first observed as a human parasite in 1838 by Dubini, and six years later he described it under the name of Ankylostoma duodenale. This observer did not succeed in establishing thoroughly the relationship between the worm and its ill-effects, though he recognized the great probability of its evil influence upon its host. Ten years later it was, however, clearly demonstrated, by both Bilharz and Griesinger that the profound anemia so common in northern Africa and known as "Egyptian chlorosis," was unquestionably produced by the parasite. In 1879 it was shown that laborers working on the St. Gotthardt tunnel were almost all infected with the worm, and Perroncito, who discovered this fact, also demonstrated that the disease prevailed in the mountains of northern Italy to a considerable extent, being commonly called "mountain cachexia" or "mine anemia."

Following these observations reports became more numerous, until at the present time we have a vast literature on the subject, coming from almost every place on the globe, where the climatic conditions favor the development of the worm.

The first case of hook-worm disease in this country, where the diagnosis was definitely established, was that reported by Blickhahn in 1893. This was followed by publications from a large number of American observers, resulting during the next ten years in demonstrating beyond question that this disease was exceedingly frequent in the southern portion of the United States. It was shown in 1902, by Stiles, that the parasite commonly found in America differs in some minor particulars from those found in Egypt and in southern Europe, and this writer therefore gave, to what was supposed to be our new-world species of the worm, the name of Uncinaria Americana. In 1903 Stiles, on account of the peculiarities presented by the worm, as found here, proposed to make a new genus for it, and renamed it the Necator Americanus. It has been shown by Loos that this so-called American hook-worm is largely present in many of the negroes of southern Africa; and there can scarcely longer remain a doubt that it was brought over by slaves, and should therefore rather have been called Necator Africanus.

Natural History of the Parasite.—The hook-

worm belongs to the order of nematodes or round worms, being related to and much resembling the small "thread-" or; "pin-worm." The two parasites present marked differences, however, which may be detected by the naked eye of one well acquainted with their peculiarities; microscopically they differ still more. Like the pin-worm, the hook-worm is comparatively small, and in the the male. The former varies in length from 11 to 14.5 mm. (average 13.87 mm.); at their thickest portion they are from 0.41 to 0.60 mm. (average 0.509 mm.); the male is from 8 to 10 mm. in length (average 8.8 mm.); at their widest portions they are from 0.30 to 0.39 mm. (average 0.343 mm.). The worm tapers toward either end, and at the cephalic extremity both sexes have about



a, Newly-laid egg. *b*. Beginning segmentation. *c*. Egg, further stage segmentation; *d*. *e*. Advanced stage segmentation. *f*. Preceding formation embryo. *g*. Embryo in first stage. *h*. Embryo just before leaving shell. *i*. Embryo after leaving shell. *j*. Embryo several days old. *k*. Embryo covered by chitinous envelope in stage to infect.

perfectly fresh state the parasite is often of a pinkish-gray color; after death, however, it generally assumes a dull grayish tint. Unlike the pin-worm this parasite is not found except in extremely rare instances in the feces, and their presence in the stools therefore plays no part in making the diagnosis of the disease.

The Necator Americanus is comparatively small, the adult female being always larger than the same diameter (0.088 to 0.132 mm.). The neck of the parasite makes a rather abrupt backward curve as the head is approached, with the result that in order to see into its mouth the worm must be viewed from its posterior aspect. When examined with a comparatively low power of the microscope, the mouth is found to be somewhat ellipsoidal in shape with the long axis anteroposteriorly. The opening is surrounded by a con-

tinuation of the chitinous envelope that covers the body. Projecting into the cavity from its antero-lateral margins there are two plates, separated from each other in the median line, which are known as the "ventral lips." Posteriorly, there is a tooth-like projection in the cavity which is known as "dorsal conical tooth," and just posterior to this there is a single plate which is known as the "dorsal lip." At a still greater depth in the cavity there are found several tooth-like structures which subserve the purpose of grasping the mucous membrane of the intestines, which is sucked into the mouth of the parasite; the structures just referred to in the anterior portion of the cavity are known as "ventral lancets," while those that are situated farther back are called "lateral lancets." The ducts of the esophageal gland unite at the base of the dorsal conical tooth, and a common duct is formed which is conducted through this tooth and opens at its free extremity—furnishing a device for injecting a probably poisonous secretion of the glands just referred to, closely resembling a similar arrangement observed in the teeth of venomous serpents.

Back of the head, and in close proximity to the esophageal mouth of the worm there is a mass of glandular structures called "head glands;" these apparently differ somewhat from the esophageal glands that lie posterior to them, but with which they are intimately connected anatomically. Still further back on either side of the esophagus lie the cervical glands, the duct of which opens on either side of the parasite's neck at some little distance from the head.

The vulva of the female worm is situated on the abdominal surface somewhat anterior to the middle portion of the parasite's body. The anal opening in both sexes is on the ventral surface near the termination of the tail.

Eggs.—The eggs of this hook-worm appear to be somewhat larger than those of the old-world species, Harris having found from a large number of measurements that they vary in length from 57.5 to 80 μ and from 35 to 52.5 μ in diameter (the average being 66.52 μ and 42.53 μ respectively). The eggs, as encountered in the feces, are oval in shape, and are covered externally by an extremely thin shell which is perfectly transparent. Between the solid contents of the eggs and the capsule, there intervenes a clear space, which is doubtless filled with fluids. When the eggs are perfectly fresh some of them contain a single granular body within their centers, within which there is a nucleus. In most instances, however, as a result of rapid multiplication, there are a number of these cell-like structures. At the proper temperature and in the presence of moisture the granular bodies within the eggs rapidly increase in number, and in 24 to 36 hours completely fill the egg cavity; shortly following this the embryo takes form, and we find in the place of the pre-existing structures within the egg a minute snake-like worm, which exhibits more or less active movement. Quickly following this the capsule of the egg bursts, and the embryo is liberated, coming out tail first.

While it is true that the eggs of the pin-worm somewhat resemble those of the parasite in question, one acquainted with the peculiarities of both would have no difficulty in distinguishing between them. The former are decidedly smaller, their shells have a double contour, they are usually somewhat flattened on one side, and frequently contain live embryos. It is furthermore true that the eggs of the hook-worm are only seen in the rarest instances in the feces—even though the parasite may exist in great numbers in the intestine of the individual—and confounding the two is therefore almost out of the question.

Embryo.—There is nothing more curious than the development of the embryo and its subsequent invasion of the human body. In fact, the method of infection is so extraordinary that when it was first announced by Loos, scientific men of all classes received it with almost universal incredulity. However, in a short time the facts in connection with it were so clearly demonstrated that there could be no longer room for doubt.

There are certain conditions necessary for the development of the eggs of this parasite after they have passed from the infected individual. There must be, to begin with, a temperature sufficiently high. The eggs do not appear to hatch to any extent below 70° F. Harris found the most suitable temperature to be between 80° and 90° F., though growth may undoubtedly occur at a still greater heat. Quite as important as the proper temperature is the admission of oxygen to the eggs, which is brought about by the feces being washed over the surface of the ground by rains, and also, by the activities of the larvæ of various flies. It is also essential that the eggs remain moist; but if they are covered entirely by water, oxygen is excluded, and they undergo degenerative changes and die within a few days when the temperature is high. Thus the requisites are a summer temperature, admission of oxygen, and a certain amount of moisture. All three of these conditions are ideally present during a greater part of the year in the South. Under such conditions there may be observed within the eggs in 12 to 36 hours, a curious snake-like body, the "embryo," which soon forces its way through the thin shell of the egg, and then burrows into the neighboring earth. When the next rain occurs, or when dew-drops collect, this tiny little creature quickly finds its way into the water, where it remains (if the water does not dry up) until the development necessary for penetrating the human body is completed. When the dew-drops dry or the pool of water evaporates the embryo burrows into the moist earth, there remaining until a fresh down-pour of water beckons it to the surface again.

When the embryo emerges from the egg it has a length of from 350 to 400 μ but in a week or so it grows to a length of 600 to 700 μ with diameters at their widest portion of from 25 to 30 μ. The worm at this stage possesses the power of very active movement. Externally it is covered by a transparent chitinous membrane about 5 μ in thickness, through which the comparatively simple

structure of the internal portion of the parasite may be observed. In a few days after the larva is hatched the body recedes from its outer covering, and a second membrane is formed over the external surface of the worm. Between the outer covering and the second one formed internal to it there is a clear space within which the worm moves. The entire body is still capable of active movement, though this is never so active as before.

The body of the parasite now undergoes a change in form; from rhabditiform it gradually becomes filariform in appearance. During this period, (6 to 10 days), the embryo molts again—there being formed a second covering that detaches itself from the body of the parasite, and which may be seen within the outermost covering already referred to, as the latter is not usually shed off at once. At this stage the embryo is "ripe" and is ready to infect, but under *proper* conditions may live for months in dew-drops, pools of water or in the moist earth. It is capable of migrating to quite a distance as compared with its microscopic size, it having been shown that on the sides of moist tunnels the embryo may crawl up to a height of at least six feet. For a long time it has been known that, when these embryos were swallowed infection with the hook-worm results, but it was only a few years ago that Loos suggested the astounding probability that they may actually penetrate through the skin of the human being, and ultimately find their way to the intestinal tract. Shortly after this Bentley made the observation that hook-worm disease and ground-itch were both exceedingly common among the coolies of India, and that the earth in the neighborhood of their habitations simply swarmed with the embryos of the hook-worm. Exposing the skin of individuals to earth containing these immature parasites, he observed that this was followed by typical ground-itch, and that at the same time all of the embryos disappeared from the earth that was being applied. He therefore concluded that it was not improbable that ground-itch was due to some action of the hook-worm embryo. Still later Loos established by actual microscopic demonstration that the young of the hook-worm are capable of penetrating the skin of man and of animals, and he eventually showed that when inoculated on the skin of the dog they pursue the following extraordinary course. After quickly boring through the skin and deeper tissues, they work their way through the lymphatics into the general blood-current, or bore directly into the smaller blood-vessels. Moving with the blood-current they pass to the heart, and are thence pumped into the smaller vessels of the lungs; here they penetrate the air-sacs, and thence make their way into the smaller bronchial tubes, then the larger ones, and finally crawl from the trachea into the throat. They are then swallowed, and passing along with the food quickly reach the small intestine, where they immediately grasp the mucous membrane with their mouths, which, being especially adapted to sucking and hanging on to any tissues that they may find congenial, they hold on to without difficulty. The parasite grows rapidly and in six or eight weeks is fully mature, after which the females begin to lay eggs, and the curious life cycle begins over again. The average life of the parasite is not definitely known; probably it is not less than six or eight years, and in some instances even considerably longer. Some of these worms appear to cause much severer disturbances in the body than others, since it is found that some persons with a comparatively small infection of the parasites suffer much more than those who harbor a considerably greater number. This must be due either to some of the worms being more virulent than others, or to certain persons being more susceptible to their disease-producing power. It is generally believed that the parasite not only acts by sucking blood, but that it secretes a poison, which, being constantly injected into the mucous membrane of the intestine, is responsible for much of the damage.

Symptomatology.—As would naturally be inferred, hook-worm disease is most common in those who come in most intimate contact with the ground. As going barefoot is an almost universal practice among children of the South, they are the ones who suffer most. Exceptionally the disease is encountered in adults, and even in persons advanced in life. The vast majority of typical hook-worm subjects are children from three to four years of age to the time when they begin to wear shoes and cease to play on the ground. As the worm, however, unquestionably lives a number of years, young persons up into the twenties commonly show more or less clearly the results of the presence of the parasites, and their stools contain eggs of these worms.

As has already been said, in the majority of instances ground-itch is the first clinical manifestation of this affection. Where, however, the number of embryos entering the body is small, no perceptible results are seen on the skin. It is not improbable that quite a number of persons, particularly in later life, get the disease very slowly, only a few of the embryos entering the body at intervals during the summer months.

The most pronounced effect of the presence of the hook-worm is a profound anemia, indicated by a dry, harsh, pale, yellowish skin and bloodless lips. It is not uncommon to find the blood reduced one-half or two-thirds in richness, and as a consequence of this the unfortunate victim suffers a multitude of ill-effects throughout his entire body. One of the most notable consequences is that the boy or girl fails to grow—it being quite common to see a young man from fifteen to twenty years of age who has the appearance of not being more than eight or ten. The individual remains a child mentally as well as physically. The tissues are relaxed, as shown by the giving way of the abdominal walls, and abnormal protrusion of the belly. As the malady progresses there is more or less dropsy in severe cases, accompanied by shortness of breath and great weakness. Ulcers may develop on the front of the legs. The patient presents a sad, hopeless countenance, it being evident that he is suffering from some serious malady. Those affected with this disease

lack energy as other sick persons do, but they are not lazy.

Diagnosis.—This is readily determined by microscopical examination of the feces, as the eggs are, as a rule, very numerous, although where the number of the worms is small a more careful study of the specimen is necessary. In the laboratories of the State Boards of Health in the South, the services of a skilled microscopist can be secured free of cost. Before treatment is undertaken the feces should always be carefully examined for the eggs of the parasite, as otherwise mistakes will arise; for, while the disease is clinically very characteristic, there are other affections that much resemble it—notably chlorosis and chronic malaria.

Prophylaxis.—Those suffering from the malady should at once be treated, because, as has already been explained, they are sources from which the disease spreads to their associates, and even back to themselves. This treatment should be carried out as far as possible in the fall, winter and spring months, since to do this in the summer (the ground around the farm houses by this time swarming with the embryos) would often result only in temporarily freeing those affected by the parasite. The eggs do not hatch in cool weather, nor is it probable that the embryos survive the cold that accompanies the winter months in the greater portion of the South. As a consequence patients treated during this period could not reinfect the ground, and the parasites not living from one summer to the next the disease would be thoroughly eradicated. Where these precautions are not taken, great care should be exercised in preventing those living in localities known to be infected from coming into direct contact with dew-drops, pools of water on the ground, or moist earth. All should wear shoes, and children should not be allowed to play out of doors at some distance from the house. Of course the most important of all preventive means is to have a toilet, particularly for the children. Indiscriminate scattering of fecal material is responsible for the prevalence of this disease, and the most stringent rules should be adopted looking toward the correction of this great unhygienic nuisance. Not only does hook-worm disease (but other affections, such as typhoid fever and dysentery) spread as a consequence of this very common practice, and there is consequently no sanitary advance that would be of so much importance to our people as providing a properly constructed water-closet in every home, schoolhouse and church, and insisting on its being used. It is also of importance that the flies be completely excluded from the toilet, and we should therefore do away with the present methods employed in constructing them. The feces should be received into some proper receptacle completely protected from flies and all animals, and at proper intervals the contents should be carried to a suitable place and buried. Precautions of this kind are unquestionably more or less troublesome, but the time consumed would in no way compare with the suffering, invalidism, and death and pecuniary loss that result from the present indifference.

Treatment.—When the more highly organized animal parasites occur in the human intestine we have in several instances drugs that kill the infective agent without seriously disturbing the general health of the patient, and most happily the hook-worm is one of the organisms that is most easily destroyed and removed in this way. On the day before the treatment is to be begun the patient is advised to eat little dinner and no supper at all. Late in the afternoon he is given a full dose of calomel (2 to 10 grains, depending upon the age and strength of the patient). Castor oil is not generally advised as all oily substances dissolve and make more readily absorbable the thymol which is to be given on the following day, and might in this way cause unpleasant effects. If the calomel does not act freely during the night a full dose of Epsom salts in hot water should be given as soon as the patient wakes up the next morning. After the bowels have thoroughly acted, finely powdered thymol in capsule is then given—the quantity depending on the age and strength of the patient (the apparent age rather than that stated by the patient, since many of these unfortunates appear 6 to 10 years younger than they really are). The dose of thymol should be divided into two equal parts, the first half being given at once and the second at the expiration of an hour. Following the administration of the medicine the patient should be instructed to remain in bed, lying on the right side to more or less assist the drug to pass quickly into the intestine from the stomach. Harris suggests that the drug should be given in the following quantities:

Up to 5 years of age,	10 to 15 grains.
From 5 to 10 years,	15 to 30 grains.
Ten to 15 years,	30 to 60 grains.
Fifteen and over,	60 to 120 grains.

In advanced age the quantity should be somewhat less than during middle life.

The patient should be allowed no breakfast and no dinner on the day of treatment, and it is not wise for him to take more liquids than absolutely necessary. A cup of coffee once or more during the day is permissible, but nothing in the nature of food should be allowed. If the patient experiences no ill effects from the thymol, it is well to put off the administration of a laxative until four or five o'clock in the afternoon, at which time some saline should be administered in hot water. After the bowels have acted well the patient may be allowed to have food.

When the treatment is carried out faithfully in the way just described it is rarely necessary to repeat it. It is, however, well after a couple of weeks to again make a thorough examination of the feces, and should the microscope reveal the presence of eggs the treatment should be repeated, and this should be done over and over again until exhaustive examinations of the feces show by absence of the eggs of the parasite that all have been expelled.

Castor oil should not be used as a purgative on the day of treatment, as it might produce poisonous effects by dissolving the thymol and aiding its absorption; alcoholic drinks should not be taken

in any form, as they act in the same manner as castor oil. It cannot be too strongly insisted upon that the drugs that kill the hook-worm might, under certain circumstances, kill the patient, and it is of the utmost importance that these medicaments be given by an experienced physician.

There are still other drugs that are more or less employed for the purpose of killing this parasite, betanaphthol especially being used by many physicians. In doses of from 30 to 60 grains it is said to act quite as well as thymol.

Iron and tonics following the administration of the thymol are of no particular value.

The public should be especially warned against patent and proprietary medicines for hook-worm disease, as they all have as a basis thymol, betanaphthol or some other drugs with more or less poisonous properties, and are therefore unsafe in the hands of those unacquainted with their proper use.

HOOPING-COUGH.—See Whooping-cough.

HOPS (Humulus).—The dried strobiles of *Humulus lupulus*. Its constituents are a liquid volatile alkaloid named *lupulin*, a volatile oil, which consists in part of *valerol* and *trimethylamin*, the crystalline, bitter principle *lupulinic acid*, also wax, resin, and tannin. Except the last named, the constituents are most abundant in the glandular powder of the strobiles, which is named *lupulin*. Dose, 10 to 45 grains. It is a bitter stomachic tonic and feeble hypnotic, increasing the cardiac action. A poultice of hops is a favorite remedy for painful conditions and in inflammations. **H., Infusum,** unof., 1/2 of an ounce to the pint. **Fluidextractum H.** Dose, 5 to 15 minims. **Lupulinum,** *lupulin*, is the glandular powder separated from the strobiles, of bright, brownish-yellow color, aromatic and bitter taste. The volatile oil exists in the Lupulin grains, and contains *valerol*, which is changed by long exposure, giving a disagreeable odor to old hops. Dose, 5 to 15 grains. **Oleoresina Lupulini,** *oleoresin of lupulin* an acetone extract. Dose, 2 to 5 grains.

HORDEOLUM.—See Stye.

HORMONES.—Internal secretions. The name applied by Starling and Bayliss to "chemical messengers" from one organ to another which effect a correlation of the functions of the organs concerned

HOSPITAL GANGRENE.—See Gangrene.

HOT-AIR TREATMENT.—In the treatment of lumbago, acute sprains, particularly of the ankle-joint, hot air is commendable. In acute articular rheumatism excellent results may be obtained, and in stiff and contracted joints, it is of great value. In chronic joint affections and in open ulcerations due to infection, whether from the bacilli of tuberculosis or otherwise, passive hyperemia as advocated by Bier is preferable.

In experiments on animals the jet of hot air from a Holländer apparatus, directed upon the bleeding surface of a kidney, liver, or severed blood-vessel, will arrest the hemorrhage by the formation of an eschar commencing around the edges and gradually spreading over the entire surface, mechanically checking the flow, and Schneider concludes that it would be equally effective on man. The heat is only 39° C. at 5 mm. from the apparatus, and hence is not sufficient to injure the organ. For several reasons Schneider found steam less effective and less convenient, masking the field of operation, etc.

An apparatus for the treatment of joints consists of a cylinder-shaped oven, lined with asbestos, on the bottom of which rests a radiator to distribute the heat equally. Above the radiator swings a hammock, upon which the limb is placed for the bath of hot air. At one end variously shaped sleeves are attached to take in or cover any part of the body. The other end of the oven is detachable, so that in case of overheating it can be quickly removed and the temperature instantly lowered. Two dampers regulate the heat, and removal of the end is therefore rarely necessary. Wood alcohol, gas or electricity may be used to generate the heat. The part to be treated is thoroughly covered with double thicknesses of a Turkish towel or blanket to protect the skin from too intense heat radiation and to absorb the moisture from the profuse sweating that ensues. The sensations of the patient are the sole guide to the degree of temperature to be administered, stopping short of discomfort. Pain requires the lowering of the temperature by the dampers or removal of the end.

The duration of a bath is usually about an hour, unless special contraindications exist. Higher temperatures can be obtained after the second or third bath, but there is great difference in the degrees of heat tolerated. Two hundred degrees Fahrenheit may be easily reached, and 410° F. at the elbow has been employed. The average temperature is 300° to 350° F. At about 20-minute intervals the parts are thoroughly wiped dry to avoid the possibility of a superficial burn.

Generally, in acute and painful affections, baths of hot air may be given every day or every other day. Chronic cases are treated less frequently. In acute sprains, as of the ankle, the hot-air bath, pushed to tolerance, should relieve all pain; a firm bandage or stockinet is afterward applied to give support and to enable the patient to walk. In large effusions 2 to 4 daily baths may suffice to allow of bandaging and walking. The hot-air treatment of joints renders them flexible, so there is no tendency to contracture; and in contracted joints it softens up the adhesions, and manipulation immediately after each bath can be easily given. The temperature of the body is slightly elevated and the pulse and respiration slightly increased during the administration of a hot-air bath.

Frazier gives the following conclusions as to the physiologic effects of hot air: (1) Temporarily increased circulation, respiration and fever; (2) moderate local anesthesia; (3) loss of weight, probaby due to loss of water from the skin and lungs; (4) a decreased nitrogenous output; (5) the effects of hot-air baths are purely local in origin. See Bier's Hyperemic Treatment.

HOT-PACK.—In giving a **hot-blanket pack** a rubber sheet and 1 or 2 woolen blankets are placed upon the bed. A heavy woolen blanket is wrung

out of water at 110° F., spread upon the dry blanket, and the patient is placed upon it and wrapped in it like a mummy. The dry blankets and rubber sheet are wrapped over this, and the patient is allowed to remain in this pack from 1/2 to 2 hours. It is useful in suppression of urine.

In **hot wet pack**, instead of wringing the linen sheet out of cold water, as in the wet pack, it is dipped into water at 110° F., well wrung out, and spread upon the blanket, as in the cold pack. The patient is wrapped in this and allowed to remain for an hour. Then he is removed to the side of the bed upon which he is to lie, lightly rubbed over with a rough wash-rag that has been dipped into water at 65° F. and squeezed out by the hand, quickly dried, and left in place. This method is useful only in obstinate insomnia.

HOUSEHOLD DISINFECTION.—See Disinfection.

HOUSEMAID'S KNEE.—A bursitis of the prepatellar bursa in which thickening and enlargement of the bursa have ensued from intermittent pressure made upon it. It derived its name from its former frequency among housemaids. It is usually chronic, but may be acute. It causes great pain and swelling; it differs from inflammation of the synovial membrane by the swelling being most superficial, and in being in front of the patella, which is obscured by it: in inflammation of the synovial membrane of the knee the patella is thrown forward and the swelling is most prominent at the sides.

Treatment.—When simply enlarged, painting with the tincture or liniment of iodin, or strapping, will sometimes disperse it. Aspiration may be employed, but incision, removal of the fluid, and drainage with aseptic dressing is better. Rest, leeches, and blistering are other means of early treatment. When greatly thickened, or when solid, the bursa and sac must be removed by dissection.

HUMERUS.—See Arm, Shoulder.

HUMULUS.—See Hops.

HUNGER.—A condition marked by a sensation of emptiness of the stomach with intense desire for food. In hunger there is great uneasiness in the epigastrium, which becomes a sinking if prolonged, and is accompanied by insatiable thirst. If fluid is withheld, the thirst becomes the chief source of distress, the face becomes pale and cadaverous, and the eyes appear maniacal, When prolonged still further, there is failure of mental power, and sometimes delirium supervenes. When hunger is exaggerated, it is known as *bulimia*, as in diabetes mellitus. It may be temporary or permanent, and in the latter case it is obstinate, weakening, and unpleasant. It may occur alone or be a symptom of various diseases of the nervous system. It is common in hysteria.

Intense hunger of temporary duration is generally present in convalescence from acute disease. Hunger may accompany migraine, hypochondriasis, and exophthalmic goiter. See Anorexia, Bulimia, Fasting, Gastric Neuroses.

HUTCHINSON'S TEETH.—See Teeth in Diagnosis.

HUNTINGTON'S CHOREA.—See Chorea.

HUXHAM'S TINCTURE.—An unofficial preparation of cinchona bark originally compounded in 1788, and still used. Its composition is as follows:

℞.	Red cinchona,	ʒ iv
	Orange peel,	ʒ iij
	Serpentaria,	gr. lxxx
	Spanish saffron,	gr. clx
	Cochineal,	gr. lxxx
	Brandy,	ʒ xl.

Digested for 4 days, expressed, and filtered, Dose, 1/2 to 2 drams.

It is a most efficient bitter tonic in debility and convalescence from low fevers, but is too weak to be used in malarial poisoning. See Cinchona.

HYDATID.—A cyst with aqueous contents, formed by the larva of a small tape-worm, Tænia echinococcus, which in its adult condition is known to infest only the dog and the wolf, while the larvæ (hydatids) are of frequent occurrence in man and other mammals. Three principal forms of hydatids are recognized: viz., exogenous, endogenous, and multilocular. The first is rarely found in man, but is extremely common in the lower animals, while the second is most frequently developed in the human subject, the third kind being found only in man (Cobbold). The term hydatid is frequently also loosely applied to vesicular tumors and to cysts of many kinds. Hydatids are most frequent in the liver; but are found in almost any tissue, even in bone. See Liver, Worms.

HYDRAGOGS.—The most active of the drastic and saline groups of purgatives. They act by removing large quantities of water from the blood-vessels. Elaterium is the typical hydragog. The principal are elaterium, gamboge, potassium bitartrate, croton oil, salines in large doses—especially magnesium sulphate—and jalap. They are to be employed in general dropsy and in serous inflammations. Magnesium sulphate, being unirritating, is often employed to increase intestinal secretions and in acute enteritis and peritonitis. See Cathartics.

HYDRAMNIOS.—See Amnii, Liquor.

HYDRARGYRUM.—See Mercury.

HYDRARTHROSIS.—See Joints (Diseases, chronic).

HYDRASTIS (Goldenseal).—The dried rhizome and roots of *H. canadensis*. It contains three alkaloids, *hydrastin*, white and crystalline, soluble in alcohol and in ether, insoluble in water; *berberin*, yellow and crystalline, soluble in hot water and in alcohol, insoluble in ether; and *canadin*, white needles, present in very small quantity. From hydrastin oxidation liberates *opianic acid* and the artificial alkaloid *hydrastinin*, the hydrochlorid of which is official. Dose of hydrastis, 10 to 45 grains.

Hydrastis is a simple bitter and a stomachic tonic, but if long used, it will derange digestion and produce constipation. It is possessed of antiperiodic powers, and is considered alterative to the mucous membranes, cholagog, diuretic,

and antiseptic. Hydrastin produces effects on the nervous system somewhat similar to those caused by quinin. Tannic acid, hydrochloric acid, and the alkalies are chemically incompatible with preparations of hydrastis.

Therapeutics.—Hydrastis is chiefly used as a stomachic tonic, an antiperiodic, a mild laxative, and an antiseptic. It is an excellent remedy locally and internally in all forms of catarrh, especially that of the stomach, duodenum, gall-ducts, bladder, uterus, and vagina. Internally it is efficient in many glandular swellings, in chronic constipation due to a sluggish state of the liver, in chronic dyspepsia, and as a substitute for alcohol in dipsomaniacs when a catarrhal state of the stomach has been induced In gonorrhea, gleet, and chronic nasal catarrh it is locally employed with much benefit, also in syphilitic affections of the mouth, throat, and nares. As a local alterative and antiseptic application it is highly recommended for unhealthy ulcers and sores; cancerous ulcerations; mercurial and aphthous stomatitis; rectal fissure, fistula, and prolapse; internal and external hemorrhoids; cracks, fissures, and abrasions of the nipples; erosion and ulceration of the cervix uteri, and in conjunctivitis with mucopurulent discharge. In gonorrhea a very efficient injection is an infusion of hydrastis, 1 dram of the powdered root to 8 ounces of boiling water, or the fluidextract diluted in the proportion of 1/2 of a dram or 1 dram to the pint of water; but it should not be used until the acute stage has subsided.

Hydrastinin has long been known as a uterine vasoconstrictor. It is considered preferable to hydrastin on account of its stimulant action on the cardiac muscle. The hydrochlorid is employed in grain doses hypodermically, using a 10 percent solution. It has been used with great benefit in uterine hemorrhage and dysmenorrhea; also in metritis, endometritis, myoma, and pyosalpingitis. More recently it has been employed in the treatment of hydrophobia, strychnin poisoning, and epilepsy, in the latter case being given by the mouth in doses of 1/4 to 1/2 of a grain up to 2 grains daily, and with benefit in 4 cases out of 6.

Preparations.—**Fluidextractum H.** Dose, 10 to 45 minims. **Tinctura H.**—20 percent strength. Dose, 30 to 90 minims. **Glyceritum Hydrastis**—has of hydrastis 2, in glycerin 1, prepared by percolation with water and alcohol. Dose, 10 to 45 minims. **Hydrastin**—the alkaloid. Dose, 1/8 to 1/2 grain. **Hydrastininæ Hydrochloridum**—the hydrochlorid of an artificial alkaloid derived from hydrastin. Dose, 1/4 to 1 grain in capsule 3 or 4 times a day, or hypodermically in 10 percent solution. **Hydrastin** (unofficial) is an impure extract precipitated by hydrochloric acid from an alcoholic solution of hydrastis, and contains berberin, hydrastin, and resin. Dose, 2 to 5 grains.

HYDRIODIC ACID (Diluted).—Ten percent of hydriodic acid is used as a substitute for iodin and the iodids. As an alterative it is believed by some to possess all the powers of iodin while it is much less offensive to the taste and the stomach. It has been used with benefit in asthma and bronchitis. Dose, 5 to 15 minims.

Syrup of hydriodic acid contains about 1 percent of the absolute acid. Dose, 1/2 to 2 drams, well diluted.

HYDROA.—See DERMATITIS HERPETIFORMIS.

HYDROBROMIC ACID (Diluted).—Ten percent hydrobromic acid. A sedative. It is used as a substitute for the bromids, being less depressant, though more irritant to the stomach, than the potassium and sodium salts. Used as a solvent for quinin it prevents the untoward symptoms of the latter drug. Dose, 20 minims to 2 drams, well diluted.

HYDROCELE.—Hydrocele is an accumulation of serum in the tunica vaginalis testis.

Chronic vaginal hydrocele forms a smooth, ovoid, or pear-shaped swelling, more or less tense, completely concealing the testicle. There is no impulse on coughing, the cord above it is distinct, and the inguinal canal is free. It begins below, slowly extends upward, and may reach an enormous size; fluctuation is distinct (unless it is too tense), and in the vast majority of cases the swelling is translucent. There is no pain or tenderness, merely a sense of dragging on the loins, owing to its weight; but if firm pressure is made behind, on the lower part, testicular sensation is usually felt. It is absolutely essential to make out the position of the testis (it may have been inverted in its descent, so that it lies in front, or dragged in various directions by old adhesions), but this may be done with much less discomfort to the patient by examining the swelling with transmitted light. The patient should stand upright, with a light held on the side on which the hydrocele is; the back part of the scrotum and the other testicle should be grasped with the left hand and drawn down, so as to make the skin as tense as possible, and the light shaded off with the right, which at the same time keeps the penis out of the way. The red glare can be recognized at once, the testis appearing as a dark shadow. If there is any difficulty, a roll of paper may be used as a tube to keep off outer rays. Variations are not uncommon. Hernia or encysted hydrocele may be present. The shape may be complicated, owing to adhesions or sacculi; the fluid may have accumulated rapidly, with severe pain; translucency may be lost, owing to the addition of blood, and the walls may have become thickened from chronic inflammation. Old hydroceles are especially deceptive; they are often perfectly globular, like a hematocele, or malignant tumor of the testis; the walls are half an inch or more in thickness, with calcareous plates inside them, and the contents are milky and semisolid with fatty matter and cholesterin; they are perfectly opaque; there is no sense of fluctuation, and, even if they are tapped, it is difficult to get enough fluid out of them for purposes of diagnosis. Practically, they can only be distinguished by their history or by exploration.

Diagnosis. *Hernia.*—Unless it is strangulated, there is always an impulse on coughing; a hernia is never translucent, and the swelling always ex-

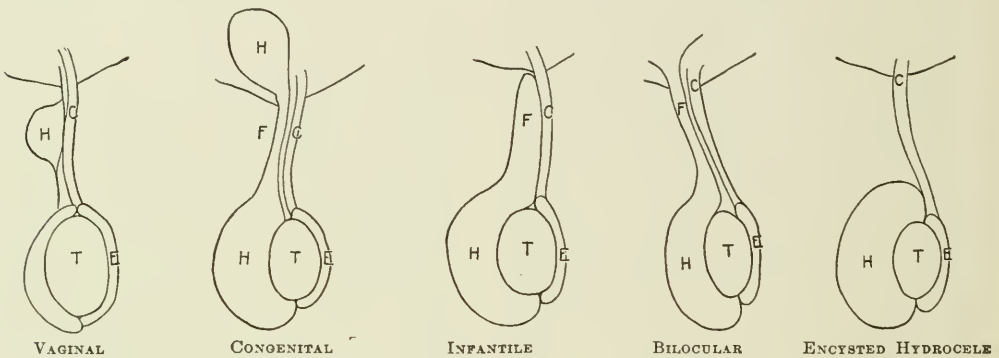
tends through the abdominal ring. An irreducible epiplocele associated with hydrocele may cause some difficulty, but if the swelling is grasped between the finger and thumb while the patient coughs, the impulse can be felt in one part and not in the other.

Hematocele and *tumors of the testis* are never translucent. Old hydroceles are, it is true, not translucent either, but in all of these exploration is essential.

Inflammatory Affections of the Testis.—Acute inflammation cannot easily be mistaken; chronic orchitis, on the other hand, attended with hydrocele (hydrosarcocele) may be very difficult to diagnose; the fluid invests the testis completely, and the state of the gland cannot be ascertained until this is withdrawn.

cysts, or a single one; and it may be immediately above the testis, so as almost to seem part of it, or in the inguinal canal, simulating a bubonocele. It is always translucent (when large enough) and tense, and it is distinguished at once by moving with the cord.

Encysted Hydrocele of the Testis.—Small cysts may be formed in the tunica albuginea, or late in life in the epididymis, but these are of no surgical importance; the former are very rare, the latter scarcely admit of recognition. A different kind is occasionally found attached to the epididymis, developed in all probability from a rudiment of the nonsexual part of the Wolffian body, and corresponding, therefore, to the parovarian cysts in the female. Usually it is single, and of no great size; but it may be multiple, or it may reach



Vaginal Hydrocele. Congenital Hydrocele. Infantile Hydrocele. Bilocular Hydrocele. Encysted Hydrocele of Cord.

Diagram of Various Forms of Hydrocele.—(*Stewart.*) *H.* Hydrocele. *T.* Testicle. *E.* Epididymis. *F.* Funicular process. *C.* Cord.

Congenital Hydrocele.—In this form the tunica vaginalis still communicates with the abdominal cavity. This is more common on the right side than on the left, and usually occurs in children, although it may be met with at any age. It is distinguished by the swelling disappearing when the patient lies down, and the sac is gently manipulated (some care is required, as the neck is usually long and tortuous); by an impulse on coughing (when the communication is sufficiently free); and by the variations in its size. It may not be associated with congenital inguinal hernia; the pressure of a truss is usually sufficient to procure obliteration of the neck.

Infantile Hydrocele.—Here the communication is shut off in the inguinal canal, but nowhere else, so that when the sac is distended, it forms a pear-shaped swelling, the smaller end of which extends up to and sometimes into the external abdominal ring. Old hydroceles of the tunica vaginalis testis occasionally irritate this, owing to the yielding of the upper part of the sac. It occurs in infants, but is by no means confined to them, and requires the same treatment as the ordinary form.

Encysted Hydrocele of the Cord.—In this form the communication is shut off in the normal manner above and below, but the intermediate (funicular) part of the serous sac is not obliterated. It may form a sausage-shaped swelling in the cord in front of the vas; or a chain of separate rounded along the cord and simulate encysted hydrocele developed from the tunica vaginalis. When small, its contents are clear and albuminous, effervescing with acetic acid, from the presence of alkaline carbonates. As it grows larger and presses upon the neighboring tubules, these not infrequently rupture into it, so that it becomes filled with spermatozoa. Sometimes these are still living when the cyst is tapped; more frequently they are dead and motionless, but their presence is almost certain when the contents are milky white and opaque (**spermatocele**). Occasionally cysts of this kind are associated with the common form, and sometimes the partition wall becomes so thin that a communication forms at last.

Treatment of Hydrocele.—**Congenital hydrocele,** whenever it appears, is a prolongation of the peritoneal cavity, and must be treated as such; a truss may be applied, and if it does not succeed, the neck may be ligated. Hydrocele (other than congenital) occurring in infancy usually gets well of itself. If it does not, lead lotion may be applied; or the swelling may be pricked (acupuncture) or tapped. Very few require anything more.

Later in life, if the tumor is of any size, it should be tapped. Occasionally it does not refill; much more frequently the fluid collects again, and if it is tapped a second time, comes back more quickly than before. Whether the patient should rest content with temporary relief of this character,

or undergo what is known as the "radical cure," must depend upon his age, the state of his health, his occupation, and the amount of inconvenience he suffers.

Tapping.—An ordinary trocar and cannula of small caliber is used, taking care that it is thoroughly cleaned and well oiled. The patient should be seated on the edge of a chair, with the knees separated, and the position of the testicle should be ascertained. The scrotum is grasped from behind with the left hand, so as to stretch the skin tensely over the swelling, and a spot is selected on the front (in all ordinary cases), between some of the large scrotal veins. The trocar is held in the right hand, the thumb or forefinger being placed on it about 1/2 of an inch from the point, so as to limit the amount of penetration, and entrance is effected with a quick and firm thrust. As soon as the point of the instrument is in the cavity, the hand should be dropped, so as to direct the point upward away from the testicle. The whole of the fluid should be removed and the little puncture covered with some dry lint. The patient should wear a suspensory bandage afterward until the dartos have recovered.

Acupuncture, piercing the sac with a harelip needle, and freely scarifying the interior, is chiefly suited to encysted hydrocele and the forms that occur in infancy.

Injection.—Tincture of iodin (1/2 of an ounce, with an equal quantity of water) is commonly used. The sac is emptied thoroughly, the fluid injected through a glass syringe (taking care that none enters the cellular tissue), and then, after being manipulated so as to bring it into contact with every part of the interior, allowed to escape again. Subacute inflammation at once sets in, with, in many cases, very severe pain, confining the patient to bed for some days. The skin becomes red, the sac refills, and even the testis may be affected. At the end of a week this should begin to subside, and in a fortnight the whole should have disappeared, and the sac should have resumed its normal size, merely leaving a little thickening at the back of the testis. Occasionally, even when cure is permanent, no visible change is produced in the sac; more often a few adhesions form; and sometimes the sac is completely obliterated. Failure occurs in at least one-third of the cases. Carbolic acid (20 minims in 2 c.c. of glycerin), corrosive sublimate (1 : 1000), and iodoform may be used instead of iodin. The pain is less severe; if the sac is a small one, it is not necessary to confine the patient to bed, and the results are as good.

This method is chiefly suited to small hydroceles of the tunica vaginalis that have not been tapped many times; it should not be employed if there is any reason to suspect chronic orchitis, if the walls of the sac are thick, if the size is large, or if the patient is old and broken down in health.

Incision.—The tunica vaginalis is laid open, the edges are sutured to the skin, and a drainage-tube is passed down to the bottom. This plan is uncertain; it necessitates confinement to bed, and sometimes it leaves a persistent sinus.

Partial incision, removing the parietal portion of the sac, is much more satisfactory. A free incision is made down to the tunica vaginalis, the sac emptied, and as much as is thought desirable cut away with scissors, avoiding large veins and leaving the covering of the epididymis and cord. No vessels require ligation; the wound is sewed up, a drain is inserted, and the dressings are arranged so as to obliterate the cavity and insure primary union. If enough is removed, the sac cannot refill; there is no pain afterward, and one change of dressings is usually sufficient. In old hydroceles with thickened walls this is the only method; but in many of these the patients are already aged and broken down, the tissues are badly nourished and prone to slough, the testis can hardly be isolated without bruising, and it is a question whether castration is not preferable. The risk is certainly less (Moullin).

HYDROCEPHALUS.—In its widest sense the term hydrocephalus embraces all accumulations of serous fluid within the cavity of the skull.

Varieties.—Internal or ventricular, or external (arachnoidean), edematous, etc., or congenital, acquired, symptomatic. Simple hydrocephalus is usually defined as that unattended by malformation of the brain. Scaphocephalus is the name applied to hydrocephalus limited to the lateral ventricles. Of 200 cases, Steiner found 100 internal, 80 edema of the pia mater, 10 external (between arachnoid and dura), and 10 were simple cerebral edema.

Acquired Hydrocephalus

Strictly speaking, hydrocephalus signifies water in the brain; but it is here restricted to the presence of a serous fluid in the arachnoid spaces, in the pia mater, in the ventricles, and in the brain substance (edema); characterized by the more or less sudden development of cerebral excitation, followed by depression and usually by death.

Etiology.—It is most common between the ages of 1 and 5, although it may occur at any age. "The predominance of the nervous system in the bodily conformation" is a strong predisposing cause. Among the exciting causes are unfavorable hygienic conditions, dentition, eruptive fevers, blows on the head, mechanic causes preventing the return of the blood from the venæ Galeni and the right sinus, compression of the jugular vein, diseases of the right heart, and Bright's disease.

Pathologic Anatomy.—The effusion may be limited to the ventricles, although there is usually considerable distention of the subarachnoid spaces and edema of the pia mater and neighboring portions of the brain, whence results more or less softening, especially around the ventricles. The choroid plexus is hyperemic, and may be the seat of minute extravasations.

Symptoms.—There are three varieties of acute hydrocephalus with characteristic symptoms: viz.:—*comatose*, *convulsive*, and *ordinary*.

The comatose variety, known also as "serous apoplexy," begins abruptly, with the phenomena

of apoplexy, the result of the sudden effusion. The pressure is usually so great on the medulla oblongata that it ceases to functionate, death resulting in a few hours, the patient rarely lasting several days.

The convulsive variety, the result of Bright's disease or of a general dropsy, is ushered in with headache, nausea, and vomiting, followed in a day or two by convulsions, passing into coma, which usually terminates fatally, although rarely a remission may precede death for a day or two.

The ordinary variety, the most common in children, begins with feverishness, headache, vertigo, photophobia, restlessness, nocturnal delirium, insomnia, twitching, and spasmodic contractions of the muscles and great hyperesthesia of the skin. Such symptoms continue for several days, when convulsions occur, followed by death, or by a continuance of the symptoms, followed by rigidity, stupor, and death.

The prognosis is unfavorable.

Treatment.—An attempt may be made to remove the fluid by diuretics and full doses of potassium iodid.

Congenital Hydrocephalus

An excessive accumulation of the cerebrospinal fluid—a cerebral dropsy—in the ventricles (*internal hydrocephalus*) or in the meshes of the pia mater (*external hydrocephalus*) or in both (*mixed hydrocephalus*), characterized by enlargement of the head and more or less pronounced nervous phenomena. It is a disease of infants or of very young children.

Etiology.—Imperfect or arrested development of the brain or of its membranes. Inflammatory changes in the ventricles and ependyma occur in the offspring of tubercular, scrofulous, or syphilitic parents.

Pathologic Anatomy.—Enlargement of the head is the chief external pathologic condition, although there is no constant ratio between the size of the head and the amount of fluid, the quantity varying from 1 ounce to 1 pint or more. The liquid is transparent, of a straw color, containing a small amount of albumin and chlorid of sodium. If the quantity of fluid is small, the ventricles are simply distended; if the amount is large, the optic thalami and corpus striatum are depressed and flattened, the roof of the ventricles thinned, and the foramen of Monro is greatly enlarged. The enlargement of the head may occur before birth and may impede or prevent natural delivery, or the head may be normal at birth and increase afterward. As enlargement progresses the bones are so thinned as to be translucent, the fontanels and sutures are widened, the lateral portions of the cranium project, the forehead bulges out over the eyes, and the orbital plates are depressed, forcing the eyes outward and downward producing a variety of exophthalmos; the head has an irregular, triangular shape, the base of the triangle being the top of the head. The scalp, being stretched by the pressure within, becomes tense and thin, and but scantily covered with hair; the veins which ramify in it are unusually prominent and large, and the entire head is elastic on pressure, because of the fluid beneath.

Symptoms.—The increased size of the head, with the emaciated condition of the child, who seemingly eats well, is what first attracts the attention. The head appears too heavy, the eyes are prominent and have a downward direction, the face is devoid of expression, old and wrinkled, the voice feeble; the mental development is not in keeping with the age. When the period for standing or walking arrives, the power is found wanting. The further history is but a continuation and exaggeration of this, until convulsions occur, which sooner or later terminate fatally.

The course of congenital hydrocephalus is usually slow, but progressively worse. The majority terminate within the first year; cases are recorded, however, of 10 and 15 years' duration.

Diagnosis.—In rachitis the volume of the head is increased, due in part, at least, to a deposit of calcareous matter on the exterior of the cranial bones. Rachitis may be mistaken for hydrocephalus in cases in which the amount of liquid is small. The differential diagnosis is based on the shape of the head—round in rachitis, square or triangular or with prominences in hydrocephalus—with the persistent downward direction of the eyes and the elasticity of the head on pressure.

Prognosis.—Unfavorable. Arrest of progress and even cures have been reported. Spontaneous cures are reported following the accidental discharge of the fluid; but such reports are exceptional.

Treatment.—The use of the finest aspirator needle to evacuate the fluid is fully justifiable. The proper situation for the puncture is the coronal suture, about 1 to 1 1/2 inches from the anterior fontanel. Firm but gentle compression of the cranium with adhesive-plaster strips should be made during the escape of the fluid and afterward. A few ounces of fluid only should be withdrawn at a time. The internal use of potassium iodid is recommended. All measures that tend to promote the constructive metamorphosis are to be used.

HYDROCHLORIC ACID (Muriatic Acid).—A liquid composed of about 32 percent of absolute hydrochloric acid gas, HCl, and 68 percent of water. It is colorless and fuming, of specific gravity 1.163, pungent odor, intensely acid reaction and taste, and is obtained by the action of sulphuric acid upon sodium chlorid, the resulting gas being carried through water, which dissolves it. It is sometimes used as a caustic. Hydrochloric acid stimulates the salivary secretions and promotes the alkaline digestive secretions. Given before meals in small doses, it relieves acidity of the stomach. If long continued, it may impair digestion. See GASTRIC NEUROSES, GASTRITIS. The dose of the dilute (10 percent) hydrochloric acid is 3 to 20 minims. See NITRIC ACID.

HYDROCYANIC ACID.—See CYANIDS.

HYDROGEN DIOXID (Peroxid).—It is a powerful oxidizing agent, detergent, antiseptic, and

germicide; and in contact with a suppurating surface it generates a white foam, the result of its action on pus. It is the basis of most hair-bleaching solutions.

Aqua Hydrogenii Dioxidi, *solution of hydrogen dioxid,* commercially known as peroxid of hydrogen, is a slightly acid, aqueous solution of H_2O_2, containing when freshly prepared about 3 percent of the pure dioxid, corresponding to about 10 volumes of available oxygen. It occurs as a colorless liquid, without odor. Slightly acidulous, producing a peculiar sensation and soapy froth in the mouth, and liable to deteriorate by age, heat, or protracted agitation. Dose, 1/2 to 2 drams diluted with 3 to 4 parts of water.

