CONTRIBUTORS

JAMES M. ANDERS, M. D