As a cleansing agent for foul wounds, ulcers, sores, and the like, it is highly efficient; and has been used with great benefit as a gargle or spray to the throat and nasal passages, in quinsy, croup, diphtheria, scarlet fever, ozena, and other morbid conditions of these parts. In diphtheria a 3 percent solution as a gargle at short intervals night and day, also given internally, has rivalled antitoxin in results. In colitis with dysentery, lavage of the intestine with a dilute solution thrice daily has proved efficient in cases where other approved measures had failed to make any impression. Used internally it imparts oxygen to the blood, improves digestion, relieves spasm of the respiratory apparatus, aborts the paroxysms of whooping-cough, and gives relief in the dyspnea of chronic bronchitis. It acts well in non-febrile cases of pulmonary tuberculosis by promoting digestion, palliating cough, and giving increased activity to chalybeate remedies, but is contra-indicated in advanced febrile cases, in which it only hastens the fatal termination.

HYDROGEN TEST.—See Gunshot Wounds (Abdomen).

HYDROMETRA.—See Hematometra.

HYDRONEPHROSIS.—A collection of urine in the pelvis of the kidney from obstructed outflow. The obstruction may be caused by an impacted calculus, a stenosed ureter, congenital deformities, or new growths. The cyst may be very small or enormous. Hydronephrosis is marked clinically by the presence of a tumor in the renal region, soft and fluctuating, and usually painless. **Intermittent hydronephrosis** is a form in which there is from time to time the occurrence of a free discharge of urine, with diminution in the size of the renal tumor; ordinarily, the retention is the result of twisting or kinking of a ureter.

Hydronephrosis is most frequent in women, and it may last for a long time if only one kidney is involved. Death occurs from uremia, from pressure on adjacent organs, or from rupture into the peritoneal cavity.

When bilateral, hydronephrosis is difficult to differentiate from ascites. The effects of the changes of posture are much less in the former condition, and the history and mode of origin of the affection are to be kept in mind. Hydatids may not be distinguished from hydronephrosis save by the history and the character of the urine, and tumors on both sides are unlikely to be hydatids. From ovarian tumor, the history, the position of the mass and its relations to the colon, and vaginal and rectal examinations must be remembered in differentiating hydronephrosis. Perinephritic abscess is distinguished from hydronephrosis by its being less hard and by the absence of pain and fever. Pus in the urine at one time or another, with rigors and pyrexia, characterize pyonephrosis. Hydatid vesicles in the urine demonstrate the nature of a cyst of parasitic origin.

Aspiration may effect an immediate cure, but generally the operation must be repeated. It is performed on the left side just below the last intercostal space; on the right side, midway between the last rib and the crest of the ilium. When repeated aspirations fail, nephrotomy must be performed and the kidney must be exposed, opened, drained and irrigated. Nephrectomy is indicated when the kidney is found extensively damaged and the other kidney is in reasonably good condition. If a permanent suppurating fistula exists, or ensues after operation, nephrectomy may also be advised. See Kidney (Surgery).

HYDROPERICARDIUM (Pericardial Dropsy).—The accumulation of water in the pericardial sac, minus inflammation; characterized by precordial distress, disturbed cardiac action, dyspnea, and dysphagia.

It is usually a part of a general dropsy, and is caused by nephritis, sudden pneumothorax, pressure of an aneurysm or other mediastinal tumor, disease or thrombosis of the cardiac veins.

The fluid may range in quantity from an ounce to 1 or 2 pints, and is of a clear yellowish or straw-colored serum, at times turbid or bloody, and of an alkaline reaction. If the amount of fluid is large, the sac is dilated, its walls are thinned by the pressure, and it has a sodden appearance.

Symptoms.—Dropsy of the pericardium is so generally associated with hydrothorax that the symptoms are but an aggregation of those attendant upon that condition, viz.: disturbed cardiac action, dyspnea, dysphagia, dry cough, and feeble circulation. The physical signs are exactly those of the stage of effusion of pericarditis, minus a friction sound.

Pericarditis with effusion and hydropericardium present nearly the same signs and symptoms, a differentiation being possible only by a history of the case and the symptoms of the attack.

The treatment depends upon the cause of the attack. If the amount of fluid in the pericardial sac is great, paracentesis will give relief.

See Heart-disease (Organic).

HYDROPHOBIA (Lyssa; Rabies).—Hydrophobia is a term popularly applied to the human disease consequent upon the bite of a rabid dog or other animal. Rabies is an acute infectious disease of animals, dependent upon a specific virus, and communicable to man by inoculation. All animals may have the disease, but it occurs most frequently in the wolf, the cat, and the dog, and is chiefly propagated by the latter, which is specially susceptible. The nature of the poison is as yet unknown; it has a special affinity for the

nervous system, and is found in the secretions, particularly in the saliva. The period of incubation in man varies from 6 weeks to 3 months. Three stages of the disease are recognized: A premonitory, characterized by depression and irritability, followed by a stage of great excitability and excessive sensitiveness to afferent stimuli, giving rise to intensely painful spasms, particularly of the oral and laryngeal muscles. The fact that the attempt to drink water will induce a spasm, making the sufferer dread the sight of it, gives the popular name to the affection. There may be rise of temperature. In the last or paralytic stage the spasms are succeeded by quiet and gradual unconsciousness, ending in death. The cerebrospinal system shows congested vessels, perivascular exudation of leukocytes, and minute hemorrhages, particularly in the oblongata (Gowers), and the larynx, trachea, and bronchi show acute hyperemia (Osler).

Hysteric or **pseudohydrophobia** develops in neurotic persons bitten by dogs, whether these are rabid or not. In the furious stage such an individual usually barks like a dog and attempts to bite himself and others. He can always be deceived by suggestion, and will thus display at one moment reflex excitement, and at the next an absence of it. He speaks often about the animal by which he was attacked, while in genuine cases this is rare. The temperature is the most valuable test, hysteric hydrophobia being an apyrexial affection. The pulse and respiration also show no quickening, as in true hydrophobia. The absence of true mental disturbance, the stationary character of the general symptoms, and the concurrence of hemianesthesia and other hysteroid symptoms help to differentiate spurious from true hydrophobia.

Treatment.—After the bite of a supposedly rabid dog or animal a constriction should be at once applied above the wound, and the bite excised or burnt with a hot iron. At the earliest moment possible the Pasteur treatment should be begun. The inoculations are preventive and protective for several years and are innocuous to the noninfected. The patient should be placed in a dark room, kept quiet and warm, and every draft of air excluded. Morphin must be used until the patient is brought under its influence, or rectal injections of potassium bromid and chloral may be given. The sensitiveness of the pharynx may be reduced by the local application of a 10 percent solution of cocain. Nutritient enemata and suppositories are to be given in order to avoid spasm in swallowing. The dog should not be killed but be confined and watched carefully to see whether signs of the disease develop. See Bites.

Pasteur's Method.—There is abundant proof that the specific virus of rabies is produced by a microorganism, though none such has yet been demonstrated by the bacteriologists. Pasteur discovered that the virus is most abundant in the spinal cord of the rabid animal and showed that its inoculation upon a healthy animal will produce the characteristic symptoms of the disease, also that the virus may be attenuated in virulence by drying the spinal cord containing it. He also found that by the repeated inoculation of viruses of increasing virulence an animal is rendered immune to rabies, whether the infection is introduced by the bite of a rabid animal or by any other method of inoculation. Upon these facts he founded his preventive treatment of this disease, which consists in the daily inoculation of the bitten person with emulsions of gradually increasing virulence, made from the dried spinal cords of rabbits that have died from inoculated rabies. By this procedure chemical substances (toxins), produced during the life of some specific organism and known to be inhibitory of its growth, are introduced into the system of the patient (V. Horsley). The period of treatment is usually 15 days, during which from 2 to 6 inoculations are administered daily with viruses of gradually increasing intensity; the number depending on the time which has elapsed between the infliction of the bite and the commencement of the treatment. This method received the unqualified endorsement of a special committee appointed by the parliament of Great Britain in 1887, the members of which included the most eminent surgeons and physicians of England. Statistics published by the New York Pasteur Institute state that during 5 years 658 cases were treated at that institution, with a mortality of 0.76 percent; and at the Paris Institute during the same period there were 7341 cases treated, with a mortality of 0.3 percent. The two sets together give 7999 cases treated, with a mortality of 0.34 percent. See also Quinin hydrochlorid; Urea.

HYDROPS.—See Edema.

HYDRORRHACHIS.—See Spina Bifida.

HYDRORRHŒA GRAVIDARUM.—A condition occurring occasionally in the pregnant woman, in which there is a periodic discharge from the uterus of thin mucus that accumulates as a result of hypertrophy of the uterine glands with excessive secretion. See Chorion.

HYDROSALPINX.—A distention of the Fallopian tube with a fluid substance, and its obstruction at the fimbriated extremity, caused by inflammation. It is frequently a result of gonorrhea. See Fallopian Tubes.

HYDROTHERAPY.—See Bath, Water, Heat, Cold, etc.

HYDROTHORAX. (Dropsy of the Pleura).—The effusion of fluid into the pleural cavities (bilateral), the result of a general dropsy from renal or cardiac disease. There is more or less clear serous fluid in both pleural sacs, compressing the lung. No signs of inflammation are present. The disease follows dropsy of the abdomen, and is marked by dyspnea, with signs of deficient blood aeration, both lungs being compressed. There is dulness over the site of the fluid, and vocal fremitus is absent. Auscultation shows absent vesicular murmur over the site of the fluid. The diagnosis is easily determined by the association of the symptoms with a general dropsy.

The treatment depends upon the condition causing the dropsy. Dry cups over the chest afford relief. If the symptoms of nonaeration of

the blood are severe, the fluid should at once be evacuated with the aspirator. See HEART-DISEASE (Organic), NEPHRITIS, PLEURISY, etc.

HYMEN, IMPERFORATE.—A congenital condition, the hymen not having an opening, and thus closing the vaginal outlet or inlet. **Abnormal forms of hymen** are: (1) *Bifenestrate*, or *hymen biforis*, with 2 openings; (2) *bilobate*, with 2 lobes; (3) *circular*, with a small foramen; (4) *cribriform*, with many holes; (5) *denticular*, with a serrate edge; (6) *double* (rare); (7) *fimbriate*, with fringed edges; (8) *horseshoe*, with its convexity downward; (9) *imperforate*; (10) *normal*; (11) *semilunar*, same as 10, or normal; (12) *hymen septus*, divided across by a slit; (13) *hymen subseptus*, covering only the anterior and posterior portions of the passage.

If overlooked until puberty, imperforate hymen may be a serious affection, as the vagina, uterus, and Fallopian tubes may become distended with retained blood and secretions. See HEMATOMETRA, FALLOPIAN TUBES, etc. If relief is not obtained, enormous distention may occur and the tubes or uterus may give way, setting up peritonitis.

Treatment.—The hymen should be divided, or a portion excised, before puberty. If distention has already taken place, perhaps the safest plan is to make a small opening and keep the parts aseptic and covered with iodoform dressings, which should be frequently changed. See VAGINA, VULVA, UTERUS.

HYOID.—See NECK (Injuries).

HYOSCYAMUS.—The dried leaves and flowering tops, collected from plants of the second year's growth, of *H. niger*, henbane. It should contain not less than 0.08 percent of mydriatic alkaloids, including *hyoscyamin*, isomeric with atropin, *hyoscin*, closely allied to atropin, and *atropin* (see BELLADONNA), the latter in very small quantity. Dose of hyoscyamus, 1 to 6 grains.

Scopola.—The dried rhizome of *S. Carniolica* (yielding not less than 0.5 percent of its alkaloids), contains the alkaloid *scopolamin*, which is chemically identical with hyoscin. Dose, 1/2 to 1 grain.

Therapeutics.—**Hyoscyamus** has similar action to that of belladonna, duboisia, and stramonium, except that it is the most calmative and hypnotic. It is more stimulant to the vasomotor system and to the cardiac accelerator apparatus than is stramonium. It has decidedly laxative and carminative effects on the intestines, and a very marked sedative influence on the urinary passages.

Hyoscyamin is considered identical with atropin in its effects on the motor apparatus and the circulation, including the heart and the vasomotor system, but having a less stimulant action on the central nervous system, producing symptoms of cerebral depression instead of garrulous delirium. It is less powerful than atropin as a mydriatic, and in a few cases it has seemed to diminish the respiratory rate. It is believed to be a hypnotic, though some deny that it possesses any soporific influence.

Hyoscin is a cerebral and spinal sedative, and a powerful hypnotic, directly depressing the higher functions of the brain, and affecting the heart but feebly. It especially affects the motor tract of the spinal cord and the cerebral cortex, slightly depresses the heart, but paralyzes respiration. It is free from irritant qualities and may be used hypodermically. Its habitual use brings on muscular paralysis and delirium of violent character. It is frequently used as a hypnotic by alcoholics and nervous subjects, and will probably be responsible for many deaths. As a mydriatic its reputation is doubtful, some observers claiming greater power for it in this respect than that of atropin, while others say that mydriasis may follow its use but is not always produced by even large doses. Severe toxic symptoms have followed the application of 4 drops of a 1 percent solution (equal to 1/25 grain) to the ocular conjunctivæ. In large doses hyoscin is a dangerous depressant of the respiration, but it may be used without unpleasant effects in medicinal doses. Whenever full doses are employed the respiration should be watched for several hours.

In every condition indicating the employment of belladonna hyoscyamus may be used. To relieve local spasm, when arterial relaxation exists or when there is pain, in whooping or nervous cough, in colic, in urinary incontinence, and combined with silver nitrate in chronic gastric catarrh, it is serviceable. Hyoscin is of especial value in nocturnal emissions and in spermatorrhea. It is contraindicated in the sore throat of scarlet fever. It will give sleep in the insomnia of heart-disease, but will tend to produce asthma rather than to relieve it. It is an uncertain remedy in nervous affections.

In simple watchfulness or insomnia:

℞. Extract of hyoscyamus,
Extract of conium,
Extract of opium, } each, gr. xx.

Divide into 12 pills. Give 1 every 2 hours.

In spasmodic affections:

℞. Tincture of hyoscyamus, ʒ ss
Cinnamon water, ʒ j
Simple syrup, ʒ ss.

Take at one dose.

In delirium tremens:

℞. Tincture of hyoscyamus, ʒ ij
Spirit of chloroform, ♏ xx
Camphor water, ʒ ij.

Take in 1 dose and repeat in 3 hours.

Preparations.—**Extractum H.** Dose, 1/2 to 1 1/2 grains. **Fluidextractum H.** Dose, 1 to 5 minims. **Tinctura H.**, 10 percent strength. Dose, 5 to 30 minims.

Preparations of hyoscyamus are very uncertain in strength and physiological activity. **Hyoscinæ Hydrobromidum**, colorless crystals, soluble in 2 of water and in 16 of alcohol. Nearly all of this salt

furnished by manufacturing chemists consists of scopolamin hydrobromid (Schmidt). Dose, 1/200 to 1/100 grain for the sane; larger doses, up to 1/30 grain, are used for the insane. **Hyoscyaminæ Hydrobromidum**, white, prismatic crystals, or a yellowish, amorphous mass, of tobacco-like odor, and acrid, bitter, nauseous taste; very soluble in water, soluble in 2 of alcohol. Dose, 1/200 to 1/100 grain. **Hyoscyaminæ Sulphas**, white crystals, or a white powder, odorless, of bitter, acrid taste; very soluble in water, soluble in 7 of alcohol. Dose, 1/200 to 1/100 grain; but higher doses are used for the insane.

Preparations of Scopola.—Extractum S. Dose, 1/8 to 1/2 grain. **Fluidextractum S.** Dose, 1/2 to 2 minims. **Scopolaminæ Hydrobromidum**, chemically identical with hyoscin hydrobromid. Dose, 1/200 to 1/100 grain.

HYPERCHLORHYDRIA.—See GASTRIC NEUROSES.

HYPEREMIA, BIER'S.—See BIER'S HYPEREMIC TREATMENT.

HYPERHIDROSIS.—See SWEAT-GLANDS, BROMIDROSIS.

HYPERMETROPIA.—See HYPEROPIA.

HYPEROPIA (Hypermetropia; Far-sightedness).—A condition of the refraction of the eye in which, when the accommodation is at rest, the focus of parallel rays of light transmitted through the eye is beyond the retina. See AMETROPIA.

Causes.—Hyperopia may be due to a lessening of the convexity of the refracting surfaces of the eye (*hyperopia of curvature*), change in the index of refraction of the dioptric media, or absence of the crystalline lens (*aphakia*). It is, however, most commonly due to a shortening of the antero-posterior axis of the eyeball (*axial hyperopia*).

Hyperopia may be looked upon as arrested development. Animals are, as a rule, highly hyperopic, and savages are generally more or less so. Children are usually hyperopic, and become emmetropic, or even myopic, while growing to maturity. Properly speaking, hyperopia is a failure of the eye properly to adapt itself for its uses in modern civilization; it is often hereditary.

The results of hyperopia on the ciliary muscle are quite noticeable. Excessive contraction produces abnormal development, particularly of the circular fibers, which become greatly in excess of the radial fibers. The continuous contraction may lead to tonic spasm, which is very difficult to overcome, and renders refraction without thorough mydriasis most unreliable.

Disadvantages.—Parallel rays of light do not focus on the retina, but form circles of diffusion, and hence a blurred image. Divergent rays impinging on the cornea form still larger circles of diffusion on the retina. The only rays that can focus exactly on the retina and give a distinct image are those rendered convergent to a certain degree by convex lenses. The eye contains a mechanism for overcoming its hyperopic defect. In order to render the rays more convergent, the anterior surface of the lens is made more convex by the continuous contraction of the ciliary muscle. In this way hyperopia, up to a certain point, varying with each individual, is involuntarily corrected. However, we can readily realize the result of a constant strain on the ciliary muscle. Nervous energy is consumed and the nervous equilibrium is disturbed, with the result not only of annoying local symptoms of pain, fatigue, and congestion, but also of more remote reflexes, such as headache, gastrointestinal disturbances, and many general neurotic disorders. As the correcting effort of the ciliary muscle is involuntary, the resultant annoying symptoms of eye-strain can only be relieved by atrophy or paralysis of the muscle, or by correction of the defect that necessitates the ciliary contraction.

Varieties.—Manifest, which is measured by the strongest spheric lens which, without mydriasis, gives the greatest acuity of vision. **Latent** hyperopia is that part of the total error which can only be revealed by mydriasis, as it is at all times masked by the accommodation. The younger and more vigorous the subject, the greater the amount of latent hyperopia. It is on account of the ever-present latent hyperopia in the eyes of persons less than 50 years old that it is necessary to paralyze the ciliary muscle in order to measure the full degree of hyperopia. The old classification of *facultative*, *relative*, and *absolute* hyperopia is too vague to be used.

Symptoms.—The objective symptoms are inconsiderable. The leading subjective symptoms are caused by the strain upon the accommodation, and may be grouped under the heading **accommodative asthenopia.** The patient will complain of inability to perform continuous near work: the letters and words are indistinct, and seem to run together. Headache and pains about the eyes are present. There is increased lacrimation and a tendency to chronic congestion of the conjunctiva. The local reflex symptoms may range from a slight palpebral conjunctivitis to intense blepharitis and even to granular lids. There may be such intense photophobia as to cause suspicion of retinal disease. There are remote systemic reflexes, such as headaches, nausea, indigestion, general neurotic disturbances, etc.

The distant vision is usually good, as the ciliary muscle is capable of overcoming a moderate defect. Hyperopia of a high degree or complicated with astigmatism markedly diminishes visual acuteness.

There is an intimate **connection between convergent strabismus and hyperopia.** It is likely that the associated movements of accommodation and convergence are controlled by the same center, or by contiguous centers acting automatically from long association. The increased strain on the accommodation causes extra innervation to convergence, which may result in permanent squint inward. Or, again, persistent stimulation of the adductors may weaken them, and thus produce divergent squint. Very often if a child is hyperopic to some extent, and unequally in the two eyes, to avoid the discomfort of a blurred or double image one eye is turned in and becomes amblyopic. It has been estimated that over three-fourths of the cases of convergent strabismus

are caused by hyperopia. We see, therefore, how very necessary it is to examine carefully the refraction of an eye beginning to converge in a child.

Hyperopia increases with age, on account of the lessening of the refractive power of the lens, caused by a change in its substance. At the age of 80 this lessened refractive power is quite apparent.

Diagnosis can be made with certainty only by the use of a mydriatic, although failure of accommodation and recession of the near-point incommensurate with age give strong reason to suspect hyperopia. The most important point in the diagnosis is the acceptance of a convex lens, and we usually estimate the full degree of hyperopia by the convex lens which gives the eye under complete mydriasis the best vision with the test-cards at 6 meters.

In the higher degrees of hyperopia the patient must choose between a small, more or less distinct, and a larger blurred image. As a rule, his choice is the latter evil, and to this end he will hold his book or instrument very close to his eye, simulating the action of a myope. In addition, the high hyperope complains of inability to see distinct objects, which makes another point of confusion with myopia. In casual examination of hyperopia with ciliary spasm, a weak concave glass may be accepted with relief. However, all confusion with myopia may be avoided by thorough mydriasis.

Besides the test-lenses, hyperopia is diagnosed and the degree estimated by the ophthalmoscope and the retinoscope. See RETINOSCOPY.

The treatment of hyperopia consists in prescribing correcting lenses. Having estimated the degree of defect, several points must be taken into consideration in prescribing glasses. It is taken for granted that the patient has been thoroughly under a mydriatic during the preliminary tests. When he comes back to the office for a prescription, it very often happens that we find at the post-mydriatic examination that a hyperope of a slight degree will not accept any of his correction, either for reading or for distance. In such case, if anisometropia is not present, and if the patient has complained of no asthenopic symptom and is apparently vigorous, we do not prescribe a glass, but tell him of his defect, and warn him of the ultimate results of eye-strain, urging him to come back at the first sign of trouble. It more often happens that a certain proportion, or even a full correction, is accepted for reading, but that all correction is rejected for distance; in such case, if there is no prominent asthenopic reflex, we prescribe only a reading-glass.

Prescription of glasses in hyperopia is a most important subject. No definite and dogmatic conclusions or rules are applicable in every case. The physician must study each case separately, and be influenced by the degree of defect, the muscle balance, the age of the patient, the constitutional condition, the asthenopic symptoms, and the occupation or habits of the patient.

It is very often necessary in young persons with strong accommodation to make considerable eduction from the full correction in order to obtain sufficient distant vision. Young and vigorous adults who have never worn glasses will not accept their full correction. In these cases the physician must be governed by his own judgment. As a general rule, we try to prescribe the highest convex lenses that allow sufficient distant vision; these are usually readily accepted for near work. If the patient is engaged in continual near work and complains of marked asthenopic symptoms, we order, for near vision, a large share of the full correction, and consider it advisable to blur slightly the distant vision. We explain to the patient that such glasses will not be satisfactory at first, but that the eye will gradually become accustomed to them, and that the glasses were not ordered to improve the distant vision, and may diminish it at first, but that the point in consideration is to effect easy near vision and to avoid eye-strain and its distressing consequences.

In cases of very high defect with enormous accommodative power weak lenses are at first ordered, and these are strengthened at short intervals until the full correction is approximated. It is surprising to note the rapidity with which the eye will accommodate itself to what was at first an unacceptable correction.

The muscle balance must always be tested before ordering glasses. In cases of orthophoria or exophoria we must reduce the correction in hyperopia to force the interni into action. The ideal hyperopic muscle balance in most office patients is about 2 degrees of esophoria with the Maddox rod, or orthophoria with the Stevens phorometer. Cases of higher esophoria need a strong correction.

In presbyopia and in cases in which a mydriatic has not been used we endeavor to order the full strength of the manifest refraction.

A final point is the **influence of the vocation.** We readily see that the musician and artist, to obtain the best acuity and accommodation at their working distances, will require a different correction from that of the copyist and engraver.

HYPERTRICHOSIS (Hirsuties; Hairiness; Superfluous Hair).—A condition characterized by excessive hair-growth, either as regards number or size.

Symptoms.—Hair may grow to an unnatural degree upon parts normally the seat of hair, as the mustache, beard, eyebrows, etc., or there may be an abnormal growth upon nonhairy regions. In the latter case the lanugo hairs of the part are hypertrophied. This is the condition so frequently seen upon the upper lip and chin of women.

Etiology.—The cause of hirsuties is obscure. Heredity is observed in the most extensive cases. The condition may be congenital or acquired; when acquired, it is apt to develop after the menopause. Diseases of the uterus and appendages may be causative in some cases. Cutaneous irritation or stimulation may also give rise to this condition.

Treatment.—The cases in which treatment is usually demanded are women with superfluous facial hair-growth.

Superfluous hair may be temporarily removed by *shaving, extraction,* or the use of *depilatories.* The sulphid of barium depilatory, recommended by Duhring, is one of the best:

℞. Barium sulphid, ℥ ij
Pulverized zinc oxid, } each, ℥ iij.
Pulverized starch, }

This is made into a paste with a little water and spread on the hairy region for 10 to 15 minutes. As soon as burning is experienced it should be removed, and should be followed by a bland ointment. Such applications must be repeated every few days, according to the needs of the case.

The only satisfactory treatment of hirsuties, however, is by means of *electrolysis.* This consists in the insertion of a fine needle into each hair follicle, and then turning on an electric current to destroy the hair papilla. The operation is somewhat painful, but nearly always within the limit of toleration.

Only stiff hairs are to be extirpated. The removal of downy or lanugo hairs is not to be attempted, as the result is likely to be unsatisfactory. The *operation* is performed in the following manner: A fine needle (iridoplatinum needle or a fine jeweler's brooch), held firmly in a specially devised holder, is attached to the negative pole of a galvanic battery. The needle is gently inserted into the hair follicle down to the papilla. The patient holds a sponge electrode (positive pole), and makes the current by bringing it in contact with the palm of the other hand. In 10 to 20 seconds a frothing occurs at the mouth of the follicle. The current is then broken by the release of the positive electrode, and the needle is withdrawn. If the papilla has been destroyed, the hair will come out on the slightest traction with forceps. If it remains firm, the operation must be repeated. A current of from 1 to 2 milliamperes is usually required.

A wheal-like elevation soon develops at the site of the operation, but disappears in the course of a few hours. Occasionally pustulation occurs.

To avoid *scarring,* attention should be paid to the following points:

(1) The use of a fine needle; (2) the avoidance of too prolonged a current; (3) the avoidance of too strong a current; (4) care not to operate at the same sitting upon hairs in too close proximity.

Hot water, calamin lotion, or a 1 : 1000 solution of corrosive sublimate, sopped on after the operation, lessens the inflammation and the tendency to suppuration and scarring. See ELECTROLYSIS.

HYPNAL (Mono-chloral-antipyrin).—A narcotic mixture of ANTIPYRIN and CHLORAL (*q. v.*).

Dose, 15 to 20 grains.

HYPNOTICS.—Remedies which produce sleep. In this wide sense the term includes the narcotics and the general anesthetics, but it is usually restricted to those agents which, in the doses necessary to cause sleep, do not disturb the normal relationship of the mental faculties to the external world (Brunton). Another definition of hypnotics is—that they produce sleep without suspending the consciousness of pain, narcotics doing both. Hypnotics may be subdivided into the following classes:

Pure hypnotics, which directly induce a sleep closely resembling the normal, without causing narcotic or other dangerous cerebral symptoms. The *bromids* are the type of this subdivision, but the list is constantly growing smaller as experience reveals toxic powers in the action of its members.

Narco-hypnotics, which induce sleep by direct depression of the cerebral functions and in larger doses are narcotic, suspending the consciousness of pain and producing coma. *Opium* is the type of this class.

Indirect hypnotics, which induce sleep by removing or suppressing any cause (not mental) which interferes therewith.

Hydrated chloral is undoubtedly the most efficient of all hypnotics. *Paraldehyd* is one of the most reliable and safe, but its sleep is transient, lasting only a few hours. *Sulphonmethane* and *sulphonethylmethane* are very efficient in some cases, but often fail entirely. *Ethyl carbamate* is feeble and uncertain, and the same may be said of *humulus* and some other agents which are not mentioned below. *Piscidia* is also somewhat uncertain in action, though its hypnotic and anodyne powers have proved very decided in many cases.

The chief hypnotics are as follows:

Pure Hypnotics.—Potassium bromid, sodium bromid, paraldehyd, sulphonmethane, sulphonethylmethane, veronal, ethyl carbamate, chloralformamid, hedonal.

Narco-hypnotics.—Hydrated chloral, chloretone, opium, morphin, narcein, hyoscin, duboisin, cannabis indica, pellotin, passiflora incarnata, piscidia erythrina, amylene hydrate, alcohol.

Indirect Hypnotics.—Antipyrin, acetanilid, acetphenetidin, strychnin, hydrocyanic acid, conium, gelsemium, ergot, digitalis.

Wilcox rejects the dangerous, unreliable and objectionable hypnotics, and retains four as amply sufficient for all ordinary cases of insomnia. These he classifies as follows:

As to Potency.—Paraldehyd, chloralformamid, pellotin, sulphonethylmethane.

As to Rapidity.—Pellotin, paraldehyd, chloralformamid, sulphonethylmethane.

As to not causing Habituation.—Pellotin, sulphonethylmethane, chloralformamid, paraldehyd.

As to Safety.—Chloralformamid, pellotin, paraldehyd, sulphonethylmethane.

For **Addiction to Hypnotics,** see LAMBERT TREATMENT FOR NARCOTIC ADDICTION.

HYPNOTISM.—The maintenance of interest in the subject of hypnotism must depend chiefly upon its relationship to practical medicine. If this can be shown of definite value, then will the study of conditions produced in hypnotic states continue to occupy the attention of scientific observers until practical results follow. If not, the psychologist and others may still utilize the interesting mental states thus exhibited for purposes of research and experiment.

The status of the subject at present is not established with sufficient clearness, though there is much evidence offered of a promising character to show that hypnotism is an important auxiliary to rational medical measures.

To define hypnotism is difficult, in view of the confusion wrought by the ignorance and bias of many of its most successful exponents. Even among the more intelligent students great diversity of view prevails as to the nature and causation of hypnotic phenomena. It is possible, however, to array certain items of belief common to scientific hypnotists, and thus present a fair concept of the state, and the art of producing them, and securing the results of suggestibility thus made possible. Hypnotism is a state of mind or a mental attitude, artificially induced, in which the powers of volition and action are altered, and during which it is possible to forcefully offer suggestions as to acts and thoughts not readily or willingly accepted at other times. The action of some of the brain centers, both sensory and motor, are arrested or suspended. It is practically necessary that the subject cooperate with the hypnotizer; it is gravely doubted whether it is possible to attain success otherwise. It is also necessary that the thoughts and acts suggested shall be free from evil or hurtful tendencies; at least so far as the subject is capable of interpreting these or their effects. In normal individuals it is not believed that the contrary is possible; they can, and usually do, resist evil suggestions in these states. It is admitted that those of a vicious or criminal bias might be influenced to commit follies or crimes under hypnotic suggestion, but most of the experienced observers have failed to meet with instances of obsession thus induced.

The hypnotic state is analogous to sleep, and it may be that hypnosis can be best explained in terms that also explain sleep. It is said by some to resemble the dormant state of a hibernating animal.

The elements of normal sleep consist of several factors: Cerebral anemia, fatigue of the brain-cells, accumulation in the tissues, and especially in the nervous structures, of poisonous waste products, which are eliminated slowly and imperfectly while the organism is active, but more promptly while at complete rest.

Finally, there is that special function of the nerve structures called "inhibition," whereby the action of a function or of an organ is directly arrested by the action upon it of another function or organ. This is capable of being rapidly induced and promptly removed. The element of inhibition is a conspicuous one in the hypnotic state. Heidenhain says: "Hypnotism is inhibition of the cells of the brain cortex which subserve consciousness and the intellectual processes." Again, the cells of the cortex subserve other functions than those of consciousness and intellection, and are also concerned in nutrition, secretion, and other vegetative activities. An undue or morbid attention to the organic processes disturbs the balances in the life of relation, and hypochondriasis results. Delbeuf says: "Hypnotism, by cutting off the intellectual life from the life of relation, enables the highest centers to assume cognizance of and to dominate the working of the organic functions." In this way perturbations in normal activities can be corrected.

Disease, according to Liebeault, implies an excess of nervous action in one direction and a deficiency in another. The hypnotist thus calls upon the patient to utilize his own forces and recover his normal equilibrium. Weakened faculties are thus capable of being developed, and latent powers brought into useful evidence. Hence persons of diseased or deficient faculties, of feeble volition, or of vicious tendencies are less, if at all, amenable to relief through suggestion.

The uses of hypnotism are undeniably distinct, though far from well defined. They serve only as a supplement or as an auxiliary to rational medical measures.

The basis of the state is suggestion, the condition of the hypnotized subject being a psychic one, in which the susceptibility to suggestion, and the ability to act upon it, are enormously increased. A practical explanation is that, whereas in ordinary states it may be, and usually is, more or less difficult to secure a complete attitude of attention, yet during the hypnotic state no matter how shallow, this is more possible. Moreover, as the state is reproduced on subsequent occasions, and as it grows deeper, and especially when the subject recognizes the wisdom and the suitability of the thought or act suggested, a more absolute obedience and persistent cooperation is induced.

When a diseased process is under consideration, an attitude is thus secured of calm receptive acquiescence, and in this the subject can be guided toward a cure. The cure is successful in proportion as this process is a mere functional derangement, evil or morbid fixed habits, or acutal structural disease. Again, an essential element in success is the degree of willingness or anxiety on the part of the subject to be relieved or cured. There is something of efficacy, perhaps, in the power of the individual hypnotizer to secure cooperation or to dominate the consciousness, but this is of small effect unless the thought suggested is a wholesome one, or consonant with the inclinations of the subject, be they good or bad. Evil acts cannot be induced in a clean consciousness, however much they may be aroused in one of unclean tendencies. The psychologic hypotheses, though interesting and suggestive, are difficult to understand or accept by the clinician; as, for instance, the "subliminal states" of Meyers, through which certain psychic powers are aroused over which normally we have little or no control.

The Production of Hypnosis (Hypnogenesis).—The effective influences may be mental or physical or both combined. Operators differ much in the methods employed, the results being similar, practically identical. All involve an "arrest of the flight of thought, concentration of attention upon one element, a restriction of the conscious field" (Newbold).

Only a small proportion of the subjects can be hypnotized on the first attempt—about 10 per-

cent. After repeated attempts (4 or 5 or more) it is claimed by competent observers that about 80 percent of average persons may be affected.

The suggestion to the subject that he shall go to sleep is the foundation for the process. A word of command occasionally, by some observers, suffices (Laria, Liebeault, Bernheim); usually after several attempts have been made, and following upon some form of strained attention.

The mental factor is always the most important, but it is practically necessary to supplement this by certain physical influences, such as sense stimulation, fatigue of attention, fixation of the eyes, monotonous or rhythmic sounds, etc.

Fixation of the attention and of the eyes are of equal importance. Some operators rely on movements of their hands, held parallel to the subject and some inches distant; these are called magnetic or mesmeric passes. Others, again, make use of such sense stimulations as touch or gentle pressure with the hands, or stroking of the limbs of the subject, particularly upon the skin. This involves the factor of warmth, and, possibly, also electric influences. The muscular sense may contribute to this effect, as the rocking of a child in the cradle; the whirling or spinning of the Dervishes; the dances of the Indians, Zunis, and other savage tribes; and also, similarly, the marching of soldiers. The waking of the subject from hypnosis (dehypnotization) is usually readily effected, oftentimes spontaneously, by a command or touch; or, if the sleep is a very deep one, by a wave of cold air, the use of a fan, or sprinkling the surface with water.

If a time limit is set by suggestion the waking can readily then be effected with remarkable accuracy. If left alone, the subject usually wakes up after a variable time. He may remain asleep for hours, or even days, but these are probably instances of trance, and more common in hysteric subjects. The hypnotic drowsiness has a tendency to pass into normal sleep.

Most normal persons are hypnotizable. The subjects of hysteria are not more readily affected than others. In them the spirit of contradiction may inhibit obedience, and a fixation of the attention on other ideas than their own ailments is not readily obtainable, and to cure them repeated and patient efforts are, as a rule, required. Again, if they become hypnotized, sometimes a trance is induced somewhat difficult to control. Insane persons are most resistant; so are stupid ones, and those mentally excitable. The best subjects are those who are capable of fixing their attention and people accustomed to obedience. Young children are not readily susceptible.

Hypnotic states differ much from each other in character as well as degree. Many fanciful subdivisions are made, but three stages are recognized (Forel): (1) Drowsiness, in which the patient can resist only by an effort; (2) hypotaxy, in which obedience is obligatory; (3) somnambulism, a profound condition of sleep characterized by loss of memory on waking of what has occurred in the state of hypnosis. There is no clear line between any of these stages; gradual transitions are everywhere to be found.

The possibilities of hypnotism may be briefly enumerated to lie in the restoration of normal functions, to remove false impressions upon the consciousness, to correct bad habits of thoughts or acts, to restore self-control, to correct evil tendencies or appetites, and to relieve painful states. When it is estimated how much of so-called diseased conditions reside in a combination of these physical factors, along with varying degrees of organic or structural damage, it will be seen that if the former is eliminated, much of the latter is not only endurable, but the disability practically ceases.

That hypnotic suggestion is oftentimes capable of producing this beneficent effect there is an overwhelming mass of evidence to show. In so far it can be said to be a valuable auxiliary to medical practice. How permanent or far-reaching is this effect cannot be accurately stated as a general proportion or in the individual instance. That valuable effects are thus wrought, and perfect ones, has been very frequently demonstrated, and in some instances cures were effected after unavailing efforts by the ablest physicians and many years of their unceasing intelligent endeavor. The results obtained are oftentimes as much a surprise to the physician as to the patient or to his former advisers. That there are dangers is true, but they are not large nor deterrent nor greater than accompany many measures fully indorsed. The worst of these is the danger of subjecting the operator to the accusation of being a humbug, thus deterring many wise men from using an agency capable of the largest good.

Hypnotic anesthesia is not valueless. Pain may be relieved thereby in operations for strabismus, single or double ankylosis of a joint, excision of exostosis of the great toe, and teeth extraction, and other minor operations. The chief objections to this kind of anesthesia are the difficulty and uncertainty in inducing primary hypnosis, the number of preliminary attempts often necessary, the immoral aspect, the fact that the process can never be generally used, and the fact that perfect anesthesia cannot be obtained readily by hypnosis. Its advantages are that when deep hypnosis with anesthesia has been once brought about it can be repeated at any time, and it is not necessary to repeat the hypnotic process, a verbal order to sleep being sufficient; the patient is not obliged to abstain from food or to make other necessary preparations, the nervous apprehension can be removed by suggestion, the process is pleasant, is free from danger, can be kept up indefinitely, can be stopped immediately, the patient can be placed in any position required without risk and will alter that position at command, and gags and other apparatus are not required. It is of especial value in throat operations and in labor, where muscular influence can be increased or diminished; there is no tendency to sickness during or after the operation, and pain after the operation or during subsequent dressing may be prevented and the rapidity of the healing process be frequently increased.

HYPOCHLORHYDRIA.—See Gastric Neuroses.

HYPOCHONDRIASIS.—A form of mental unsoundness closely allied to melancholia, of which it often forms the initiatory stage. It is characterized by a morbid anxiety relative to the physical health, the patient observing himself with restless care, magnifying trivial departures from perfect action of his organs, and becoming absorbed in precautions regarding them and his state of health. It is a chronic disorder, which may attach throughout life, rendering it shorter in length and sadly diminishing it in utility and happiness.

In melancholia there is a tendency to suicide, while in hypochondriasis a strong desire for life exists and impels the subject to endless search for the cure of his ailment. He delights in consulting medical men and entering into minutest details. The melancholic often despairs of relief, and the description of this condition is often confused, frequently incoherent and unintelligible. The prognosis is more favorable when hereditary tendencies are less marked, and the liability to mental strain or shock and to sexual and alcoholic excesses is minimized, and the change from a life of activity to one of forced or uncongenial leisure is most gradual.

Moral treatment is alone of any influence in most cases. Relief of the conditions—such as anemia, gouty manifestations, fecal accumulations, intestinal catarrh, hemorrhoids, or syphilis—should be obtained. Alcoholic and sexual excesses must be shunned, and travel, especially under congenial and judicious companionship, and the encouragement of regular, definite, and useful employment for both the attention and the physical powers, are most potent means of relief. Ridicule is rarely or never of service. See NEURASTHENIA.

HYPODERMOCLYSIS.—The infusion of saline solution under the skin. See INFUSION, TRANSFUSION.

HYPODERMIC MEDICATION.—The introduction of drugs, in concentrated form into the subcutaneous connective tissues, to produce a rapid or powerful effect, to medicate tissues locally, especially nerve-trunks, to avoid disturbance of the alimentary canal, and for economy.

The ordinary hypodermic needle has a barrel of the capacity of 20 minims. For the administration of the antitoxin of diphtheria the capacity runs as high as 100 minims. The cap, nozzle, and piston consist ordinarily of nickeled metal or silver, while usually the barrel is of metal or glass. The packing is of leather or of wash-leather, and should always fit tightly. The minims are marked on the piston. A simple sliding motion, and not a screw action, is to be given the piston. After use, the instrument should be boiled, tepid antiseptic water should be drawn into the needle and ejected, and a fine wire drawn through the needle itself and left there to keep the canal patent and clean. The best and most recent hypodermic syringes are made wholly of glass.

The medicine should be in solution, of neutral reaction, freshly prepared, the usual menstruum being distilled or sterile water. The most suitable localities for the injection are the external aspect of the arms and thighs, the abdomen, back, and calves of the legs. On the external portion of the thigh an area 2 inches square exists over which the insertion of a fine hypodermic needle is not felt. Solutions should have (1) as high solvent power as possible, (2) be as permanent as possible and not deteriorated by keeping, and (3) be unirritating. Carbolic acid, boric acid, camphor, and other substances may be used to prevent development of organisms.

The advantage of hypodermic injection is great, but it has its limitations. Hypodermic injection of such drugs as Epsom salts, or such powerfully irritating and depressing ones as colchicin and cantharidin, further no useful end.

The method of application is most important, and pain in most instances can be avoided. The area should first be cleansed and rendered aseptic, and, of course, the needle is to be aseptic. For this purpose it may be boiled or dipped in carbolized oil or some unirritating antiseptic. Some drugs, like ergot or ergotin, inevitably give more or less pain when administered hypodermically, but careful manipulation will reduce this to a minimum. Local ill effects from hypodermic medication are chiefly pain, phlegmonous swellings and consequent abscess, slight bleeding, or ecchymosis. Certain parts of the body should be avoided: *e. g.*, regions where subcutaneous cellular tissue is scanty, such as the skin over the tibia, parts of the cheek, forehead, etc. It is well to avoid the neighborhood of large vessels, and, unless special influence is desired, the nerve-trunks, as well.

The classic practice of pinching up a fold of the integument before inserting the hypodermic needle is entirely wrong both in theory and in practice. It is never done by persons who habitually use this instrument on themselves, and they are admittedly the most expert of all operators in this line. It increases the liability to local soreness, and often produces bruises and ecchymoses which might be avoided by following the method described below.

After nearly filling the syringe with the solution to be used, the needle, if separate, should be screwed on tightly; and with the instrument held in a vertical position, point uppermost, the excess of solution over the amount required should be ejected, thus expelling air bubbles and filling the needle itself. A site having been selected where there is no danger of penetrating a vein or an artery, the needle should be quickly inserted at a right angle with the surface, and carried on into the subcutaneous tissue for fully one-half its length. It should be held steadily, and not moved around, so as to avoid injuring the tissue. The piston should be pressed down slowly, and when the injection has been delivered, the needle should be quickly withdrawn, and no attention paid to the few drops of solution which may follow it. Only the very finest needles should be used, except in cases in which the patient is struggling and liable to break the needle by his movements. The point of the needle should be perfect and its surface highly polished. It is far better to use a new

needle every day than to risk one's reputation for skill on a blunt-pointed and rough-surfaced instrument. Potter has injected a strychnin solution in this manner on some 300 patients during three years, 3 and 4 times daily in the same upper arm for a month in each case, without having produced any more serious result than a hyperemic zone around some punctures in a very few instances. If the solutions are freshly prepared with clean water, the needles sharp, clean, and bright, and the injections delivered *beneath* the skin, and *not into it*, there is no danger of producing abscesses, or even indurations, with the agents ordinarily employed in this manner.

The hypodermic syringe has been responsible for drug addiction in many instances, therefore it should never be placed in the hands of patients and the physician should be most careful when ordering drugs such as morphin, cocain, chloral.

Compressed tablets for hypodermic use are prepared by the prominent manufacturers, and are furnished in glass tubes containing from 20 to 25 tablets each. They are very small, are entirely free from any foreign material, are sufficiently soluble, and are put up in short tubes which can be carried in cases to fit the vest pocket. The tablets may be readily dissolved in a teaspoon at the bedside, or in the syringe itself if the instrument has a screw-hole large enough to admit the tablet before screwing on the needle.

List of HypodermicTablets.—A regular supply of hypodermic tablets includes the agents named in the following list, though many others are prepared by the manufacturing chemists:

Aconitin (crystals), 1/500 gr.; apomorphin hydrochlorid, 1/10 gr.; atropin sulphate, 1/200, 1/100, 1/50 gr.; caffein sodiobenzoate, 1/2 gr.; cocain hydrochlorid, 1/8, 1/4 gr.; codein phosphate, 1/2, 1/4, 1/8 gr.; coniin hydrobromid, 1/100 gr.; colchicin, 1/30 gr.; corrosive sublimate, 1/30, 1/60 gr.; corrosive sublimate and urea, 1/25 gr.; digitalin (soluble), 1/100 gr.; duboisin hydrochlorid, 1/100 gr.; ergotin, 1/4 gr.; gelsemin hydrochlorid, 1/50 gr.; hyoscin hydrobromid, 1/100, 1/50 gr.; hyoscyamin, 1/100, 1/50 gr.; morphin bimeconate. 1/3, 1/4, 1/6 gr.; morphin sulphate, 1/8, 1/4, 1/3, 1/2 gr.; morphin and atropin No. 1 (morphin sulphate, 1/8 gr.; atropin sulphate, 1/200 gr.); morphin and atropin No. 2 (morphin sulphate, 1/4 gr.; atropin sulphate, 1/150 gr.) nitroglycerin, 1/200, 1/100, 1/50 gr.; physostigmin sulphate, 1/100 gr.; picrotoxin, 1/50 gr.; pilocarpin hydrochlorid, 1/3 gr.; quinin chlorhydrosulphate, 1 gr.; scopolamin hydrobromid, 1/100 gr.; sodium arsenate, 1/10 gr.; sodium nitrite, 1, 1/2, 1/4 gr.; spartein sulphate, 1/30 gr.; strychnin nitrate, 1/100, 1/60, 1/40 gr.; strychnin sulphate, 1/100, 1/60, 1/30, 1/20 gr.

HYPOGLOSSAL NERVE, LESIONS. — The hypoglossal is the motor nerve of the tongue, and supplies also the depressors of the hyoid bone and the hypoglossus and geniohyoid of the elevators. It arises from the medulla oblongata beside the olivary body. Its cortical center is probably the lower part of the ascending frontal gyrus or the root of the third frontal convolution. It is subject to paralysis and spasm.

Etiology.—(1) *Cortical disease* is frequently responsible for paralysis of the tongue on the opposite side, as is seen in the numerous cases of hemiplegia associated with this condition. The same accident occurs when the fibers between the cortex and the nucleus in the medulla are invaded. Apoplexies and other causes of compression, softening, thrombosis, and embolism are agencies operating to this end. (2) *Nuclear disease* is another cause. It is usually degeneration, rarely sudden softening; the former as a part of bulbar palsy and locomotor ataxia, and the latter from vascular obstruction. The effect is almost always bilateral, the nuclei being so close together that it is scarcely possible to involve one only, although such isolated result has occurred in sudden cases, and, rarely, in slow ones, as in tabes and general paralysis. (3) *Infranuclear disease* may operate at various sites: (*a*) Within the medulla the root-fibers may be invaded by a tumor or by softening. (*b*) Outside the pons the fibers may be damaged by the products of meningitis, simple or syphilitic, and by new formations.

The nerve may be compressed in its foramen by outgrowth of bone. Outside the skull the nerve is compressed by tumors, by inflammatory products, or injured by disease communicated from caries of the upper cervical vertebræ, and by penetrating wounds. Hence, the spinal accessory often suffers coincidently, and there is paralysis of the palate, occasionally of the vocal cords, with or without wasting of the trapezius and sternomastoid. The hypoglossal may be the seat of neuritis (Tyson).

Symptoms. Hypoglossal Paralysis.—This is motor only. When there is supranuclear disease, in addition to the palsy of the tongue there is hemiplegia, but no wasting of the tongue, which is protruded toward the affected side, nor change in electric reaction. In nuclear disease the lesion is apt to be bilateral palsy. The tongue lies motionless in the floor of the mouth, and speech and deglutition are seriously impaired. Mastication is interfered with, mainly because the tongue cannot regulate the position of the food, the proper muscles of mastication being intact. There are atrophy and reaction of degeneration. The mucous membrane is thrown into folds. The condition is likely to be a part of a bulbar palsy. In infranuclear disease only one nerve is affected; there is wasting, with reaction of degeneration, and fibrillary twitching. Speech is not much impaired, nor swallowing.

Spasm.—Spasm of the tongue as an isolated event is very rare. It may be unilateral or bilateral. It commonly occurs as a part of some other convulsive affection, as epilepsy or chorea, or spasm of the facial muscles. It may also occur in hysteria. In the biting of the tongue in epilepsy the organ is thrust between the teeth by spasmodic contraction of the genioglossus and caught by the jaws through a spasm of the masseters. Spasm of the tongue occurs in some forms of stuttering, the spasm often preceding the explosive utterance of words. In other cases there are various protrusions and

deviations of the tongue, produced in some instances by irritation of the fifth nerve, variously induced: it may be, by a carious tooth. The spasm may be clonic, the tongue being thrust in and out many times in a minute, at others more slowly. It may be associated with facial spasm. It may occur during sleep.

Diagnosis.—This is generally easy. If there are hemiplegia and palsy, but no wasting of the muscles of the tongue, no reaction of degeneration, the lesion is supranuclear. If there is paralysis of the tongue on the one side, and of the limbs on the opposite, there is probably a unilateral lesion in the medulla below the nucleus. When the disease is on the surface of the medulla, the paralysis is commonly unilateral, and is associated with paralysis of the corresponding half of the palate and vocal cord, because of the involvement of the spinal accessory.

Prognosis.—The prognosis is usually unfavorable, because the lesion is incurable.

Treatment.—The treatment embraces that of the disease producing it. The symptom of lingual paralysis may be treated with electricity—with an electrode in the shape of a tongue depressor. The treatment of spasm has been by sedatives, including bromids, by iodids, and by electricity.

HYPOPHYSIS.—See Pituitary Body.

HYPOPYON.—See Cornea.

HYPOSPADIAS.—See Penis (Deformities).

HYSTERECTOMY.—The uterus may be removed by way of the abdomen or through the vagina.

Abdominal hysterectomy may be complete or the womb may be amputated at the internal os. Unless the uterus is removed on account of malignant disease, supravaginal amputation of the uterus is to be preferred.

The steps of this operation are as follows: An incision is made in the median line of the abdomen, 4 or 5 inches in length. The ovarian artery is ligated in the top of the broad ligament, about an inch from the pelvic wall; a second ligature secures it at the uterine cornua. The round ligament, with its artery, should next be ligated about 2 inches from the uterus. Similar ligatures should then secure the opposite ovarian artery and round ligament. The broad ligament should now be divided as far as the uterus, cutting on the inner side of the ligature on the round ligament. The peritoneum covering the anterior and posterior surfaces of the uterus is now divided transversely at a point a little above the internal os and stripped well down toward the vaginal vaults.

The uterine arteries are now ligated close to the cervix, care being taken to avoid the ureters, which pass about 3/4 of an inch from the cervix at this point. The uterus is then amputated by a wedge-shaped incision through the cervix.

The cervical canal is now sterilized with a solution of bichlorid of mercury (1 : 500), and the flaps of the cervix are brought together by 3 or 4 interrupted sutures. The stump of the cervix is now covered by bringing together the reflected layers of peritoneum, and the broad ligaments are closed by interrupted sutures. The remaining steps of the operation consist of the toilet of the peritoneum and closure of the abdominal wound.

Vaginal hysterectomy may be performed for the relief of cancer or any tumor which is sufficiently small to pass through the vagina.

The steps of this operation are as follows: The cervix is seized with a tenaculum and drawn downward and forward. A transverse incision is made through the posterior vaginal vault, and Douglas' pouch is opened. The cervix is now drawn backward and the uterovesical pouch is opened. The broad ligaments are next secured in successive portions by forceps, and the uterus is cut away. A light gauze pack is now introduced in the upper part of the vagina. The tampon and forceps are removed at the end of 48 hours. The uterus may also be removed by a combination of the vaginal and abdominal methods.

HYSTERIA. Definition.—Hysteria may best be defined as a psychoneurosis. The psychic element is the essential one, but it is difficult to limit or define it. Perhaps the best conception of hysteria is by regarding the disease as a state in which the various normal associations of the mental, sensory, and motor centers of the brain are interrupted, and in which there is seen, as a consequence, a vast array of purely temporary deliria, accompanied by functional lesions of the sensory and motor tracts. This leads to curious mental reactions, such as emotional and intellectual disorders, with convulsions, and to paralyses of motion and sensation.

Causes.—Hysteria has many well-recognized causes. Among these the most prominent is *heredity*. The disease is engrafted usually on a neurotic stock, and this ancestral base may have been prolific, not only of hysteria itself, but of other nervous disorders, such as insanity, epilepsy, and neurasthenia. Briquet found 25 percent of neurotic relations among 351 hysterics, but only 2 1/2 percent among nonhysteric patients.

Next to heredity, *trauma* is the most important cause of hysteria. It acts more potently in men even than in women, especially in association with alcoholism. It is also active in children. It is especially important from a medicolegal standpoint, as such cases closely simulate organic disease. Trauma is especially likely to cause the so-called permanent stigmata of the disease, in contradistinction to the paroxysmal form. It is unusually active when associated with shock or fright, as in severe accidents.

Eye-strain is a very frequent cause of hysteria, pseudo-epilepsy, hystero-epilepsy and similar nervous disorders.

Acute and chronic diseases of various kinds may act as exciting causes of hysteria. It thus happens that hysteria is sometimes a complication of organic disease, and hence may seriously confuse the diagnosis. Among the diseases causing hysteria are the exhausting and febrile diseases, those entailing pain and anxiety, and those that cause fright. Hysteria has been noted in cases of epilepsy, in organic nervous disease, such as tabes, and in syphilis. It has also been seen in the puerperium.

Emotional and moral shock is a potent cause of hysteria. Fright, disappointment, shame, anxiety,

and grief may all act thus. The sight of some frightful accident, the loss of a near relative, disappointment in love, a threatened disgrace, and pecuniary embarrassment may be mentioned. Religious excitement, especially among the ignorant, has long been known as a cause of hysteria.

The various *toxemias* may cause hysteria. Among these are states of chronic poisoning from alcohol, tobacco, lead, mercury, and bisulphid of carbon. In fact, any poison that lowers nerve tone may be supposed to have a hysterogenous quality.

Errors in education may lead to hysteria; especially in children. Overindulgence, and the morbid excitement of the emotions, as by unhealthy fictional literature, as well as excessive severity and cruelty toward children, may cause the disease.

Occurrence.—Hysteria prevails extensively and is not confined to any race or country. It is seen in men as well as in women; and children, contrary to the belief of former years, are distinctly prone to it. It has even been described in the lower animals. The tendency to it diminishes toward middle life. In women, according to some French statisticians, it is most common about the twentieth year. In the Paris hospitals hysteria is even more common in men than in women.

Symptoms.—The symptoms of hysteria are usually divided into the *paroxysmal* and *interparoxysmal*. This is done for convenience of description, but the distinction is also of clinical significance, because the two classes of symptoms are by no means always found in the same patient.

By the **paroxysmal symptoms** are meant those that are convulsive in character. A certain proportion of hysterics, but by no means all, are subject to fits. These fits have quite a definite character, sufficiently so to admit, if they are carefully studied, of a complete differentiation from epileptic and other convulsions. Following the method of Charcot, the hysteric fit is best analyzed and studied by dividing it into 4 stages. But, beforehand, it is necessary to recognize that the hysteric convulsion is usually preceded by prodromes. These are mental, and are marked by change of character, depression of spirits, moodiness, irritability, and emotional excitability. These prodromes are sometimes recognized by the patient, and may also be apparent to friends and attendants who are familiar with the case. Disturbance of sleep and of digestion may also appear. The fit itself is usually ushered in with an *aura*. This may be an intense, circumscribed pain in the head, called *clavus*, or pain in the ovarian region, or the sense of a ball rising in the throat—the well-known *globus hystericus*. Other prodromes or auræ may consist of various motor and sensory disorders, which are likely to remain even after the fit, and are, hence, appropriately described among the interparoxysmal symptoms.

The hysteric fit may, as just said, be divided into 4 periods.

The first or epileptoid stage begins as a tonic convulsion. The body is stiffened out, usually in opisthotonos, and all the muscles of the limbs are rigid. The eyes are set, either crossed or in conjugate deviation. The teeth are clenched, the breath labored or arrested, the pulse quickened. This tonic soon merges into the clonic spasm. In this latter the muscles are convulsed in a way very similar to that of true epilepsy. During the whole of this first stage the consciousness is obtunded, but not often entirely lost, and sensation is much impaired or even abolished. The tongue is not bitten, no bodily injury is sustained, and there is no involuntary discharge of urine or feces. As the clonic spasm gradually relaxes, the patient lies supine, with closed and tremulous eyelids, noticing little or nothing, or perhaps passing into a slight apparent sleep. In mild cases this first or epileptoid stage may constitute the whole of the attack, and thus the case may closely simulate epilepsy.

The second stage is called the period of grand movements, or *clownism*. In this the patient throws the body into various extravagant movements and positions. Some of these are apparently purposive, and all of them are disordered and without system. Such movements, of great variety and violence, have characterized some of the epidemics of hysteria that have occurred in the past, especially during the Middle Ages, and in more recent times under the influence of religious excitement.

The third stage is one of passionate attitudes; it is a sort of dramatization. The patient acts in response to an emotional or even a delusional state of mind. This and the preceding stage are only well marked in cases of extreme severity. The two stages may be merged into one, in which the patient seems to be in a sort of frenzy, portraying a greatly disordered state of the intellect and emotions.

The fourth or last stage is one of delirium. The motor excitement subsides, and the patient remains for a while in a semiconscious state, marked by emotional disturbance, especially sadness accompanied by tears. It must be understood that the hysteric fit is not always clearly subdivided as described here, but that abortive or undeveloped attacks may occur which present various modifications and combinations of the symptoms described. In severe cases profound modifications of paroxysmal hysteria occur, most prominent being somnambulism, catalepsy, and trance.

The interparoxysmal symptoms of hysteria are sometimes called the **stigmata.** They occur between the attacks, or even, in many cases, quite independent of convulsions. In fact, they are often seen in patients who never present the paroxysms. They are of first importance because they simulate organic diseases. They may be sensory, motor, visceral, and psychic.

The sensory symptoms of hysteria may be anesthesia, hyperesthesia, or paresthesia.

Anesthesia is very common, and should always be searched for. It may be a complete hemianesthesia, a monoanesthesia, or an anesthesia in spots. The hemianesthesia is complete from crown to sole, and involves the mucous surfaces of the eye, mouth, and nose. In some cases it can be transferred from one side to the other. The

monoanesthesia may involve an arm or a leg. It is usually sharply demarcated at its upper limit at a right angle to the limb—hence presenting the form of a gauntlet or a stocking. The anesthesia in plaques, or spots, may present a great variety of forms, the various anesthetic areas being scattered over the surface without regularity of size or distribution.

Hyperesthesia is of next importance. Intense pain, limited to a small area on the head, is common. This is the symptom called **clavus**. Hyperesthetic zones, especially over the ovaries, and along the spine and under the floating ribs, are common. Pressure upon these may induce a fit in susceptible patients, and, *per contra*, may abort a paroxysm. Intense neuralgic pain in the breast or in a joint may closely simulate the effect of organic disease. This is seen in hysteric joints.

Paresthesia is closely allied to hyperesthesia, but is not common in the disease.

The special senses may become anesthetic in hysteria. Amaurosis may exist in various forms. The most common is a contraction of the visual fields and alterations in the color field. Complete blindness is occasionally seen, and in very rare instances a homonymous hemianopsia. Hysteric deafness has been reported, and abolition of taste and smell, especially on the anesthetic side in hemianesthesia, may be present.

The motor symptoms of hysteria may assume the form of paralysis, contracture, tremor, or incoordination. *Paralysis* is common. It may be a hemiplegia (often accompanied by hemianesthesia), a monoplegia, a paraplegia, or even, very rarely, a universal palsy. Any form of paralysis may be accompanied by contracture, but in some cases the palsied limb is flaccid. There may be slight wasting, and in some cases a characteristic blue edema. The deep reflexes may be increased, and even ankle-clonus has been claimed to be present. The duration is sometimes very prolonged. The onset may be sudden, following one of the causes already mentioned, especially trauma or an emotional shock.

Contracture is common, and may be most obstinate. There is usually some loss of power, but the two states are not necessarily associated. Pressure on a nerve-trunk may induce an attack, sometimes accompanied by a hysteric fit.

Tremor is an important symptom. It is usually of a vibratory kind (from 8 to 12 vibrations to the second). Sometimes it is coarser and more like an intention tremor. It may be caused by trauma or shock, and is sometimes seen in toxic cases (as from alcohol, lead, or mercury).

Incoordination, or astasia abasia, is an occasional symptom. In severe cases the patient can neither walk nor stand. In others the gait is extremely disordered, without true paralysis. The patient, on sitting or lying, has control of the movements, and may even be able to progress on "all fours."

The visceral and internal disorders of hysteria are numerous. Among them may be mentioned aphonia, vomiting, coughing, hiccuping, rapid respiration, yawning, tachycardia, vasomotor disturbance, distention of the bowel and phantom tumor, pyrexia, and anuria. A free discharge of limpid urine is common after a fit.

The psychic symptoms of hysteria may be classed together as presenting the common characteristic of morbid suggestibility. The hysteric patient is usually highly susceptible to unwholesome impressions, these varying according to the mental characteristics of the individual. It must not be forgotten, however, that hysteria is a genuine disorder, and not one of simulation and mere perversity. This psychosis is not incompatible with mental and moral traits of a high order.

Diagnosis.—Hysteria must be distinguished from the innumerable diseases which it more or less simulates. Among these are epilepsy, paralysis from organic disease, and affections of the sense organs. It must not be confused with malingering or with other mental disorders, especially paranoia. In one sense hysteria does not simulate exactly any disease. It is an affection *sui generis*, with its own unmistakable stigmata, and is to be recognized by a careful study of these. See Epilepsy.

Pathology.—Hysteria, being a psychoneurosis, has no recognizable gross anatomy. It doubtless depends upon a faulty state of the functions of the higher brain centers. The attempt to explain it by any mechanic theory (as by the motility of the neurons) has not been generally received with favor. The nutrition of the brain-cells may be impaired in some cases, but the exact pathology of the disease is obscure, just as the exact mechanism of all brain states is obscure.

Treatment.—The successful treatment of hysteria requires, more than all other affections, the use of **suggestive therapeutics.** The practitioner must aim to gain a mental ascendancy over his patient. This requires tact, moderation, and a thorough appreciation of the essential features of the disease. Errors of refraction should be carefully corrected by the proper lenses. As strictly subsidiary agents may be mentioned hydrotherapy, electricity, massage, isolation, diet, and sustaining drugs. The rest cure is indicated in severe cases. Depressing or sedative drugs should be used with the utmost caution, and in most cases not at all.

I

ICE.—Ice is refrigerant and analgesic. It constricts the caliber of small vessels, and thus acts as a hemostatic, antisecretant, and antiphlogistic. Pieces of ice held in the mouth allay the sensation of thirst. Small lumps can be slipped between the lips of a sleeping infant in acute angina, and the little patient be kept comfortable by the inflamed structure being thus bathed with cold water. Hemorrhages from the mouth, throat, and nose, and even from the lungs, are indirectly controlled by allowing pieces of ice to dissolve in the mouth. Cold, wet compresses are useful applications to be made to the skin of the neck when disposition to recurrent catarrhal pharyngitis is marked.

The local application of cold, by contracting the walls of the blood-vessels and diminishing nervous irritability, is a powerful and valuable agent in the treatment of acute inflammations of the eye. It is most useful in traumatic cases and in high grades of conjunctivitis, notably the gonorrheal form. It may be applied dry, by means of small ice-bags, or by cold water being passed through coils of metallic or rubber tubes; but wet applications are more convenient and are generally efficient. The simplest apparatus consists of a bowl of iced water, or, better, a lump of ice, by the patient's side, and some pledgets of lint or linen. The latter should not be folded more than once, and should be changed every few minutes, as, if left on too long, particularly if their thickness prevents rapid evaporation from the linen fold, the surface next the eye becomes warm and an alteration of heat and cold is produced, which may do more harm than good. The application should be continuous, since vascular reaction follows the removal of the cold. Care should be taken not to continue this treatment too long. The sensations of the patient are generally a very safe guide, and it is not well to insist upon a continuance of the application when it ceases to be agreeable. As a rule, cold should not be used when there is a tendency to slough.

Obstinate vomiting is often checked by swallowing fragments of ice. Ice is applied to the head in cerebral congestion, to the spine in chorea, etc., locally in hemorrhoids, bubo, orchitis, and to the uterus in postpartum hemorrhage. Ice-bags placed along the spine in epilepsy when the circulation is sluggish, the hands and feet always clammy and cold, will restore warmth, relieve headache and symptoms of incipient paralysis. Ice in a bag may often be employed beneficially as an anodyne in inflamed ovary or testicle.

In dysentery, when the lower part of the colon is affected, the local use of ice sometimes has an almost marvelous effect. The whole aspect of a very severe and alarming case, in which the symptoms indicate that the colon is affected high up, may be changed in a single hour by the continuous use of ice suppositories. While it is not necessary to have the pieces of ice entirely regular in shape, care should be exercised that no sharp edges are left. The suppositories should be rapidly used, one being put into the rectum every 3 or 5 minutes, so as to get, for at least 1/2 of an hour to 1 hour, the effect of the continuous application of cold.

Ice is used directly or in one of the following ways:

Ice-bag, a bag of waterproof material, filled with ice, for application to any part of the body. **Ice-cap,** a bladder or rubber cap filled with pounded ice for application to the head in case of congestion. **Ice-cot,** a bed cooled by ice, so as to reduce the temperature of the patient. **Ice-cradle,** a device that consists in the suspension, over a febrile patient in bed, by means of iron frames or barrel-hoops, of a number of zinc buckets kept half filled with ice and inclosed in a light covering. The patient is covered with a muslin sheet and provision is made for the circulation of pure air in the cradle. The temperature of the patient is to be taken at least every 4 hours, and if it falls to 100°, the apparatus is to be removed. If a sense of chilliness appears, hot bottles are to be applied to the feet. **Ice-poultice,** or **ice-compress,** an application of broken ice used for local refrigeration. See COLD.

ICHTHALBIN.—Ichthyol albuminate occurs as a greenish-brown powder, odorless and almost tasteless, insoluble in water but soluble in alkaline solutions. It contains 75 percent of ichthyol, and is used in syphilis, also in scrofula with a lowered condition of nutrition. Dose, 15 to 30 grains thrice daily.

ICHTHARGAN.—Silver ichthyolate. A compound of ichthyol and silver, claimed to contain 30 percent of metallic silver and 15 percent of sulphur in organic combination. It is reported to combine the bactericidal action of the silver salt with the penetrating and antiphlogistic action of ichthyol. Solutions of 1 in 2000 to 1 in 500 are used in gonorrhea. It is freely soluble, is claimed to be more strongly bactericidal than silver nitrate and far less toxic.

ICHTHOFORM.—Ichthyol formaldehyd. A dark-brown odorless powder. It is recommended internally in intestinal sepsis and externally in endometritis, in ozena, and in wounds, ulcers, etc. Dose, 10 to 30 grains.

ICHTHYOL.—Sodium sulphoichthyolate. A preparation obtained from certain varieties of fossiliferous shale occurring in the Tyrolese Alps. It has a characteristic bituminous odor and taste. It is a good antiphlogistic, and has proved efficient in eczema and psoriasis, and in rhinology, ophthalmology, and gynecology. It is freely soluble in

water, feebly so in alcohol and ether, but mixing with fats in all proportions. **Sodium ichthyolate** is the form usually employed for internal use, and may be given in the dose of 2 to 10 grains. It is best prescribed in pills and capsules.

Ichthyol is of real service in skin-diseases, such as chronic eczema, acne, urticaria, prurigo, lupus, and keloids. To cover its disagreeable odor, oil of citronella should be added, somewhat as follows:

℞.	Ichthyol,	ʒ ij
	Lard,	ʒ j
	Oil of citronella,	gtt. xv to xxx.

In erysipelas an ointment of 20 percent strength may be employed, or a watery solution containing one dram to the ounce may be painted on by a camel's-hair brush. It is very efficacious in the pain and swelling of the joints in acute rheumatism, during and after the attack. The ointment to be here used should have the strength of 30 parts of ichthyol to 70 of benzoinated lard. Ichthyol combined with mercurial and belladonna ointments is also beneficial in this condition. To remove lymphatic enlargements, and in the treatment of bruises, sprains, and chilblains, and in the various inflammatory affections of the female genital organs, such as ovaritis, endometritis, and parametritis, it is peculiarly valuable. It is remarkably efficacious in removing periuterine and pelvic exudations.

Ichthyol possesses marked advantage in the treatment of diffuse inflammation of the external auditory meatus and auricle. A 20 percent strength with cosmolin base is admirable in ulceration of the septum and of fissure at the edges of the nostril. In the proportion of 1 grain to 6 ounces of lime-water ichthyol has been recommended in the treatment of purulent rhinitis. Its derivatives: sodium, calcium, ferric and lithium ichthyol and ichthermol or mercury ichthyolate have the actions of their constituents.

ICHTHYOSIS (Fishskin-disease; Xeroderma).

Definition.—A congenital chronic hypertrophic disease, characterized by dryness and scaliness of the skin and a variable amount of papillary hypertrophy.

Symptoms.—Two forms of the disease are distinguished—ichthyosis simplex and ichthyosis hystrix.

Ichthyosis simplex is the common variety encountered. There may be merely dryness and harshness of the skin, with fine, furfuraceous scaling (*xeroderma*). Frequently, however, the disease is more marked, exhibiting variously sized reticulated scales, which may be small and thin or large and thick, resembling fish-scales. Upon the arms and legs the epidermis forms diamond-shaped or polygonal plates, bounded by the natural furrows of the skin.

Ichthyosis hystrix is a rarer and more severe variety. It is characterized by papillary hypertrophy, showing itself clinically as irregular or linear, corrugated, warty or spinous, horny patches.

Ichthyosis simplex involves more or less the entire body surface. It is most marked, however, upon the extensor surfaces of the arms and legs. Ichthyosis hystrix affects only limited areas of the skin, such as the arm, neck, axilla, umbilicus, etc.

The course of ichthyosis is extremely chronic. The disease begins usually in the first or second year of life, increases in severity until adult age is reached, and then remains stationary, thus continuing throughout the patient's lifetime.

Ichthyosis is markedly influenced by the seasons. It is always worse in cold than in hot weather. In the spring and summer, when perspiration is increased, great improvement takes place.

The disease is not inflammatory, and there is, as a rule, no itching. It is, however, not infrequently complicated by eczema.

Etiology.—Ichthyosis is a congenital disease, although it does not, as a rule, manifest itself before the first or second year. A hereditary influence exists in many cases.

Pathology.—The pathologic process consists of a hyperplasia of the cells of the corneous and mucous layers of the epidermis. The papillary layer of the corium is in many cases also hypertrophied.

Diagnosis.—The characteristic features of ichthyosis are: The harsh, dry skin; furfuraceous scales and polygonal plates; the localization of the eruption; the history and the absence of inflammatory symptoms.

Prognosis.—The prognosis is unfavorable as to cure. Considerable relief, however, may be afforded by proper treatment.

Treatment.—Internal treatment is of little or no value. External treatment is to be solely relied upon. This has for its object the removal of the epidermal scales and the softening of the skin with unguentous substances.

Baths are of great value, and are to be employed frequently. Either a simple warm bath or an alkaline bath (sodium bicarbonate, 4 to 8 ounces to bath) may be used. In mild cases frequent bathing, followed by the inunction of some oily or fatty substance, will be all-sufficient. For this purpose petrolatum, lard, olive oil, oil of sweet almonds, diluted glycerin, etc., may be employed. A simple and efficient inunction consists of:

℞.	Lanolin, Petrolatum,	} each,	ʒ j.

In severe cases the following plan is advised: Friction with soft soap twice daily for 4 or 5 days, followed by a bath and the inunction of a simple ointment.

Iodid of potassium in ointment form has been highly spoken of:

℞.	Potassium iodid,	gr. xx
	Glycerin,	ʒ j
	Lard,	ʒ j.

In ichthyosis hystrix caustics, the Paquelin cautery, or the knife may be necessary to remove the hypertrophic tissues.

ICTERUS.—See JAUNDICE.

IDIOCY.—See INSANITY.

IDIOPATHIC DILATATION OF COLON.—See HIRSCHSPRUNG'S DISEASE.

IDIOSYNCRASY.—Any peculiar and not obviously correlated reactions against external influences exhibited by any individual. It is not to

be confounded with "constitution," which is the foundation of the individual—his powers, capacities, and organizations—nor with temperament. Any single peculiarity of an individual is commonly spoken of as "an idiosyncrasy." It may be mental or physical, innate or acquired, permanent or temporary. Instances of idiosyncrasy are found in those who swoon at the sight of blood or of beet-root, horror and fainting induced by the odor of roses or apples, etc. In another group the higher nerve-centers play no part, the phenomena being of reflex production or due to direct poisoning of the system or organs. For instance, eggs, honey, sugar, or fish may produce gastric pain, nausea, or vomiting; strawberries may be a violent poison to some, producing shock; convulsive spasms may be excited by the odor of musk or civet; asthma may be aroused by the smell of ipecac.

There are cases in which minute doses of opium or belladonna may poison some persons, while in others enormous doses may be taken with impunity. The causes of innate idiosyncrasies are, for the most part, unexplained. Imaginary idiosyncrasies are found in those who, held by prejudice or misled by fancy or unsound judgment, declare that particular foods or medicines disagree with them. It is usually possible to evade such obstacles and assertions by tact, undermine them by argument, or dissipate them by firmness.

IGNIPUNCTURE.—A method of cauterization employed in the treatment of certain forms of hypertrophy by the introduction of platinum needles heated to whiteness by the electric current.

ILEUM.—See Intestines.

ILEUS.—See Intestinal Obstruction.

ILIUM.—See Hip-joint.

ILLAQUEATION.—A method of changing the direction of misplaced cilia, by withdrawing them, by a noose, through an opening in the adjacent tissue of the lid. Unfortunately, the eyelashes frequently regain their abnormal positions by reason of their own elasticity. See Eyelids.

ILLEGITIMACY.—See Legitimacy.

ILLUSION.—A deception, false appearance, or mockery, sometimes used synonymously, but incorrectly, with hallucination. Illusion denotes the erroneous conception by the mind of some external object—a false interpretation of an actual perception. Illusions are consistent with sanity. Expectant attention at the moment an external object is perceived exerts a subtle influence upon the observer or auditor. It falsifies to an alarming extent the experiments of scientific and especially medical men; but these are not symptoms of insanity. Illusions arising from the exaggeration or perversion of internal sensations constitute the prominent symptoms of the hypochondriac.

IMBECILITY.—See Insanity.

IMMOBILITY.—Absolute rest. It is one of the most potent factors in healing. It is a fundamental and generally applicable surgical principle, especially in the treatment of bruises, wounds, sprains, and fractures, and in articular diseases. Repair is in direct proportion to rest, and the nearer rest is to immobility, the more perfect the repair. Physiologic position and equable pressure contribute to immobility, and mechanic contrivances are, as a rule, essential. Molds and splints are the most useful forms; bags of sand, shot, and water, together with weights, pulleys, and springs, are means employed. Molds of millboards, gutta-percha, paraffin, starch, dextrin, potassium silicate, plaster-of-Paris, and strips of wood and metal are materials used. Wire molds and successive strips and layers of bandages may be used to immobilize a part. Gum, starch, or chalk may be added over the layers of the apparatus in process of construction. Rigid molds and splints may be usefully combined with suspension to secure immobility. See Fractures, Dislocations, Chest, etc.

IMMUNITY.—Immunity may be described as the condition or state of an individual who is nonsusceptible to a given disease. (This applies equally well to animals.) Human beings are, practically speaking, immune to certain diseases of animals and *vice versâ*. If, however, man or animal is subject to a change of environment, or suffers in some way to lessened body resistance, naturally resistant subjects may be infected with certain diseases. The exact cause (or causes) of this phenomenon is unknown; but there are various theories which in a way, make certain phenomena appear intelligible.

There is strictly speaking no such thing as an **absolute immunity.** While certain animals appear under natural conditions to be nonsusceptible to diseases, yet when they are placed in an unfavorable atmosphere or the quantity of food is cut down, or their general condition is in some way interfered with, they can be readily infected with the bacterium or parasite of that disease to which they are ordinarily immune.

Natural immunity does exist, and is evidenced by man being immune to such diseases as hog cholera or swine plague, and animals being naturally resistant to small-pox, scarlet fever, etc.

Active immunity is where an animal or human being is rendered nonsusceptible to certain infections, by injections of living or dead bacteria, toxins, nonvirulent cultures of bacteria, or cultures attenuated by injecting them in the presence of an antiseptic. These inoculations are begun in small doses and repeated at stated intervals until no symptoms follow injections of massive doses. **Passive immunity** can be brought about by the injection of antitoxic or antimicrobic sera. (These sera are obtained respectively, from an animal immunized against a toxin and one immunized against a bacterium.)

What is spoken of as **acquired immunity** is a condition brought about in an individual, who has passed through a given disease (as small-pox, scarlet fever, measles). All diseases do not confer immunity upon an individual who has had one attack of that disease; some really predispose to other attacks as for example, pneumonia, erysipelas, diphtheria, rheumatism, etc. Vaccinia is generally recognized as variola in the cow and when a person is successfully vaccinated with cow-pox he passes through a modified form of the disease (varioloid).

As to the **theories of immunity,** most of these set forth that some substances or bodies (which the Germans refer to as "antikorpers" or antibodies) are formed in the individual; and these are antagonistic to the bacterium or to its toxin.

One of the oldest suppositions was the **exhaustion theory.** This had for its basis the hypothesis that, while the disease lasted in an individual, something was gradually being exhausted which made the soil or pabulum unsuitable for another invasion and foothold of that infective agent.

Another theory was that of **retention** in which it was maintained that something inimical to the infective agent was retained in the body and thus a second attack was not brought about. The **humoral theory** was one in which it was believed that the humors of the body exhibited bactericidal properties against the infective agent.

The **theory of phagocytosis** as put forward by Metchnikoff has for its basis the fact that different white cells of the blood (polynuclear and large lymphocytes) as well as somatic cells (endothelial cells and fixed connective tissue cells) exhibit an engulfing process in which bacteria are taken in by these cells, and destroyed. He claims that the destruction of bacteria is due to substances elaborated by the granules of the white blood-cells, which act as a ferment, and thus digest them. The polynuclear leukocyte or microphage elaborates what is called microcytase, and the large lymphocyte or macrophage elaborates macrocytase. The endothelial and fixed connective tissue cells also exhibit this digesting action, but the substances have not been so thoroughly or completely studied as those of the leukocytes.

The so-called **lateral chain or side chain theory of Ehrlich** is one which has received the greatest consideration. Ehrlich sets forth, that each cell has (theoretical) side chains, whose function it is to assimilate some suitable food stuff. Each of these processes is specific for this particular substance and will not unite with any other. Even in health these side chains are present and are constantly being produced, cast off, and reproduced in the same way that other structures of the body are. As an example of the action of the specificity of these side chains, let us imagine a cell provided with side chains for tetanus, cholera, diphtheria and typhoid fever. Suppose the individual is attacked with diphtheria. As soon as the disease manifests itself and the toxin of the **bacillus diphtheriæ** has commenced to act on the system, the side chains for this particular food stuff (toxin) unite with the molecules of toxin. As the union is complete the side chain is thrown off into the circulation, having neutralized by its union the molecules of the toxin. None of the other side chains of this cell unite with **this toxin,** but if the patient is taken ill with any of the other diseases mentioned, the poisons will be acted upon and neutralized by the specific side chains, exactly as in diphtheria.

A lack of, or an overabundance of, specific side chains may explain the nature of natural immunity.

These side chains have also been referred to as **receptors** on account of their combining affinity for foodstuffs. They have been grouped under three heads according to their action. The first group has a single unsatisfied combining group and fixes or unites molecules of simple constitution; the second group has a combining group for the food molecule and another group which is active or zymotoxic, leading to some physical change; and the third group relates to those having one action of the food molecule and another which fixes a ferment in the fluid medium around an **amboceptor.** Now an amboceptor is a product or substance which is produced in the body of an animal which has been gradually immunized against a certain bacterium or a cell of any type. When the serum of such an animal is brought in contact with the cells against which it was immunized, it will cause a destruction of these cells. This is due to the interaction of two substances—the **amboceptor** or **immune body** and the **complement.** This latter substance is contained in white corpuscles normally and the process of **cytolysis** does not take place unless the complement is present. Complement can be destroyed by heat which makes an **inactivated serum,** but can be **reactivated** by the addition of serum of an animal of the same species.

This theory seems in harmony with the action of antitoxins as well as many of the antisubstances.

Bordet's test of the detection of human blood may also be explained by this theory. A rabbit is inoculated with human red blood cells, at first in small dose and later with gradually increasing doses. After a certain time, the animal is sacrificed. Its serum is separated and is brought in contact with human red cells. In a very short time, **hemolysis** takes place and precipitation of the broken down red cells occurs, indicating a specific action. If this serum is brought in contact with the red cells of another mammal no reaction takes place.

Where stains (upon clothing, implements, carpets, etc.) are suspected to be human blood, these are dissolved in normal salt solution and brought in contact with this humanized rabbit serum. If a positive reaction occurs (hemolysis and precipitation) the stain can be said almost certainly to be human blood, while if a negative reaction takes place (no hemolysis) the stain may have been of rust or the blood of some other animal.

In the development of any antibody all that is necessary is the repeated injection into a guinea pig or other animal, of the material or cell against which it is to be used.

The injection of a toxin will generate an antibody for this toxin (antitoxin); thus the injection of the typhoid bacillus will generate an antibody which will destroy the typhoid bacillus; injection of liver or muscle tissue will produce an antibody to these substances. In other words, the reaction is specific, the typhoid antibody will not destroy any other bacillus; the antitoxin of diphtheria will not neutralize or destroy any other toxin, etc.

The production of these antibodies (antisera) is a great help in the identification of certain species of bacteria by the so-called agglutination tests or

serum diagnoses. See Serum Therapy and Vaccine Therapy.

IMPETIGO.—An acute inflammatory skin-disease characterized by one or more pea-sized or finger-nail sized, discrete, rounded, and elevated firm pustules, unattended, as a rule, by itching or other subjective symptoms. The pustules are rounded, with thick walls, and are surrounded by areolæ. They appear suddenly, and come out one after another during the first week of the attack, attain full size, and then undergo absorption or crusting. No scar or pigmentation follows. The disease is likely to occur in children.

Impetigo contagiosa is an acute, contagious, inflammatory disease of the skin, characterized by discrete, flat, superficial vesicles or blebs, which rapidly become pustular and dry upon the skin as thin crusts. The eruption is most common upon the face and hands. The lesions begin as flat vesicles or blebs, which, in the course of 24 hours, become vesiculopustular or pustular. Rupture soon occurs, the exudate drying upon the skin as thin, wafer-like crusts, which appear to be "stuck on." The edges of the crusts become detached, curl up, and the crusts drop off, exposing to view reddish spots which soon fade. The lesions at times show a tendency to umbilication. A coalescence of neighboring pustules may occur, leading to the formation of patches of considerable size. In severe cases there may be slight febrile disturbance. Itching is slight or absent. Occasionally the eruption takes on a circinate form.

The affection is chiefly seen in poor children. It is likely to accompany pediculosis capitis, as the result of scratching. Epidemics of contagious impetigo are not uncommon in institutions for children. The affection is caused by inoculation with the ordinary pus microorganisms, particularly the staphylococcus pyogenes aureus. The chief characteristics are the discreteness, superficiality, and autoinoculability of the lesions. The affection may be cured in a week or ten days, or, indeed, may get well spontaneously.

Treatment.—The crusts are removed with soap and warm water, after which the following ointment may be used:

℞. Ammoniated mercury, gr. x to xl
Petrolatum, ʒ j.

Impetigo herpetiformis (*herpes pymœicus*) is a very rare disease of the skin, characterized by the formation of superficial miliary pustules that may be discrete, but are usually closely set. The contents of the pustules are at first opaque, but become greenish-yellow, and dry up into dirty-brown crusts. The disease spreads until the whole surface is covered with swollen, crusted, and excoriated patches. It develops first on the inner side of the thighs, and about the groins, navel, breasts, and axillæ, and is mainly seen in pregnant women. The termination is fatal, as a rule.

IMPOTENCE.—Lack of power, applied especially to male incapacity of procreation. It is variously qualified as *atonic*, when due to spinal or central exhaustion; *paralytic* or *paretic*, when the impulse that leads to the performance of the function is abolished; *psychic*, when due to fear, bashfulness, or mental disturbance; *symptomatic*, when due to some drug or to a disturbance of the health.

Psychic impotence results from undue predominance of the cerebral inhibiting centers. Irritable impotence results from undue excitability of the nervous centers. Paralytic impotence results from injury, disease, or degeneration of the nervous centers. Irritable impotence is most common, and occurs after habitual masturbation or excessive venery. The semen is ejaculated before penetration has been effected, and the erection speedily subsides.

Aphrodisiacs determine blood to the penis and urinary organs and cause morbid erections without any voluptuary sensations and desires. The most common aphrodisiac is cantharides. In atonic conditions of the organs 10 to 15 minims of the tincture of cantharides may be given for a short time every 3 or 4 hours. Diluted phosphoric acid, phosphate of iron, strychnin, and ergot of rye are used in impotence. Cold douches to the genitals are of great value. Electricity is a remedy of some efficacy in certain forms of impotence. Interrupted currents passed in two directions—from the perineum to the glans penis, and from the groin along the spermatic cord to the testicles—may be used. The results are often disappointing. Special treatment is required in cases due to injury. Abstinence and hygienic measures are to be used in connection with electricity.

℞. Fluidextract of damiana, ʒ ijss
Tincture of nux vomica, ʒ vj
Compound tincture of cinchona, enough for ʒ iv.
Make into a mixture. Give a teaspoonful 3 times daily after eating.

℞. Zinc phosphid, gr. vj
Extract of nux vomica, gr. xx.
Make 40 pills. One pill 3 times a day.

See Nocturnal Emissions, Sterility.

IMPREGNATION.—The result of the union of the ovum and the spermatozoon. This may occur in the uterus, tubes, or ovaries. Impregnation is most likely to occur during the first 10 days after menstruation; it is least likely to occur between the fourteenth and twenty-first days. See Fetus, Pregnancy, etc.

INCOMPATIBILITY.—The relation between medicines that renders their admixture unsuitable. This incompatibility may be *physiologic*, *chemic*, *physical* or *therapeutic*. In the first case the incompatibility may be unintentional or intentional.

Chemic incompatibility generally results from neglect on the part of the prescriber of the most common chemic reactions, such as that:

1. Acids tend to combine with bases and to form salts.

2. Weak acids or bases are displaced from their combinations by stronger ones, so that salts in solution, when brought together, generally exchange their radicles, especially if by doing so an insoluble compound can be formed.

3. A salt in solution is easily decomposed by a

strong alkali if the salt is one having a weak or volatile base.

4. A substance in solution may be decomposed by another without precipitation, the product being soluble in the solution.

5. Alkaloidal salts are precipitated from their solutions by the addition of fixed alkalies, their salts, or salts which produce insoluble compounds. Oxids of the fixed alkalies decompose salts of the metals proper and those of the alkaloids precipitating their bases; but the base may be soluble in an excess of the alkali.

6. Tannic and gallic acids and vegetable substances containing them precipitate albumin, alkaloids, and most of the metallic oxids, and form inky solutions when brought into contact with the persalts of iron. Tannic acid precipitates gelatin.

7. Glucosids are incompatible with free acids or emulsin.

Insoluble Salts.—The following more or less insoluble salts will be formed whenever the materials of which they are composed are brought together in solutions: The hydroxids, carbonates, phosphates, borates, arsenates, and tannates of most earthy and heavy metals and alkaloids, and the metallic sulphids; the sulphates of calcium and of lead and the subsalts of mercury; the chlorids, iodids, and bromids of bismuth, silver, lead, and subsalts of mercury; the iodids of quinin, of morphin, and of many other alkaloids.

Table of Precipitant Solutions (Potter).

The following table shows the most important instances of solutions which mutually precipitate each other, the letter P meaning "forms a precipitate with," and S. =solutions:

Solutions of—	Alkaloidal S. (Generally).	Metallic S. (Generally).	S. of Lead Salts.	S. of Silver Salts.	S. of Calcium Salts.	S. of Magnesium Salts.	S. of Albumin.	S. of Gelatin.

Explosive compounds result from the admixture of powerful oxidizing agents with substances which are readily oxidizable. The most important members of these two classes are as follows:

Oxidizers.—Chlorin and its oxids, free hydrochloric acid, nitrohydrochloric acid, chlorates, hypochlorites, chromates, chromic acid, permanganates, nitric acid, nitrates, bromin, bromates, iodin, iodates, silver oxid, peroxids (dioxids).

Oxidizables or Combustibles.—Phosphorus, hypophosphites, sulphur and sulphids, glycerin, sugar, alcohols, oils, ether, tannin, cork, charcoal, creosote, dry organic substances, powdered iron and zinc, arsenic trioxid, cyanids, oxalates; ferrous, mercurous, and stannous salts.

Explosions have resulted from mixing fluidextract of uva ursi with certain samples of spirit of niter, chromic trioxid with glycerin, potassium permanganate with glycerin, nitric acid with glycerin, silver nitrate with creosote, silver oxid in pill with extract of gentian, potassium chlorate with glycerin and tincture of ferric chlorid. Calcium chlorid triturated with sulphur in a mortar has exploded; so also has calcium or sodium hypophosphite when triturated alone. Tincture of iodin with ammonia forms a high explosive, especially when triturated in the presence of water. Catechu and potassium chlorate have exploded in the mouth from the friction of a dry toothbrush. Hydrogen peroxid is peculiar in that it acts both as an oxidizer and as an oxidizable agent. It reduces oxidizable substances, and is itself reduced, and is, hence, incompatible with all the substances mentioned above. Nitrites may act in the same way under favorable circumstances.

Poisonous compounds may be formed by the admixture of many substances in solution, such as:

Potassium chlorate with potassium iodid in solution together do not react at ordinary temperatures, but in the system they evolve a poisonous agent, probably potassium iodate.

Potassium chlorate with syrup of ferrous iodid liberates iodin from the iodid in the warm stomach, causing severe gastric irritation, perhaps gastritis of dangerous degree.

Dilute hydrocyanic acid or potassium cyanid with calomel forms the bichlorid and bicyanid of mercury, both virulent poisons; with metallic hydroxids, carbonates, subnitrates, or subchlorids, cyanids of the metals are formed which are even more poisonous than the acid itself in its usual diluted form.

Pharmaceutic incompatibility differs from chemic incompatibility in the absence of chemic action, and is generally produced by adding one substance to another which, through difference in solubility, causes a precipitation of solid matter or a separation of part of the liquid. The separated constituents may be active, and hence important; or inert, and therefore unimportant.

Instances of this are the addition of an acid to a quinin and licorice mixture, resulting in precipitation of the glycyrrhizin (relied on to cover the taste of the quinin) by the acid; or the use of quinin, tincture of ferric chlorid, and licorice together; or the prescribing of solutions of chloral and potassium bromid with an alcoholic preparation, the

choral separating at the top as an alcoholate; or the neglect to prescribe acacia, or some other emulsifier, in mixtures of an alcoholic fluidextract of a resinous body with an aqueous preparation. When a fluidextract is diluted with a liquid differing in composition from those used in the fluidextracts, the gum, albumin, resin, and mucilage often separate. Water is the solvent for albuminous, gelatinous, gummy, and saccharine bodies and for a large number of inorganic salts. Alcohol is the solvent for volatile oils and resins, gum-resins, resinoids, balsams, and all drugs containing these as their active principles.

Instances of pharmaceutic incompatibility:

Resinous tinctures or fluidextracts with aqueous solutions.

Tincture of guaiac with spirit of nitrous ether.

Compound infusion of gentian with infusion of wild cherry.

Compound infusion of cinchona with compound infusion of gentian.

Essential oils with aqueous liquids in quantities exceeding 1 drop to 1 ounce.

Fixed oils and copaiba with aqueous liquids (except excipients).

Tinctures made with alcohol with those made with diluted alcohol.

Alcoholic tinctures and fluidextracts with aqueous preparations.

Spirit of nitrous ether with strong mucilages.

Infusions generally with metallic salts.

Therapeutic incompatibility arises when two agents are administered together which oppose each other in their action on the human system: as, for instance, belladonna in any form with physostigma. But in many cases physiologic antagonists are designedly prescribed together, one as a guard against the action of the other, as in the hypodermic administration of morphin guarded by atropin. See ANTAGONISM.

The dangers of incompatibility may in great measure be avoided by the use of the utmost simplicity in prescribing.

The subject can only be briefly considered here, but the following **simple rules** of Potter may help the burdened memory of the student and the practitioner.

Never use more than one remedy at a time, if one will serve the purpose for which you are prescribing.

Never use strong mineral acids with other agents, unless you know exactly what reaction will ensue. They decompose salts of the weaker acids, and form ethers when combined with alcohol. Never combine free acids with hydroxids or carbonates.

Select the simplest solvent, diluent, or excipient you know of, remembering that the solvent power of alcohol and of water for their respective substances decreases in proportion to the quantity of the other added.

Generally, do not combine two or more soluble salts; for such salts in solution, when brought together, usually exchange their radicles, thereby forming an insoluble compound.

Never prescribe a drug with any of its tests or antidotes.

Never prescribe a glucosid—as santonin, colocynthin, etc.— in combination with free acids or with a substance containing emulsin, as these agents will decompose it.

Aconite should be ordered in water alone; mercuric chlorid by itself, in water, or in simple syrup. The latter drug is incompatible with almost everything, even the compound syrup of sarsaparilla being said to decompose it.

Potassium iodid decomposes most of the metallic salts, and is one of the drugs which are best administered along.

The following-named substances are incompatible with so many others that it is best to always prescribe them alone; they are best given in simple solution: Alum, dilute hydrocyanic acid, dilute nitrohydrochloric acid, sulphuric acid, mercuric chlorid (corrosive sublimate), iodin and iodids, syrup of ferrous iodid, potassium permanganate, potassium acetate, potassium bromid, tartar emetic, tincture of guaiac, morphin acetate, morphin hydrochlorid, quinin sulphate, liquor calcis, liquor potassii hydroxidi, liquor potassii arsenitis, liquor ferri nitratis, tinctura ferri chloridi, zinc acetate, iron and quinin citrate, free chlorin in solution, tannic and gallic acids.

Silver nitrate and lead acetate and subacetate, though incompatible with almost everything, may be combined with opium, the latter forming therewith a compound which, though insoluble, is therapeutically active as an astringent and anodyne lotion. Silver nitrate with creosote forms an explosive compound.

Tannic and gallic acids, and substances containing them (as the astringent bitters), precipitate albumin, alkaloids, and most soluble metallic salts. They may be prescribed with the protosalts of iron, but not with its persalts. Calumba is the best vegetable tonic to use with ferric salts, as it contains neither tannic nor gallic acids. Tannic acid precipitates gelatin.

Iodin and the soluble iodids are incompatible with the alkaloids and substances containing them; also with most metallic salts.

Alkalies neutralize free acids and precipitate the alkaloids and the soluble nonalkaline metallic salts. Oxids of the alkalies decompose salts of the metals proper and salts of the alkaloids, precipitating their bases; but the base may be soluble in an excess of the alkali.

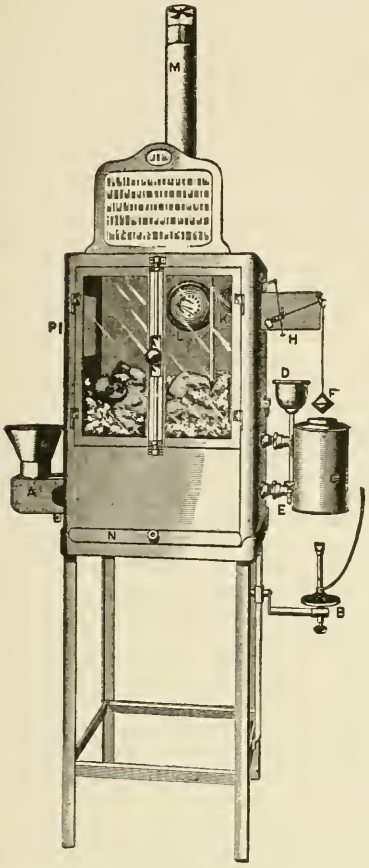
Resinous tinctures or fluidextracts—*e. g.*, tinctura cannabis indicæ—when combined with aqueous solutions, should always have acacia or some other emulsifying agent added, to prevent the separation of the resin, which otherwise will be deposited on the sides of the bottle or will float on top of the mixture.

Tincture of digitalis should be mixed with aqueous or syrupy solutions, for in such cases precipitation or decomposition of the active principles may occur. This tincture is injured by admixture, and is best administered on sugar or dropped on a piece of bread.

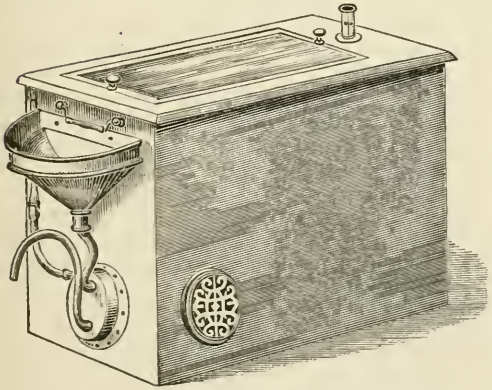
INCONTINENCE.—Inability to control the evacuation of the feces or the urine; involuntary evacuation. This term is sometimes used as a

synonym of venereal indulgence and lewdness. See Defecation, Urine (Incontinence), etc.

INCUBATOR.—An apparatus devised for the purpose of rearing premature children. It consists, essentially, of a box large enough to contain the child, the interior of which can be heated, and thus kept at a uniform temperature of 86° to 90°F.

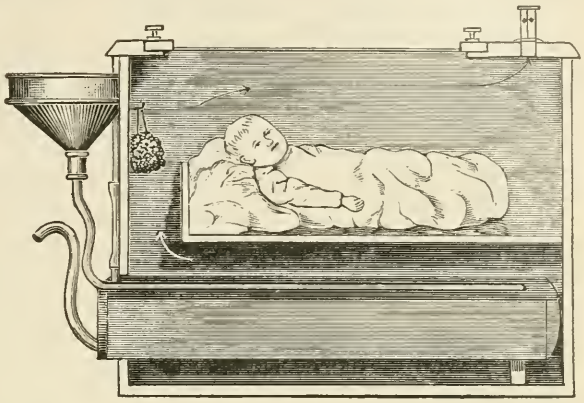


Lion Couveuse.

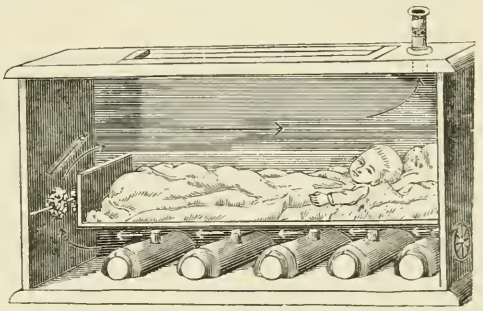


Auvard's Couveuse (Exterior View).

The best incubator is probably the **Lion couveuse**, which is self-regulating. **Hirst's modification of Auvard's**, is so constructed that the air is kept constantly pure and the humidity normal. A very good substitute can be made in a few moments by taking a baby's bath-tub, putting in it several layers of cotton-wool and a number of bottles filled with hot water. Into the tub the child is placed, well protected by a blanket, the bottles as they become cool being refilled with warm water. **Crede's incubator** consists of a copper tube made with double walls, between which water at the desired temperature may be kept, and withdrawn by means of pipes and stop-cocks. In **Tarnier's incubator** the temperature is somewhat similarly kept at 86° to 88° F. by water compartments.



Auvard's Couveuse (Interior View).



Tarnier's Incubator or Couveuse.

INDIAN HEMP.—See Cannabis Indica.

INDICAN.—See Urine (Examination).

INDIGESTION.—See Gastric Neuroses, Gastritis, Enteritis, etc.

INEBRIETY.—See Alcoholism.

INFANT, CARE.—After the cord has been ligated and cut, the eyes should be cleansed with a saturated solution of boric acid, after which, if there is any vaginal discharge from the mother, 1 to 2 drops of a 1 percent solution of silver nitrate should be instilled in each eye. The mouth should also be gently cleansed, for which may be used a soft cloth and boiled water.

The baby should be oiled to remove the vernix caseosa, and then bathed in water at 100° F., carefully dried, and the cord dusted with a powder of salicylic acid 1 part and starch 19 parts, or with powdered boric acid or bismuth subnitrate, and dressed with sterile cotton or gauze.

Bathing.—For the first 10 days, or until the cord has separated and the stump dried, a full tub bath should not be given, warm water and a soft cloth or sponge being used without disturbing the dressing over the cord. After this a daily bath should be given in water at 98° F., which may be cooled in 6 months to 95°, and in 1 year to 90°.

Clothing.—A wide flannel bandage should be applied rather snugly about the abdomen and the child dressed in a soft, well-fitting flannel shirt, a petticoat suspended from the shoulders, and woolen stockings, over which is placed the ordinary dress.

After being dressed, the child should be laid in a crib in a quiet, darkened room, and covered with a woolen blanket.

Hot-water bottles should be placed about it if the extremities are blue or cold.

Diaper.—The napkin or diaper for a baby should be made of Canton flannel or stockinet, as these are more absorbent than the cotton material generally used. They should not be hemmed.

Dusting-powder should be freely used in all the folds of the skin to prevent chafing. This is especially important in very fat babies. Starch, talcum, stearate of zinc, etc., may be used for this purpose.

Outing.—In summer the infant may be taken out-doors when 1 week old; in the fall or spring at 1 month; and in winter, on pleasant days when not windy, at 3 months of age.

Sleep.—The new-born infant should sleep about 22 hours out of a possible 24; gradually diminishing this until at 2 years the child should sleep at least 12 hours of the day, and at 3 not less than 11. Sleep is largely a matter of habit with young children, and they cannot be too early inducted into correct habits in this matter. The infant should sleep consecutively from 11 P. M. to 5 A. M., whether nursing or not. It should also have a morning nap from 12 to 2 P. M., for which purpose the child should be undressed and put to bed with unchanging regularity: if possible, in a room set apart for that purpose, with temperature 64° to 70°.

Ventilation.—Steam-heated apartments, slovenly help, and the exigencies of the modern dwelling have much to do with our enormous infant mortality in all large cities. No child, nor adult either, for that matter, can remain well and breathe the vitiated air of a single room. Such poisoned air makes the mother nervous, neurasthenic, and nagging, and works even more injury upon a tender infant. From 240 to 300 cubic feet of space should be the minimum permissible for each person in a living- or sleeping-room, and some arrangement should be made by which at least 600 cubic feet of vitiated air should be withdrawn from such rooms every hour, for each person.

Care of Premature and Feeble Infants.—In the care of premature infants all authorities concede the points to be: (1) To secure a temperature of 95° F., or slightly lower, about the child; (2) to conserve its strength; (3) to nourish the child.

The second point in the care of premature infants is the conservation of their strength. The infant, exhausted by the long or difficult labor, is too often called on to endure the ordeal of a rigorous bath, rather than to be allowed the needed rest. A gentle rubbing of the skin with warm sweet oil softens up the vernix caseosa so that it can be easily wiped away and leaves the skin clean, soft and pliable and the child not in the least exhausted by the process.

The costumes of incubator babies should be as abbreviated as possible, to do away with all unnecessary handling—a diaper of cheese-cloth and a small shirt being sufficient. Cheese-cloth diapers are far less bulky and more absorptive than any other, and are more quickly dried, so that the mistake of putting a damp diaper on a baby is less likely to occur. Small shirts, as a covering to the cotton, are necessary, as the infants soon pull out the cotton, and may swallow it.

The whole problem of feeding infants becomes more difficult of solution as one deals with a premature child. If the mother has, after 3 or 4 days, a good breast of milk which flows readily, and the child will suck, this is the ideal arrangement; but even then an uncertainty exists as to how much food the child gets; it tires so easily that it stops nursing often from exhaustion rather than from satisfaction. Then, too, such long times spent at the breast are a source of exposure to the child, though surrounded by hot bags and well protected; the quantity taken is also uncertain; it is well not to wait to see it lose weight before using artificial food. See INFANT FEEDING, MILK (Modified), MODIFIED MILK.

The Administration of Drugs to Children.—The matter of administering medicine to children is one of great importance, and the study given this subject by Dauchez is full of suggestion. In the therapeutics connected with childhood the more simple the prescription, the more concise, the freer it is from odor, and the smaller its volume, the better it will be accepted.

In prescribing, therefore, it should not be forgotten:

1. That the substances most easily administered are the tinctures and alcoholic extracts, in the form of drops (aconite, digitalis, belladonna, laudanum, etc.), mixed with sweet liquids, as black-currant syrup, Malaga wine, currant syrup, prune-juice, orange-juice, licorice, coffee, and sometimes distilled water. Certain powders that are very active may be mixed in small doses with soups which the children take as daily food; thus may be used scammony, bismuth, magnesia.

2. That powders, on account of the minute quantity which it takes for a dose, are valuable forms for the administration of drugs to children (scammony, jalap, calomel, santonin, etc.); these can be placed on the child's tongue and are easily swallowed by taking a sip of water.

Further, the elixirs, the biscuits (scammony), the pastils (lactate of iron), the chocolate (iodids), the electuary (honey and syrup of althea), mixed with sulphur, with senna (1/2 to 2 drams), magnesia, (1/2 to 2 1/2 drams), confections, and syrups can be used in pharmacy to mask the taste of drugs according to the special liking of the child.

One should avoid using prescriptions containing over 5 drams, 1 ounce, or 2 ounces; at least, not over this amount should be administered in 48 hours to a child of 8 to 10 years of age.

In prescribing very powerful drugs it is well to avoid danger by prescribing them always in solutions of known percentage.

3. In prescribing poisonous drugs certain rules should be observed. Although there is no positive rule in this matter, the dose for a child under 5 years should be 1 to 1 1/2 drops of a tincture or alcoholic extract for each completed year (?), and always in fractional doses up to 6 and 8 years.

Active substances (belladonna, opium, nux vomica, etc.), should be prescribed for children under 5 years in doses ranging from 1/12, 1/6, to 1/4 grain, and in an amount of fluid varying from 5 to 10 drams, and divided into teaspoonful or dessertspoonful doses in the 24 hours. The number of teaspoonful or dessertspoonful doses given in 24 hours should be carefully calculated.

4. In giving very active drugs to very young children it is generally best to write out the name and amount of the drug fully, and not in figures, and to state at the top of the prescription that it is for a very young child, and that the drops should be counted.

In certain cases where the tolerance and docility of the child are not good, recourse may be had to certain medicaments that are capable of being absorbed through the skin or mucous membranes, such as fumigations of naphthalin, tar, benzoin, carbolic acid, creosote, balsams, resins, etc., inhalations of oxygen, eucalyptol, turpentine, tincture of iodin, and camphor.

INFANT, DEVELOPMENT.—A child should be able to hold up its head by the fourth month, to sit up by the seventh month, to walk by the twelfth to fourteenth month, to talk from the twelfth to the eighteenth month.

Closure of Fontanels.—Posterior, second month; anterior, eighteenth to twentieth month.

Weight and Size (Average).

	Weight.	*Height.*
At birth,	7½ pounds.	20 in.
At 6 months,	16 pounds,	25 in.
At one year,	20 pounds.	29 in.
At 2 years,	26 pounds.	32 in.

The height of girls is about the same as boys—the weight usually about 1 pound less.

It is important to weigh a baby frequently, at regular intervals, as this is the best means of judging if it is being properly nourished.

The following table, taken from Holt, shows the **relative increase in weight** for boys and girls, for each from 1 to 16 years:

Age.	Boys.	Girls.
	Pounds.	*Pounds.*
Birth	7.55	7.16
Six months	16.00	15.50
Twelve months	20.50	19.80
Eighteen months	22.80	22.00
Two years	26.50	25.50
Three years	31.20	30.00
Four years	35.00	34.00
Five years	41.20	39.80
Six years	45.10	43.80
Seven years	49.50	48.00
Eight years	54.50	52.90
Nine years	60.00	57.50
Ten years	66.60	64.10
Eleven years	72.40	70.30
Twelve years	79.80	81.40
Thirteen years	88.30	91.20
Fourteen years	99.30	100.30
Fifteen years	110.80	108.40
Sixteen years	123.70	113.00

The increase in the length of the child's skeleton is most rapid during the earlier months of its life, decreasing with each year up to the fifth in about the following ratio: First year, 16 to 20 cm. (5 to 7 inches); second year, 10 cm.; third year, 7.5 cm.; fourth year, 6.5 cm.; and during the fifth year to the sixteenth or eighteenth year there is a yearly increase of 5 cm. (1 1/2 inches); after the eighteenth year this growth decreases to 3 to 4 cm. per annum until the full growth is attained, between the twentieth and twenty-fourth years.

Growth is retarded by poor nourishment, impure air, and certain diseases of nutrition, such as scrofula, etc. On the other hand, certain exanthemata and other as yet unknown conditions have the power at times of greatly accelerating growth; but such rapidly growing children are apt to become feeble, and require especially good food, much rest, and relief from their studies.

INFANT FEEDING.—Upon the food which an infant receives depends not only its present growth and nutrition, but also, perhaps, its future development and health.

The very high mortality during the first year may be traced in a large proportion of cases to nutritional disorders, the result of improper feeding.

To insure any measure of success in rearing an infant the food must be adapted *in quantity* to the capacity of the stomach, which varies according to the age, weight, and condition of the child; *in quality* to its digestive powers and to the requirements for growth and nutrition; and *in intervals of feeding* to certain rules allowing time between feedings for digestion to take place and for the digestive organs to rest.

As in that of adults, the elements of infants' food are proteins, fats, carbohydrates, mineral salts and water. In infants the relative proportions must differ from that required for older persons, because they cannot assimilate certain forms of food, and because provision must be made not only for the natural waste of the body, but for the enormous growth which takes place the first year, the child nearly trebling in weight.

The proteins, which are furnished by the casein and other albuminoids in milk, replace the continual nitrogenous waste of the cells of the body.

The fats, which are furnished by the cream, prevent the nitrogenous waste and add to the body weight.

The carbohydrates, furnished by the sugar, are partly converted into fats, and thus increase the weight. They are also an important aid to the proteids in being a source of body heat.

The mineral salts, freely furnished in milk, are more important in infancy than in later life, owing to their aid in building up the osseous system. They also aid in promoting cell formation.

The water is necessary to dissolve all the other constituents of the food so they may be more readily acted upon by the weak digestive organs of the child. It is needed also in large quantities for the rapid elimination of waste products.

In proportion to weight an infant requires six times as much water as an adult, and cool sterile water should be given it to drink from time to time.

In feeding infants three methods are available: *Breast feeding,* either by mother or nurse; *mixed feeding* (a combination of the breast and bottle); *artificial* or *bottle feeding.*

Breast Feeding.—Of these three methods the first, when practicable, should always be followed, but to procure the best results certain rules should be observed. The child should be put to the breast in 1 or 2 hours after birth, and once in 4 or 6 hours for the first 2 days. While the nourishment secured from the breast at this time is but slight, it is all the child requires, and suckling accustoms the mother to nursing, aids uterine contraction, and rids the breasts of colostrum, which is all that is secreted at this period, and which, besides furnishing sufficient nourishment for the child, also acts as a laxative.

After the second or third day, when the milk appears, the child should be nursed at regular intervals, as given in the following table:

Age.	Intervals.	Number of Feedings in 24 Hours.	Number of Night Feedings.
From birth to 4 weeks...	2 hours.	10	1
From 4 to 6 weeks.....	2 hours.	9	1
From 6 to 8 weeks.....	2½ hours.	8	1
From 2 to 4 months....	2½ hours.	7	0
From 4 to 10 months...	3 hours.	6	0

The breasts should be kept clean, and after each nursing they should be washed with a solution of boric acid. The child should be allowed to nurse about 15 minutes, but not allowed to remain at the breast longer than 20 minutes, and should not be allowed to go to sleep while nursing. It is best to nurse alternately from each breast. The mother should hold the nipple between her fingers to regulate the flow of milk.

Symptoms of Inadequate Nursing.—A temperature of 102° to 104° F. the first week, without other signs of disease, indicates insufficient nourishment. Other symptoms are: No gain in weight, irregular and unhealthy appearing stools, restless sleep, frequent fretfulness or crying, and nursing a long time without being satisfied. In these cases the cause may be found to be: Milk poor and scanty; milk good, but scanty; milk abundant, but of poor quality. By regulating the diet and habits of the mother these conditions may, in most cases, be corrected. Nursing by the mother should not be attempted under the following conditions: If she is tuberculous; if there were, during parturition, complications, such as septicemia, convulsions, or nephritis, or if she is epileptic, choreic, syphilitic, or very weak and delicate.

A child will seldom do well on the breast longer than 9 months, and at the longest 1 year; but children should not, when possible to avoid it, be weaned during hot summer weather, or during a period when the teeth are being erupted.

Weaning should always be done gradually. By giving the bottle with diluted milk at certain times or by occasionally giving water to drink by the bottle the child will become accustomed to its use, and take to it kindly when the breast is given up. In cases when sudden weaning is necessary it should be remembered that the food given at first must be much weaker than that required for a child the same age who has been accustomed to the bottle.

Wet-nursing may, under certain circumstances, be advisable, but the difficulty of securing a reliable and healthy nurse and the success with which a child may be reared when properly fed artificially make the occasions rare when it is both advisable and possible to employ a wet-nurse.

Mixed feeding may be resorted to in any case in which the milk supply of the mother is deficient or when the drain upon her health is unduly great. It is especially often necessary during the first few weeks when slow convalescence causes the milk to be insufficient.

In all cases of mixed feeding the same care should be taken that the food is properly prepared and adapted to the child's needs as in cases exclusively bottle-fed.

Artificial Feeding.—In human milk is furnished the best nourishment for infants, and it meets all the requirements for a perfect food; therefore, in the selection of an artificial food it is necessary to secure one which contains all the elements, and those as nearly as possible in the same proportions, as found in mothers' milk. Cows' milk meets one of these requirements, as it is composed of the same constituents, but, however, not in the proper proportions to meet the requirements. Fortunately, it is not difficult by certain simple methods to change the proportions of the different ingredients until they resemble those of **human** milk, and thus secure a food which the child can easily digest, and which will afford proper nourishment.

The following table shows the essential points of difference between milk from the two sources mentioned:

	Human Milk.	Cows' Milk.
Reaction	Alkaline.	Acid.
Specific gravity	1031.	1029.
Fats	4 percent.	4 percent.
Sugar	7 percent.	4.30 percent.
Proteids	1.50 percent.	4.00 percent.
Salts	0.20 percent.	0.70 percent.
Water	87.30 percent.	87.00 percent.
Bacteria and other foreign matter.	Usually none.	Always more or less.

The fats are the only ingredients which are alike; of the others, in cows' milk the proteins must be greatly reduced, the sugar increased, the salts reduced, the acidity overcome, and, as far as possible, the bacteria removed. See Milk (Modified, Sterilized, and Filtered).

Practically, outside of milk laboratories fitted up for the purpose, it is impossible to deal in exact percentages; and in home modification it is only possible to prepare a diet which is approximately correct, but by beginning with a modification low in proteids and fats, and gradually increasing these elements, it will not be difficult to furnish the child with proper and sufficient nutriment.

Some infants have such feeble digestive powers that they will require the greatest care in their feeding, and it will be necessary to try a number of variations before a suitable diet may be found. Care should be taken in these cases not to give too strong food at first, well diluting the milk, and, if found necessary, peptonizing it before feeding. See Milk (Peptonized).

It is well to feed an infant the first 4 to 6 weeks upon a modified whey diet, which is also found to agree well with those who are in a weak and debilitated condition from any cause.

Whey is prepared as follows: To 1 pint of fresh, lukewarm milk is added 1 teaspoonful of essence of pepsin or liquid rennet. This is stirred for a moment and then allowed to stand until firmly coagulated; the curd is then broken up with a fork and the whey strained off through coarse muslin. The whey should be diluted with water before administering, and, except when fed to those with very feeble digestive organs, should have cream added to it to increase its strength, after which it may be rendered still more easy of digestion by peptonizing.

Formulas.—The following recipes will serve as guides in the preparation of a diet suitable for an average healthy baby of the age given. These may be varied to suit the individual case by adding more milk or more cream, or by further diluting with water, as indicated by the condition of the child.

In every case before being administered the mixture should be sterilized, Pasteurized, or, for the reasons mentioned, preferably filtered, and warmed to 98° to 100° F. See Milk (Filtered.)

Formula No. 1 (for a child 1 week old):

℞. Cream, ℥ ij
Whey, ℥ iij
Lime-water, Water, each, ℥ ij.

Feed every 2 hours.

Formula No. 2 (age, 4 to 6 weeks):

℞. Cream, Whey, Water, each, ℥ ss
Milk-sugar or cane-sugar, ℥ ss
Bicarbonate of sodium, gr. v.

Feed every 2 1/2 hours.

Formula No. 3 (age, 2 to 3 months):

℞. Cream, ℥ ss
Milk, ℥ j
Water, ℥ jss
Sugar, ℥ ss to j
Bicarbonate of sodium, gr. v.

Feed every 2 1/2 hours.

Formula No. 4 (age, 4 to 5 months):

℞. Cream, ℥ j
Milk, ℥ ij
Water, each,
Sugar, ℥ j
Bicarbonate of sodium, gr. x.

Feed every 3 hours.

Formula No. 5 (age, 6 to 8 months):

℞. Cream, ℥ j to ij
Milk, ℥ iv
Water, each,
Sugar, ℥ j to jss
Bicarbonate of sodium, gr. x.

Feed every 3 hours.

In some cases condensed milk will be found to agree well with a child, but it is too rich in sugar and deficient in fats, and while infants fed upon it may become fat, they are apt to develop rickets or scorbutus. This fault may, in a measure, be overcome by adding cream to each feeding. Condensed milk should be diluted from 6 to 12 times with water, according to the age of the child.

It is necessary that the bottle be sterilized by boiling before each feeding; that the nipple should be turned inside out and scrubbed 2 or 3 times a day, and, when not in use, kept in a solution of borax or bicarbonate of sodium; that a long nursing tube be not used, as it cannot be kept clean; and that the bottle be held for the baby and not laid in the crib for it to suck at will.

To insure success in artificial infant feeding, as well as in breast feeding, certain rules in regard to the amount, the intervals, and the manner of feeding must be observed. The following table gives the intervals of feeding and the amounts

necessary for an average healthy child. The latter must be altered in certain cases, as a small child will take and require much less food than a larger one of the same age:

GENERAL RULES FOR FEEDING

Age.	Intervals (Hours).	Number of Feedings in 24 Hours.	Number of Night Feedings.	Number of Ounces at Each Feeding.	Total Number of Ounces in 24 Hours.
1 week.....	2	10	1	1	10
2 weeks....	2	10	1	1 1/2	15
4 weeks....	2	9	1	2 1/2	22 1/2
6 weeks....	2 1/2	8	1	3	24
8 weeks....	2 1/2	8	1	3 1/2	28
3 months..	2 1/2	7	0	4	28
4 months..	2 1/2	7	0	4 1/2	31 1/2
5 months..	3	6	0	5 1/2	33
6 months..	3	6	0	6	36

Symptoms of Inadequate or Improper Feeding.—Abnormal stools, colic, vomiting, and no gain, or a gain in weight of less than from 4 to 8 ounces a week, show that the food is not properly nourishing the child.

Excess of sugar is liable to give colic, and thin, green, and very acid stools. Fats in too large quantities often cause regurgitation and vomiting, and diarrhea with fat in the stools. Excess of casein gives colic, and usually constipation, and the presence in the stools of hard white curds. See Milk, Modified Milk.

INFANTILE DISEASES.—The ordinary exanthems and other infantile and children's diseases are considered under their special headings.

INFANTILE SPINAL PARALYSIS.—See Paralysis, Infantile Spinal.

INFANTILE SYMPTOMS.—On account of the inability of the physician to obtain subjective information, objective symptoms are of the greatest value in the diagnosis and treatment of infantile diseases. For this reason the various signs of importance will be considered separately.

The Cry.—On inspecting an infant the characteristic features of the cry are important in making a diagnosis. A child will cry from discomfort, hunger or thirst, pain, brain-disease, habit, anger, and from weakness or exhaustion.

The cry of pain is constant and loud; it is most frequently caused either by colic or earache; if from the former, it is more paroxysmal, and is likely to be accompanied by drawing up of the legs and squirming movements of the body.

The condition of uric acid infarction in young babies frequently gives rise to violent attacks of crying, which are especially severe when the urine is being passed.

The cry of hunger or thirst is very similar to that of pain, but is at once relieved if food or drink is given; this will also relieve the cry of indigestion, but for a very short time only, when the pain will begin again.

In anger or habit there will be a loud and violent cry, but it may usually be quieted by diverting the child's attention or humoring it in its whims or desires. The hydrocephalic cry from brain-disease is a shrill shriek, which is quieted suddenly and is repeated at intervals.

The cry of weakness or exhaustion is feeble and whining, and may be almost constant.

A nasal tone is noticed when there is obstruction in the nostrils; a loud, brazen cry in spasmodic croup; and a hoarse cry is syphilitic or catarrhal laryngitis.

By their cry babies also express their discomfort, which may arise from improperly adjusted clothing, a cramped position, wet diapers, cold feet, and from being tired or sleepy.

On the other hand, in certain diseases, as in severe pneumonia or pleurisy, there is an unwillingness to cry, on account of interference with the function of respiration.

In carefully observing an infant's physiognomy much valuable information may be gained as to the nature of its ailments, and from the condition of the countenance the physician may be able, in many cases, to detect the existence of disease, and perhaps determine its location.

The following general rules have been found useful as a guide in this practice:

The face of a healthy sleeping child wears an expression of perfect repose; the eyelids are closed, lips slightly parted, and a faint sound of regular breathing may be heard, though there is no movement of the nostrils.

Incomplete closure of the eyelids and exposure of the whites of the eyes show pain. Twitching of the lids, with perhaps oscillation of the eyeballs or squinting, marks the approach of a convulsion. A smile during sleep signifies abdominal pain or colic, and chewing motions of the mouth, gastrointestinal disturbance. Dilatation of the alæ nasi shows embarrassed respiration, as in severe lung affections.

When awake and passive, the face of a healthy infant indicates little but a wondering observation; but with the onset of disease the picture is altered, and an expression of anxiety or of suffering appears, the features become pinched, and lines are seen about the eyes and mouth.

Pain sets its mark upon the countenance most of all, and, by noting the part of the face which is most changed, it may be possible to fix the seat of the disease.

As a rule, the upper third of the face is modified in brain affections, the middle third in diseases of the chest, and the lower third in abdominal lesions. Contraction of the brows shows pain in the head; sharpness of the nostrils, pain in the chest; and drawing of the upper lip, pain in the abdomen.

Lividity of the lips and eyelids is seen when the blood is imperfectly aerated, and a faint purple tinge about the eyes and mouth when the circulation is weak

An earthy tinge of the face indicates gastrointestinal disorders; a waxy pallor, kidney disease; and paleness is noticed in any acute or chronic disease.

A flush on one or both cheeks is seen in inflammation of the lungs or pleura. Puffiness of the eyelids and fulness at the bridge of the nose are indications of dropsy from nephritis.

In marasmus the face has a peculiar appearance, the skin is wrinkled and of a leaden color, eyes large, the lips pallid and drawn so as to leave the mouth partially open and the chin projecting, and altogether the expression is that of a sickly aged person. The pupil of an infant varies frequently, but is usually dilated during health when awake, but often closely contracted when asleep, dilating again rapidly when the child awakes. The occurrence of fixed or permanent contraction or dilatation of the pupil indicates cerebral irritation.

Positions of an Infant Indicating Disease.—In a healthy sleeping child the position of the body is graceful, easy, and motionless. With the onset of disease, accompanied by pain, the infant is restless, and tosses about in bed. With the onset of some of the acute diseases, as measles, influenza, etc., on the other hand, the child often lies for hours in a drowsy state.

As a general rule, the following conclusions hold good: Sleeping with the head thrown back and the mouth open, and perhaps snoring, is a sign of enlarged tonsils or adenoid growths. The tendency to "sleep high" indicates cardiac or lung affection. "Sleeping cool" (kicking the clothes off) and sweating, especially of the head, indicate rickets. Boring the head in the pillow and opisthotonos are noticed in cerebral diseases.

Persistent lying on the face is an evidence of photophobia. Frequent carrying of the hand to the head, ears, or mouth shows headache, earache, or pain from dentition, and frequent rubbing and picking the nose is an indication of gastrointestinal irritation.

The existence of colic is shown by writhing movements of the body, drawing the legs up and down, and clenching the hands. When the thumbs are drawn in, the palms of the hands and the fingers clasped over them, or if the toes are strongly flexed or extended, a convulsion may be expected.

The feces, with an exclusively milk diet, should have a bright mustard-yellow color, be of the consistence of ointment, feebly acid, and contain about 85 percent of water, white flecks of fat, calcic lactates, traces of bilirubin, intestinal epithelial cells, and mucous bacteria. These bacteria have not yet been fully studied and differentiated, but the bacterium lactis aërogenes and various micrococci seem to be fairly constant. One hundred parts milk diet should produce about 3 parts of feces, on an average.

Meconium is the name given the dark-green feces first passed by the new-born child, from their resemblance to inspissated poppy-juice. Meconium is viscid, odorless, feebly acid, and consists of partially digested amniotic fluid, epidermal cells, fine hairs, cholesterin crystals, and intestinal epithelial cells, but contains no products of decomposition nor bacteria when first voided.

Urine is secreted *in utero* and is voided both before and often during the act of birth. The kidneys are relatively large at birth, and often show a peculiar reddish discoloration of their papillæ, produced by a deposit of uric acid crystals and urates, especially well marked in those children whose supply of oxygen has been deficient at birth. This is the so-called uric acid infarct, and is of little pathologic significance. The *quantity* of urine increases rapidly for the first 5 days; after that more slowly. At first it averages from 12 to 13 ounces (417 c.c.); after 2 years it reaches 15 ounces (500 c.c.), rising to 18 or 19 ounces (600 c.c.) at 4 years. The specific gravity of the urine increases up to the tenth day; after that it slightly diminishes. Average specific gravity, 1005 to 1010. The urine of early life is often turbid, dark, and acid; later it becomes clear straw yellow, and generally neutral in reaction. The excretion of urea is relatively less in children than in adults, and still less, relatively, are the phosphates. The same is true of chlorid of sodium.

Anuria, or retention of the urine, in the new-born not infrequently unduly alarms the mother or nurse. Frequently urine is voided during birth, and the fact escapes the attention of the nurse, and, on the other hand, there may be suppression for 12, 24, or even 48 hours, without any subsequent injury to the child. In these latter cases, when no malformation can be detected, the existence of uric acid infarcts in the kidneys may be suspected. Even these rarely give rise to calculi, though it is possible that they may, unless they are early dissolved away by the free use of warm sugar-water, which is the only thing that should be used, except an occasional hip-bath, in the place of the gin, sweet spirit of niter, marshmallow, or parsley tea so often administered to these unfortunate infants. All such drugging invariably gives rise to indigestion and flatulence.

Temperature at birth is 99° F. (37.7° C.), falling in a few hours a degree or more Centigrade (37.7° to 36.2°), but rising again within 36 hours to about its initial height. The temperature in a young child is best taken in the anus or vagina; and it should be remembered that comparatively trifling causes in infants may produce relatively great variations in temperature, especially through depressing agents. In general, the temperature rises during the forenoon, reaches its highest point in the afternoon, begins to sink about six, and reaches its minimum in the early morning hours, shortly after midnight. It should also be remembered that in very young children the temperature may be high (105° to 106° F.) without necessarily grave results, except in those predisposed to eclampsia.

Significance of Variations of Temperature.—Lowered temperature is found in anemia, profuse hemorrhage, collapse, death agony, and sclerema neonatorum, hydrocephaloid, and in children prematurely born. In early infancy there is no absolute relation between organic lesions and the

height of temperature observed, for high fever, great restlessness, and even convulsions may disappear quickly, and leave absolutely no lesions behind (Bouchut).

A temperature above 100° F. (37.8° to 38° C.) during the first 4 days of life is pathologic. The same is true of rise of temperature during sleep.

The morning and evening differences in temperature in the fevers of children are, as a rule, greater than in the adult.

High febrile heat with sudden chilling of the extremities is one of the frequent phenomena of fever in very young children.

Flatulence is one of the young child's most frequent ailments. The evacuation of wind or the passage upward of sour-smelling eructations generally affords temporary relief. Such children are very irritable, from the pains being repeated at every meal, and especially annoying at night, when the child is apt to be feverish and seized with fits of screaming. At such times the feet are cold, though the bowels, hands, and cheeks, are hot. The appetite, generally, is ravenous, the child eating everything that is offered it, but nevertheless continues to waste and suffer from various intercurrent ailments, such as nettle-rash, strophulus—red and white gum—thrush, "inward fits," diarrhea, aphthæ, bronchitis, etc.

The treatment of infantile flatulence and colic consists, first, in the immediate relief of its agonizing pain, and, secondly, in the removal of its cause, which usually must be sought for either in indigestion or malaria. See Colic (Infantile).

Constipation is one of the minor and more frequent ailments even of very young infants. It arises both from errors in feeding and from the relatively pouch-like condition of the colon in children under two years of age. This is often aggravated by a mild degree of gastric or intestinal catarrh, which coats the feces with mucus, and thus interferes with peristalsis. Constipation is never to be neglected in the hope that nature will bring matters around all right after a time, but, on the contrary, every effort should be made to encourage, and, if necessary, mechanically assist, a daily motion from the bowels until the child is two years of age, after which the anatomic cause of the child's constipation rectifies itself.

Treatment.—In very young children nothing is better than a daily warm oil or soapy water enema, or a small glycerin suppository. Milk of magnesia may be added to the nursing-bottle p. r. n., and for older children Starr recommends:

℞ Resin of podophyllin, gr. ss
Alcohol, q. s. to make a solution
Syrup to ℥ iij.
One dram once or twice daily.

This can be recommended as efficient, but is often obstinately refused, even on sugar, by some children.

In such cases cascara cordial may be substituted with good results, remembering that if persevered in, eventually a proper habit is established.

Under no circumstances, except by the positive order of a physician, should a young child be allowed to remain constipated over 36 hours.

Diarrhea.—See Diarrhea (Infantile).

Vomiting in Infants and Children.—Regurgitation and vomiting are of frequent occurrence in infancy, owing to the vertical position and cylindric shape of the stomach at this period of life. Nursing babies who are healthy in every respect often vomit habitually, the milk thus thrown up being unaltered or but slightly curdled, as it has been in the stomach but a short time. This form of vomiting is caused by the infant taking from the abundant breast more than it needs and more than it can digest. It may be caused by a reflex act, the stomach being overloaded, or by moving the child or making pressure over the stomach, and it is not accompanied by any violent effort or retching. This form of vomiting does not so commonly occur in bottle-fed babies, as they are less often fed an overabundance. The treatment consists of diminishing the quantity of food taken, removing the child from the breast as soon as its hunger is satisfied, forcing it to take the milk slowly, and keeping the child quiet for some time after it has nursed.

Vomiting is nearly always present in cases of acute gastric indigestion both in infants and children. It is usually preceded by fever, comes on some time after feeding, and the material vomited is sour and offensive. It may cease after the contents of the stomach have been thrown up, or serum, mucus, or bile may be vomited for some time subsequently.

The treatment consists of rest for the stomach by withholding all food for 12 to 24 hours, or longer if the symptoms continue, the administration of small pieces of ice, calomel 1/12 of a grain, with sodium bicarbonate 1 grain and bismuth 5 grains, or equal parts of lime-water and compound tincture of cardamom in teaspoonful doses, with later the institution of proper feeding, if it had previously been faulty.

Other causes of vomiting are acute intestinal obstruction, general peritonitis, certain nervous diseases, or tumor of the brain, and meningitis. Vomiting is one of the most frequent symptoms to mark the onset of the acute infectious diseases. Certain children will persistently vomit substances not agreeable to them.

Convulsions.—See Convulsions (Infantile).

Paralysis.—See Paralysis (Infantile).

INFILTRATION ANESTHESIA.—This is produced by the local ischemia, the pressure to which the tissues are subjected, the lowered temperature from the cool injection, and to the direct action of the contained drugs. The materials required are a good hypodermic syringe and the following solutions: **Schleich's solutions** for infiltration anesthesia: *No.* 1, *Strong*, has of cocain hydrochlorid 3 grains, morphin hydrochlorid 1/2 grain, sodium chlorid 3 grains, distilled water, sterilized, 27 drams, of which 6 drams may be used during one operation. *No.* 2, *Normal*, cocain hydrochlorid 1 1/2 grains, morphin hydrochlorid 1/2 grain, sodium chlorid 3 grains, distilled water, sterilized, 27 drams, of which 3 1/2 ounces may be

used at one operation. *No.* 3, *Weak*, cocain hydrochlorid 1/6 grain, morphin hydrochlorid 1/2 grain, sodium chlorid 3 grains, distilled water, sterilized, 27 drams, of which a pint may be used at one operation. (Schleich's solution). Two drops of a 5 percent phenol solution should be added if the solution is not fresh. Two other solutions are recommended, one containing double the quantity, the other one-tenth the quantity, of cocain. The very strong solution is used for inflammatory lesions, the weak for prolonged operations. The needle is introduced almost parallel with the skin, into the malpighian layer, a drop pressed out, and successive injections are made along the line of, or area in which, anesthesia is desired. After the skin is anesthetic, the subcutaneous tissues may in like manner be infiltrated. When pain ensues in the operation, it is due to the fact that infiltration has not been thorough. When the first small area has been anesthetized, a sufficient number of new circles adjoining the first may be made, and the adjacent skin can thus be painlessly infiltrated and the fluid forced into the tissues. Fasciæ, muscles, and peritoneum can be anesthetized in this way. The anesthetic influence lasts for about 20 minutes. If a longer time is required than this, infiltration may be repeated. See Cocain.

INFLAMMATION.—A condition of nutritive disturbance characterized by hyperemia, with proliferation of the cells of a tissue or an organ, and attended by one or more of the symptoms of pain, heat, swelling, discoloration, and disordered function.

"Inflammation is the succession of changes which takes place in a living tissue as the result of some kind of injury, provided that this injury be insufficient immediately to destroy its vitality." (Sanderson).

"Inflammation is the reaction of the tissues to local injuries calling forth protective and reparative measures; an imperfect pathologic adaptation often leading to consequences that are dangerous *per se*, and defeat its purposes" (Hektoen).

Vascular and circulatory changes are essential in inflammation, but in nonvascular tissues these changes occur in the neighboring tissues, whence nutritive materials are obtained.

The first phenomenon of inflammation is dilatation in capillaries, venules, and arterioles, resulting in acceleration of the blood-current and active hyperemia. This is followed by a retardation of the circulation, oscillation and stagnation of the blood-currents, exudation of liquor sanguinis, migration or diapedesis of corpuscles, changes in the perivascular tissues, and by the formation of embryonic tissue. The inflammation may extend by continuity or contiguity, by the blood, or by the lymphatics, and terminate abruptly at an early stage, by delitescence, by resolution, by new growth, or by necrosis or death of the inflamed part.

The predisposing causes of inflammation comprise those conditions which lower the general angility, such as old age, cardiac and vascular demrevaetnt, alcoholism, plethora, gout, syphilis, rheumatism, tuberculosis, diabetes, Bright's disease, anemia, and diseases and injuries of the nerves. The exciting causes are mechanical, such as blows and wounds; chemical, such as strong acids or alkalies, stings of insects, and bites of animals; thermal, either heat or cold; and bacterial. The effort, on the part of certain authors, to establish the dictum that inflammation is always caused by microorganisms, has not been successful. It must be emphasized, however, that by far the most important factor in surgical inflammations is infection.

The symptoms are divided into local and constitutional. They vary with the cause, the seat of the disease, and the constitution of the patient.

Local Symptoms.—Discoloration or Redness.—This depends upon hyperemia and determination or afflux of blood to the part; it is most marked in highly vascular tissues. It is not always a necessary accompaniment of the inflammatory process; it is not well marked in inflammation of muscular or fibrous tissues. There is no discoloration when the brain or nerves are inflamed. When there is biliary derangement, there is tendency toward a yellow color. The discoloration is most marked at the focus of the morbid action; it varies in intensity from a slight flush to a deep purple, and it may be circumscribed or diffused. Redness is not always a sign of inflammation; to be of value in diagnosing a case it must be permanent, not transitory, and is to be taken in connection with the other signs of inflammation.

Heat, which can be detected by the surface thermometer, is always present, no matter how deeply situated the disease may be. It is due to an increased flow of blood, to friction against the walls of the vessels of the part, and to cell proliferation. The inflamed part is a heat-producing area, thus causing fever by overheating the blood. The two symptoms always present in inflammation are heat and disordered function.

Tumefaction or Swelling.—This is due to capillary engorgement, effusion of liquor sanguinis into the perivascular structure, and tissue metamorphosis or cell proliferation. The amount of swelling varies with the nature of the tissue inflamed; in dense tissue, such as bone and cartilage, there is very little swelling; it is most conspicuous in parts where there is an abundance of lax connective tissue. When a serous or synovial membrane is inflamed, the effusions are poured into the cavities which they form. The swelling may be soft, and pit on pressure, resulting from inflammatory edema or it may be hard, when it is due to fibrinous exudation. This condition may prove beneficial by unloading the blood-vessels, or it may do harm by cutting off the blood supply or by causing an obstruction, as in edema of the glottis and stricture of the urethra.

Pain is usually felt at the seat of the morbid action, but in exceptional cases it is experienced in parts remote from the disease; hence it does not always point out the situation of the inflammation: as, for example, in psoas abscess, latent pneumonia, coxalgia, and vesical calculus. Pain sometimes suddenly ceases in a part, which is a

sign of commencing mortification, unless this condition is due to the influence of opiates previously administered. Pain is more violent when the covering of an organ is affected than when an organ itself is inflamed: as, for example, in pleuritis and peritonitis.

The causes of pain are compression, stretching, irritation, and disorganization of nerves; it is variable in degree. Its character varies: it may be sharp and lancinating, as in inflammation of serous membranes; acute and throbbing, as in formation of pus; dull and heavy, as in periosteitis; annoying, as in toothache; sickening, as in inflammation of the testes; itching, as in affections of the skin; or burning and scalding, as in gonorrhea.

Pain in inflammation comes on gradually, is persistent, aggravated by pressure and muscular contraction, and is fixed; there is febrile disturbance, accompanied by redness, heat, and swelling. The pain of spasm comes on suddenly, is intermittent, relieved by pressure; is not fixed, there is no fever, and it is not accompanied by redness, heat, or swelling. The pain of neuralgia is paroxysmal and intermittent, is aggravated by pressure, and, like that of spasm, is not fixed, and is unaccompanied by fever, redness, heat, or swelling. In very dense tissue the pain is throbbing, which, in a great majority of cases, denotes the formation of pus. Pain is aggravated by the dependent posture of the part.

Functional Disorder.—In inflammation there is increased sensibility: as, for example, in carbuncle, boil, whitlow, etc.; impairment of special function, as when the eyes, nose, and larynx are affected; increased irritability, due to reflex muscular phenomena as in cystitis, gastritis, dysentery, etc.; and derangement of the secretions, as when the skin, liver, kidneys, etc., are attacked.

Constitutional Symptoms.—In mild cases there is no general constitutional disturbance; but if the inflammation is at all severe, the condition known as **fever** will ensue. The one sign characteristic of fever is elevation of temperature, and it is an index to the morbid action. Fever generally manifests itself about 24 hours after the local inflammation is established; it is generally ushered in with a chill, or what is termed a *rigor*. Although the patient feels cold, if his temperature is taken, it will be found to be above normal. A succession of chills denotes sudden increase of temperature. It continues to rise, and, after a varying interval, the patient feels excessively hot; then a profuse perspiration may break out, the temperature fall more or less, and the rigor is over. As a rule, the temperature of the rectum and of the vagina is one degree higher than in the axilla. The temperature in the morning should be taken between the hours of 7 and 9 o'clock, and that of the evening between 5 and 7 o'clock.

Another set of symptoms depends on the scantiness of the secretions of the body. The tongue becomes furred and unclean, there is a great thirst, want of appetite, the bowels are constipated, the urine is less in quantity and high colored, the skin is hot and dry, the respiration and heart's action are increased. Nervous complications arise; the patient is languid and complains of severe headache, which may be followed by a confusion of ideas, going on to delirium.

The treatment of inflammation requires, first of all, removal of the cause, followed by local and constitutional measures. In the **local treatment** of inflammation remedies serviceable at one stage may be harmful in another. Rest and elevation are suitable to all stages, and always indicated. In cerebral concussion rest is to be obtained by quiet, darkness, the avoidance of stimulants and meat, by the application of ice to the head, and by the use of purgatives to prevent reflex disturbance. Splints and bandages are of service to secure rest in fractures, inflamed joints, and strains. Elevation of a part relieves swelling and tension. An inflamed hand should be placed in a sling, and an inflamed foot raised on a pillow, etc.

Cold is an agent that requires seasonable and cautious application. It is of most service in the prevention of inflammation or its extension, and in controlling the process in the early stages. Its action should be continuous, as intermittent application tends to increase the inflammation. In the form of an ice-bag, Leiter's tubes, or by irrigation with ice-cold water, cold is early serviceable.

A cooling lotion, consisting of alcohol 1 part and water 1 part, or saltpeter (nitrate of potassium) 5 parts, chlorid of ammonium 5 parts, and water 16 parts, is recommended, care being taken that the temperature is not kept below 45° F. The cold lotions may be contained in ice-bags.

The effect of cold applications is very powerful in the treatment of inflammation; it restores the tonicity of the capillaries by contracting their caliber, thus retarding effusion into the surrounding structures; it reduces the temperature; it arrests tissue metamorphosis and promotes diffusion of the effused materials into the vessels; it relieves tension and pain by restoring the equilibrium of the vessels. See Cold, Ice.

Heat and moisture cause a free flow of blood to the part, and are most serviceable when inflammation has been fully established or suppuration is threatened.

Local blood-letting relieves the inflamed part and tension, and is often of great benefit when not applied over the part, as in leeching behind the ear, or over the temple in inflammation about or in the eye. See Leeching.

Bier's Stasis Hyperemia.—Bier's method of damming back the venous blood in a limb is achieved by applying an elastic bandage round the limb well above the inflamed part, just so tightly as to cause the limb to become a bluish red and a little swollen. But the extremity must not be allowed to become blue and cold, the pulse must continue to be well felt, and the patient must not feel pain. Often this method has failed through lack of familiarity in the technic. See Bier's Hyperemic Treatment.

When the inflammation is fully developed, the indications are to abate swelling and promote absorption. To this end are employed: (1) Compression; (2) the local use of astringents and sorbe-

facients; (3) the douche; (4) massage; and (5) intermittent heat.

Compression supports the vessels and enables them to take up the effusion and stimulates the lymphatics. It is especially serviceable when much swelling exists. It should not be employed too tightly, nor applied to a limb circularly, but laterally or between splints. The fingers and toes are indicators of the deleterious effects of compression.

Astringent and sorbefacient means consist of the use of solutions of lead acetate, tincture of iodin, silver nitrate solutions, and the employment of mercurials, ichthyol, etc. Lead-water solutions are usually mixed with laudanum in a mixture called lead-water and laudanum, and employed cold or hot. It is made as follows:

℞. Tincture of opium, Solution of lead acetate, } each, ʒ j
Water, O j.

It is best applied by soaking flannel or some absorbent material with the solution and laying it on the inflamed part. It is not used in the treatment of open wounds.

Tincture of iodin is usually employed by painting it on or around the inflamed area with a camel's-hair brush, several coats being applied at one time. It is of especially great benefit when repeatedly applied to inflamed glands, muscles, and joints. It is not employed in treating open wounds. Silver nitrate is of particular use in treating mucous membranes of the throat, mouth, and genital organs. It may be employed in various strengths, according to the condition.

Ichthyol is used mostly in ointment form, in a strength of from 25 to 50 percent, with lanolin. It is to be rubbed on the inflamed part several times daily. In skin-diseases, synovitis, frostbite, bubo, chilblain, and other conditions it is of value. Oil of citronella, 20 minims to 1 ounce of ointment, may overcome the disagreeable odor.

Mercurials are chiefly employed in the form of blue ointment, pure or diluted. It is spread upon lint and applied over a joint, gland, tendon, etc. In periostitis and in chronic inflammations this mercurial is most serviceable, alone or in combination.

The *douche* may be employed by means of water poured from a height upon the inflamed part, or by having the water flow through a tube. Either hot or cold water may be used, or they may be alternated. This plan of treatment is particularly useful in chronic inflammation of joints and tendons. In pelvic inflammations hot vaginal douches are much employed.

Massage is of particular value in chronic inflammations, and is to be employed when rest is discontinued and active function is to be restored. It strengthens local nervous control and promotes the movement of blood, lymph, and other tissue fluids.

Intermittent heat is employed in the restorative process, and stimulates the reparative processes, as well as relieving tension.

When suppuration threatens, heat, in the form of (1) fomentations, (2) poultices, (3) water-bath, and (4) dry heat, is indicated. A fomentation is made by wringing out a piece of flannel dipped in hot water, applying it to a part, and covering with waxed paper, oiled silk, or protective. Ten to twenty drops of turpentine may be sprinkled on the flannel. Steam may be employed instead of hot water. The water may contain some antiseptic, such as carbolic acid or corrosive sublimate. Poultices are usually made of flaxseed meal or slippery-elm bark, but arrow-root, starch, bread and milk, potatoes and turnips, are also used. Lint soaked with hot water and covered with some impermeable material may be employed. Opium, 2 grains to 1 ounce of poultice mass, may be added to relieve pain. An antiseptic poultice is made by dipping gauze into a hot solution of corrosive sublimate, wringing out, and covering with oiled silk. A hot-water bag applied over it will maintain the heat. The water-bath is seldom used. Dry heat may be applied by means of heated cloths, by Leiter's tubes, through which hot water flows, or by a hot-water bag.

Irritants are used for their local effect to increase the supply of blood to a part, while counterirritants affect some distant part by bringing blood to the surface and away from the area of inflammation. Irritants are serviceable in chronic inflammations, while counterirritants relieve pain and congestion in early inflammations, and later promote absorption of exudates. Friction acts as a counterirritant, and may be employed with liniments. Blisters are serviceable in pleural effusion, inflamed joints, pericarditis, pneumonic consolidation, acute and chronic rheumatism, congestive coma, and meningitis. A small piece of lint dipped in chloroform, applied to the surface, and covered with oiled silk and a watch-glass will quickly blister. Lard and ammonia, in equal parts, will blister in 5 minutes. Cantharidal collodion or plasters are mostly used. The hair should be shaved before applying a blister. The plaster is removed in 2 hours in children and the aged, and in 6 hours in strong adults. If no vesicle exists, a poultice may be applied for a few hours. A vesicle should be opened by a needle and the contents evacuated. To heal the blister, it may be greased with cosmolin or zinc ointment; but if it is to be kept open, after cutting away the stratum corneum, cosmolin 1 ounce, with 4 to 6 drops of nitric acid added, may be spread on the part.

Constitutional treatment of inflammation includes the use of: (1) Venesection, (2) arterial sedatives, (3) cathartics, (4) diaphoretics, (5) diuretics, (6) anodynes, (7) antipyretics, (8) emetics, (9) mercury and iodids, (10) stimulants and (11) tonics, (12) diet.

Venesection is rarely employed at the present time; but it may occasionally be indicated to relieve distention of the right heart, or to lessen the amount of toxin in the circulating blood, especially when followed by the intravenous injection of salt solution. Blood-letting is contraindicated during epidemics, in typhoid conditions, gangrenous, ulcerative, or suppurative processes,

erysipelas, in corpulent persons, in extremes of age, in drunkards, and in debilitated or nervous individuals.

The effects of general blood-letting are to relieve arterial tension, diminish the volume, accelerate the current of the blood, relieve the tissues of effused material, and reduce the temperature by withdrawing a large amount of pyrogenous or fever-producing material from the general circulation. It likewise promotes the action of other remedies. When these desirable effects are produced, the condition may be maintained by the use of arterial sedatives, such as tincture of veratrum viride, aconite, gelsemium, or tartar emetic.

The *diaphoretics* in general use are acetate of ammonium, citrate of potassium, Dover's powder, fluidextract of jaborandi, pilocarpin hydrochlorid, lemon-juice, with bicarbonate of potassium.

The *diuretics* in use are infusion of digitalis, salts of potassium, citrated caffein, colchicum, cocain, coffee, etc.

Cathartics are used to evacuate the bowels, deplete the mucous membrane, excite the action of the liver, salivary glands, and mucous follicles, and to stimulate the absorbents, thereby inducing them to remove inflammatory deposits. Calomel and the salines are the best.

Enemata of warm water, or soap and water, to which turpentine or vinegar may be added are frequently employed. Glycerin suppositories may be used to unload the bowels, to take the place of cathartics.

Emetics are indicated when the skin is hot and dry, the tongue heavily coated, and when there exists a sense of great weight at the epigastrium. All emetics should be followed by copious drafts of warm water. The emetics generally used are alum in doses of a dram, sulphate of zinc in 20 grain doses, sulphate of copper in like quantity, mustard and salt, ipecacuanha in 20 grain doses, tartar emetic in 2 grain doses. Emetics should not be prescribed in inflammation of the brain, eye, or of the viscera below the diaphragm.

Mercury is indicated when the pulse is soft, skin relaxed and moist, and when there is a general tendency to restoration of the secretions, and not before. It reduces the plasticity of the blood and causes absorption of the embryonic tissue. It is of great benefit in membranous croup, hepatization of the lungs, iritis, syphilitic inflammation, and similar diseases. It is usual to combine a small quantity of opium with the mercury, to prevent it being carried off by the bowels. Mercury is contraindicated in persons of strumous habit, the old, ill fed, badly nourished, and the anemic.

Opium is applicable to the treatment of inflammation in all stages of the disease. The exhibition of opiates should be preceded by blood-letting when admissible; in other cases by a cathartic. The remedy should be administered in full doses, as small doses act as stimulants, while larger doses act as sedatives.

Hypnotics.—When the patient is restless, but not suffering acute pain, hypnotics are indicated, such as phenacetin, 5 grains; sulphonal, 15 grains; bromid of potassium, 30 grains; chloral, 10 grains, taken at bedtime. Paraldehyd, in doses of 1 dram, freely diluted, or hydrobromid of hyoscin in doses of 1/120 of a grain, may be used; if the patient suffers great pain, 1/6 of a grain of any of the salts of morphin may be added. Sometimes a glass of milk-punch, ale, or whisky will answer.

Tonics.—The principal are quinin, iron, and nux vomica, or its equivalent, strychnin.

Antipyretics.—These are principally quinin, given in 20 grain doses, administered about an hour before the evening exacerbation; salicin in doses of about 15 grains during the intervals; acetanilid or antipyrin administered by the stomach or hypodermically.

Antiphlogistic Regimen.—In the early stages of inflammation the patient has no desire for food, nor should he be induced to eat, as it may produce a feeling of great distress, as well as nausea. At this period iced lemonade is very grateful. After the administration of a cathartic, a fluid diet may be resorted to. Suitable articles are beef-tea, milk, soups with the fat skimmed off, meat-extracts, koumiss, raw oysters, sweetbreads, soft-boiled eggs, egg-nog, etc. A patient on a liquid diet should have at least 2 pints of milk, with 1 pint of beef-tea, during 24 hours. Stimulation by brandy, whisky, sherry, Madeira wine, etc., must be resorted to when necessary.

INFLUENZA (La Grippe).—A specific, contagious, epidemic affection characterized by catarrhal inflammation of the mucous membrane of the respiratory tract, accompanied by a mucopurulent discharge, fever, and prostration. There is a strong tendency to the development of bronchopneumonia. At times symptoms referable to the gastrointestinal system predominate; at other times the symptoms are mainly referred to the nervous system. The aged, weak, and young often succumb. The disease is popularly called by its French name, la grippe. The period of incubation is a few hours to 3 or 4 days.

Etiology.—The exciting cause is the bacillus of influenza, first described by Pfeiffer in 1892. This microorganism is rod-shaped, narrower in the middle than at the two extremities, nonmotile, and in size is one of the smallest of bacilli yet discovered. It may be seen singly or in pairs; often in chains of 3 or 4. The central portion of the bacterium does not take the stain as deeply as the two bulbous ends. It stains well with Loeffler's methylene-blue solution or with the Ziehl-Neelsen fluid.

The bacillus may be found in the nasal and bronchial secretion. It has been found in the blood.

Predisposing Causes.—Adult or old age, debility, nervous temperament. One attack predisposes to subsequent attacks.

Pathology.—There is congestion of the nasal mucous membrane and respiratory passages, with the exudation of an excessive amount of whitish, tenacious mucus, in which is found the specific microorganisms in abundance, together with various micrococci. In some cases the stomach and intestines may be congested. There is often enlargement of the spleen and mesenteric glands.

Symptoms and Clinical Course.—The onset is marked by chilliness, flashes of heat and cold, sneezing, nasal discharge, intense frontal or occipital headache of a paroxysmal character, cold perspiration, cough, expectoration of a whitish and tenacious mucus, chest pains, fever 101° to 103°, and profound exhaustion. The symptoms are often associated with severe muscular pains. In some cases the nervous manifestations, such as mental depression, mental confusion, and delirium, are quite marked. Gastrointestinal symptoms, such as nausea and vomiting, tympanites and diarrhea, are often present.

The fever, as a rule, remains elevated for 3 or 4 days, and often ends by rapid lysis. The pulse is increased in proportion to the temperature, and may be full or small, sometimes irregular. In many cases the cough continues for an indefinite duration, and catarrhal pneumonia is a very common sequel. The skin is dry and hot; often sudamina and herpes develop. Urticaria is common.

Complications and Sequels.—Inflammatory conditions of the respiratory tract, especially pneumonia and bronchopneumonia are the most frequent. Hyperpyrexia, cerebrospinal meningitis, nephritis, pericarditis, and cardiac neuroses are also encountered as complications. As sequels may be mentioned phthisis, mania, confusional insanity, melancholia, neurasthenia, insomnia, neuritis, neuralgia, persistent headache, and lymphatic enlargements.

Diagnosis.—The diagnosis ordinarily is readily made, although doubtless during an epidemic many cases are called influenza that are really cases of simple bronchitis, angina, or nasal catarrh. The diagnostic features, in addition to the catarrhal factor, are the short fever, extreme prostration, and muscular rheumatic pains. In typhoid there are a typical temperature, epistaxis, diarrhea, and longer course.

Prognosis.—In the young the prognosis is good. In the very old it is guardedly favorable. Complications are prone to occur.

Treatment.—Absolute rest in bed and a liquid nutritious diet are indicated. If the tongue is coated or the bowels constipated, calomel in fractional doses (1/6 grain) may be given until 1 grain or 1 1/2 grains have been taken. For the excruciating pains and hyperpyrexia 5 grains of phenacetin may be given every 3 or 4 hours.

Or:

℞.	Codein sulphate,	gr. vj
	Phenacetin,	ʒ j
	Salol,	ʒ j.

Divide into 12 powders. One powder every 3 or 4 hours.

Quinin (4 grains) should also be given every 3 or 4 hours with the above prescription. In some cases sodium salicylate, 7 grains every 4 hours, or preferably aspirin, exerts a beneficial effect. Solution of potassium citrate (1 tablespoonful every 2 or 3 hours) is beneficial.

An excellent prescription is the following:

℞.	Quinin sulphate,	gr. xxxvj
	Extract of aconite,	gr. ijss
	Phenacetin,	ʒ j
	Dover's powder,	gr. xij.

Divide into 24 capsules and take two every three hours.

Whisky (4 drams) may be given as a stimulant every 3 or 4 hours. For the excessive nasal discharge and congested nasal mucous membrane a local application may be made:

℞.	Menthol,	gr. jss
	Liquid vaselin,	ʒ j.

Apply to the nostrils on absorbent cotton once or twice daily.

For insomnia, trional (15 grains) or sulphonal (10 grains) may be given at night.

During the convalescence the patient should take a general tonic, such as the elixir of the phosphates of iron, quinin, and strychnin, after meals.

INFUSION OF SALINE SOLUTIONS.—Senn has insisted that the operation of transfusion of blood is an absolute failure. Death from hemorrhage is not prevented by it, and the blood elements do not subsequently retain their vitality, the blood pigment being passed in the urine. After severe hemorrhage the injection of nutritive elements is not necessary. What is needed is the restoration of the intravascular and intracardiac pressures. Moreover, the dangers of embolism and of infection are superadded, the material to be used for the transfusion is often difficult to obtain, and there is no single element of value beyond that obtained by the intravenous infusion of a salt solution, so that the operation of transfusion of blood is to-day almost abandoned. Infusion of saline solutions has in great part replaced the old operation of transfusion.

In the sense used here infusion relates to the introduction under the skin (**hypodermoclysis**) or into the veins (**venous infusion**) of a solution which in chemic composition, specific gravity, and temperature nearly approaches the inorganic portion of the blood serum. It is sometimes called "normal salt solution." "Physiologic salt solution" or "physiologic saline solution" is, approximately, a decinormal solution (one-tenth the strength of "normal solution") of sodium chlorid. It is called "physiologic" from its use in investigations upon the blood in the physiologic laboratory. Solutions of sodium chlorid containing 0.65 to 0.75 percent of the salt preserve the blood-corpuscles from shriveling when withdrawn from the veins, and do not bring about their disintegration. The total percentage of saline constituents and the proportions of the several salts contained in normal blood are variously stated by different observers. Of sodium chlorid there is about 0.5 percent, and of other sodium salts (sulphate, carbonate, and phosphate) about 0.1 percent additional; potassium, calcium, and magnesium salts bring up the total to a figure given by one observer at 0.645 percent, and by others as high as 0.9 percent.

The therapeutic saline solution cannot, therefore, be made to comply with an ideal, or even average, standard of blood-serum composition; and to insist upon a definite percentage and constitution is, in the present state of knowledge, useless pedantry. For most purposes a solution of sodium chlorid will answer, and the convenient proportion of a dram to the pint, or its approximate equivalent of 8 grams to the liter, is easily remembered and sufficiently accurate.

In cases of threatened or actual diabetic coma, or in any other condition in which it is deemed necessary to alkalinize the blood, sodium carbonate may be substituted for a portion of the sodium chlorid; and Cohen has found one-third of the total saline strength a convenient and safe proportion of this agent when used by the subcutaneous method.

Locke and Hare have suggested a general formula for "artificial serum," which contains in the liter:

℞.	Calcium chlorid,	0.25 gm.
	Potassium chlorid,	0.1 gm.
	Sodium chlorid,	9.0 gm.

An artificial serum of the following formula may be used instead:

℞.	Sodium chlorid,		gr. l
	Potassium chlorid,		gr. iij
	Sodium sulphate,	each,	gr. xxv
	Sodium carbonate,		
	Sodium phosphate,		gr. ij
	Boiling water,		Oj.

It is extremely important, whatever formula may be employed, that the solution and all the apparatus used be properly sterilized. In an emergency, in any household, a teaspoonful of sodium chlorid may be dissolved in a pint of water, and the solution sterilized by boiling. If the water contains foreign particles that cannot be strained out, and there is no proper filter at hand, the water must be allowed to stand, after boiling, until sedimentation occurs, when the supernatant fluid should be poured off, again sterilized, and used. When time permits, distilled water, filtered water, or other pure, clear water should be used for the solution. One may sometimes find pure spring-water, which contains very little mineral matter, useful and handy.

The therapeutic saline solution should be introduced at a temperature of about 38° C., or 100° F.; and if the process is slow, care should be taken to maintain the heat meanwhile. It may be introduced directly into a vein, a process often erroneously termed "transfusion," but properly called "venous infusion" or it may be introduced into the circulation indirectly, through the absorbents, beneath the skin—"subcutaneous infusion" or "hypodermoclysis"; or it may be introduced into the peritoneal sac—"peritoneal infusion"; or it may be introduced into the intestine—"enteroclysis." Subcutaneous infusion is the usual and most convenient method. Venous infusion is resorted to when time is a prime object; or peritoneal infusion, as especially advocated by Sir B. W. Richardson in the collapse of cholera, may be employed when subcutaneous infusion is too slow and the venous method dangerous or inexpedient.

Enteroclysis may be used when time is not at all pressing and if one desires to avoid puncturing the skin. It is uncertain, but often efficacious. Venous infusion Cohen is now little inclined to resort to, except under distinct stress of urgency, as the hypodermoclysis is reasonably prompt; and, indeed, for one who is neither a surgeon nor a physiologic investigator unfamiliarity with the manipulations of venous infusion—comparatively simple as they are—may act as a deterrent, or induce greater delay while skilled assistance is being sought, than the difference between the methods as to the rapidity of absorption.

Surgeons have used intravenous infusion of saline solution with great success in cases of shock and collapse, in hemorrhages following wounds and operations, and in other conditions in which the action of the heart had to be maintained. It acts mechanically by filling the vessels and raising blood-pressure. Chemically or dynamically it seems to stimulate diuresis, and especially to favor elimination of toxins of various kinds. It likewise permits free bleeding to be done to relieve congestion and stasis and remove waste and poison from the vessels, as it supplies the necessary quantity of fluid to continue circulation, just as it does in loss of blood from other causes.

It is indicated to supply fluid following blood losses or other drains; as a stimulant in shock and collapse, particularly when accompanied by loss of blood; and as an internal detergent in toxemias (comas), whether from septic poisoning, as in puerperal fever, from acute infectious diseases, such as pneumonia, typhoid fever, the exanthemata, tuberculosis, etc., from acute or chronic disease of the liver, kidney, or other excretory agents—among which puerperal nephritis must be specially mentioned—or from intoxication by drugs, as alcohol, opium, and the like. The rise of temperature which, in Cohen's experience, has invariably followed both intravenous and subcutaneous infusion is to be regarded favorably, as a sign of reaction. The quantity of fluid introduced at one time varies from half a pint to a quart.

Hypodermoclysis may be given in the thigh, the buttocks, the back, the chest, or, in women, in the submammary region. If one place is insufficient, several may be used successively. During the flow of the fluid the tissues should be massaged toward the heart to promote absorption. The apparatus Cohen employs is very simple: A needle taken from an aspirator set, attached to 4 1/2 feet of black rubber tubing, connected with a hard-rubber funnel. Everything, including the physician's hands, being clean and sterile, the funnel, tube, and needle filled with solution, and the skin properly prepared, the needle is thrust into the subcutaneous tissues to a depth of about 2 inches, the funnel is elevated to a height of 3 or 4 feet, the solution, as it enters the tissues, is forced onward by manipulation, and the funnel is kept filled by an assistant. · A rubber bag or other receptacle,

such as the glass jars used by the surgeons for irrigation solutions, may be substituted for the funnel, and the introduction of a section of glass tubing about 2 feet from the needle permits one to watch the passage of the fluid, and to interrupt it at once by pressure with the fingers should any foreign particles be detected in the current.

Arterial Infusion.—This method of infusion of blood or of normal salt solution has been performed to avoid the danger of venous embolism: a little air in an artery will do no harm. The radial artery is most convenient. It should be surrounded by 3 ligatures, and the one nearest the heart being tied at once, the distal ligature is but slightly tightened to cut off anastomotic blood supply. The artery is transversely cut, the syringe inserted pointing toward the periphery, and fastened by the third ligature. The second ligature is now loosened and the solution injected. After transfusion, that portion of the artery which held the cannula should be excised, the peripheral ligature being fastened tightly. The method is troublesome and not without danger, and is no better than the harmless hypodermoclysis. See TRANSFUSION, INTRAVENOUS INJECTION.

INFUSIONS.—Liquid preparations, made by treating vegetable substances with either hot or cold water. They are not boiled, though boiling water is often employed.

TITLE.	COMPOSITION.	AVERAGE DOSE.
Infusum digitalis (*Infusion of digitalis.*)	Digitalis, 1.5 percent. Alcohol, 10.0 percent. Cinnamon water, 15 percent.	2 drams.
Infusum pruni virginianæ (*Infusion of wild cherry.*)	Wild cherry, 4 percent. Glycerin, 5 percent.	2 ounces.
Infusum sennæ compositum (*Compound infusion of senna;* also called Black draught.)	Senna, 6 percent. Manna, 12 percent. Magnesium sulphate, 12 percent. Fennel, 2 percent.	4 ounces.

The pharmacopeia also contains a general formula for infusions according to which the preparation would represent 5 percent of any drug desired. The strength of infusions of energetic or powerful substances should, however, be specially prescribed by the physician.

INGROWING NAIL.—See NAILS (Diseases).

INHALANTS.—An inhalant is a remedy which is diffused in the air and is drawn in the nose, mouth, and throat by the act of breathing. It is thus opposed to the spray, in which the remedy is thrown in. It may be accepted tentatively that no form of the vapor of water can be relied upon to carry medicinal agents in the respiratory passage further than the larger divisions of the bronchial tubes. It is far different with volatile substances. The vapor of ether and chloroform and of the numerous volatile oils presumably reaches the alveoli of the lungs and is absorbed by the pulmonic vessels. Many of the volatile oils yield stimulating inhalants which are conveniently combined with steam. These are indicated in chronic inflammation, accompanied by hypersecretion. In the judgment of many practitioners stimulating inhalations are of doubtful worth, since the agents cannot be used in strength sufficient to relieve the symptoms without exciting spasm of the glottis or other irritative effect. This is less true than formerly, owing to the increase of the number of agents from which selections can be made; while for the sedative and antispasmodic inhalants, whether used in the medium of steam or otherwise, no doubt remains of their value in many conditions of disease. Nevertheless, inhalations must be used with discrimination to insure safety and success.

Steam is the favorite inhalant. It is a convenient means of diffusing moist heat. Like other forms of water, it tends to dilute mucus and thus diminish its irritative power. It removes the sense of dryness so common in acute affections of the throat. In tonsillitis it favors the formation of pus, and is thus indicated when it is desired to hasten suppuration. Its use is contraindicated in pharyngitis when there exist relaxed states of the glands and membranes, with hypersecretion. It will be observed that the uses and abuses of steam are much the same as those of moist heat in other forms than steam. It can be variously medicated by the use of apparatus known under the name of steam-sprayers.

Steam should be inhaled: *i. e.*, should not be forced in the nose and throat. It is often borne when sprays excite irritation. In many individuals with irritable mucous membranes, when an attempt is made to spray the throat the tongue instinctively ascends at its basal half and occludes the passage of air. Properly to use the spray in such cases the mouth should be wide open and the tongue depressed. If difficulty is experienced, the nostrils must be closed. If the trachea and bronchi are to be reached, the inspirations must be deep.

INJECTIONS.—See ENEMA, HYPODERMIC INJECTION, VAGINAL DOUCHE, GONORRHEA, CYSTITIS, etc.

INOCULATION.—The introduction into the circulation of the virus of infectious diseases or of certain medicinal agents. See DIPHTHERIA ANTITOXIN, SERUM THERAPY, VACCINATION.

INOSCOPY.—Jossuet's method of predigesting the coagulum of suspected exudates prior to search for tubercle bacilli. Though of considerable value, it is not so accurate as cytodiagnosis and animal inoculation. See CYTOLOGY.

Technic.—The fluid is collected in a sterile flask and allowed to clot. The coagulum is then removed and washed and treated with 30 c.c. of a solution to digest the fibrin (pepsin 2 grains, sodium fluorid 3 grains, glycerin and strong hydrochloric acid of each 10 c.c., distilled water to 1000 c.c.). At incubator temperature digestion will be complete in about 24 hours. Then the fluid is centrifuged 10 minutes. Two smears are made of the sediment, albumin fixative being added to them. After being fixed in the flame each smear is stained with carbol-fuchsin.

INSANE, COMMITMENT, AND CARE OF.—One of the most responsible duties of the physician in active practice is the commitment and care of the insane. To deprive a citizen of his liberty is a serious matter; the law looks with suspicion upon any attempt in this direction and practically all the states have passed stringent regulations not only as to the manner of commitment to both public and private institutions, but have also established regulations as to the care of the insane, their transportation from one place to another, and the care of their property, including rights and duties of guardians, etc. In the New England and Middle Atlantic States the regulations are fairly uniform.

Institutions are divided into three classes:

(1) General and private hospitals, where restraint is permitted only for short periods in cases of febrile delirium, and in cases of mental diseases only until the patient can be committed and transferred to one of the following institutions.

(2) State or municipal asylums or psychopathic hospitals under the care of state or municipal authorities. Municipal and county institutions are subject to the state laws of lunacy.

(3) Private institutions for the care of the insane, which are licensed by the state usually through a lunacy commission or commissioner, and subject to the same rules of commitment and care of the insane as are state institutions.

When the physician is consulted as to the commitment of a patient of unsound mind, he should give advice to the parties interested as to the different institutions, who will then make personal arrangement with the institution to which the patient is to be committed. This should always be done by the family or other interested parties, so as to relieve the physician of any suspicion of interest in the commitment of the patient. Having made financial and other arrangements for the reception and care of the patient, a blank form of commitment from the selected institution (each institution has its own special form, all of which are uniform as to the state lunacy requirements) is handed to the physician who proceeds to make an examination in order to determine whether the patient is of sufficiently unsound mind to require restriction of his liberty. In most of the states the law requires an examination by two physicians who shall have been in active practice at least three years (in Pennsylvania five years). The examinations must be made separately, *i. e.*, not in joint consultation. The physicians must not be officially connected with the institution to which the patient is to be committed or be related by blood or marriage to the patient. The certificate of commitment filled out in detail is sworn to before a magistrate (in Pennsylvania) or a probate judge, who after the examination signs the commitment papers and sends the patient to the designated institution. In Massachusetts, the patient must be present in court, and if for any reason this is deemed unadvisable, this must be so stated by the committing magistrate. In some of the Southern and Western states, a physician is appointed by the court to make an examination. In Alabama, the judge must call one respectable physician and other trustworthy witnesses to fully investigate the case, and either with or without the verdict of the jury decide the case as to sanity and indigence. In Arkansas, a time shall be appointed by the judge for a hearing, and at such time such competent witnesses as are produced shall be heard; in addition to which, the alleged insane person must have been examined by one or more physicians, who present in writing the results of their examination including the answers to certain questions prescribed by the statute. In California, at least two graduates in medicine must appear at a hearing before a judge of court of record, listen to the testimony of at least two witnesses and must then make a personal examination of the alleged insane person. Whatever method of commitment is prescribed by the particular state in which the patient is committed, the committing physician is held to a definite responsibility, both as to his diagnosis and to following in detail of the laws regulating lunacy and the commitment of the insane. The physician may be liable for a civil action for an improper commitment, and may also be liable to criminal prosecution for improperly "committing to an insane hospital or asylum a person who is not insane." For these reasons physicians should make a careful and painstaking examination not only as to family history and previous history of the patient, but also as to his present physical and mental condition. He should not depend upon the hearsay of others who may be more than interested in the commitment of the patient, but should convince himself from the statement of the patient as to the presence of hallucinations, delusions, etc. If the examination is thorough, and the physician has a reasonable degree of knowledge, and skill, and experience, and has used ordinary care and diligence, he cannot be held responsible for an honest error of judgment. If there is any doubt as to the mental condition, repeated examinations should be insisted upon and the patient should not be confined in an asylum unless the physician is more than reasonably certain of mental disease.

Detention wards for observation of the insane may be found in most of the large municipal hospitals. These wards are not as a rule covered by the lunacy laws. If the patient is detained there for a longer period than five days, it is in distinct conflict with the statute. Inasmuch, however, as it is to the advantage of the patient to remain in such a ward in preference to the immediate commitment to an asylum, the question of the legality of such detention has not been raised. It should be remembered in this connection, that while the state gives the right to a family or others to arrest or restrain an insane person to such an extent and for such length of time as may be necessary to prevent injury or damage to themselves or to the lunatic, yet a person harmlessly insane cannot be arrested without a warrant even though the purpose is to detain him until proper commitment can be had.

Whether the lunatic be in or out of the asylum, and quite independent of the question of commit-

ment, a commission *de lunatico inquirendo* may be appointed by the court to determine the mental condition. Such a writ may be applied for on behalf of a lunatic already confined by those in favor of reestablishing his control over his own estate or by relatives of a man in possession of his estate, but whom they consider unable to administer it. In case of an affirmative decision on the part of the court, the patient may be directly committed to an institution or detained there from a previous commitment. A *habeas corpus* proceeding may have the same result in either direction. The commission may be composed, as in Pennsylvania, of a practitioner of law, a practitioner of medicine, and a layman, to hear evidence, or the court may appoint a commissioner, usually an attorney, who appoints a jury, usually of six, to hear evidence, and reports to the court its findings which may or may not be approved. In some of the states, those addicted to the chronic abuse of alcohol, opium, cocain, etc., may be committed as such to institutions for the care of the insane, or to special institutions for a period varying from a few months to a year, by a judge of the probate court.

Any one desiring to treat persons of unsound mind in his own house must comply with regulations established by the laws of particular States. When a person living in his own home is under treatment for insanity, a medical attendant is justified by common law in adopting measures of restraint necessary for personal safety or proper treatment. To change the patient to an asylum or other place needs certain legal requirements and forms. Each of the United States possesses its own lunacy laws. Certain fundamental principles of law underlie all requirements. A person mentally deranged so as to be dangerous to himself or others if remaining at liberty, may be confined by any one, but only for such time as is necessary to institute proceedings requisite to determine the insanity. Such person restraining another, however, is liable in damages to the person so arrested if the lunacy is not proved. It is always a judge's province, in an issue framed to determine the insanity of an individual, to decide whether sufficient evidence of insanity appears to warrant a submission of that issue to the jury. The law presumes all persons to be sane until otherwise proved, and the burden of proof is upon the person alleging insanity. When once insanity is proved, however, the presumption is that insanity continues, and the burden of proof shifts to the opposite side: *i. e.*, the party alleging insanity.

The opinions of witnesses as to a person's sanity or insanity are to be regarded only in connection with the facts upon which such opinions are based. Persons competent as experts on the subject of insanity may give opinions based on facts observed by themselves or upon hypothetic questions based on the evidence appearing in a case. See EXPERT TESTIMONY.

INSANITY.—A derangement or abnormal condition of the mental faculties, with or without loss of volition and of consciousness. Insanity may be due to defective development, to acquired disease, or to natural decay. It is characterized, according to its form, by a variety of symptoms, the most common of which are change of character and habits, moroseness, confusion, elation, melancholy, mania, delusions, and hallucinations. The psychotic tendency is the chief predisposing cause, and on this some one of the many exciting causes will act and result in the final breakdown. The vast majority of cases of insanity occur between the ages of 25 and 45. Melancholia, mania, delusional insanity, and dementia are the four principal types of the affection. According to **Krafft-Ebing**, insanity may be divided into two great groups, according as the disorder is the result of a disturbance of the developed brain or of an arrest of brain development. He places insanity ordinarily so called under the first head; his subdivisions are as follows:

A. Mental affections of the developed brain.
  I. Psychoneuroses.
    1. Primary curable conditions.
      (*a*) Melancholia.
        a. Melancholia passiva.
        β. Melancholia attonita.
      (*b*) Mania.
        a. Maniacal exaltation.
        β. Maniacal frenzy.
      (*c*) Stupor.
    2. Secondary incurable states.
      (*a*) Secondary monomania.
      (*b*) Terminal dementia.
        a. Dementia agitata.
        β. Dementia apathetica.
  II. Psychic degenerative states.
    (*a*) Constitutional affective insanity (*folie raisonnante.*)
    (*b*) Moral insanity.
    (*c*) Primary monomania.
      a. With delusions.
        aa. Of a persecutory tinge.
        aβ. Of an ambitious tinge.
      β. With imperative conceptions.
    (*d*) Insanities transformed from the constitutional neuroses.
      a. Epileptic.
      β. Hysteric.
      γ. Hypochondriac.
    (*e*) Periodic insanity.
  III. Brain-diseases with predominating mental symptoms.
    (*a*) Paralytic dementia.
    (*b*) Cerebral syphilis.
    (*c*) Chronic alcoholism.
    (*d*) Senile dementia.
    (*e*) Acute delirium.
B. Mental results of arrested brain-development: Idiocy and cretinism.

Kraepelin's Classification of Mental Diseases.

I. Infection psychosis:
  a. Fever delirium.
  b. Infection delirium.
  c. Infection weakness. (Neurasthenia.)
II. Exhaustion psychosis:
  a. Collapse delirium. (Acute delirium.)
  b. Acute confusion. (Amentia.)
  c. Chronic nervous exhaustion.
III. Toxic psychosis:
  1. Acute intoxication.
  2. Chronic intoxication.
    a. Alcoholism.
    b. Morphinism.
    c. Cocainism.
IV. Thyrogenic psychosis:
  a. Myxedematous insanity.
  b. Cretinism.

V. Dementia præcox:
  a. Hebephrenic form
  b. Katatonic form.
  c. Paranoid form.
VI. Dementia paralytica: (Paresis, General paralysis.)
VII. Organic dementia:
VIII. Involution psychosis:
  a. Melancholia.
  b. Presenile insanity.
  c. Senile dementia.
IX. Manic depressive psychosis:
  a. Maniacal states.
  b. Depressed states.
  c. Mixed states.
X. Paranoia.
XI. Neuro-Psychosis:
  a. Epileptic insanity.
  b. Hysteric insanity.
  c. Traumatic insanity.
XII. Degenerative psychosis:
  a. Constitutional perversion.
  b. Compulsive insanity.
  c. Impulsive insanity.
  d. Sexual perversion.
XIII. Arrested psychical development:
  a. Imbecility.
  b. Idiocy.

Idiocy and **Imbecility** are sometimes regarded as distinct phases of mental unsoundness, idiocy being the more profound defect and a fundamental congenital condition, but the distinction is not marked. As yet, the causes of idiocy and imbecility have not been definitely established. Intemperance and syphilis in the parents are generally regarded as predisposing causes. Marriages in close consanguinity are held by many to be causes. The experience of the Jewish people, however, among whom marriages between uncle and niece are not unknown, does not seem to bear out this as a law of heredity. It has been claimed that defects, mental or physical, are more apt to be transmitted to offspring when parents are in close consanguinity, and this view has led to the forbidding of such marriages in many places. Pennsylvania, for example, has a law forbidding the marriage of first cousins. Incidents and accidents of pregnancy and parturition are causes of idiocy.

Idiocy is distinguished from other forms of mental disorder by being congenital; and this condition is manifested by imperfect development of both body and mind. The idiot, from an original defective structure of the brain, is able to acquire only a limited degree of intellectuality. His instincts, habits, and appetites are largely animal. Often there is no sign of recognition, nor indication of memory, in which respect he is below many animals. There are some cases of idiocy, however, in which the want of cerebral development is not so great, and some intelligence is manifested, with a partial development of some few of the faculties. Such idiots are docile and tractable; they are capable of being taught many things by careful and judicious training, even to talk and read; and thus being materially improved.

Physical Peculiarities of Idiots.—These are manifested in smallness of the head, in the majority; thickness of the lips, which are often fissured, particularly the lower one; enlargement of the tongue, salivary glands, and tonsils; vaulting of the hard palate; irregularity of the teeth, with tendency to early decay; deficiency of the lobules of the ears; defects of vision, such as myopia and congenital cataract; weakness and clubbed appearance of the fingers and thumbs, and want of power over the sphincters. In some idiots the head is preternaturally large, especially in congenital hydrocephalus.

An *autopsy* will generally disclose a deficiency of gray matter (from a defective size of the brain) and a want of proper development of the convolutions; sometimes an absence of the entire cerebellum, of the pineal gland, of part of the fornix, of the olivary bodies, thalamus, and corpus striatum; and an absence, or rudimentary state, of the corpus callosum, and soft commissures. Deaf-dumbness is common. Some are born deaf, dumb, and blind.

While the higher faculties are wanting, there often exists a marked development of the lower ones, such as the love of money, sexual feelings, gluttony, and filthy habits, together with a slow and tottering gait.

The different symptoms of insanity are considered under their separate alphabetic headings. See DELIRIUM, DELUSIONS, MANIA, MELANCHOLIA, etc.

INSECTICIDES.—See DISINFECTION.

INSECT STINGS AND BITES.—See BITES AND STINGS.

INSENSIBILITY.—See COMA.

INSOLATION.—See HEAT-STROKE.

INSOMNIA.—Want of or inability to sleep.

Etiology.—Among the causes of insomnia, those of a predisposing character are the female sex, old age, nervous temperament, and intellectual pursuits. Of exciting causes are functional or organic diseases of the brain, worry, anxiety, grief and bodily pain, noise, if not monotonous, fever, coffee, tea, etc. Insomnia is most frequent among the insane, and is the most distressing accompaniment of melancholia. Other prominent causes are habit, indigestion, genitourinary disorders, autotoxemia, gout, lithemia, syphilis, habitual constipation, anemia, vasomotor changes, neurasthenia, eye-strain, and hallucinations of sight and hearing.

Treatment.—In treatment of chronic insomnia a normal and sufficient general nutrition is to be secured as the basis for normal cerebral nutrition, but this does not imply overfeeding. A useful criterion is the body-weight in reference to the height and usual or normal condition of the individual, and diet is to be regulated on this basis. The distribution of the blood is to be equalized, with the balance, however, tending to anemia of the brain rather than the reverse, though by no means to the extreme. The derivation of blood may be accomplished by hot baths to the feet or to the lower half, or even the whole body, emphasized, if necessary, by a little mustard. The well-known expedient of a small amount of easily digestible food just on going to bed or on waking up in the course of the night probably acts, to a considerable extent, at least, in the same way. Hot toddy adds to a slight direct narcotic effect, the early vasomotor dilating action of alcohol. Another illustration of the same influence is to be found in the intense drowsiness that comes over one who has

been for a long time in the cold and who sits down in front of a cheerful fire, when the blood, previously driven to the interior of the body, flows outward again as the arterioles dilate.

Cold feet are often an accompaniment or partial cause of insomnia, and it is well to promote the circulation in them by a hot bath for 5 minutes, followed by a short cold douche and friction, rather than simply to attempt to warm them by hot bottles and the like.

There is strongly recommended in cases of sleeplessness the wearing of the moist abdominal bandage, or what the Germans call "Neptune's girdle." This was one of the favorite remedies of Priessnitz.

Warm baths, as is well known, produce a calming effect and tend to bring on sleep, and Alldorfer has attempted to apply such a method to patients when a sedative effect is desired, and yet when a bath is inapplicable. His method consists in wrapping the lumbar region and belly with linen cloths soaked in warm water, and then covering them with oiled silk or rubber cloth, so as to prevent evaporation, while the whole is kept in place and loss of heat prevented by a flannel cloth. This procedure is of ready performance, and the author says that by this simple means he has obtained most astonishing results in the treatment of insomnia. By dilating the large vessels of the intestinal tract by the warmth applied, a condition of anemia of the brain is produced favoring sleep. These large intestinal vessels have been very properly termed the waste-gates of the circulatory system.

According to Edes, a plan sometimes resorted to in desperation by victims of insomnia, that of producing great bodily fatigue—as, for instance, by a walk far beyond the usual habit or ability—is an extremely bad one, and usually fails entirely of its object. As with the circulation, a certain medium degree of fatigue is required for the best kind of sleep, and if increasing the burden is to be of value, it must be shifted so as moderately to fatigue new portions of the brain, and not deepen the old ruts from which it is already too difficult to dislodge the current of the thoughts. Mere labor which fatigues the muscles without engaging the attention in something outside the fixed and disturbing current of associations does not fulfil this indication. Moderate gymnastic exercises carried out in bed have been commended.

Reading one's self to sleep with a suitable book is a common and commendable device. The book, however, is not a matter of indifference. It should not be at all in the direction of one's anxious daily occupations, nor sufficiently exciting to set up a train of thought intense enough to be itself a cause of wakefulness; and, on the other hand, it must have enough interest to sufficiently divert the mind. Probably nothing could be more valuable and efficient, were it generally available, than music, which would, however, require a delicacy of adaptation to the individual case that would greatly interfere with its practical applicability. The prescription most frequently made for chronic insomnia, and in most cases undoubtedly the best, is that of complete rest or a vacation, recommendations more easily given than taken. Absolute vacancy of mind is talked about but never artificially attained, and relief from mental activity means relief from the habitual train of thought, most probably of a depressing or anxious character. It is especially difficult to obtain the proper conditions at home or among familiar surroundings. A vacation in the country is by far the best method of getting the necessary diversion, but here also there is a choice. The disturbances which drive away sleep come from within, and the occupation of the vacation must be such as will displace morbid activities by healthy ones, not intense, but sufficient to predominate. If the patient has nothing else to think about, he will be sure to think about his troubles. Life in the woods, with adventure enough to command the attention of the invalid in an entirely different direction, is desirable.

Some of the mild hypnotics may be given in very small doses as placebos. A graduated series of powders, with sugar of milk to maintain the bulk, and enough quinin to maintain the taste, beginning with a full dose of sulphonal and ending with none of it, is a convenient way of ridding the patient of the drug habit.

Hypnotics may be roughly divided into two classes: Those which diminish the nervous irritability which keeps the patient awake, and those which distinctly, though perhaps not profoundly, narcotize the nervous centers. The most typical of the first class are the bromids, among which Edes prefers the potassium salt, as the most powerful, believing that the fear of any depressing effect of the basic element upon the heart is purely imaginary; at least in such doses as should be or are likely to be used in the treatment of insomnia. The bromids are better given in 2 or 3 doses during the latter part of the day, and in many chronic cases through the day, than in a single large one, although the latter plan has worked well also. In cases in which a good deal of nervous excitability and restlessness during the day—"nervousness" *par excellence*—is added to the insomnia, a bromism lasting a few days or a week or two is occasionally admissible. The bromid of potassium, under circumstances demanding mental activity, even in considerable doses, is not a distinct hypnotic, although, when given properly, it will allow a patient to sleep if it does not make him do so. The same is true of its action when given with narcotics that are liable by themselves to produce an excitant effect. Opium or cannabis indica may be converted by it from an excitant to a sedative.

Opium, with its alkaloid, morphin, the first of narcotics, notwithstanding its undoubted power and the fact that sleep usually follows a sufficient dose after a varying interval, is not a desirable hypnotic in the strict sense of the word. According to Edes, in small doses it is untrustworthy, in many persons having the reverse of the desired effect, while in large doses its disadvantages far outweigh its benefits. When, however, the want of sleep is dependent upon pain, the case is entirely different. It would be peculiarly dangerous in a case of neurasthenia. Cannabis indica is not a hypnotic alone, but often does well in combination with bromid.

Choral has been to a great extent abandoned for safer if less powerful drugs. Of the immense number of other hypnotics of recent introduction, mostly of coal-tar or alcoholic origin, each of which had in turn been brought forward as agreeable, certain, and free from danger or disagreeable after-effects, Edes only mentions three.

Sulphonal, used with care, is little likely to do harm, except that which attaches to any habit of the kind or dependence upon artificial aids to sleep.

The tardiness and permanency of the action of sulphonal, undoubtedly a consequence of its difficult solubility and slow absorption, cannot be looked upon as a disadvantage when properly allowed for. A second good night without a renewal of the dose is by no means an exceptional occurrence, even when the dose has not been excessive. It seldom fails in the dose of 15 grains if given well dissolved and early enough in the evening. In dose of 5 grains or less it is somewhat of a placebo. The full dose should not be repeated on the same night, and it should not be given continuously—that is, upon successive nights—for any length of time. If its use is to be prolonged beyond an emergency period of 4 or 5 days, the interval should be more than 48 hours.

Trional is more soluble and rapid in its action, but seems to enjoy most of the advantages of sulphonal except the important one of having its effect last over 2 nights.

The peculiarities of each may be best utilized by reserving the sulphonal for a patient who has not slept for several nights, and who, it is fairly clear, is not going to get a good night unassisted, so that the medicine may be given early—namely, at 6 or 7 P. M.—in order that its effect may be developed at the regular time for going to sleep. Trional, on the other hand, may be kept for a case in which sleep is likely to be well begun, but when it is likely to be broken off very early in the night and not renewed without a hypnotic. It is preferable for a provisional prescription, since the dose may be given at any time in the night necessary and the effect will not be too far distant. Paraldehyd is a rapidly acting and safe narcotic, probably coming much closer in its mode of action to alcohol than the coal-tar preparations (Edes).

Hyoscin, 1/100 of a grain of the hydrobromid, hypodermically, is useful in insomnia from intense mental excitement. Duboisin, 1/100 to 1/30 of a grain hypodermically, is more calmative than hyoscin. Ignatia is better than morphin for nervous erethism. Gelsemium is indicated in mania, overexcitement, and the insomnia of drunkards. Sumbul, 30 minims of the fluidextract, is efficient in insomnia of chronic alcoholism when given with a little spirit of chloroform.

℞. Paraldehyd, ℥ j
Alcohol, ℥ jss
Tincture of vanilla, ℥ ss
Water, ℥ j
Simple syrup, enough for ℥ iv.

Take a teaspoonful or two every hour until sleep is obtained

℞. Choral hydrate, ℥ ij
Potassium bromid, ℥ iij
Tincture of opium, ℥ j
Syrup of orange, ℥ iij
Water, enough for ℥ ij.

A teaspoonful at a dose. May be repeated if necessary.

INSTRUMENTS, CARE AND PREPARATION.—See Abdominal Section.

INSULAR SCLEROSIS (Disseminated, Cerebrospinal, or Multiple Sclerosis).—A disease characterized by scattered islets of sclerosis in the brain and cord. It is called *sclerose en plaques disseminées* by the French, and *multiple sclerosis* by the Germans. It is distinctly a disease of early adult life, and is of about equal frequency in the two sexes. The causes are obscure. The disease has been observed to follow infectious diseases, exposure to wet and cold, and traumatism. In some cases a neuropathic predisposition has been present. The symptoms vary according to the situation of the islets; the most common are motor derangement, a jerky tremor, paresis or paralysis, and ocular symptoms, as diplopia and amblyopia, with nystagmus, and occasionally atrophy of the discs. The tremor is ordinarily absent during repose, but appears on attempted movement, and is hence designated intention tremor. The speech is a characteristic one, very slow, each syllable being pronounced with difficulty; hence it is said to be of a *scanning* nature. Vertigo is also a very frequent symptom, and in the advanced stage the mind undergoes deterioration, and dementia may make its appearance. The knee-jerks are exaggerated, and ankle-clonus is present. The lesions of the disease are small grayish or yellow gelatinous patches scattered throughout the brain and in both the white and gray matter of the cord. See Brain, Spinal Cord.

INSURANCE EXAMINATION.—See Life Assurance Examination.

INTERCOSTAL NEURALGIA.—This is the form of neuralgia most frequent in anemia and hysteria of women. It must be differentiated from the pain of caries and of aneurysm felt in the intercostal region. Inflammation of the pleura is often mistaken for it. In intercostal neuralgia the pain is constant, and is exaggerated by movement. A local intercostal neuralgia, confined to one spot, usually along the course of the nerve or at the exit from the spinal canal, is known as **pleurodynia.** Herpes zoster or zona occurs with the most exaggerated form of intercostal neuralgia. The eruption is usually preceded by the pain. It consists of a series of pearly vesicles, which take 2 or 3 days to develop and gradually disappear. The most distressing feature is the presence of pain after the eruption has subsided.

Treatment.—As a rule, the neuralgia recurs unless the general health is improved, and hence tonics and hygienic measures are to be employed. Often a change of air or of surroundings will effect a relief. Iron is a specific in cases with chlorosis or anemia. All forms of arsenic are beneficial. Quinin has been overrated, but is valuable if there

are malarial complications. Strychnin, cod-liver oil, and phosphorus are advantageous. For the relief of the pain, antipyrin, antifebrin, and phenacetin are sometimes of value. Morphin is to be used with great caution. Gelsemium is highly recommended. Of local applications, chloroform liniment, camphor and chloral, menthol, the oleates of morphin, atropin and belladonna with lanolin, may be tried. Freezing with the ether spray is sometimes successful. The positive pole of the electric current may be placed near the seat of the pain until the current causes slight tingling or burning. The surgical treatment of intractable neuralgia embraces nerve-stretching and excision. The thermocautery and acupuncture are used in very chronic forms. See NEURALGIA.

INTERMITTENT CLAUDICATION.—See ARTERIOSCLEROSIS.

INTERMITTENT FEVER.—See MALARIAL FEVERS.

INTERNAL SECRETIONS.—See ORGANOTHERAPY.

INTERTRIGO.—An erythematous eruption or lesion of the skin produced by friction of adjacent parts. See ERYTHEMA.

INTESTINAL ANTHRAX.—See ANTHRAX.

INTESTINAL OBSTRUCTION.—Obstruction of the passage of fecal matter along the intestinal canal.

Varieties.—(1) Acute intestinal obstruction; (2) chronic intestinal obstruction.

Acute Intestinal Obstruction

Location.—It usually involves the small bowel.

Etiology and Pathology.—(1) Strangulation; (2) intussusception (invagination); (3) twists (volvulus), and knots; (4) foreign bodies.

Strangulation is the most frequent cause of acute intestinal obstruction, and is most often due to adhesions or bands of peritoneal tissue. Most cases occur after the twentieth year. The seat is generally located in the small bowel.

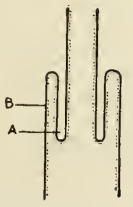


DIAGRAM OF INTUSSUSCEPTION.—(*After Rose and Carless.*) A. Intussusception. B. Intussuscipiens.

DOUBLE INTUSSUSCEPTION.

Intussusception is due to one portion of the bowel slipping into the lumen of another portion, and may even protrude at the rectum. It is generally a disease of childhood.

Twists and knots (volvulus) commonly occur only after the age of 30, in those cases in which the bowel has a long mesenteric attachment. The usual site is in the region of the cecum.

Foreign bodies may be gall-stones, coils of lumbricoid worms, or the result of large doses of bismuth.

Chronic Intestinal Obstruction

Location.—It involves the large intestine.

Etiology and Pathology.—(1) Fecal accumulation; (2) stricture of the bowel; (3) inflammatory changes in the bowel; (4) tumors or abscesses; (5) chronic peritonitis.

Fecal accumulation is a very frequent result from the imperfect gastric and intestinal digestion of such foods as cheese, boiled milk, cabbage, and beans.

Strictures are usually the result of a malignant growth.

Inflammatory changes may occur as the result of traumatism.

Tumors or abscesses may so compress the lumen of the bowel as to cause chronic intestinal obstruction.

Symptoms of Acute Intestinal Obstruction.—There is intense localized pain, an anxious countenance, feeble pulse, normal or subnormal temperature, and often syncope. Vomiting comes on early, first being of the contents of the stomach; later the vomitus becomes greenish or stercoraceous. Complete constipation follows, the abdomen becomes exceedingly tender to the touch, is greatly distended with gas, yielding a tympanitic note on percussion. The normal peristaltic movement is altered and there is a loud gurgling, or borborygmus.

Symptoms of Chronic Intestinal Obstruction.—In this variety constipation gradually ensues, and pain, which at first is only slight, within the course of a few days becomes more severe, and later presents the symptoms observed in the acute variety.

Diagnosis is not always possible. When first called to see a case with the signs of intestinal obstruction—that is, pain, vomiting, constipation, and possibly distention of the abdomen—the physician should exclude the possibility of external strangulated hernia, not merely contenting himself with an examination of the femoral and inguinal rings, but also making a search in the less common situations of hernia, such as the obturator foramen and sciatic notch. Further diagnosis depends upon the subjective and objective symptoms.

Treatment.—When no diagnosis can be clearly made, the treatment may at first be expectant, but no long delay is admissible if surgery is to have a fair chance of saving the patient. Thus, in acute cases nothing should be given by the mouth save small pieces of ice to suck, the stomach should be emptied by irrigation with warm water with the siphon stomach-tube, and the patient placed under the influence of morphin, injected subcutaneously. An enema may be given, but purgatives must, of course, be avoided. The relief, however, obtained by these means is often deceptive, and if the obstruction continues, it is worse than useless to waste further time in giving drugs. It is better at once to open and explore the abdomen before irreparable harm has been done. If when first seen

Location in right iliac region; dulness on percussion.	4. Diffuse inflammation; tympanitic resonance.

the patient is already collapsed and his condition is such that he could not bear the shock attending exploration, a small incision may be made through the abdominal wall and the first piece of distended intestine that presents secured to the edges of the wound and opened. In **chronic cases** the diet should be restricted, only small quantities of the most digestible food being given at a time; and as soon as a diagnosis can be made, measures should, of course, be taken for relieving, if practicable, the obstruction.

In **impacted feces,** when medical means and enemata have failed, the rectum may require clearing with a scoop or other suitable instrument.

In **obstruction from impacted gall-stones** or other foreign bodies, after the usual remedies have been unsuccessful, the abdomen may be opened and the gall-stone or foreign body removed through an incision in the intestine, or else made to pass, by gentle manipulation, through the ileocecal valve. The incision should be made in the longitudinal axis of the gut, and not opposite the impacted body, where the coats may be damaged, but a few inches further down. The gall-stone or other foreign body may then be removed, breaking it first, if necessary, and the wound afterward united by Lembert's suture; or should the walls of the gut be softened by ulceration, a portion of the intestine may be resected, and the continuity of the tube restored by one of the methods of enterorrhaphy. An impacted gall-stone may sometimes be broken up with a needle without opening the intestine.

In **internal strangulation** abdominal section is the only procedure of any avail, and ought, like herniotomy, to be undertaken early, and not merely as a last resource.

In **volvulus** of the sigmoid flexure insufflation with air or hydrogen, or a large enema, will at times succeed in untwisting the intestine. If these means fail, no time should be lost in opening the abdomen. If there is great distention, Treves advises that the inflated coil be punctured through the abdominal parietes.

In **intussusception,** when *acute*, copious injections of warm water to empty the lower bowel, followed by insufflation of air or hydrogen, the patient in the inverted position, and thoroughly relaxed under chloroform, will often succeed in the early stages, and should be given a fair trial. In the meantime opium may be given in doses suitable to the age of the patient, food withheld, and the stomach emptied by an emetic or irrigated with warm water. These means failing, celiotomy must be performed. If the signs of strangulation are well marked, too much time should not be lost in trying injections and insufflation, lest the bowel become so damaged or the intussusceptum so adherent to the intussuscipiens as to render the prospect of success hopeless. In infants intussusception, unless relieved by injections, inflations, etc., or by early operative means, may be said to be almost invariably fatal.

It is infinitely better to open the abdomen of every patient who is not relieved within twelve hours after the beginning of the attack than it is to continue with measures which have already proved ineffectual.

In *chronic* cases, although there is less need for early operative interference than in acute, as the bowel may remain incarcerated for some time before becoming strangulated, it should not be delayed too long, lest the intussuscepted portion become adherent to the sheath. Should it appear probable that this has already happened, two courses are open: either to open the abdomen or to keep the patient under the influence of opium in the hope that the intussusceptum may slough off and be passed by the anus. The latter measure is not commended. In exceptional cases of intussusception of the sigmoid flexure the mass may be drawn out of the anus, the gut above and below united by sutures, the intussusceptum cut away, and the united gut reduced.

For **stricture of the large intestine** left inguinal colotomy should be performed when the obstruction is in the rectum or lower part of the sigmoid flexure, and typhlotomy when in the transverse or descending colon. Should the strictured portion be readily reached in performing the operation, it may, if the disease is localized, be cut out, and the bowel secured to the wound, or, better, the two portions of bowel united.

In **stricture of the small intestine** enterotomy may be performed as a palliative; or, under suitable conditions, enterectomy, with union of the intestines by one of the recognized methods.

In **contractions**, when the intestines are matted together by chronic peritonitis or cancer, when medical means have failed, enterotomy may prove of temporary benefit by relieving the distention.

The treatment of **appendicitis and peritonitis** are discussed under their separate headings.

For **surgical procedures**, see Abdominal Section, Intestines (Surgery).

INTESTINES, DISEASES.—See Intestinal Obstruction, Enteritis, Enterocolitis, Colic, Appendicitis, etc.

INTESTINES, PHYSICAL EXAMINATION.—In the majority of instances in which the objective methods of examination are applied the patient should be lying on his back with thighs flexed on the abdomen. Palpation may be done while the patient is in various attitudes, on back, on one side, or on abdomen.

Inspection detects the region affected, and reveals the cutaneous appearance, venous engorgement, various eruptions, local enlargements, pulsation, and peristaltic movement.

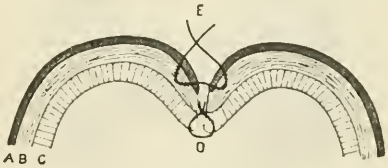
Palpation elicits pain, presence of gas in bowels, size, shape, and hardness of tumors.

Percussion yields a tympanitic note in the healthy condition, detects painful areas, outlines the area of tumors, and indicates the character of contents of tumor, whether solid or filled with gas. If ascites is present, dulness should be noted in the most dependent parts, while patient is lying on the side, and it will gravitate to the opposite side when the patient is turned, and dulness will be replaced by a tympanitic note.

INTESTINES, SURGERY.—**Wounds of the intestine** should be drawn gently through the aperture and the wound of its coats united by Lembert's sutures. Should the intestine be torn completely across, its continuity should be restored by some form of circular enterorrhaphy, as that of Senn, Maunsell, or Paul, or by Senn's bone-plates, Murphy's button, or Laplace's forceps. If its coats are much lacerated, the lacerated portions should be first excised. These methods have so reduced the time required for restoring the continuity of divided intestine that only in exceptional cases should the patient's general condition render it necessary to draw the injured gut into the wound, stitch it to the parietes, and make an artificial anus. In gunshot wounds of the intestines Senn's inflation method is useful in determining if there are one or more wounds. The rectum is first inflated, and the lowest wound detected by the escape of the gas. This wound is then sutured, the inflation repeated, and the gas extends up to the next wound, and so on.

Section of Intestine United by Lembert's Seromuscular Suture.—(*Spencer and Gask.*)

It is the practice in all cases of intestinal wounds to sew up the wound, however small. This is now usually done by interrupted sutures, the two peritoneal surfaces being placed in contact. The sutures are best applied by Lembert's method, as shown in the accompanying diagram, in which it is seen that the suture passes through the peritoneal and muscular coats only, avoiding the mucous membrane, since if this is included, there is danger of peritonitis from leakage along the thread. The sutures, which may consist of fine China silk, should be introduced about 2 lines from the edge of the wound and brought out at the margin of the serous coat, and then passed in the same manner on the opposite side. If, however, the edges are lacerated, the sutures should be introduced further from the wound, and brought out a good line from the margin, so as not to include the bruised tissues. Sufficient sutures should be passed to insure the parts being everywhere in apposition, and should not be tied too tightly, lest gangrene, the commonest cause of nonunion, ensue.



Czerny-Lembert Suture.—(*Spencer and Gask.*)

A. peritoneal; B. muscular; and C. mucous coats. D. mucous stitch. E. Lembert stitch.

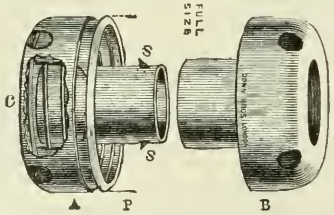
The peritoneal surfaces thus placed in contact unite by adhesive inflammation. The sutures either remain encysted or ulcerate through the mucous membrane and drop into the interior of the bowel. It is not safe to suture the wound (1) when the wound runs longitudinally along the mesenteric aspect, inasmuch as gangrene of the part cut off from its vascular supply will inevitably

ensue; (2) when suturing would reduce the lumen of the gut to less than half its normal size; (3) when there is much bruising of the gut; (4) when there are several wounds close together. In such cases the injured portions of the intestine should be excised and the two ends united by some form of circular enterorrhaphy, or an intestinal anastomosis may be formed.

Circular enterorrhaphy is the union of the ends of the completely divided intestine with the peritoneal surfaces in contact by a row of sutures around the circumference of the bowel. The Lembert method of a single row and the Czerny-Lembert method of a double row have in recent years usually been employed. The objection to these methods is the great number of sutures required, and hence the length of time consumed in the operation—a serious drawback in abdominal cases—and the danger of extravasation at the mesenteric attachment. Many, therefore, employ Maunsell's or Connell's method of suture. **Connell's method** consists of a "a single continuous in-and-out Glover's suture through all the coats, by which the edges of the gut are turned inward, so that all sutures are buried within the peritoneal fold. Over this a row of seromuscular Lembert's sutures are inserted. It has been objected that by this method a marked edge is formed, which narrows the lumen of the bowel, but this results from taking up too much of the edge of the gut in the sutures. If, however, the circular enterorrhapy threatens to narrow the lumen unduly, a short longitudinal incision should be made into each end of the bowel on the aspect opposite to the mesentery, so as to enlarge the ring to an oval. To strengthen the line of union a strip of omentum may be stitched over the line of suture."

Intestinal anastomosis, or the restoration of the continuity of the intestine after complete division or excision of a portion, may be done by Murphy's button, Laplace's forceps, or Moynihan's forceps.

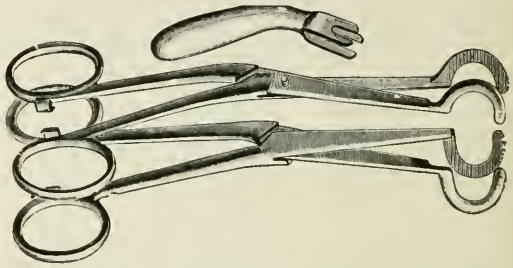
Murphy's Anastomosis Button.—By this contrivance an end-to-end approximation or a lateral anastomosis may be quickly accomplished without sutures. The button consists of two



MURPHY'S BUTTON.

A. Male half. B. Female half. P. Spring flange. *s, s.* Springs projecting through openings in hollow stem. Part of the cap of the male half has been cut away at *c* to show circular spring which acts on flange. The round holes in the caps are for drainage.

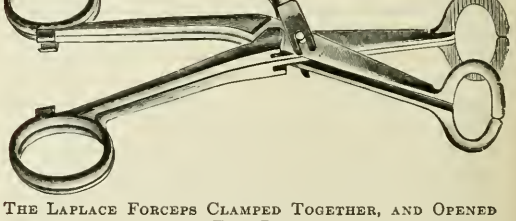
halves. The male half, A, has a spring flange, P, for keeping up pressure on the approximated intestine. The two springs, *s,s*, projecting through openings in the hollow stem, act as the male thread of a screw when the shank is telescoped within the stem of the female half, B. The intestine having been clamped, pass the running thread, by the overhand stitch, round the cut end of the intestine, beginning and ending opposite the mesenteric attachment. One return stitch should be taken at the mesenteric attachment to close the



THE LAPLACE FORCEPS BENT INTO SEMICIRCLES, AND CLAMPED TO HOLD IT TOGETHER.

triangular interval which exists at the reflection of the mesentery from the gut. Insert one half of the button in the end thus prepared, tighten the running thread so that the intestine is puckered up round the stem of the button, tie the ends of the thread, and cut them short. Secure the other half of the button in a like manner in the other end of the intestine. Press the two halves together and the peritoneal surfaces are held in close and accurate contact.

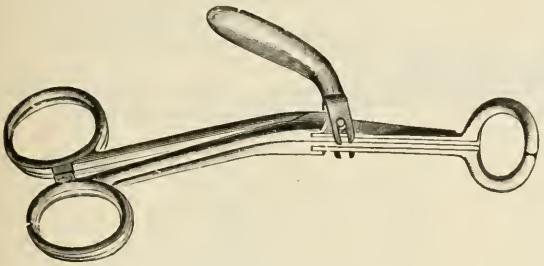
Laplace Forceps.—Of the mechanic means of effecting intestinal anastomosis the forceps designed by Ernest Laplace is the most promising. It consists of two parts, and is really a hemostatic forceps, curved into a semicircle on each side, only held together by means of a clasp; it opens as two rings. It is opened within the intestine, and serves the same purpose as Senn's rings or any other ring that has been devised, bringing serous membrane to serous membrane. Accurate suturing is the operation of the present. Therefore, if



THE LAPLACE FORCEPS CLAMPED TOGETHER, AND OPENED AS TWO RINGS.

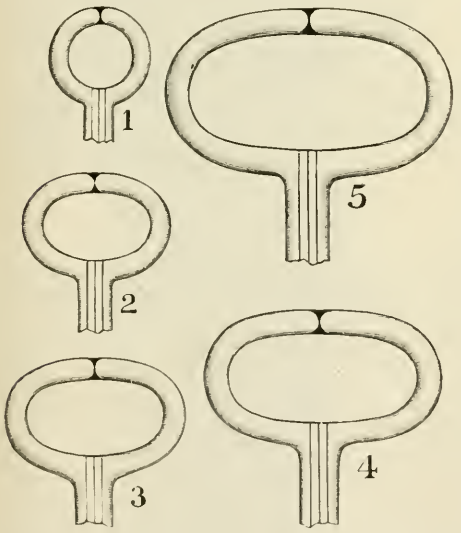
this forceps is within the gut, and sutures are applied, as they would be with the help of Senn's rings, it follows that sutures are introduced all around, except where the forceps penetrates the parts that are sutured. The suturing being done, the forceps is released by loosening the clasp and then withdrawing it from the small opening:

first one half, then the other, when the operation is finished by a stitch or two. This forceps will serve for the operation of end-to-end anastomosis, and also of lateral anastomosis.



The Forceps Closed.

End-to-End Anastomosis.—Having resected the required amount of intestine, the two ends are first united by a fixation stitch at the four cardinal points. This assures the right relation of the mesentery in the two ends of the gut. The forceps is introduced between two of these stitches. The blades are opened apart so that one penetrates one end and the other the other end. The serous surfaces are inverted or pushed in. This may be facilitated by drawing a thread around the united ends between the two blades. The forceps is clamped. When the forceps is clamped, serous membrane is in apposition to serous membrane. The sutures are then applied all around the clamped surfaces, to the point where the forceps



Various Sizes of Rings made for the Forceps Blades.

penetrates the gut. The clamp is removed; one half of the forceps is removed. The other half is then removed. The operation is completed by adding one or two stitches to close the opening through which the forceps was removed. The caliber of the gut is preserved.

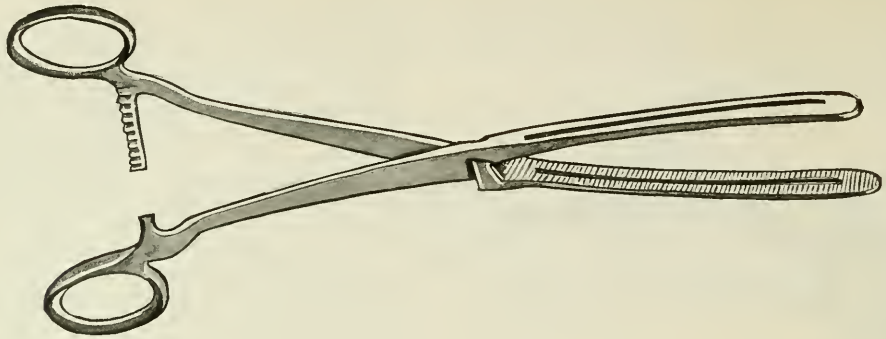
Invagination.—Should it be desired to make an enterostomy, with invagination of the ends of the gut, the forceps here illustrated facilitates the invagination, and obliterates the ends of the gut. It is a long, slender, straight, hemostatic forceps. The end of the gut is clamped and pressed down within the caliber of the gut; the serous membrane on each side thus rises, and is rapidly sutured under the control of the instrument. When the suturing is done, the instrument is loosened and withdrawn; one more suture is applied at the point where the instrument penetrated. This makes a very good stump, and is very expeditious.

Circular or lateral anastomosis is satisfactorily performed by means of Moynihan's forceps and sutures. In the lateral method the loops of gut to be anastomosed are brought outside of the abdomen, the contents squeezed out and the clamps applied. The two loops of gut are then united for about 4 inches by a row of continuous Lembert sutures passed through all the coats except the mucous membrane. This suture is knotted when the approximation has been made and the needle is temporarily laid aside. The bowel is then

Invagination Forceps.

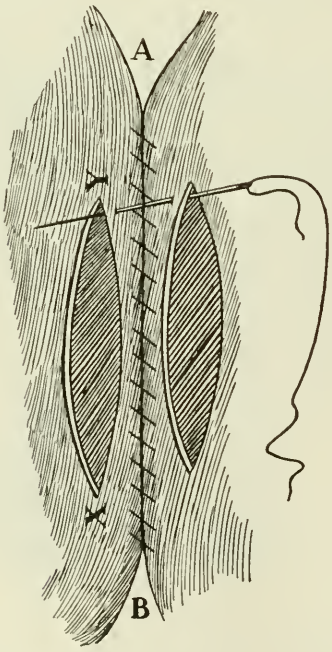
opened for a distance of about three inches on each side of the line of sutures. The mucous membrane is cut away with scissors. The adjoining edges are now united by a continuous perforating catgut suture, involving all the coats of the intestine and shutting off the intestinal cavity from the line of Lembert sutures. Connell's suture is frequently used in this step of the operation. It is an in-and-out Glover's suture by which the edges of the gut are turned inward so that all knots are placed within the lumen of the bowel. As this suture progresses the opposite angle of the wound is reached, but without interruption it continues to draw together the more widely separated borders; when it has reached the point of beginning the terminal thread is knotted with the first, which was left long, and thus the perforating suture is finished. A return is now made to the primary sero-serous suture which is carried again completely around the bowel and buries the perforating suture. Some operators remove the clamps when the perforating suture has been completed; others leave them on until the serous suture has been completed. The line of suture is enforced with interrupted Lembert sutures at any points where it is necessary.

Enterotomy, or Nélaton's operation, consists in opening the abdomen by a short incision in the middle line or in the right or left groin, seizing the first piece of distended intestine that presents, and securing it to the wound by sutures and then opening it. This operation is employed in cases when the obstruction is believed to be in the small intestine, though the diagnosis of the situation is



Moynihan's Forceps.

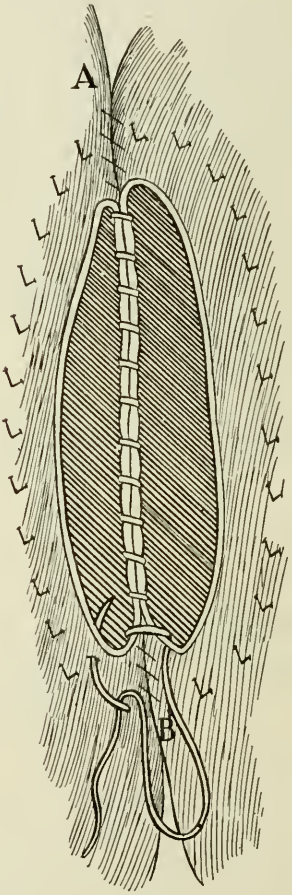
uncertain, and when the patient's condition is such that the severe shock and the prolonged manipulation that necessarily attend celiotomy (the operation otherwise indicated) would probably be fatal. It may also be employed in cases of obstruction due to contractions consequent upon the matting together of the small intestines from chronic inflammation, cancer, etc. It should be thoroughly understood, however, that the operation is only intended to relieve the distention of the intestines and prevent their rupture. It does



(*Binnie.*)

not attack the seat of obstruction, but by relieving the acute symptoms it may give time for a diagnosis in doubtful cases, and the patient's condition after it may so far improve as to allow of a more radical course of treatment on a future occasion.

Enterectomy consists in opening the abdomen and excising a portion of the intestine. It may be required for irreducible intussusception, carcinomatous stricture, gangrene from strangulation by bands, the closure of fecal fistulæ, wounds of the intestine, etc. Open the abdomen as in celiot-

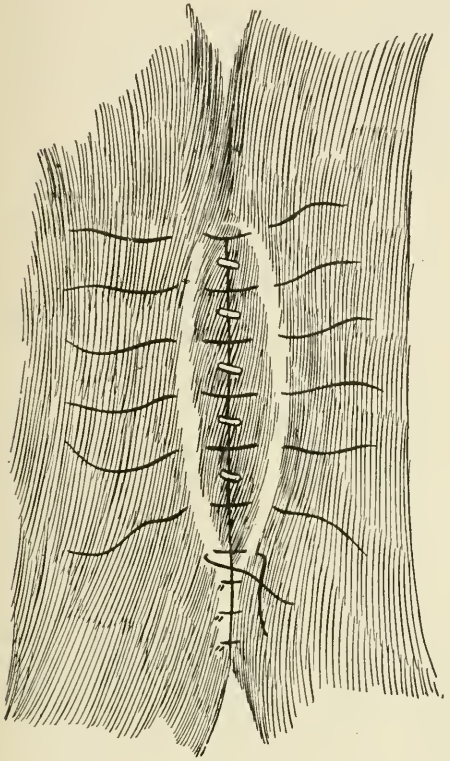


(*Binnie.*)

omy; draw the portion of intestine to be removed well out of the wound, and pack it round with moist antiseptic gauze; clamp the intestine with a rubber tube passed through a small incision in the

INTESTINES, SURGERY

mesentery above and below, to prevent the escape of feces; cut out the diseased or damaged part; tie all bleeding vessels; and then unite the intestine by one of the methods already described. Or if the intestine is much distended and the patient in a state of extreme collapse, secure both the proximal and distal portions of the intestine to the wound in the abdominal parietes by sutures. After the contents of the overdistended bowel have been evacuated and the gut has regained its tone, the



(*Binnie*)

two portions may be united and returned to the abdomen. For the removal of the cecum the incision should be made in the right iliac fossa. According to whether small intestine, colon, or cecum is excised, the operation is spoken of as enterectomy, colectomy, or typhlectomy.

Inguinal colotomy is the operation of opening the sigmoid flexure of the colon in the left groin (*Littre's operation*). It has been much employed of late in place of lumbar colotomy, especially for carcinoma of the rectum before distention of the colon consequent on the stricture has occurred. Its chief advantages over the lumbar operation are: (1) That there is less difficulty in finding the gut; (2) that there is less danger of peritonitis, in that, as the peritoneum has to be opened, all proper precautions can be taken; (3) that the wound is more superficial, and, consequently, there is less risk of infiltration of the tissues and septic poisoning; and (4) that the groin is a more convenient situation for an anus than the loin. An oblique incision about 2 inches long is made 1 inch from the anterior superior iliac spine, at right angles to a line drawn from the umbilicus to the iliac spine, 1 inch of the incision being below and 1 inch above the line. Divide the skin, superficial and deep fascia, muscles, fascia transversalis, and the peritoneum on a director. If the gut does not present in the wound, carefully search for it with the fingers. It may be known by the longitudinal bands of muscular fibers, by the epiploic appendices, and by its mesentery running to the left, whereas that of the small intestine runs to the right. Having found the colon, introduce a flat sponge into the wound to prevent the entrance of blood, and stitch the parietal peritoneum to the skin with four sutures. Remove the sponge and draw down the colon until the mesocolon is taut, so as to avoid prolapse of the bowel subsequent to the operation. Draw the bowel well into the wound, pass a piece of glass rod beneath it through the mesocolon, so as to produce a good spur, and thus prevent the feces going down the distal end of the intestine, and secure the gut to the parietal peritoneum by sutures passed through only the peritoneal and muscular coats. Apply an antiseptic dressing, with a piece of protective next the bowel to prevent its adhering to the gauze, and at the end of 3 to 5 days, when adhesions have had time to form, cautiously open the gut by cutting through it on to the glass rod. Some surgeons, for the purpose of forming a spur, draw the gut forward by a ligature passed through the mesentery; others, with the same aim in view, divide the colon and secure both open ends to the wound; while others, again, close the lower end by means of Lembert's sutures, and drop it back into the peritoneal cavity. No food should be given by the mouth for the first 12 or 24 hours, and then liquid diet until the gut is opened. If the bowel is greatly distended at the time of operation and threatens to burst, it may be opened at once; or should vomiting and distention come on after the operation, it may be opened before the usual 4 or 5 days have elapsed. Some surgeons give opium as a routine practice; others withhold it unless there is pain or restlessness. If the bowel does not act spontaneously after the gut has been opened, a gentle saline purge or an enema may later become necessary. The bowel below the wound may also require washing out by an enema.

Lumbar colotomy is the opening of the colon in the left lumbar region (*Callisen's operation*), or in the right (*Amussat's operation*). The former should be chosen when the disease is in the rectum or lower part of the sigmoid flexure; the latter when there is any doubt whether it may not be in the transverse colon. That on the left side, the common operation, need only be described. Place the patient on his right side, slightly inclining toward his face, with pillows under his abdomen or beneath his loin, in order to make his left side prominent. The outer border of the quadratus lumborum, the guide to the colon, should then be marked; it is situated 1/2 of an inch posterior to a line drawn vertically upward from a point midway between the anterior superior and posterior superior spines of the ilium. Then make an incision about 4 inches long between

the last rib and crest of the ilium from the erector spinæ obliquely outward and downward. Divide the skin, fascia, and various layers of muscles—viz., the latissimus dorsi, external oblique, internal oblique, and transversalis—and the transversalis fascia on a director, and the quadratus lumborum will now be exposed at the inner part of the wound, and may be known by its fibers running upward and inward. When the colon is distended, it will bulge in the wound; when contracted, however, it may be sought in the wound by carefully scratching through the fatty tissue covering it, with 2 pairs of dissecting forceps. If there is much difficulty in finding it, pass by rectum a small catheter, if practicable, through the stricture, and inflate the colon. The colon may be distinguished from the peritoneum, which sometimes presents in the wound, by its situation immediately external to the quadratus lumborum and below the kidney; by the presence of the longitudinal bands of muscular fibers; by the thickness of its coats on nipping it up by the fingers; and, at times, by in this way feeling scybalous masses of feces in its interior. The peritoneum, on the other hand, may generally be known by the absence of the above characters, and, if it is nipped up, by the intestine being felt to slip away from between the fingers. Having found the colon, secure it to the skin. This is usually done by passing a silk suture by means of a curved needle on a handle, first through the skin, then through the bowel, and then through the skin on the opposite side of the wound, and repeating the procedure at the other end of the wound. The bowel is then opened in a longitudinal direction, the loops of suture by which it is transfixed hooked out by the finger and divided, and the bowel secured to the integument by the four sutures thus formed. A better and more convenient way of passing the sutures—which should then be of wire—is by Smith's cleft-palate needle. If this is used, a series of sutures are passed, first through the skin, and then through the wall of the bowel, and tied before the bowel is opened. Should the peritoneal cavity be opened by mistake, it must be carefully closed by suture before the incision is made into the colon.

Some surgeons perform lumbar colotomy in two stages, like gastrotomy; but if the operation is carefully done in the way described, this is hardly necessary. The bowel beyond the wound may subsequently require clearing with an enema. Indeed, it has been proposed to close completely this part of the bowel by operation, so as to prevent feces passing down it.

Cholecystenterostomy, or the establishment of an opening between the gall-bladder and the intestine, may occasionally be required for immovable obstruction of the common bile-duct, as from cancer about the head of the pancreas, duodenum, etc., involving the duct. Having opened the abdomen as in other operations on the gall-bladder, draw the gall-bladder and duodenum into the wound, and, having made an incision into each, unite them by suture, or, better, by Murphy's button or Laplace's forceps. When the latter method is employed, a running thread is first passed through all the coats of the duodenum, and then another thread in like manner through all the coats of the gall-bladder. An incision is next made into the duodenum within the running thread, two-thirds of the length of the diameter of the button to be used, the button slipped in, and the thread tied tightly round the central cylinder. A similar incision is made in the gall-bladder, its contents evacuated, the other half of the button inserted and secured by the running thread in a similar way. The two halves of the button, held by the fingers, are now pressed together, thus fixing the serous surfaces in contact. The spring in the button produces pressure atrophy of the tissues embraced by it, leaving an opening as large as the button, which, thus freed, is passed by the anus (Walsham).

INTOXICATION.—A word popularly used to denote the effect of the excessive use or of an overdose of an alcoholic liquor; in a wider sense, any poisoning; the state resulting from an overpowering dose of any poison. See ALCOHOLISM, AUTOINTOXICATION, SEPTICEMIA, UREMIA.

INTRASPINAL ANESTHESIA.—This is produced by the injection of a local anesthetic into the subarachnoid space. Cocain and eucain are seldom used at the present time. Stovain has a strong affinity for the motor nerves, and may, in high anesthesia, cause paralysis of the respiratory muscles. Tropacocain and novocain possess less of this affinity, hence are safer; the usual dose is from 1/2 to 1 grain. The solution is prepared by dissolving the drug selected (previously sterilized) in cerebrospinal fluid, which is drawn into the syringe containing the anesthetic, after the introduction of the needle into the subarachnoid space. In order to make the solution of a higher specific gravity than the spinal fluid and so remain in the lower part of the spinal theca, Barker uses distilled water 1 c.c., glucose 0.05 gram, and stovain 0.1 gram. The syringe should be boiled in plain water, as the soda solution employed for other instruments may diminish the efficacy of the anesthetic. The patient lies on the side, or assumes the sitting posture; in either case the back should be bent forward in order to increase the space between the vertebral arches. The operator places one finger upon the spine of the fourth lumbar vertebra, which is on a line between the two iliac crests, and enters the needle fitted with a stylet, just below and to the right of this point, in a slightly upward and inward direction, until the dura has been punctured, which in the adult is usually at a depth of 2 1/2 inches. The stylet is withdrawn and 1 dram of the cerebrospinal fluid allowed to escape. The anesthetic solution is then slowly injected; the needle withdrawn, and the puncture sealed with collodion. The patient is then placed in proper condition for operation, but never should the head and shoulders be on a lower level than the lumbar vertebræ, as the fluid may gravitate toward the medulla and cause respiratory paralysis. Anesthesia results in about 5 minutes and lasts from 1 to 3 hours or longer. No attempt should be made to induce anesthesia above the diaphragm. Headache, nausea, and vomiting are frequent sequelæ, and evidence of

transient and permanent cord injuries has been noted. The *chief dangers* are infection, injury to the cord, and poisoning from the anesthetic employed. The *mortality* has been estimated at 1 in 200. From what has been said it may be gathered that the method is destined to pass into desuetude (Stewart).

INTRATRACHEAL INSUFFLATION OF ETHER (Meltzer-Auer).—This promises to supplant the various forms of apparatus designed to prevent collapse of the lungs during intrathoracic operations, since it not only obviates the danger of pneumothorax but automatically ventilates the lungs. It is of great value also in operations about the mouth and pharynx, in that it keeps the anesthetizer out of the way, eliminates the possibility of obstruction of the air passages, and prevents the inhalation of blood, mucus, vomitus, and other deleterious substances. It should prove of service in operations for intestinal obstruction in which fluid is constantly regurgitated from the stomach, in operations for goiter and similar conditions in which the trachea is displaced or distorted, and in operations in which the patient must lie face downwards. According to Peck the relief of all strain upon the respiratory apparatus and consequently the relief of much strain upon the heart and central nervous system is one of the most valuable features of the method. "Overetherization is impossible." In cases of apnea from opium poisoning, etc., air, or air mixed with oxygen, can be blown into the trachea, thus maintaining aeration of the blood until spontaneous respiration returns. The patient is first etherized in the usual way; then, with the aid of a Jackson laryngoscope, a silk elastic catheter is inserted into the trachea to a point just short of its bifurcation, and the catheter connected with the insufflation apparatus. The catheter should be about half the length of the glottis in diameter. *i. e.*, about 24 F. for the average adult, and correspondingly smaller for children. It should have two marks on it, one 13 cm. and one 26 cm. from the tip. When the latter mark is opposite the teeth the first mark is opposite the glottis, and the tip 5 cm. above the bifurcation of the trachea. One must be sure the tube is not in the esophagus. The tube may be held in place with a special clip, or fastened to the cheek with adhesive plaster. The apparatus devised by Elsberg or a simpler home-made contrivance may be employed. The air is driven by foot bellows (or an electric blower, in which case an oil filter is needed) through a wash bottle containing hot water, thus filtering, warming, and moistening the air, which is then delivered to a bifurcated tube, one branch of which passes directly to the tube connected with the catheter and the other to the ether reservoir, the ether reservoir having another tube on its opposite side joining the tube connected with the catheter. By manipulating clamps on stop-cocks on these branches the patient may receive pure air, pure ether vapor, or a mixture of air and ether. In the Elsberg apparatus the percentage of ether and air is regulated by a hand wheel which is connected with an indicator, so that the anesthetizer knows the exact quantity of ether the patient is receiving. The tube leading to the catheter is connected with a manometer, which records the pressure of the air current passing through it. The average pressure during anesthesia should be 20 mm., but, if indicated, it can be increased to 40 or even 50 mm. Every minute or two, however, the pressure should be reduced to zero for an instant to allow the lungs to deflate. The percentage of ether needed varies with the patient, half ether and half air probably being the average. "If the patient is cyanosed, it means either that the tube is not far enough in the trachea or that too large a tube has been introduced" (Elsberg). At the end of the operation quick recovery from the anesthetic can be secured by insufflating pure air, thus blowing the ether from the lungs. Hoarseness and pulmonary complications are not produced by insufflation anesthesia, post-anesthetic vomiting is less common than after other methods, and shock from operation seems to be less marked (Peck and Elsberg) (Stewart).

INTRAVENOUS INFUSIONS.—See Infusion of Saline Solutions.

INTRAVENOUS INJECTION.—The intravenous injection of mercuric chlorid in the treatment of syphilis was originally suggested by Professor Guido Baccelli, of Rome, who had previously been quite successful in the treatment of the pernicious as well as the other forms of malarial fever by the intravenous injection of the salts of quinin. The good results obtained in this manner impressed Baccelli with the advantage of direct medication to the corpuscular elements of the blood in certain phases and types of disease. At first it was thought that the drug would cause coagulation of the blood, but experiments on the lower animals proved the contrary. Baccelli injected a dog intravenously with a solution of mercuric chlorid 1 : 1000 until 5 cm. of the salt were injected in a single dose, without subsequent toxic symptoms and only slight salivation. He then directed his experiments to the treatment of some obstinate cases of organic syphilis, which had resisted all other treatment, by the intravenous injection of mercuric chlorid 1 : 1000, commencing with doses of 0.001 gram (equivalent to 1 gram of the solution) and progressively increasing the dose to 0.005 gram. His investigations met with the most brilliant results, and since then thorough investigation into the merits and value of the method has been made by Baccelli, Jemma, Colombini, Nieddu, Campana, and many others throughout Italy.

In the preparation of the fluid for injection the following formula is used:

℞.	Mercuric chlorid,	1 gm.
	Sodium chlorid,	3 gm.
	Water,	1000 gm.

A small quantity of alcohol may be added to facilitate solution. The mixture should be well stirred, and filtered until perfectly clear. It is advisable, but not necessary, to sterilize it, that it may be aseptic and to facilitate solution.

A ligature is applied above the elbow, and any one of the superficial veins in the neighborhood,

which soon become prominent, may be selected as the point for injection. The point selected and the surrounding area are then thoroughly scrubbed and disinfected with a 1 : 1000 solution of mercuric chlorid or a 5 percent solution of carbolic acid. The needle, previously sterilized, is plunged directly toward the center of the vein, at the point selected, and a few drops of blood allowed to ooze out, assuring entrance into the vessel; the barrel is carefully applied, avoiding any entrance of air.

Loosen the ligature and make the injection, at first using only 1 gram of the solution, and progressively increasing to 4 grams at a dose. Occasionally, on the withdrawal of the needle there is some extravasation of blood into the neighboring subcutaneous tissue; but this is absorbed very quickly, and is only of occasional occurrence. Repeated injections may be made in the same vein. In a case reported by Jemma 75 injections were made in the median cephalic vein. This vein and the median basilic are the best to use.

There are two precautions that should be remembered: First, always use a fresh solution, which the physician should prepare himself, to be assured that the salt has not decomposed, which is often the case after the solution has been standing some time. No after-dressing is needed, and it is not necessary to cover the wound of puncture with collodion. Second, do not use a concentrated solution. That of 1 : 1000 is to be preferred, but in late injections a 1 : 500 solution may be used.

The advantages claimed by the advocates of intravenous injection are:

1. There is absolute certainty of absorption, which cannot be obtained by hypodermic or other methods.

2. There is little or no pain. Intramuscular and hypodermic injections are very painful. The subconjunctival injections in the treatment of syphilitic iritis are impracticable on account of the pain. This method is as successful, and painless. In using the hypodermic treatment it is not possible to use any local anesthetic successfully.

3. There is no disturbance of the digestive tract during treatment. In fact, a slight salivation and diarrhea, temporary only, are the only local disturbances reported.

4. There is more rapid absorption and therapeutic effect than by any other method.

5. Less of the mercurial salt is required.

6. Absolute exactitude of dosage can be obtained, which is a rational necessity. Owing to variations in absorption, this is the only method that offers this advantage.

7. It seems to be completely safe; not one accident has been recorded.

8. It is perfectly reliable. All cases reported have shown some improvement, and never any retrogression.

9. Abscesses are absent. These cannot always be avoided in the hypodermic method.

10. There are no dermal irritations or eruptions, such as follow friction or inunctions.

11. The hysteric or nervous symptoms sometimes associated with the hypodermic method are never observed with the intravenous injections.

12. It is successful often when all other methods fail.

13. There is no history of recurrence after a cure.

14. Mercuric chlorid has a preservative action on the red blood-corpuscles, and hence must be valuable intravenously in such a disease as syphilis, in which there is a strong tendency toward destruction of the red blood-corpuscles and subsequent anemias.

The objections offered to the intravenous method may be summarized as follows:

1. In the early stages of syphilis the lesions are in the skin and connective tissue, and, therefore, intravenous injections do not offer the most immediate and satisfactory method of medication.

2. Syphilitic gummata have no vascular supply, and the intravenous injections do not directly reach them. Despite this fact, it is more than probable that the gummata are influenced by mercurial medication as rapidly by the intravenous injections as by any other method.

3. There is a belief that mercuric chlorid, intravenously, has only a temporary action, being quickly eliminated, necessarily making the treatment longer in such a case than with hypodermic injections of solutions of insoluble salts (Colombini).

While it is true that insoluble salts are eliminated more slowly than the soluble, and hence have a more permanent effect, yet observation of the relative merits of soluble and insoluble mercuric salts has shown that mercuric chlorid has a decided preference and gives the most satisfactory results generally. This is most likely due to the rapid absorption and action of the drug, in contradistinction to the slow and uncertain absorption of the insoluble salts. Uncertain elimination and absorption are always unsatisfactory factors to deal with in therapeutics, and complicate any attempt at definite and scientific treatment.

The disadvantages of intravenous injections are as follows.

1. The needle may not reach the vein; but this can be remedied by applying the needle first and awaiting the appearance of a few drops of blood.

2. Some of the blood may extravasate into the subcutaneous tissue adjacent to the point of injection; but this has been of very rare occurrence, and the blood is soon absorbed.

3. There is likely to be a slight stomatitis at first.

4. There is the appearance of albumin in the urine after the injections, which, however, is also often a result of hypodermic administration.

5. There is, in all intravenous injections, a subsequent polyuria and increase of urea, but neither has any special disadvantage.

6. During the injection, through a reflex action on the circulatory center, fainting may supervene, but is of no vital import.

7. Jemma has seen slight salivation immediately after injection of small doses. This is likely to happen in any administration of mercury.

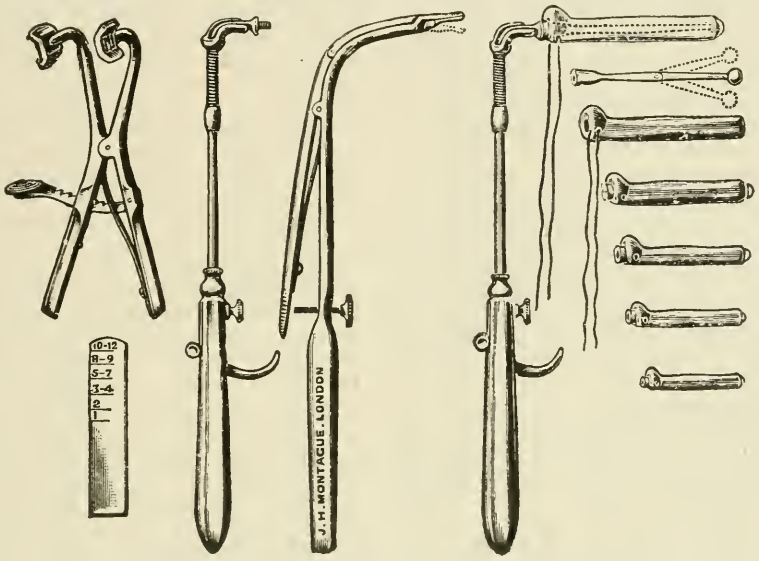
Since Baccelli's first investigations, various

other preparations of mercury have been advised, and simple saline solutions have been advocated. See INFUSION.

INTUBATION.—The passage of a tube into or past the larynx, to allow the entrance of air into the lungs in croup, diphtheria, etc., or to dilate a stricture, etc.

The great **indication for intubation** by O'Dwyer's tubes is laryngeal diphtheria. Before the discovery of antitoxin, in the majority of cases of laryngeal diphtheria the symptoms became urgent enough to demand intubation for their relief. Under the influence of this remedy 60 percent recover without mechanic aid. It will be apparent, then, that in a given case our decision as to the necessity for intubation will be modified by the fact whether antitoxin has been previously administered. We may defer operation in a case already under the influence of this remedy, whereas in another case, presenting identical symptoms, we may feel warranted in intubating at once, because 12 to 24 hours must elapse before amelioration of symptoms can be expected. If at the end of 24 hours a study of the symptoms leads us to the conclusion that the patient is not better, then intubation should be performed. In all cases presenting any one of the following symptoms prominently—namely, deep epigastric recession with each inspiration, labored and prolonged expiration, extreme restlessness, spasmodic attacks coming on at intervals, or persistent cynosis—intubation is indicated. In enthusiastic confidence in antitoxin too much is often expected from the remedy, and in cases seen late it may be wise to intubate and administer this remedy rather than give the remedy and wait for its effect. Antitoxin and intubation are in no way antagonistic.

Technic.—The O'Dwyer tubes and apparatus are almost universally used. The shortest tubes are 1 1/2 inches in length; the longest 3 inches. At the upper end is a diamond-shaped head, flattened in front and provided with a small eye to carry a thread. Below is a neck which expands into a fusiform enlargement. Each tube is provided with a jointed guide, which can be screwed on to an introducer. This consists of a stem set on a handle and carrying a sliding tube, so arranged that when the cannula is in position it can be pushed off the guide and left as the latter is withdrawn. Finally, there is an extractor for the purpose of getting the cannula out again. The cannulas and guides are made in 5 sizes, the smallest being suitable for a child under 2 years of age.*



To the left is the mouth gag and the scale for determining the proper sized tube according to the age of the patient. Next is the introducer, next the extractor. On the right are the tubes, which are expanded above to rest on the ventricular bands; with a prominence posteriorly which rests between the arytenoid cartilages. The middle of the tube is enlarged, the enlargement resting just below the vocal cords, to prevent displacement of the tube upward when it is in position. Between the tubes on the right is the obturator, which fits into the tube and is screwed into the holder, and which is hinged in the middle so that it may be withdrawn after the tube is in position.

"The patient should be held firmly upright on the left thigh of an assistant, whose legs are tightly closed on the patient's legs. The left arm of the assistant is thrown around the back of the patient, holding the left hand and arm of the latter, while with the right hand the assistant holds the patient's right hand. The right side of the patient is firmly held against the breast of the assistant, the left side of the patient being free. The second assistant stands back of the patient, holding the head

* The paragraphs in quotation marks are from the article on Intubation by W. K. Simpson, "Medical News."

firmly in a suspended position, and steadying the mouth-gag with the left hand. There should be no twisting of the neck of the patient, who should be held perfectly straight. This cannot be too strongly emphasized, as it especially pertains to the successful introduction of the tube. The proper-sized tube having been chosen according to the scale, it should be threaded, always using braided silk of a size which will pass easily through the opening in the tube, and of a length which will permit of being looped over the patient's ear when the tube is in position, and so tied that the knot is always at a point furthest away from the tube. The operator, standing or sitting in front and a little to the right of the patient, at a height which gives easy access to the mouth, the patient's mouth being well open and the gag on the left side, passes his left forefinger well down into the larynx over the epiglottis until he feels the two small tips of the arytenoid cartilages, which indicate the posterior portion of the larynx. Then the introducing instrument is quickly passed down over the palmar tip of the left forefinger until the end of the tube engages in the larynx, gentle pressure being continued until the tube is well down in the larynx, when the left forefinger is transferred to the head of the tube, and the obturator removed by liberating the sliding catch on the handle of the introducer. The left forefinger should remain gently pressing the head of the tube until the obturator is well out of the mouth. Care should be taken that the obturator is not removed in any way from the tube until the latter is well down in the larynx, thus avoiding any danger of stripping off or wounding the mucous membrane.

"**The means of knowing that the tube is properly placed** in the larynx are, first, the relief in breathing; and, second, the characteristic cough which immediately occurs, and is of a moist metallic character, produced by mucus and air passing through a metallic tube. This cough should always be expected, and if not present, should be provoked by the administration of a teaspoonful of diluted whisky or brandy. The character of the cough is peculiar, and is far better appreciated by being heard than from any description. Oftentimes, in moribund cases, the cough may be delayed or be but feeble when it is heard. The cough is valuable in clearing the trachea of secretions, and as an indication of the firmness with which the tube is retained in the larynx. Another way of determining whether or not the tube is in the larynx is by passing the left index-finger down into the esophagus and feeling the tube through the anterior wall of the former. This means is of great service if for any reason the breathing is not fully relieved and if it is desired to be positive as to the position of the tube.

"Accidents.—If, after the introduction of the tube, the breathing is not relieved or becomes suddenly worse, the question of having pushed down with the tube some detached membrane is to be considered. This is one of the accidents that may happen, but, as a matter of fact, is very rare. If it were of frequent occurrence, it would be of most serious objection to the operation. The reason of its infrequency is that the stenosis is not entirely due to a complete membranous cast of the larynx and trachea, through which the tube has to pass, but to lessening of the lumen of the larynx by infiltration of the submucous tissue. This may be easily observed in a cross-section of a larynx from a case of diphtheritic croup. The accident mentioned is more likely to occur in late cases of croup in which the membrane has begun to exfoliate, and at any time when traumatism has been occasioned by the introduction of the tube. It is accompanied by excessive coughing and a flapping sound caused by the loosened membrane. If, for this or any other reason, the breathing is not relieved, the tube should be withdrawn by the string and the child encouraged to dislodge the loosened membrane by coughing, after which a second attempt at introduction should be made. It sometimes happens that pieces of detached membrane accompany the withdrawal of the tube. If it is reasonably certain that loose membrane is blocking the tube and is not readily expelled, a short cylindric tube (foreign-body tube) may be inserted. These tubes for a given age are much larger in caliber than the ordinary ones, and allow large masses of membrane to be expelled. Owing to their larger size they should not be left in the larynx more than a few hours, on account of the pressure which they cause.

"Another accident which may possibly occur is the introduction of the end of the tube into one of the ventricles of the larynx. This is obviated by using the present type of tubes, somewhat bulging on the end, which thus permits them to override the ventricles, and by keeping in the median line during introduction. Introduction of the tube into the esophagus will sometimes occur. This may be appreciated by failure to relieve the difficult breathing, and by attempts on the part of the patient to expel the tube or by efforts to swallow. If the string is observed to be disappearing within the mouth, it is evident that the tube is in the esophagus, and it should be immediately withdrawn. This accident is an avoidable one, and need not occur if the proper rules are followed. The tube may be occasionally swallowed when coughed up by the patient.

"**The string** should be permitted to remain in place, being passed over the left ear, until quiet breathing is restored—from 15 minutes to half an hour—and should then be removed by cutting one side of the loop close to the mouth, taking hold of the long end, and withdrawing while the left forefinger is making gentle pressure down on the head of the tube. Never, under any circumstances, remove the string without making pressure on the head of the tube, as the string becomes twisted in the mouth and will be caught in the eyelet of the tube and the latter itself withdrawn unless the counterpressure is made. Another very important precaution in regard to the string is that the person holding the child should never release the child's hands until the string is removed by the surgeon. Almost the first thing a child will do if the hands are released is to instinctively pull at the string, resulting, of course, in withdrawal of the tube.

"It is the practice of some, in preparing the child, to tightly incase the arms and chest in a draw-sheet wrapped around the body. While this keeps the hands out of the way, it is open to the objection of two firmly constricting the chest, and in case of artificial respiration being necessary, much valuable time may be lost. Also, some operators prefer to introduce the tube while the patient is in the dorsal position."

Removal of the Tube.—In preantitoxin days the average period during which the tube was allowed to remain in the larynx was from 6 to 7 full days. Under the present mode of combined treatment the time may be somewhat shorter, varying, in different experiences, from 3 to 5 days; in private practice, preferably 5 days.

"The principal indications for removing the tube previous to its final removal are severe discomfort or pain from pressure, especially if the pain is radiating in character, thus indicating the occurrence of ulceration, severe attacks of coughing, and sudden stenosis due to the lodgment of membrane in the lumen of the tube. This last-named condition is, perhaps, more likely to arise earlier under the antitoxin treatment on account of the earlier exfoliation of the membrane. In some instances, however, if the membrane is sufficiently loosened to block up the tube, the latter will be coughed up with the membrane. This is especially the case with the present rubber tubes, especially if the tube does not fit too tightly. If, under these circumstances, the tube is expelled, its reintroduction may not be necessary, or, at any rate, the necessity for reintroduction will, as a rule, be sufficiently delayed to permit reintroduction by the physician in charge.

"In extracting the tube the same precautions as to the position and management of the patient as during introduction should be followed. The instrument for this purpose is called the extractor. Before being used it is absolutely imperative that the thumb-screw on the under side of the instrument should be so set that the proximal jaw can open just sufficiently to exert the proper amount of pressure within the opening in the tube. If the jaws are open too widely, there is great liability of lacerating the surrounding mucous membrane in ineffectual attempts at removal. It is good practice to test the degree of opening of the extractor on a tube of the same size as the one in the larynx. In extracting, the left forefinger should be passed down on the head of the tube until the opening is felt, and then the extractor, closed, is passed down until the point strikes the head of the tube and enters the opening in front of the tip of the finger. When in the opening in the tube, the jaws of the instrument are opened by thumb-pressure on its handle, and the tube withdrawn, pressure being continuous until the extractor and tube are removed from the mouth. Never have the thumb on the lever until you feel sure that the end of the instrument is in the tube. The operation for extracting is, perhaps, more difficult than that of introduction, as it requires a finer degree of touch to determine the opening in the head of the tube, and the difficulty is increased in proportion to the smallness of the tube. Modifications, from time to time, have been made in the head of the tube and in the extractor, to facilitate removal, but the original procedure just described is the one almost universally employed. Extraction by pushing out the tube from below without any instrument may successfully be performed, if for any reason great difficulty is experienced in the application of the usual method; or in case of emergency when the tube must be removed by the nurse in the absence of the surgeon. This is done by slightly inverting the patient, and, with mouth open, placing the thumb in the episternal notch and pushing the tube up in the mouth and grasping it with the fingers of the other hand or with a pair of ordinary forceps. This can be done by any one of ordinary intelligence in charge of the case, and is, under these circumstances, a most admirable method of extraction.

"**After removal of the tube** the patient should not be left until there is sufficient evidence that the tube will not have to be replaced. A small dose of an opiate may then be given to allay cough and irritation. Slight cough and hoarseness generally continue a few days to two weeks—especially the hoarseness—which, however, pass away without incident.

"**Feeding** after intubation is best accomplished by having the child in an inclined position, the head being down. This is commonly called the 'Casselberry' method. It is best performed by raising the foot of the bed, removing the pillow, and bringing the child to the edge of the bed on the side, and using for the purpose of feeding an ordinary duck-shaped feeding-cup. This procedure prevents, in a great measure, fluids from entering the tube and the accompanying paroxysms of coughing. However, it is remarkable how some children, with a tube in the larynx, will readily learn to swallow in the ordinary upright position. It is also very excellent practice to keep the patient in the feeding position during the entire period in which the tube remains in the larynx, in order to lessen the chances of secretions passing down through the tube, and thus, possibly, causing the development of pneumonia. The frequent removal of the tube for purposes of feeding has been advocated by some, but such a practice should be condemned. The food should be fluid or semisolid, solid particles of food being avoided so as not to run the danger of large pieces being drawn into the tube. In case great difficulty is experienced in the use of the mode of feeding mentioned above, recourse may be had to alimentation through the esophageal catheter, passed either through the nose or through the mouth, or, as a last resort, rectal alimentation may be employed.

"It is most important to watch the respirations during the entire period of intubation, as bearing on the progress of the disease. If they continue about normal, it is indicative of favorable progress; if they show a tendency to increased rapidity it is indicative of extension of the membrane. Fortunately, however, the latter does not occur so frequently as it did in preantitoxin days."

INTUSSUSCEPTION.—See INTESTINAL OBSTRUCTION.

INUNCTION.—The epidermic method of administration of drugs, consisting in the promotion of the passage of a medicament between the cells of the epidermis by more or less energetic friction. If a systemic effect is desired, a region where the cutaneous surfaces are thin, as the insides of the thighs or the axillæ, is chosen, and the rubbing may be carried on gently for a variable time and be aided by heat: as, for instance, before a fire or after the parts have been previously warmed. The inunction method is an old and effectual plan of conveying mercury into the system by the skin. A dram or less of mercurial ointment mixed with an equal part of lard or vaselin should be rubbed into the skin on the inside of the thighs, legs, and arms before bedtime, using different limbs on successive nights. The friction should be continued for half an hour and be gentle. The surface should not be washed, and the same flannel underclothing should be worn night and day. If irritation of the skin ensues, the surface must be washed clean and rubbing discontinued. Inunction is a most convenient way of treating hereditary syphilis. The ointment should be spread on a flannel roller and the body of the child swathed therein.

Inunction is an excellent method of introducing fatty substances into children and persons who cannot take oils by the stomach. The inunction of castor oil will produce purgative effects. Cod-liver oil and other fats, oleates, etc., are rubbed into the skin of the armpits, the popliteal space, and other parts of the body, for local and systemic effects.

INVOLUTION.—The return of the uterus to its normal size and condition after labor. This process is mainly fatty degeneration and atrophy of the hypertrophied uterus and adnexa. It continues over a period of 6 weeks, during which time the uterus is reduced in weight from 2 pounds to 2 ounces, and in length from 12 inches to 2 1/2 inches.

Involution may be excessive (*superinvolution*) or defective (*subinvolution*).

Superinvolution.—An exaggeration or abnormal prolongation of the process of involution. This is a rare condition, said to be due to great loss of blood during labor, prolonged lactation, and puerperal peritonitis. Amenorrhea and nervous disturbances are the chief symptoms.

The diagnosis is made by physical examination, which shows a very small uterus. Senile atrophy can be excluded by the age of the patient; infantile uterus by the fact that she has borne children.

The treatment consists in attention to the general health of the patient, the administration of tonics, and the use of pelvic massage.

Subinvolution.—A retardation or arrest of the process of involution. This is of rather frequent occurrence.

It is caused by: (1) any condition which increases the pelvic blood supply, such as fibroid tumors, pelvic inflammatory conditions, early resumption of sexual intercourse, and premature rising from bed; (2) any condition interfering with contraction of the uterus, such as retained secundines, uterine displacements and adhesions.

The diagnosis is made by a bimanual examination, which shows the uterus much larger than normal. The fundus uteri should be at the level of the symphysis pubis about the tenth or twelfth day after labor. Irregular bleeding, which may persist for some days or weeks, is a common symptom.

The treatment of subinvolution varies with the cause. Thorough curettage should usually precede other treatment. Rest in bed, copious vaginal douches of hot water, abstinence from sexual intercourse, and correction of constipation, are all beneficial. Displacements must be corrected. Tonics are indicated, the most useful being a capsule of ergotin (1 grain), strychnin (1/20 of a grain), and quinin (2 grains).

IODALBIN.—A brown powder of pleasant odor containing about 21.5 percent of iodin in combination with blood albumin. After passing apparently unchanged through the stomach it is slowly dissolved in the small intestine and has the same action as the soluble iodids with the advantage of slower elimination. Dose, 5 to 10 grains.

IODIN.—I = 126.53; quantivalence 1; specific gravity, 4.948 at 17° C. (62.6° F.). A nonmetallic element with metallic luster, volatilizing at a low temperature, and giving off a crimson-purple vapor. It occurs in cod-liver oil, in most marine plants, and in shell-fish. It is soluble in alcohol, in solution of potassium of iodid, and in solution of sodium chlorid. In its elementary state it is an irritant to the skin, and is much used as a tincture to produce counterirritation.

Therapeutics.—Iodin is irritant to the mucous membranes and to the skin. Applied to the latter it stains a deep yellowish-brown color and combines with the albumin of the tissue, causing considerable pain and subsequent exfoliation of the epidermis. Vesication may be quickly produced if the quantity used is large. Inhaled, its vapor irritates the respiratory mucous membrane, producing sneezing, cough, dyspnea, also pain in the chest and the frontal sinuses. In the gastro-intestinal canal it is equally irritant.

Iodin is alterant, rubefacient, vesicant, caustic, antiseptic, and parasiticide. When iodin is applied to the skin or mucous membrane, it is irritant or caustic. It stains the skin yellow, creates sensation of warmth if in small quantity, or burning if in larger quantities, and excites a superficial inflammation, followed by desquamation. In some subjects the application of the tincture of iodin results in vesication. Pure iodin kept in contact with the tissues produces a brown, dry eschar. The vapor of iodin is often irritating to the mucous membranes of the air-passages, causing increased flow of mucus, and even spasm of the glottis. As a simple counterirritant iodin is frequently employed when it is desired to maintain a mild, persistent influence.

The tincture is the preparation that is generally used. It is best applied by painting over the part with a camel's-hair brush or a swab. Differences

obtain between individuals as to the degree of susceptibility to iodin. For those of a sanguine temperament, in whom the skin is fair and the hair light, the stronger preparations must be used with caution. If an application causes pain, the iodin should be washed off with alcohol, whisky, cologne, or, what is best, a solution of iodid of potassium, and the pain subdued by the application of a starch poultice. A crop of itching papules will often follow the use of iodin under ordinary conditions.

Iodin is used in diseases associated with disorder of the processes of nutrition. In enlargement of lymph-glands in fibroid phthisis, in hypertrophy of the thyroid gland and of the tonsils, in cervical and ovarian cysts, it is of value. It ought not to be employed in cases in which rapid changes are going on in a gland, such as pus-formation, since it furthers the process. The fumes may be inhaled to stimulate the bronchial mucous membrane, but not in phthisis. In chronic bone-disease, applied externally as an ointment it is of service. Its external uses are many and important, and it is particularly useful in children, and in from 1 to 3 coats painted on at one time, and no more. A good black coating should be painted on at one time, and not repeated until the skin has desquamated. If reapplied soon after a good coat has already been put on, it will cause burning pain which nothing will relieve except removal.

As a counterirritant the tincture is used on sprains and bruises. It may be used in pleurisy, harassing irritative cough and chronic bronchitis, phthisis (when a spot in the chest becomes sore), lupus, chronic rheumatism, synovitis, in pleurodynia and intercostal neuralgia, tineæ tonsurans and circinata, and in erysipelas. For inhalation, 20 to 30 drops of the tincture may be dropped into a jug or vessel holding about 2 pints of boiling water, and the iodized steam inhaled, the head being covered to prevent the escape of the vapor. When used night and morning for 5 minutes each time, it will relieve the itching of the nose and of the inner canthus of one or both eyes, with the sneezing and running at the nose of a watery fluid and severe frontal headaches. In acute coryza relief may be had from sniffing from the bottle containing iodin, the heat of the hand disengaging the vapor. It is much used in local application in the practices of rhinology, laryngology, and even ophthalmology.

Antidotes, Antagonists, and Incompatibles.—Starch is the antidote to free iodin, but the stomach must be evacuated, as the resulting iodid is active. Albumin, starch, lime-water, tannin, and soap may be used in poisoning by the iodids, and free emesis should be induced. In chronic iodid poisoning a free salivary flow, brought on by chewing pyrethrum root, will hasten elimination of the drug. Restoratives and vasomotor tonics, as quinin, digitalis, etc., are therapeutically antagonistic.

Incompatibles with iodin and the iodids are the mineral acids, metallic salts, alkaloids and their salts, ammonia, etc. If potassium iodid is combined in solution with potassium chlorate, a poisonous compound will result. As potassium iodid decomposes nearly all the metallic salts, and is incompatible with so many substances, it is best prescribed alone, or in some simple vehicle, a favorite one being the compound syrup of sarsaparilla. It may be prescribed with tincture of cinchona, an ounce of which dissolves 30 grains, or in combination with liquor potassi arsenitis, which prevents the iodic eruption to some extent. In the "mixed treatment" of syphilis it is combined with the biniodid of mercury. It is better borne when combined with nux vomica or potassium acetate, or alternately with ammonium carbonate, 2 parts of the latter to 1 or 1 1/2 of the iodid (Gull).

Test-paper for Iodin in Saliva and Urine.—A sheet of filtering-paper is dipped in a 5 percent solution of cooked starch. When dry, it is marked off into 5 cm. squares, and in each square 2 or 3 drops of a 5 percent solution of ammonium sulphate are dropped and dried, sheltered from intense light. The ammonium sulphate loses its power in 2 or 3 weeks; it is best applied fresh. To test the intestinal absorption let the subject swallow a glutoid capsule containing a little iodoform. Then mark the hour on the first square, and number the rest. The subject then deposits some saliva on the corresponding square every hour, and an exact record of the intestinal absorption is obtained, as the paper turns blue in contact with any traces of iodin.

Iodids.—**Potassium iodid** is the most frequently used, and mostly administered in either the simple solution, the compound infusion, or syrup of sarsaparilla. It is almost specific in tertiary syphilis and its results, such as neuralgia, paralyses from gummata, ulcerations, syphiloma of the internal viscera, lupus, chronic rheumatism, and sciatica. Doses varying from 5 to 150 grains to systemic saturation are employed. In mercurial poisoning, to remove the products left behind by pneumonia, pleurisy, and pericarditis, in the early stage of hepatic cirrhosis, in acute catarrh and hay-fever, and in aneurysm, potassium iodid is employed. In tonsillitis and sore throat a weak solution (2) to 5 grains to the ounce) is a good gargle.

Sodium iodid may be used instead of the potassium salt, but requires larger doses. **Strontium iodid** is less liable to produce eruptions, and has been used with benefit in scrofulous, rheumatoid, and cardiac disorders.

Ammonium iodid is an excellent remedy in acute catarrh, hay-fever, duodenal catarrh and accompanying jaundice, and in capillary and chronic bronchitis, given in grain doses and frequently repeated. It is more irritating than the other iodids, and is more energetic in action, but less stable. See Ammonium.

Hydriodic acid is used as a substitute for the iodids and for iodin. It is used almost entirely in the form of the syrup, which contains 1 percent of absolute hydriodic acid. The syrup should be kept in a dark place and not exposed to air. Its advantages are its activity, agreeable taste, and the fact that it rarely disorders the stomach.

Iodoform, aristol, europhen, and **iodol** are described under their respective titles.

Preparations.—**Tinctura Iodi,** strength 7 percent Dose, 1 to 3 minims; but it is generally used as a local application, or for injection into cavities. **Liquor Iodi Compositus** (*Lugol's solution*), has of iodin 5, potassium iodid 10, in distilled water to 100. Dose, 1 to 10 minims, well diluted. **Unguentum Iodi,** has of iodin 4, potassium iodid 4, glycerin 12, benzoinated lard 80. **Churchill's Tincture of Iodin** (unofficial), contains iodin 75 grains, potassium iodid 1 1/2 drams, alcohol 1 ounce, and is used locally, chiefly in gynecology **Ammonii Iodidum,** a deliquescent, granular, white salt soluble in 1 of water and in 9 of alcohol at 59° F. Dose, 2 to 10 grains. **Potassii Iodidum,** a colorless, deliquescent, crystalline salt, of saline and bitter taste; soluble in 0.8 of water and in 18 of alcohol. One ounce of this salt dissolved in 1 ounce of water makes nearly 1 1/2 ounces of fluid, so that 7 1/2 minims of the solution would be required to obtain 5 grains, a fact to be remembered in prescribing. Dose, 5 to 20 grains. **Unguentum Potassii Iodidi,** has of the iodid 10, potassium carbonate 0.6, hot water 10, benzoinated lard 80. **Sodii Iodidum,** minute deliquescent crystals; soluble in 0.6 of water and in 1.8 of alcohol. Dose, 5 to 20 grains. **Strontii Iodidum,** colorless, hexagonal plates, of bitter, saline taste; very soluble in water and in alcohol. Dose, 5 to 20 grains. **Acidum Hydriodicum Dilutum,** contains not less than 10 percent by weight of hydriodic acid, HI. Dose, 5 to 15 minims. **Syrupus Acidi Hydriodici,** contains about 1 percent of the absolute acid. Dose, 1/2 to 2 drams, well diluted.

IODIPIN.—There are two preparations of sesame oil, one, for hypodermic use containing 25 percent of iodin, the other 10 percent. Iodipin is carried to every tissue of the body, however administered, its iodin being converted into soluble iodids, and its fat being oxidized and acting as a nutrient (Winternitz). It may be given internally for a long time without disturbing the digestion or producing iodism. It is an efficient substitute for the iodids, and is said to be even more efficient than the latter, by reason of its slower rate of elimination.

IODISM.—The term applied to the condition produced by the prolonged use of iodin and its compounds. The symptoms are irritation of mucous membranes, violent coryza, sore throat, acute conjunctivitis, profuse mucous discharges, headache, and irritation of the kidneys and skin. The earliest signs are the metallic taste in the mouth, particularly before breakfast, slight tenderness of the gums and teeth, an increase in salivary secretion, morning nausea, and lack of appetite. Acne does not come on very early. If the iodids are not withdrawn, these symptoms are aggravated and the coryza becomes intense. The pustular and other bleb-like changes in the skin go on to active suppuration, and sometimes the eruption is furuncular, or even purpuric.

Strontium iodid is less likely to produce iodism than any of the other salts of iodin. When well diluted, excretion is promoted, and the development of unpleasant results is less likely. The ptyalism of the iodids generally occurs in persons who have previously taken mercurials, which have been deposited in the tissues and are set free by the iodid and come again into the circulation.

Elimination and withdrawal of the drug in full dose is the indication for the treatment of iodism. Chewing pyrethrum root will establish free salivary flow and hasten elimination, while quinin, digitalis, and other restoratives and vasomotor tonics are beneficial.

Tincture of belladonna in doses of 5 minims with each dose of iodid of potassium has the almost infallible effect of obviating the disagreeable catarrhal symptoms. These symptoms in some subjects very much resemble those of hay-asthma —persistent sneezing, profuse watery discharge from the nostrils, frontal pain, etc. This control of belladonna over the iodin symptoms is attributed to its effect upon the salivary secretions. It may be supposed that other substances having a similar control over the salivary secretions would exert a like control over iodin, but belladonna will be found most serviceable because of the convenience with which it can be administered.

IODOFORM.—Triiodomethane, CHI_3. Iodid of formyl. A compound containing about 96 percent of iodin. It is an antiseptic and a feeble anesthetic, and is highly useful for local application to wounds, abrasions, and indolent sores. Internally it is a tonic. It seems to exert a special influence upon tuberculous processes. Its odor may be disguised by means of thymol (2 drops to the ounce) or oil of rose (1 drop to the dram). Dose, internally, 1 to 6 grains.

Therapeutics.—Iodoform is chiefly employed in local diseases as an antiseptic, anesthetic, and alterative agent. It may be dusted in fine powder over a wound or sore, or used in ethereal solution to saturate gauze or absorbent cotton. It is particularly useful as an application to sloughing and phagedenic ulcers, gunshot wounds, chancroids, fistulæ, sinuses, and painful affections of the rectum or uterus. Internally it may be used as a general tonic and alterative in syphilis and other cachexias, also for neuralgia, and is frequently prescribed with iron. Triturated with tannin it forms a useful application to the cervix uteri in erosions and ulcerations thereof, or an iodotannin may be prepared by saturating the tincture of iodin with tannic acid, and applied on a cotton tent to the uterine mucous membrane in many chronic affections of that organ. Tuberculosis is successfully treated by iodoform, which certainly does check the activity of the bacillus of that disease. Diabetes has been apparently cured by iodoform, and syphilis has been combated successfully thereby in lieu of potassium iodid.

Agents Which Have Been Recommended to Neutralize the Odor of Iodoform.—Among the statements made in this connection may be included the following: Ehrmann recommends an admixture of tar with iodoform, and it is said the result gives a spicy odor, resembling neither ingredient. This, it is claimed, may be further disguised by the addition to the powder of liquid styrax. Oppler adds 1 part of copper sulphate to 2 of iodoform. Gillette with 100 parts of iodoform com-

bines 1 of sulphate of quinin and 3 of powdered wood charcoal. Cantrell uses with every 15 grains of iodoform 3/4 grain of menthol and 1 drop of essence of lavender. Jaksch recommends a 2 percent admixture of creolin with iodoform. Among other agents may be mentioned ground coffee, balsam of Peru, oil of bitter almond, oil of cade, thymol, coumarin, attar of rose, oil of bergamot, and oil of coriander; of the agent last named 8 drops may be added to a dram of the drug. A serious objection to the use of many of the deodorants could be found in the addition of a septic material to one assumedly sterile.

Poisoning.—Numerous instances are on record of the toxic effect being produced by the local application of the drug. It appears to be more quickly absorbed than are other forms of iodin preparations. If a disposition to toxic effect from a moderate quantity is obtained, iodoform should be abandoned. Iodoform is, with some individuals, irritative to the skin, and may excite dermatitis.

According to Treves, the conditions favorable for poisoning are clean, granulating wounds or burns, abscess cavities, fistulæ, and sinuses; cases in which the powder is applied under pressure or covered with impermeable dressings, as well as in instances in which the drug comes in contact with mucous surfaces, as may occur after dressing the wound in colotomy. The symptoms of poisoning may appear shortly after the application of the powder, or be deferred for days or weeks.

Two forms of poisoning occur, the acute and the chronic. In the *acute* form the symptoms are violent, and generally develop suddenly. Vertigo, headache, sleeplessness, and delirium follow. The temperature rises, the pulse ranges from 150 to 180 in the minute, vomiting and even mania ensue. The patient wastes, and may die in a state of exhaustion attended by coma. In the *chronic* form malaise, loss of strength, depression of spirits, slight fever, a rapid pulse, and headache are prominent symptoms. The patient becomes apathetic, melancholy, weak, and apprehensive. This train of symptoms may extend over a period of from a week to months before dissolution.

IODOFORMOGEN.—An odorless compound of albumin and iodoform. It is a light yellow powder insoluble in water. It is three times lighter than iodoform, and therefore more economic to use. It is almost odorless.

IODOL.—Tetraiodopyrrol. A pale yellow inodorous, tasteless powder, insoluble in water, soluble in 3 parts of alcohol, 15 parts of ether, 50 parts of chloroform, and 15 parts of oil. It contains 89 percent of iodin. On account of its freedom from odor and its nontoxicity it has been recommended as a substitute for iodoform. It dissolves readily in the gastric juice. Dose, 1 to 10 grains.

IODONE.—A periodid of phthalic anhydrid and talcum; a surgical dressing and dusting powder containing 2 percent of available iodin.

IODOTHYRIN.—The active principle of the thyroid gland. It has apparently the same properties as the gland, but is said to be of a more definite strength and devoid of objectionable material. Dose, 1 to 5 grains in tablet form.

IONIC MEDICATION and **IONIZATION.**—See CATAPHORESIS.

IOTHION.—A yellowish liquid containing 77 percent of iodin. It acts like iodin and the iodids but it is claimed to be rapidly absorbed by the intact skin and it is said to be a satisfactory substitute for iodin and iodids. A 25 to 50 percent ointment with a mixture of equal parts of wool fat (lanolin) and petrolatum as a base is applied in the same manner as mercurial inunctions.

IPECAC (Ipecacuanha).—The dried root of *Cephaëlis Ipecacuanha* or *C. acuminata*, growing in Brazil and Columbia. It contains *cephaëlin*, a crystalline alkaloid; *emetin*, an amorphous alkaloid and a methyl compound of cephaëlin; also a third alkaloid in very small quantity, a glucosid named *ipecacuanhic acid*, starch, gum, and a trace of a volatile oil. Dose of the powdered root, as an expectorant, 1/2 to 2 grains; as an emetic, 10 to 20 grains.

Therapeutics.—Ipecac is much used as an emetic, being safe, efficient, and nondepressant, though slow of action. It is the best agent of the kind to relieve the stomach in acute indigestion and bilious sick headache, and an ipecac vomit is frequently very serviceable at the commencement of eruptive, continued, and periodic fevers. The syrup is a favorite domestic emetic to cut short an attack of spasmodic laryngitis, and it may be used beneficially in membranous croup and capillary bronchitis. In small doses ipecac is an excellent stimulant of the gastric and hepatic functions, and an expectorant of great value. In atonic dyspepsia, catarrhal jaundice, intestinal colic, bronchial asthma, hay fever, bronchial catarrh, acute laryngitis and pharyngitis, also in nervous and other coughs, it has rendered good service. In still smaller doses, ♏ j of the wine frequently repeated, it is an efficient antiemetic in vomiting of nervous origin, and especially in the vomiting of pregnancy, also in that of gastric atony as seen in chronic alcoholism; its action in this affection being due perhaps to its possessing a sedative influence upon the pneumogastric in small doses. It is an excellent remedy in hemoptysis if given in small and frequently repeated doses until nausea occurs. As an antihemorrhagic it has been efficiently used in epistaxis, menorrhagia and post-partum hemorrhage, in the latter affection given with ergot. In doses of a grain several times a day it has given satisfaction in cases of idiopathic neuralgia, hyperhidrosis, intermittent fever, erysipelas, acute and suppurative hepatitis and opium narcosis, also in many of the affections which frequently complicate the puerperal state.

Dysentery is a disease in which large doses of ipecac (20 grains every 4 hours) are used with great success, especially in the epidemic form and in the summer dysentery of teething children. Tolerance must be established to produce its curative action. In small doses (1 minim of the wine), frequently repeated, it will relieve many kinds of vomiting, especially those of nervous origin.

Emetin hydrochloride has been used with much success in amebic dysentery. It may be administered by mouth in doses of 2 grains, or hypo-

dermatically in doses of 1/2 to 3/4 grain. It has also been used in cases of pyorrhœa alveolaris.

A common emetic:

An emetic for children:

℞. Powdered ipecac, gr. xx
Boiling water, ℥ v
Pour on and strain and add:
Honey of squills, ℥ ss.

Give a teaspoonful every 10 minutes until it acts.

In bronchitis:

℞. Wine of ipecac, ♏ xx
Solution of ammonium acetate, Water, each, ℥ ss.

To be taken 3 times daily.

For children threatened with croup or bronchitis:

℞. Wine of ipecac, ℥ iij
Syrup of tolu, ℥ v
Mucilage of acacia, ℥ j.

Give a teaspoonful every hour or second hour.

Preparations.—**Fluidextractum I.**—Dose, as an expectorant 1/2 to 2 minims; as an emetic 10 to 20 minims. **Syrupus I.**—strength 7 percent. Dose, as an expectorant 10 to 20 minims; as an emetic 2 to 6 drams. **Vinum I.**—strength 10 percent. Dose, 10 to 20 minims. **Pulvis I. et Opii** (*Dover's Powder*)—has of ipecac 10, powdered opium 10, sugar of milk 80, triturated together to a fine powder. Dose, 3 to 15 grains. **Tinctura I. et Opii,** has of tincture of deodorized opium 100 evaporated to 80, fluidextract of ipecac 10, diluted alcohol to 100, and is a fluid representative of Dover's powder. Dose, 3 to 15 minims. **Pilulæ Laxative Compositæ**—have in each pill gr. 1/16 of ipecac (see under PILLS). Dose, 1 to 4.

IRIDECTOMY.—Excision of a portion of the iris. It is performed in glaucoma, in cataract extraction, for the removal of foreign bodies and growths, in complete synechiæ, and for optic purposes. Having first secured a lid-speculum in position, a fold of conjunctiva, near the cornea and opposite the place where the incision is to be made is seized by fixation forceps. A keratome is entered through the cornea at the scleral border, the point being kept nearly perpendicular to the sclera until it has reached the anterior chamber, when the handle is depressed so as to bring the blade parallel to the iris. The blade is then pushed forward until it has made a wound sufficiently large for operation; still depressing the handle, the blade is withdrawn slowly, and iris forceps are thrust through the wound closed, and opened in the anterior chamber to seize the iris. The iris is then drawn out of the wound, and as much of it as desired is excised by fine iridectomy scissors held firmly against the eyeball and parallel to the wound. The stump of the iris is then carefully returned to the anterior chamber, no portion of it being allowed to become incarcerated in the corneal incision. The delicate McClure iris-scissors are the best for cutting the iris, but they are rather expensive, and not always obtainable. The eye should be thoroughly cocainized, and the operation should be done under antiseptic precautions; after the operation the eye should be thoroughly irrigated, a light bandage applied, and the eye kept closed until the corneal incision has become united. The incision may be made with the Graefe knife instead of the lance-shaped keratome.

Iridotomy is performed when the pupil for any reason is occluded by a thickened and opaque capsule or with exudations from the iris. One mode of operation is with a needle-knife having a double cutting-edge, with its shank so constructed as completely to fill the coneal wound, thus preventing any escape of aqueous. This knife is thrust through the cornea midway between its center and circumference and the occluding membrane is divided at right angles with the line of greatest tension. When the iris is to be incised so as to make an artificial pupil, a lance-knife is used instead of a needle-knife, and introduced in the same way as before, and withdrawn half way, allowing some of the aqueous to escape, thus carrying the iris forward. The knife is thrust through the iris and then withdrawn. De Wecker's scissors for iridotomy are entered closed, and opened in the anterior chamber, one blade passed through the cut in the iris, and the blades brought together through the iris, thus elongating the incision.

Iridocystectomy is preferable to iridotomy. An incision is made with a Beer's knife through cornea, iris, and the thickened or adherent lens-capsule. Next a Tyrrell hook or one branch of a pair of iris-forceps is passed into the opening in the iris. The edge of the iris (and capsule) is drawn out of the corneal wound and cut off close to the cornea.

Iridodesis consists of drawing the pupil into a new shape and position, and is accomplished by making a small incision in the cornea and drawing a part of the iris, including some of the pupillary border, into it, and fixing it with a ligature. This operation is now almost obsolete.

IRITIS.—**Hyperemia of the iris** is due to congestion of the iridic vessels preceding iritis or accompanying some inflammation of the adjacent tissues. It is recognized by the contraction and discoloration of the pupil, and the sluggish reaction to atropin. If the hyperemia becomes so intense as to produce an exudate, there is a genuine inflammation, called iritis.

Plastic Iritis.—An inflammation of the iris in which a scant, fibrinous exudate is deposited on the anterior or posterior surface of the iris, the pigment-layer at the edge of the pupil thereby becoming adherent in places to the capsule of the lens. This binding down of the iris to the lens is the cause of the immobile pupil.

Symptoms.—The patient complains of intense pain radiating over the forehead and face, and which is not proportionate to the severity of the disease. The pain is worse at night. There is lacrimation, photophobia, and dimness of vision. In some cases the subjective symptoms may be

very slight. The objective symptoms are pericorneal injection, haziness of the pupil, loss of luster in the iris, and contracted, distorted, or unsymmetric pupil. Hyperemia of the optic nerve is said to accompany iritis.

Course and Sequels.—An uncomplicated iritis running its course in from 2 to 4 weeks is an exception. Permanent adhesions, or synechiæ, of the iris, by organized exudate between it and the surface of the capsule of the lens, are often left behind, and render relapses of iritis likely. The whole pupil may become blocked with organized exudate, and thus produce loss of vision in the eye affected. It there are many severe recurrences of attacks of iritis, circular adhesions may form between the lens and iris, and destroy communication between the anterior and posterior chambers. In such a case the iris bulges forward from the tension of the aqueous that collects in the posterior chamber, causing the condition known as "ballooned iris," or "umbrella iris." Unless an artificial pupil is formed at once by iridectomy, reestablishing the communication between the chambers, the whole eye will be destroyed.

Causes.—What is called *idiopathic iritis* is generally the result of some general systemic dyscrasia, although one eye only is often affected. Syphilis is the most common cause. Other causes are tuberculosis, rheumatism, gout, gonorrhea, diabetes, nephritis, and the severe infectious fevers. Often the only explanation of the origin is exposure to cold, or "catching cold" in the eye. Secondary iritis follows inflammation of the adjacent tissues; even a conjunctivitis may lead to iritis. Traumatism, with or without infection, or a foreign body in the iris are causes of the inflammation.

Treatment.—The most important element in the treatment is to prevent or overcome adhesions of the iris. If possible, a history of an injury or clinical manifestations of some systemic condition known to cause iritis should be elicited. It is especially important to institute immediately general treatment in syphilis, rheumatism, and gout. The iodids, salicylates, salol, and mercurials are useful along with the usual general treatment. Tuberculin injections should be employed in tuberculosis. See Tuberculosis, Ocular. The diet should be chiefly of milk and broth during the acute stage. The pupil should be immediately dilated by atropin, and if it yields to the drug and is perfectly circular, a rapid improvement may be expected. Caution must be used in the administration of atropin to persons past 45, or in cases showing increased tension of the eyeball, or in which there is idiosyncrasy to the drug. If the pupil resists dilatation, the atropin solution should be heated; or a drop of 5 percent solution of cocain every 3 or 4 minutes 4 or 5 times, and then another application of atropin, should be tried. If the iris is still bound down, 6 or 8 leeches, or a mechanic leech, should be applied to the temple, and mercurial inunctions begun, using a hot bath and profuse diaphoresis before each inunction. Atropin must be kept up throughout the treatment. If it causes much conjunctivitis, scopolamin may be substituted. The pain is best relieved by local depletion with leeches, or artificial scarification over the temple, or hot, moist compresses to the eye for 15 minutes every 2 hours. Antipyrin, morphin or other analgesic may be administered. Profuse diaphoresis, with a Dover's powder, hot drink, foot-bath, and blankets, is of great value, and may be repeated several times. If all other means fail, puncture of the cornea will relieve the tension. Iridectomy is not indicated in the inflammatory stage except when there is a circular synechia obliterating communication between the anterior and posterior chambers. If there are enough adhesions left to warrant belief that there will be future relapses, iridectomy should be performed after the inflammation has subsided. This is a prophylactic measure of great importance. Smoked glasses should be worn all through the disease. Alcoholic beverages should be interdicted.

Serous Iritis.—A chronic inflammation in which an inflammatory product, poor in cells, settles in the anterior chamber, causing a haziness of the aqueous, and deposits on the posterior surface of the cornea, on account of which the disease is sometimes called **descemetitis.**

Symptoms and Diagnosis.—The chief objective signs are the deposits in the aqueous and on the back of the cornea, the haziness of the aqueous, the increase in the depth of the anterior chamber, and the signs of acute iritis in a milder degree. Pain and other subjective symptoms are inconsiderable, and the pupil may be dilated. There is often a rise of tension, due to the chemic and physical changes in the aqueous, causing simulation of glaucoma.

The important **sequels** are striated opacities on the back of the cornea, which never quite clear up, posterior synechia, and, if the ciliary body is affected, vitreous opacities, and possibly opacities in the lens.

Causes.—Serous iritis occurs in debilitated and anemic young persons, and has been ascribed to syphilis and other general dyscrasias. It is commonly bilateral, which fact points to a systemic cause. It may occur after cataract operations.

Treatment.—The patient's general health should be attended to, and good food and hygienic measures instituted. To keep the pupil dilated and break up adhesions, atropin twice a day is necessary. To hasten absorption of the inflammatory products, heat, diaphoresis, and the iodids are useful. The depressed physical condition of the patient generally forbids any rigorous mercurial treatment. The deposits may be mechanically removed by releasing the aqueous by repeated paracenteses. If there is much rise of intraocular tension, atropin must be suspended and eserin substituted. Repeated paracenteses will here prove of great value. Iridectomy may be indicated in the worst cases.

Suppurative Iritis.—A condition in which the inflammatory product is purulent, and saturates the tissues of the iris and overflows into the anterior chamber, forming a **hypopyon,** which is more fluid than the hypopyon following inflammation of the cornea.

Symptoms.—In this condition the iris is highly hyperemic, and is swollen and discolored yellow by the pus in its matrix. The chief symptoms are: The marked changes in the iris; the swollen pupillary border of the iris, which often occludes the pupil; the fluid hypopyon, which changes position, in distinction to the stationary fibrinous clot of pus in corneal disease; the history of infection, chiefly through a wound. In this day of aseptic precautions, suppurative iritis after operation is very rare. Diabetes is said to be a systemic cause. If the disease is due to infection through a wound or following an operation, there is great danger of general involvement of the eye, and such cases should be regarded as very dangerous. What have seemed idiopathic cases have often yielded readily to treatment and left no sequels.

Treatment is that of simple iritis, and should be energetically pursued—rapid mercurial inunctions, atropin, and paracenteses, after the height of the inflammation has been passed. Serum or vaccine therapy should be given a trial. For idiopathic or diabetic cases, the salicylates have been used to great advantage.

Iritis nodosa is an inflammation in which small nodes or tubercles are seen on the iris. Nodules are sometimes noticed on the iris in both simple and suppurative iritis, but the name is usually applied to conditions in which small gummata or tubercles are found on the iris.

Gumma of the iris is a local expression of tertiary syphilis, and generally yields to antisyphilitic treatment. There is usually seen near the pupillary edge of the iris a yellowish mass, about the size of a split pea, surrounded by a brownish-red base. A history of syphilis is generally obtainable.

Tubercles of the iris usually occur in groups, are some distance from the edge of the iris, and are grayish or pale yellow in color. The adjacent lymph-glands are swollen, and there is a history of tuberculosis. Tubercular iritis usually attacks young persons, while gummata are mostly seen in advanced life. Gummata may disappear under the iodids and mercurials, or may leave the iris atrophic or immobile. In tubercular iritis the prognosis is bad. In severe cases the eye must be enucleated. Excision of the tubercles is useless. Tuberculin therapy seems most encouraging and is gaining more and more favor. See Tuberculosis, Ocular.

IRON (Ferrum).—Fe = 56. Quantivalence, II, IV. A metal having a luster varying from silver-white to gray. In pharmacy, a fine, nonelastic, soft wire is used. Reduced iron consists of metallic iron in fine powder. It is a fine, gray-black, lusterless powder, odorless, tasteless, and insoluble in water and alcohol, but soluble in dilute sulphuric acid. Dose, 1/2 to 2 grains, after meals.

Therapeutics.—Iron is a normal constituent of the blood (1 part to 230 of red blood-corpuscles), and, given medicinally, it promotes appetite and digestion and increases the number of red corpuscles. In the stomach the salts are converted into the chlorid, and in the duodenum into an albuminate. In large doses, or in small ones long continued, iron produces indigestion, nausea, and vomiting. The iodid, chlorid, nitrate, and sulphate are astringent, and act injuriously on the teeth. The tincture of the chlorid is considered as diuretic. Externally, many of the soluble salts make excellent styptic and astringent preparations.

The chief indication for iron is anemia. Plethora is a contraindication. Iron should generally be given after meals.

It is well known that it is by no means a matter of indifference what form of preparation of iron is used in different cases of anemia, and nothing is more common than to find a particular preparation succeed after many others have failed. Burney Yeo has considered this question as follows:

In the first place, the state of the digestive functions should be examined carefully. If with a coated tongue there are a loss of appetite, flatulent distention, and other signs of dyspepsia or chronic gastric catarrh, the digestive functions should be improved before any form of iron is prescribed, and some such formula as the following should be ordered:

℞. Solution of bismuth citrate, ʒ iv
Sodium bicarbonate, ʒ ij
Aromatic spirit of ammonia, ʒ iij
Tincture of nux vomica, ʒ ij
Infusion of calumba, to make ʒ viij.
Two tablespoonfuls an hour before food twice a day.

If there is constipation, the following pill should be given daily, immediately before or after dinner, or supper, when dinner is taken at midday:

℞. Extract of aloes, gr. jss
Powdered ipecac, gr. ss
Quinin sulphate, gr. j
Soap, gr. ss
Make 1 pill.

After a week or 10 days of this treatment one of the milder preparations of iron may be given, and then 5 grains of iron ammoniocitrate added to each dose of the foregoing mixture, and 1 grain of ferrous sulphate to each of the pills. Subsequently the mixture may be replaced by a modification of Blaud's pills, in which the whole of the ferrous sulphate is not decomposed by potassic carbonate, but an excess of sulphate is left in the pill.

℞. Exsiccated ferrous sulphate, gr. lxxij
Potassium carbonate, gr. xij
Powdered nux vomica, gr. xxiv
Soap, gr. vj.
Divide in 24 pills. To be coated with a suitable covering. From 1 to 3 after each meal.

Some prefer to give the insoluble preparations of iron immediately or about an hour after food, in order that they may be dissolved by the gastric juice, and so absorbed with the food; and in some

cases in which there is an intolerance of iron preparations this is a good plan. The *ferrum reductum* [the solubility of reduced iron in gastric juice has been estimated by Quevenne: when 50 centigrams (7 1/2 grains) of reduced iron were treated with 100 grams (3 ounces) of gastric juice, 51 milligrams were dissolved, or about one-tenth], in 2- or 3-grain doses, may be given in pill or powder, or the *ferri carbonas saccharatus* in 5- to 10-grain doses in the same manner, 3 times daily after food.

In atonic leukorrhea, in the dose of 2 to 5 grains, ammonioferric alum is given. The arsenate of iron is used in 1/16 to 1/12 grain doses in skin-diseases. The carbonate of iron is given largely in the treatment of amenorrhea. The tincture of the chlorid of iron may be administered in 10-drop doses every hour as a specific in erysipelas. It is useful in chronic Bright's disease, and as a local application it is valuable in diphtheria and in tonsillitis. It should be administered through a glass tube to protect the teeth. In chronic affections of the respiratory organs the phosphates of iron, quinin, and strychnin are beneficial. The syrup of the iodid of iron is much used in scrofulous states and in struma. Monsel's salt finds application in hemoptysis (in a fine spray), in uterine hemorrhage (when diluted) or the hemorrhage from polypus, in nose-bleed, in intestinal hemorrhage, in hematemesis, and in tonsillitis and pharyngitis (in equal parts with glycerin).

In melancholia:

℞. Quinin valerate,
Iron valerate,
Zinc valerate, } each, gr. xx.

Divide into 20 pills; 1 pill 3 times daily.

In cardiac dropsy:

℞. Potassium bicarbonate, gr. x
Iron and ammonium citrate, gr. v
Tincture of digitalis, ♏ x
Infusion of buchu, ʒ j.

To be taken 3 times daily.

In diphtheria:

℞. Tincture of iron chlorid, ʒ ij to iij
Potassium chlorate, ʒ j
Dilute hydrochloric acid, gtt. x
Simple syrup, ʒ iv.

A teaspoonful every 2 hours.

See Anemia.

Untoward Effects.—Prolonged administration of iron causes frontal headache and gastric distress in those unaccustomed to its use. The constipation resulting may be relieved by mild purges and laxatives. These untoward symptoms show themselves especially in gouty or rheumatic persons. Nocturnal incontinence of urine may follow the administration of iron in children. A constant desire to urinate, with excessive mucus formation in the bladder, sometimes ensues. Iron is antidotal to arsenic when precipitated from any liquid preparation by the addition of an alkali, such as ammonium or magnesium carbonate. The latter in itself is antidotal, and it should be preferred to precipitate the iron. When ammonia is used, the precipitate should be well washed to remove the irritating excess. The antidote should always be given in large quantities, and as much as a pint should be precipitated. Too much of the magnesia cannot be given, and it should be freely used to bring about the precipitate. See Arsenic.

Incompatible with *metallic iron:* Hydrogen dioxid, oxidizers, potassium chlorate, potassium permanganate; salts of antimony, copper, bismuth, lead; mercury, and silver. With *ferrous salts:* Alkalies, carbonates, chromates, chlorates in acid solution, ferricyanids, gold salts, hydrogen dioxid, mercuric salts, phosphates, permanganates, sulphids, tannic acid, silver salts. With *ferric salts:* Acacia, albumin, alkalies, apomorphin, aloin, benzoates, carbonates, creosote, balsam of Peru, benzoin in alcoholic solution, diuretin, gallic acid, gelatin, guaiac, guaiacol, hydriodic acid, hypophosphites, hyposulphites, iodids, morphin; oils of bay, cloves, cinnamon, pimento, thyme, and wintergreen; pyrogallol, resorcin, salol, salicylates, sulphids, sulphites, tannic acid, vegetable infusions and decoctions. With the *tincture of ferric chloride:* Acacia, albumin, alkalies, carbonates, gelatin, lime-water, magnesium carbonate, piperazin, vegetable decoctions, infusions, and tinctures. With *ferrous sulphate*: Alkalies, carbonates; chlorids of ammonium, barium, and calcium; gold and silver salts, lead acetate, lime-water, piperazin, potassium iodid, potassium nitrate, Rochelle salt, sodium borate, tannic acid, vegetable astringent infusions.

Preparations.—**F. Carbonas Saccharatus** has at least 15 percent of ferrous carbonate. A greenish-gray powder, of sweetish taste at first, changing to ferruginous. Partially soluble in water, but soluble in dilute hydrochloric acid with evolution of CO_2. Action—slightly stimulant to the digestive tract. Dose, 2 to 10 grains. **Massa F. Carbonatis** (*Vallet's mass*), ferrous sulphate 100, sodium carbonate 46, honey 38, sugar 25, syrup and distilled water, each, to make 100 parts. Has 42 percent of ferrous carbonate. An astringent, nonirritant, ferruginous tonic. Dose, 1 to 5 grains after food. **Pilulæ F. Carbonatis** (*ferruginous pills, chalybeate pills, Blaud's pills*), made by mixing ferrous sulphate, about 2 1/2 grains for each pill, with potassium carbonate, sugar, tragacanth, althæa, glycerin and water. Dose, 1 to 3. **Mistura F. Composita** (*Griffith's mixture*), has of ferrous sulphate 6, myrrh 18, sugar 18, potassium carbonate 8, spirit of lavender 60, rose-water to 1000. Is really a solution of the carbonate formed by reaction between the two principal constituents. An excellent chalybeate. Dose, 2 to 6 drams. **F. Chloridum** (*perchlorid of iron*), orange-yellow, deliquescent pieces, of styptic taste and acid reaction, freely soluble in water, alcohol or ether. Action—strongly astringent, hemostatic. Dose, 1/2 to 1 1/2 grains. **Liquor F. Chloridi,** an aqueous solution of the preceding, containing 29 percent of the anhydrous salt, with some free HCl. Action is strongly astringent and styptic. Dose, 1 to 3 minims, well diluted. *Creuse's tasteless solution,* is

an agreeable preparation; it has liquor ferri chloridi 1 ounce, acidum citricum 544 grains, sodii carb. 1000 grains or q. s., aqua destil. 1 ounce, alcohol, q. s. Dissolve the citric acid in the water, heat to the boiling point, gradually adding the sodium carbonate until the acid is neutralized; mix with the iron solution and add alcohol up to a total of 4 ounces. Dose, 20 to 30 minims, diluted. **Tinctura F. Chloridi,** a hydro-alcoholic solution of ferric chlorid containing about 13.3 percent of the anhydrous salt, corresponding to about 4.6 percent of metallic iron. Has of the preceding solution 35 in alcohol to make 100. A bright, brownish liquid, of ethereal odor, styptic taste and acid reaction. Is used in mistura ferri et ammonii acetatis. One of the best preparations of iron. Action—ferruginous tonic. Dose, 5 to 15 minims in water, syrup or glycerin. **F. Citras,** garnet-red, transparent scales, slowly soluble in water, not in alcohol. Action—mildly stimulant. Dose, 2 to 6 grains. **F. Hypophosphis,** a white or grayish-white powder, odorless, tasteless, slightly soluble in water, freely so in HCl or in a solution of sodium citrate. Action, ferruginous tonic. Dose, 1 to 5 grains. **Pilulæ F. Iodidi,** made with reduced iron, iodin, licorice, sugar, acacia, and water, covered with a coating of balsam of tolu in ether. "Blancard's pills" differ from these only in being covered with a coating of reduced iron to protect the interior from oxidation, but it also protects them from the solvent action of the gastric juice. Dose, 1 or 2 pills, thrice daily. **Syrupus F. Iodidi,** a syrupy liquid containing 5 percent of ferrous iodid. Action—ferruginous tonic. Dose, 5 to 30 minims. **F. Hydroxidum** (*hydrated ferric oxid*), a brown-red magma, wholly soluble in HCl without effervescence. Should be freshly prepared by mixing together solution of ferric sulphate 100, ammonia water 138, and water to 300 grams. It is the chemical antidote for arsenic. Dose, 1 dram in water, frequently repeated. **F. Hydroxidum cum Magnesii Oxido** (*ferric hydrate with magnesia*), is a more convenient and more efficient antidote for arsenic than the preceding, as the excess of the alkaline precipitant is non-irritant, and is itself an arsenic antidote. The two following solutions should be kept ready: (1) Solution of ferric sulphate 40 c.c. in water 125 c.c. (2) Magnesium oxid 10 grams rubbed up with water 750 c.c. in a bottle of 1000 c.c. capacity. When wanted, shake the latter to a homogeneous magma, add it to the former gradually, and shake them together to a uniform, smooth mixture. Should be given in large doses (4 ounces) and frequently repeated. **F. Phosphas Solubilis,** bright-green, transparent scales, of acidulous, saline taste, soluble in water, not in alcohol. Used as an adjuvant to laxative pills to prevent the after reactionary constipation. Dose, 1 to 6 grains. **F. Pyrophosphas Solubilis,** green, transparent scales, of acidulous taste, soluble in water, but not in alcohol. Is almost tasteless and unirritating, and nonconstipating. Dose, 2 to 5 grains. **F. Sulphas,** large, pale, bluish-green prisms, efflorescent, of saline, styptic taste, and acid reaction, soluble in water, insoluble in alcohol. Is chiefly used to make the dried sulphate and other preparations. Dose, 1 to 5 grains. **F. Sulphas Exsiccatus,** a grayish-white powder, nearly soluble in water, consisting of the preceding salt, heated gradually until it ceases to lose weight. The most astringent and irritating ferrous salt, but an excellent one in small doses. Dose, 1/2 to 3 grains in pills. **F. Sulphas Granulatus,** the same salt as the sulphate, precipitated by alcohol from solution in dilute sulphuric acid. Dose, 1/2 to 5 grains. **Liquor F. Subsulphatis** (*Monsel's solution*), an aqueous solution of chiefly basic ferric sulphate; a dark, reddish-brown, almost syrupy liquid, of very astringent but not caustic taste, and acid reaction, mixing with water and alcohol in all proportions without decomposition. Is but slightly irritating and powerfully astringent, chiefly used locally as an astringent and hemostatic, but may be given internally in doses of 1 to 5 minims well diluted. The salt obtained by its evaporation, *Ferri Oxypersulphas* (*Monsel's salt*), is used in astringent ointments. **Liquor F. Tersulphatis** is an aqueous solution of normal ferric sulphate, containing 36 percent of the salt. Has the properties described for the preceding. Used to make other preparations of iron. **Liquor F. et Ammonii Acetatis** (*Basham's mixture*), prepared with tincture of ferric chlorid 4, diluted acetic acid 6, solution of ammonium acetate 50, aromatic elixir 12, glycerin 12, water to 100. An excellent and very pleasant preparation, having some diuretic and diaphoretic powers. Dose, 2 to 6 drams well diluted. **F. et Ammonii Citras,** transparent, garnet-red scales, deliquescent, readily soluble in water, insoluble in alcohol. Dose, 2 to 6 grains. **Vinum F.,** has of iron and ammonium citrate 4 percent. Dose, 1 to 4 drams. **F. et Ammonii Sulphas** (*Ammonio-ferric alum*), pale, violet crystals, efflorescent, of styptic taste and slightly acid reaction, soluble in 3 of water, insoluble in alcohol. Is the least astringent of the sulphates of iron, but more so than any of the salts formed by vegetable acids. Dose, 3 to 15 grains. **F. et Ammonii Tartras,** transparent, reddish-brown scales, slightly deliquescent, of sweetish and slightly ferruginous taste, very soluble in water, insoluble in alcohol. Contains an equivalent of about 25 percent of ferric oxid, and has but slightly irritant qualities. Dose, 2 to 6 grains. **F. et Potassii Tartras,** transparent, garnet-red scales, slightly deliquescent, of sweetish and slightly ferruginous taste, very soluble in water, insoluble in alcohol. Is the least disagreeable in taste of all the iron preparations, and but slightly astringent and not constipating. Dose, 2 to 6 grains. **F. et Quininæ Citras,** thin, transparent, yellowish-brown scales, slowly deliquescent, of bitter taste, slowly soluble in water, slightly soluble in alcohol. Contains 11 1/2 percent of dry quinin. Action, astringent and stimulant to the digestive tract. Dose, 3 to 5 grains. **F. et Quininæ Citras Solubilis,** thin, transparent scales, of greenish, golden-yellow color, rapidly soluble in cold water, partly soluble in alcohol. Dose, 3 to 5 grains. **Vinum F. Amarum,** has of the preceding 5 parts, tincture of sweet orange 6, syrup 30, white wine to 100. Dose, 1 to 4 drams. **F. et Strychninæ Citras,** transparent

garnet-red scales, deliquescent, readily soluble in water, slightly so in alcohol. Contains 1 percent of strychnin. Action, astringent and stimulating. Dose, 1 to 3 grains. **The Glycerite, Elixir, and Syrup of the Phosphates of Iron, Quinin and Strychnin** are described under PHOSPHORUS. **Syrupus Hypophosphitum Compositus,** has of ferric hypophosphite 2 1/4 percent, and is described under PHOSPHORUS. **Pilulæ Aloes et F.** are described under PILLS.

IRRIGATION.—The application of water, especially a stream, to an inflamed or abnormal tissue for purposes of moistening, antisepsis, cooling, or flushing the part.

It may be practised with various temperatures of water, pure or medicated. Plain cold water is frequently employed, but it is rarely safe to irrigate with ice-cold water. See COLD, ICE. . Irrigation is of especial value in cleansing cavities, such as the nose, the pleura in empyema, the bladder, urethra, vagina, and rectum. In treating foul wounds irrigation carries off secretions and, when antiseptic, prevents putrefaction and promotes healing. Wetting of cloths and of the bed may be prevented by the use of rubber blankets, pads, and bed-pans, with proper position.

Water may be allowed to flow from a tap or to drop on a joint or part; a liquid may be left to trickle from a suspended can or bucket, or through an elevated tube, on the siphonage principle. As a rule, it must be continued for many hours, often several days, before beneficial results are realized, while the details of usage give a great field for ingenuity.

In the cleansing of wounds and ulcers, irrigations with solutions of mercuric chlorid or boric acid are constantly employed. Plain sterilized water is used to irrigate the abdominal cavity after section or normal salt solution may be employed. The nasal douche is a form of nasal irrigation. See CYSTITIS, GONORRHEA, HEAT, WATER, etc.

ISCHEMIA.—See ANEMIA.

ISCHIORECTAL ABSCESS.—See RECTUM (Inflammation).

ISCHURIA.—Retention or suppression of urine. See URINE.

ISINGLASS (Ichthyocolla).—The swimming-bladder of the sturgeon, *Acipenser huso.* It occurs in horny, semitransparent sheets, that form a jelly with hot water. It is the purest form of gelatin, and is used as a food, for clarifying liquids, and as a test for tannic acid. **I., Emplastrum,** court-plaster; it consists of isinglass 10, glycerin 1, alcohol 40, water and tincture of benzoin q. s., spread upon fine white silk bolting-cloth and dried. See GELATIN.

ITCH.—See SCABIES.

ITCHING.—See PRURITUS.

IVY-POISONING (Dermatitis Venenata).—This form of inflammation is due to the contact of deleterious animal and vegetable substances. Among these may be mentioned the acids and alkalies, croton oil, mustard, cantharides, anilin dyes, etc. The dermatologist is more particularly interested in the dermatitis produced by poisonous plants, chiefly the *Rhus toxicodendron, poison ivy* or *oak,* and the *Rhus venenata, poison sumach* or *dogwood.*

Symptoms.—From a few hours to several days after exposure the hands, face, and genitals (in a typical case) become the seat of innumerable vesicles and blebs, accompanied by swelling and great burning or itching. The eruption is carried to various parts of the body by autoinoculation. The eruption lasts from 1 to 4 weeks, disappearing spontaneously. Some individuals are extremely susceptible to ivy poison: so much so that proximity without contact suffices to bring on an attack. Other individuals enjoy comparative immunity.

The treatment consists of the application of mildly astringent and sedative lotions and ointments. At the very outset lotions are to be preferred. A solution of the hyposulphite of sodium, 1 dram to the ounce, often relieves the itching and acts most happily. A saturated solution of boric acid is almost as efficient, and is to be preferred when the face is involved. Many laud the use of the fluidextract of grindelia robusta, 1 dram to 4 ounces of water. This is a time-honored application, and is certainly most grateful to the skin. When the vesicles and blebs have ruptured and the skin is covered with crusts, sedative ointments are to be used. A salve, for instance, containing carbolic acid 10 grains, boric acid 30 grains, to 1 ounce of ointment base, may be advantageously employed.

When large areas of the body are affected, medicated baths may be used with good results. The alkaline bath—containing a handful of the ordinary washing soda (sodium carbonate) to 20 gallons of water—is most soothing to the inflamed skin.

J

JABORANDI.—See PILOCARPUS.

JACOB'S ULCER.—See EPITHELIOMA.

JACTITATION.—A restless and anxious tossing to and fro, from one posture to another; a symptom of conscious or unconscious distress observed in all severe mental affections. It is associated with certain severe febrile diseases, with severe pericarditis, or as a sequence of uterine or other hemorrhages. A restlessness amounting to jactitation may occur in those suffering from severe or long-continued pain. It must not be confounded with chorea, in which the absence of pain and of marked febrile disturbance, together with the history of the patient, will establish a ready diagnosis.

JALAP.—The dried tuberous root of *Exogonium purga*, a Mexican plant. It should contain not less than 8 percent of total resin, which is composed of two glucosids, *jalapin*, soft, soluble in ether, and *convolvulin*, which is hard, insoluble in ether and the more active of the two. Dose, 5 to 20 grains.

Jalap is an active cathartic, producing copious and watery stools, with considerable tormina and tenesmus, also sometimes nausea. It is more drastic than senna and less irritant than gamboge, but in overdoses may produce dangerous hypercatharsis.

Convolvulin in sufficient dose is an active irritant poison, producing gastroenteritis and narcotism. Its action as a purgative seems to be wholly local, as from its intravenous injection no catharsis results, yet it exerts little if any irritant action on the conjunctiva, nasal mucous membrane or skin. It is not eliminated in the urine or the feces, and is therefore probably destroyed in the system by oxidation.

In olden times jalap and calomel were used together, in doses of 10 grains each, as a routine purgative prescription. Less ponderous doses are now considered equally efficient, and 1 grain of each agent, with the same quantity of extract of hyoscyamus as a corrective, may be used with advantage at the onset of fevers and inflammations. As the compound powder, it is much employed to produce free watery evacuations in ascites and anasarca. Being nearly tasteless, it is a useful cathartic for children, and may be administered in syrup of rhubarb (2 to 5 grains in 1/2 ounce). As a vermifuge it is efficient as an adjunct to more powerful agents, and is employed with calomel and santonin for the expulsion of lumbrici. Jalap is contraindicated in all inflammatory conditions of the intestinal mucous membrane.

Preparations.—Resina J., *Resin of jalap*, prepared from a tincture by precipitation by water. Is insoluble in water, soluble in alcohol. Dose, 1 to 5 grains. It is an ingredient of pil. cathartic. comp. and pil. cathartic. vegetabiles.

Pulvis J. Compositus, *Pulvis purgans*, has of jalap 35, potassium bitartrate 65, thoroughly mixed. Dose, 10 to 45 grains.

JAMESTOWN WEED.—See STRAMONIUM.

JAUNDICE (Icterus).—Deposition of bile pigment in the tissues of the body.

Varieties.—(1) Hepatogenous or obstructive jaundice; (2) hematogenous or nonobstructive jaundice.

Hepatogenous Jaundice

Etiology.—(1) Obstruction by gall-stones or parasites; (2) catarrhal condition of bile-duct or duodenum; (3) stricture of gall-duct; (4) pressure from tumors in the neighboring organs (cancer of liver, pancreas, etc.); (5) altered blood-pressure in the vessels of liver, causing greater pressure in the smaller ducts than in blood-vessels.

Symptoms and Clinical Course.—Deposition of the biliary pigments in the skin or conjunctivæ, causing a distinct yellowness or bronzed hue. It is often first detected in the conjunctivæ. The urine is of a dark amber or blackish color, staining the linen frequently, and with nitric acid shows the play of colors denoting the presence of biliary pigment. The pulse is slow and full; the feces are light in color, on account of the absence of the bile pigment. Often the pigment may be detected in the perspiration, and may be so pronounced as to stain the bed-linen. Usually some form of skin-eruption supervenes, and it may keep the patient irritable on account of its itching character.

The mental symptoms are quite marked, there being great dejection of spirits and despondency. The appetite is lost and nausea is almost constantly present.

Diagnosis.—The yellowness of the skin and conjunctivæ should be distinguished from the greenish appearance in chlorosis, most common in females under 20; and from Addison's disease, in which the pigment is darker and less uniform than in jaundice. Bile is present in the urine of jaundiced patients from obstruction of the bile-ducts, while in Addison's disease it is absent.

Hematogenous Jaundice

Etiology.—(1) It results from rapid destruction of the liver cells, as in hypertrophic cirrhosis of the liver and in acute yellow atrophy. (2) It may be brought about by toxic agents causing a rapid destruction of the red blood-cells, such as is seen in snake-poisoning, yellow fever, malarial hemoglobinuria, relapsing fever, arsenical or phosphorus-poisoning.

Symptoms and Clinical Course.—The jaundice is not so marked as in the obstructive form. Guiteras has often called attention to the fact that jaundice in the patient suffering with yellow fever can only be appreciated at a distance.

In hematogenous jaundice the stools are generally normal in color, pulse may be accentuated, and the skin does not itch.

Prognosis depends upon the cause.

Treatment is the same as in simple catarrhal jaundice. See GALL-BLADDER (Diseases).

Simple Catarrhal Jaundice

Synonyms.—Inflammation of the common bile-duct, catarrh of the bile-duct, catarrhal hepatitis.

Definition.—Jaundice resulting from a catarrhal condition of the biliary passages.

Etiology.—(1) An infectious agent (undetermined); (2) catarrh of the duodenum, extending up the common bile-duct; (3) certain diseases, such as pneumonia, typhoid fever, etc.

Pathology.—The mucous membrane of duodenum and bile-ducts is engorged with blood, the lumen of ducts being occluded by thick tenacious mucus. If of long standing, necrosis may be set up, with consequent formation of ulcers.

Symptoms and Clinical Course.—Jaundice, as the name implies, is the predominant symptom. The onset may be ushered in by a sense of nausea, vomiting, dull frontal headache, mental hebetude, constipation, high-colored scanty urine, slow full pulse, and slight fever. Patients with catarrhal jaundice are fretful and lose all ambition; are careless of the future and most despondent.

The duration is from 1 to 3 weeks.

Diagnosis.—The occurrence of jaundice without pain, feeling of nausea, despondency, slow full pulse, and slight fever (101°) usually distinguishes the disease from other causes productive of jaundice.

Prognosis is favorable.

Treatment.—Rest in bed is demanded. The diet should be regulated, only allowing liquid foods, such as beef-juice or beef-broth, stewed fruits, and cooked vegetables. The patient should be allowed no starches or fats; he should take milk, eggs, oysters, beef-broth; plenty of green vegetables at each meal; use cold water freely, avoid high seasoning in food and all liquors. The common distaste for food in catarrhal jaundice is a good indication to give no food whatever for a day or two and to be content to relieve the thirst with copious draughts of water which are usually relished and well borne. The treatment is that of the gastrointestinal catarrh producing the cholangitis. In the beginning it is advisable to administer fractional doses (1/4 grain) of calomel every hour until 6 or 7 doses have been taken, followed by a saline purge, if necessary. Should the patient show a tendency to remain constipated, the bowels may be kept open with the solution of magnesium citrate or by means of salines. Probably the remedy most used is sodium phosphate in doses of 1 dram, taken 2 or 3 times daily as a laxative. The effervescent salt is quite agreeable. Carlsbad salt (1 dram) may be taken for the same purpose, also the Hunyadi Janos and Saratoga mineral waters in sufficient quantity to produce 1 or 2 stools a day. In the more chronic cases lavage may be practised every 2 or 3 days, the fluid containing about 1 grain of silver nitrate. High enemata, by means of the long rectal tube and fountain syringe, may at the same time be administered 2 or 3 times a week. A series of small blisters over the right hypochondrium may do good. See GALL-BLADDER (Diseases).

Jaundice of the New-born
(Icterus Neonatorum)

Etiology.—It results: (1) *Physiologically* from the destruction of large numbers of red blood-cells during the first few days after birth, or from severance of the placental circulation, permitting absorption from the bile capillaries; (2) *pathologically*, as in congenital absence of biliary ducts, syphilis, or septic poisoning.

Treatment.—Usually medicines are not indicated. If bowels are constipated, castor oil (1 dram) or an enema of soapsuds and lukewarm water may be used. A daily lukewarm bath should also be given to keep the skin active and for its stimulating effect.

JAUNDICE, ACUTE FEBRILE.—See WEIL'S DISEASE.

JAWS, DISEASES.

Diseases of the Gums.—See GUMS.

Alveolar Abscess.—(*q. v.*).

Epulis.—This term, though formerly employed to signify any tumor growing from the gums, is now usually restricted to the variety that was then distinguished as the fibrous or common epulis. An epulis consists principally of fibrous tissue, but may sometimes contain a few myeloid cells. It frequently appears to depend upon the irritation of a carious stump, and springs from the periodontal membrane lining an alveolus. Beginning as a swelling of the little tongue-like process of gum between the teeth, as it increases in size it appears as a hard, fleshy, circumscribed, smooth or slightly lobulated elastic growth, covered by mucous membrane. When it has existed some time, ulceration of the surface may occur, and one or more teeth become loosened or fall out.

Treatment.—It should be excised with bone-forceps or a small saw, care being taken to cut away a small piece of the bone beneath, as otherwise it is likely to return. When quite small it may be shaved off, a thin layer of the bone at its base gouged away, and the offending tooth or teeth removed.

Myeloid sarcoma (*myeloid epulis*) is occasionally found on the gums as a rapidly growing vascular tumor of a purplish-red color and soft spongy consistency. It should be entirely removed with the underlying bone, as otherwise it will return. The hemorrhage during removal is generally free, and may require the actual cautery to restrain it.

Epithelioma (*malignant epulis*) of the gums is rare. In the upper jaw it has a marked tendency to creep up into the antrum (*creeping epithelioma*) and to simulate caries or necrosis of the jaw. Complete excision, with removal of the uppr jaw if the antrum is involved, should be undertaken if there is a fair chance of getting the whole of the disease away and if the glands are not much involved.

Inflammation and abscess of the antrum is generally due to the irritation of the fang of a carious

tooth. It is attended by deep-seated pain, followed by swelling, edema, heat, and redness of the cheek and lower eyelid, and, when very acute, by sharp constitutional disturbance. The pus may overflow into the nose or escape by the side of a tooth; or, in other instances, may distend the cavity and cause the bony walls to bulge.

The treatment consists in providing a free exit for the pus as soon as formed, either by removing the carious tooth, and perforating the antrum through the bottom of the alveolus, or, if the teeth are sound, by perforating the anterior wall within the mouth through the canine fossa. The cavity should then be kept clean by antiseptic lotions.

Closure of the jaws is the term applied to a condition in which the lower jaw cannot be opened, at least not to any extent. It may be due to: (1) Spasm of the masseter muscle consequent upon the irritation attending the eruption of a wisdom-tooth for which there is not room; (2) cicatricial contraction following ulceration of the mucous membrane induced by cancrum oris, syphilis, lupus, the abuse of mercury, etc.; (3) ankylosis of the temporomaxillary joint; (4) hysteria.

Treatment.—When dependent upon the eruption of a wisdom-tooth, the tooth itself, or, under some circumstances, the second molar, must be extracted. When dependent upon cicatricial contractions, the forcible opening of the mouth by a screw-gag and maintaining it open by a cork placed between the teeth will, in slight cases, suffice. In other instances division of the cicatricial bands, and subsequently keeping the jaws separated, is successful, although this proceeding does not appear to have been always successful. When the bands are very dense, or the closure depends upon ankylosis of the temporomaxillary joint, a new articulation must be made by dividing the ramus of the jaw and removing a wedge-shaped piece of bone in front of the cicatricial contractions.

Necrosis of the Jaws.—Necrosis is more common, and, when it occurs, more extensive in the lower than in the upper jaw, a fact due in part to the toorer blood supply of the former, and in part to the predilection of necrosis for compact rather than for cancellous bone. Though the necrosis may affect the whole of the jaw, it is more often limited to the alveolar process or to the anterior wall. The teeth may loosen and fall out; but at times they retain their connection with the gums and remain *in situ* after the removal of the sequestrum.

The causes of necrosis of the jaw, as of necrosis elsewhere, generally depend upon inflammation of the periosteum or bone, which in the case of the jaw appears especially to be induced by the fumes of phosphorus, the abuse of mercury, carious teeth in strumous subjects, syphilis, the exanthemata, cancrum oris, and, lastly, injury, as in extracting a tooth. **Phosphorus-necrosis** is generally believed only to affect the subjects of carious teeth, but some maintain that it is a local manifestation of a general phosphorus poisoning. It is much less common since the amorphous form of phosphorus has been used for making matches. The production of new bone in necrosis of the lower jaw is generally extensive. In the upper jaw new bone is not formed after complete removal. In phosphorus-necrosis a characteristic pumice-like deposit of new bone is formed.

Symptoms.—Necrosis generally begins with severe pain and deep-seated swelling, which may at first be mistaken for toothache or alveolar abscess, followed by suppuration and bursting of the abscess, either in the mouth or externally on the face, and the formation of sinuses. The breath, as a rule, is horribly fetid, and there is sharp constitutional disturbance, which, in phosphorus-necrosis, is sometimes excessive, and may end in septicemia or pyemia. On probing the sinus, dead bone is detected. This sign will usually distinguish necrosis from the creeping form of epithelioma, for which, especially in the upper jaw, it may be mistaken.

Treatment.—The bone, as soon as loose, should be removed, if possible, through the mouth. In the meantime the parts should be kept aseptic by syringing with an antiseptic fluid or carbolic lotion, or by insufflation of iodoform, incisions being made through the periosteum to insure a free drain, or a respirator may be worn to neutralize the fetor. Internally, tonics and stimulants and nourishing diet should be given, and iodid of potassium if there is a syphilitic taint.

Tumors of the upper jaw may be cystic or solid, and the latter innocent or malignant; while cysts may likewise occur in the malignant solid tumors.

Cystic tumors may be produced: (1) In connection with the fang of a carious tooth; (2) by an error in development of the enamel sac covering the crown of a tooth (*dentigerous cysts*); and (3) by obstruction of a mucous follicle in the lining membrane of the antrum. These cysts usually contain a serous, gelatinous, or a brownish fluid, in which cholesterin is often found. The condition known as *dropsy of the antrum*, and formerly believed to depend merely upon an accumulation of fluid in that cavity owing to the occlusion of the opening into the nose, would appear to be due to one of these mucous cysts completely filling the antrum.

Dentigerous cysts, which may also occur in the lower jaw, are due to an error in the development of the enamel sac, usually of the permanent teeth. They differ from the ordinary dental cyst, depending upon the irritation of a decayed fang, in that in the latter the fang will generally be found projecting into the cyst, whereas in the dentigerous variety the crown alone, which has not been cut, or in some cases the whole tooth, will be found in the cyst.

Solid tumors may spring from the periosteum covering the exterior of the bone, or from the mucous or the periosteal lining of the antrum. They may have a fibrous, cartilaginous, osseous, myxomatous, adenomatous, sarcomatous, or carcinomatous structure; but fibrous and sarcomatous tumors are the most common, while cartilaginous are very rare. Ossification of the sarcomatous growths is of occasional occurrence. They may be closely simulated by tumors of a like diversity of structure growing from the malar bone, the sphenomaxillary fossa, or the base of the skull.

Symptoms and Diagnosis.—Clinically, it is not always possible to determine the exact structure of these tumors, nor is it essential, the surgeon's aim being rather to distinguish the solid from the fluid, and the innocent from the malignant, and to make out their origin and present attachments. When the tumor, whether cystic or solid, innocent or malignant, begins in the antrum, it sooner or later fills that cavity, and then in its further growth causes the walls to bulge in various directions. Thus, the bulging of the anterior wall causes a swelling on the cheek; of the internal wall, an obstruction in the nose; of the inferior wall, a depression of the palate; and of the superior wall a protrusion of the eye. A rounded projection on the cheek, a sensation of fluctuation felt through the anterior wall of the antrum with the finger in the mouth, or an eggshell-like crackling produced by the yielding of the thinned and partially absorbed walls, the presence of a carious tooth or the absence of one of the teeth in the series (in the case of a dentigerous cyst), will point to the cystic nature of the swelling, and puncture with a trocar and cannula will clear up any doubt. Should the tumor be solid, it will probably be *innocent* if of slow growth and there is absence of pain and glandular enlargement, nonimplication of the skin, and noninfiltration of surrounding parts; but *malignant* if of rapid growth and there is severe pain, early escape through the walls of the antrum, implication of the skin, involvement of glands, and protrusion of a fungous mass in the mouth, nose, or on the cheek. In malignant disease, moreover, the patient will probably be either young, in the case of sarcoma, or advanced in life, in the case of carcinoma; but if a small piece of the growth can be obtained, a microscopic examination will settle the point. When the growth springs from the malar bone, it may either project forward on the cheek or into the mouth between the cheek and the bone, and the bulging of the walls of the antrum will be absent. When it arises from the sphenomaxillary fossa or base of the skull, it will commonly project into the nasopharynx, where it may be detected by the finger or rhinoscope, while the whole maxillary bone will be pushed forward. It should not be forgotten, however, that tumors beginning in the antrum, especially the fibrous and sarcomatous, encroach upon the surrounding parts, and, conversely, that the cavity of the antrum may be invaded by growths not primarily connected with it; so that when a tumor in this region has attained a large size, it may be impossible to determine its origin, or, indeed, the whole of its actual attachments.

Treatment.—For cystic tumors, excision of a portion of the wall from within the mouth will generally suffice, if a free drain is subsequently insured. At times the thinned walls of the cyst may be crushed together by the fingers with advantage. When the cyst is associated with a solid growth, the latter may sometimes be scraped away, otherwise the upper jaw must be partially or completely removed. When the tumor is *solid* and of an *innocent* nature, and entirely confined to the antrum, it may be removed by excision of the superior maxilla; but, as a rule, no more of the bone should be taken away than is absolutely necessary, the orbital plate and hard palate being preserved if possible. When the tumor arises behind the bone, there is often great difficulty in getting it away, as its attachments may be more extensive than is imagined. If thought advisable to attempt its removal, this may be done by excising the superior maxilla and clearing away the growth; or the maxilla may be turned outward, the growth removed, and the bone replaced (*Langenbeck's method*).

When the growth is *malignant* and confined to the antrum, the superior maxilla may also be excised; but when it has invaded the surrounding parts, it becomes not only a question whether it can be completely got away, but whether the immunity from its return will not be of too short duration for the patient to undergo the risk of the operation.

Complete Excision of the Upper Jaw.—Having extracted the central incisor tooth on the diseased side, make an incision down to the bone in the direction shown by the dark line in the accompanying figure. Dissect back the flap thus marked out from the bone, securing the larger arteries as they are divided. Make a longitudinal incision through the mucous membrane lining respectively the floor of the nose and the roof of the mouth as far back as the soft palate, and then a transverse one along the junction of the soft palate with the hard palate on the diseased side. Now pass one blade of the long jaw-forceps into the mouth and the other into the nose, and divide the alveolar process and hard palate; cut through the nasal process of the superior maxilla, and then through the malar bone, carrying the forceps into the sphenomaxillary fissure. Seize the bone with lion-forceps, and wrench it away from its remaining attachments. The internal maxillary, or any other large artery, should be tied, and hemorrhage from smaller vessels restrained by plugging the wound with strips of iodoform gauze. When the bleeding has stopped, any growth that may remain should be cut away or destroyed with the actual cautery. Unite the edges of the wound with horsehair sutures and the lip with harelip pins. Healing occurs readily and with little deformity. An obturator with false teeth should subsequently be fitted to the mouth.

Lines of Incision for Removal of Upper and Lower Jaws. —(*Walsham.*)

Partial excision of the upper jaw usually consists in leaving the orbital plate, and is done by dividing with a keyhole saw the front wall of the antrum along the margin of the orbit, and completing the operation as above described.

Resection of the upper jaw (*Langenbeck's operation*) consists in turning the maxillary bone outward so as to get at a tumor behind it, and then replacing the bone. As the connections of the

bone along its outer part are left intact, its vascular supply is not completely cut off, and it soon forms fresh adhesions when placed back in position.

Tumors of the lower jaw, like those of the upper, may be cystic or solid, innocent or malignant.

Cystic tumors, as in the upper jaw, may be developed in connection with an uncut tooth (*dentigerous cyst*) or around the fang of a decayed tooth. They are then unilocular. *Multilocular cystic tumors* have a marked predilection for the lower jaw. They are probably due to invasion of the jaw by epithelium from the gum. The epithelial masses undergo degeneration, leading to cysts, often of considerable size. These tumors grow very slowly, and may gradually destroy the whole bone, reducing it to a mere shell; but if completely removed, do not recur locally. They never affect the glands or become disseminated.

The solid tumors may grow from the periosteum covering either the outer or the buccal aspect of the jaw, or from the interior of the bone, which they then expand around them. The osseous tumors usually take the form of exostoses, and are not uncommon about the angle of the jaw. The more regular shape of the lower jaw, its compact structure, the absence of a cavity like the antrum, its more isolated condition, and the absence of surrounding cavities like the nose, orbit, and sphenomaxillary fossa, make the diagnosis of tumors in it more easy. The signs are similar to those of tumors of the upper jaw.

Treatment.—Cystic tumors are best treated by free incision of a portion of their wall. In the case of the multilocular cysts the whole or part of the jaw may be removed. In excising solid innocent tumors no more of the bone should be sacrificed than is necessary to extirpate the disease; and such removal, when possible, should be done from within the mouth. Myeloid growths springing from the interior of bone may often be enucleated, and not recur for many years, or not at all. When the tumor is large and encroaches upon the ramus, the affected half of the jaw, or, if both halves are affected, the whole jaw should be removed by disarticulation, as if the ramus is merely sawed across, leaving the coronoid process and condyle; these are apt to be drawn forward by the temporal and external pterygoid muscles and prove a constant source of annoyance. When the growth is malignant or of large size, and the skin and neighboring soft parts are implicated and the glands extensively involved, no operation, as a rule, is admissible. Cysts developed in connection with solid growths may be laid open and the tumor scraped away, or part or the whole of the jaw, if the growth is malignant, may be removed.

Excision of the Lower Jaw.—Having extracted the central or the lateral incisor tooth, make an incision down to the bone (in the way shown in the black line in the accompanying figure) through the lower lip, along the lower border of the jaw, and thence up the ramus, nearly but not quite to the lobule of the ear to avoid the facial nerve, tying both ends of the facial artery as it is cut. Dissect up the flap thus formed from the bone, and divide the bone with saw and forceps opposite to where the tooth has been extracted. Seize the bone with the lion-forceps, drawing it outward and upward, and divide the soft tissue on the inner surface with a narrow-bladed scalpel, keeping close to the bone to avoid the gustatory nerve and the submaxillary gland. The origin of the geniohyoglossus should be spared, if possible, as otherwise the tongue tends to fall backward, and has before now caused suffocation. If this muscle must be divided, pull the tongue forward by a ligature through its tip. Next separate the internal pterygoid, depress the jaw, and divide the temporal muscle at its insertion into the coronoid process. Open the articulation from the front, divide the external pterygoid, and carry the knife beyond the condyle, taking care not to rotate the jaw outward lest the internal maxillary artery be stretched round the neck of the condyle and be thus torn or divided (Walsham).

JAWS, INJURIES.—Dislocation of the jaw is possible only in the forward direction over the eminentia articularis. It is usually bilateral, although occasionally unilateral and sometimes congenital. The bilateral dislocation is usually brought about by yawning or laughing, or is caused by straining the jaws apart, as in taking too large a bite of fruit.

Symptoms.—Both condyles are advanced between the surface of the temporal bone and zygomatic arch; the mouth is open, and the patient is not able to shut it by pressure made on the chin; the lower teeth are on a line anterior to the upper;

Dislocation of the Lower Jaw.

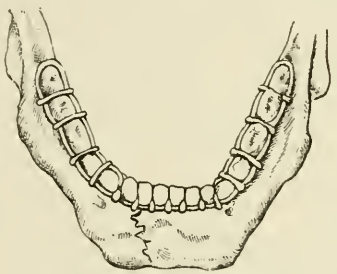
the appearance is that of a person yawning; the pain is severe; the saliva is increased and dribbles from the mouth. If the lower jaw is partially dislocated, one condyloid process only advances, while the other remains in the articular cavity.

Treatment.—To reduce the luxation the patient is seated in a chair with the head against the back of the chair or the body of an assistant. Standing in front of the patient, the operator, with thumbs well wrapped to protect them from the teeth, places them upon the last molar teeth and grasps the chin with the free fingers. Pressure is made downward and backward, and as soon as the condyle is loosened, the jaw is closed by pushing it over the condyle and pressing up the chin, using the thumbs as levers. Failing in this, wedges may be placed between the teeth and the chin pushed up

by the hand or a tourniquet around the head and chin. In unilateral displacement the wedge is to be used only on the dislocated side. After reduction, a bandage, preferably a Barton bandage, should be applied for over two weeks, being changed daily. The use of a liquid diet is advised for 3 weeks after dislocation.

Fracture of the lower jaw is most common through the mental foramen: *i.e.*, near the canine tooth. Occasionally it is through the neck of the ramus, or the coronoid process may be broken off. Fractures of this bone are nearly always compound.

The fractured parts are to be adjusted, the loose and detached teeth pushed back, and the mouth rinsed with hot water to cleanse it and check hemorrhage. It may be necessary to compress the carotid artery to control the hemorrhage. A pad of lint should be placed under the broken parts and a four-tailed bandage applied, the ends crossing each other as they leave the symphysis, the two upper ends being tied at the nape and the two lower over the vertex of the head. A splint may be made out of card-board, soaked and applied to the broken jaw, being shaped to the symphysis and body. It should be lined with lint and held by a bandage, as a four-tailed bandage. Felt or gutta-percha may be molded to the parts and held by a Gibson or Barton bandage. The teeth may be fastened with wire, the fragments themselves be wired together, or an interdental splint employed.



DENTAL SPLINT APPLIED.—(*Spencer and Gask.*)

Liquid food is to be given, and the mouth washed frequently. Dressings may be changed every second day. Union is usually complete in 5 weeks.

Fractures of the Upper Jaw.—The superior maxilla is seldom broken, unless great and direct violence has been employed; its fracture is generally accompanied by an external wound, as in gunshot injuries or a kick from a horse. The fracture is often comminuted and is sometimes attended by concussion of the brain, or by fracture of other bones of the face; it is often produced by force transmitted from the malar bone, the latter remaining sound. The superior maxilla possesses extraordinary reparative powers.

Treatment.—Preserve and replace all fragments and splinters, the tendency to heal being very great. The patient must avoid chewing any hard substances until the detached fragment has become attached to the bone. When the alveolar process is broken into two or more fragments, the pieces must be pressed into place and the jaws closed, so that the lower jaw may serve as a support. To maintain apposition apply a Barton or Gibson bandage. It may be necessary to apply fine wire to the teeth, if displacement continues; or an interdental splint composed of gutta-percha may be used. Loosened teeth must be pressed into their places.

Should the nasal process be broken, a director should be applied through the nose to elevate any depression that may exist.

Fracture of the Zygomatic Arch.—This accident is rare, and is produced by direct violence, usually occurring on the temporal side of the suture.

The signs of this fracture are an irregular projection or depression of the fragments, with rapid swelling of the parts. The displacement will occur either outward or inward. There will be neither motion nor crepitus.

Treatment.—Should there be no displacement, apply an anodyne lotion and keep the parts quiet with a Gibson or Barton roller. If there is outward displacement, the fragments may be adjusted by pressure on the projecting angle, afterward applying a soothing lotion. If the displacement is occasioned by depression of the malar bone, it will be adjusted by restoration of that bone to its proper position, which requires extensive manipulation. The question of surgical interference must depend upon the urgency of the symptoms.

JERK.—A sudden muscular movement. A jerk produced by a sudden or quick stroke over a tendon or region gives an indication of the innervation of a part. This is commonly seen at the knee, and here is known as the **knee-jerk.** The contraction of the quadriceps femoris is then obtained. The legs are crossed one over the other and a sharp blow is made by the edge of the hand or some moderately wide instrument upon the patellar tendon just below the patella. The knee-jerk is usually absent in advanced locomotor ataxia, in diseases of the anterior gray cornua, in infantile paralysis, in the late stages of pseudohypertrophic paralysis, and often in meningitis, in diphtheria, and in diabetes.

The jaw-jerk, or chin-jerk, is a contraction of the muscles of mastication produced by a stroke on the lower jaw or chin when the mouth is opened. It may be obtained in health, but when marked, is indicative of extensive cerebral lesion, such as multiple sclerosis or general paralysis.

The wrist-jerk is obtained by a stroke upon the tendon of the extensor indicis or extensor ossis metacarpi pollicis, when they are made prominent by passive extension of the supine hand of the patient in that of the examiner. It may occur in health.

The elbow-jerk, or triceps-jerk, is obtained by striking the triceps tendon while the arm is supported and the forearm allowed to hang loosely downward parallel with the body.

See REFLEXES.

JOINTS, DISEASES.—Diseases of the joints should be divided into acute and chronic.

Acute Joint-diseases

Simple Synovitis with Effusion.—Acute serous synovitis is the commonest form of joint-disease.

As a rule, it is the result of a contusion or cold, but may arise without any known cause. It may be caused by the infectious fevers, gout, rheumatism, gonorrhea, or syphilis. In point of frequency the joints involved are the knee, the elbow, and the ankle. Among the joints less frequently involved are the hip, the shoulder, and the small joints of the extremities. The pathology of the disease is limited to changes in the synovial membrane, in which the usual manifestations of irritation and inflammation develop according to the cause producing the disease.

The result is an intraarticular effusion, serous or hemorrhagic. From the admixture of lymph flocculi the effusion has a tendency to become turbid. When this effect is the result of an irritation, such as is produced by a trauma, the presence of a blood-clot, the pinching of the synovial folds, or irritation from toxic causes, such as occur in gout and in some cases of gonorrhea, there is a congestion of the synovial membrane, injection of the vessels, with the entire surface reddened, particularly about the line of attachment to the articular cartilages. The cartilages undergo no change, and by their pearliness are therefore in strong contrast to the reddened synovial surfaces. From the synovial membranes there is effused at first an increased quantity of synovia, and soon the exudate becomes closely allied to the serous effusion found elsewhere. Clear at first, it has a tendency to become turbid from the admixture of disintegrated epithelial cells and of leukocytes. The turbidity is often increased by the presence of blood discs, from minute hemorrhages into the joint-cavity. Within the exuded fluid flocculi of fibrin, in greater or less abundance, are usually found. These may be attached to the synodial fringes and to the more dependent portions of the joint, or they may be floating about in the free exudate.

In mild cases of synovitis the condition described lasts from a week to ten days, when, by the gradual absorption of the exudate and the return of the distended vessels to their natural condition, the joint resumes its normal appearance and function. In other cases absorption goes on very slowly or it may altogether fail to take place, under which circumstances there is established the condition known as **hydrarthrosis,** the chief feature of which is the effusion into the joint.

Simple Purulent Synovitis.—In less favorable cases or in consequence of improper management the exudation increases often to enormous proportions. Its character may also change; turbid at first, from the admixture of few cellular elements, these increase until the exudate assumes a purulent character. The rapidity with which the effusion becomes purulent is at times so great that the synovitis in these cases seems to be purulent from the beginning. Except from the latter, the condition of the joint-interior does not vary at first in the simple purulent form of synovitis from the serous.

Particularly in children, as Volkmann and Krause have shown, there may be a purulent effusion into the joint without destruction of the articular surfaces or permanent impairment of synovial membrane, joint capsule, or ligaments, provided spontaneous perforation occurs or an early outlet is made for the discharge.

Dry Synovitis.—In certain cases of acute synovitis the fluid exuded may be very small in quantity or altogether absent. In proportion, the flakes of fibrin are greatly increased, until they may appear as a continuous layer covering the articular surfaces and forming a deposit of varying thickness on the synovial membrane and cartilages. The fibrin thus thrown out shows remarkable tendency toward organization. The smooth, glistening character of the serous surfaces is lost. In its place there are masses of fibrin, often unevenly disposed, and by joint-movement often drawn into shreds of unequal length and adherent at one or both ends. If ankylosis does not occur, these shreds may speedily become detached and present themselves in the form of many small bodies, the size of a pea or bean, round or ovoid, and consisting of concentric rings of fibrin (rice bodies). In other cases the joint surfaces are speedily welded together by the organization of the exuded lymph. Ankylosis may sometimes follow an acute dry synovitis with remarkable rapidity.
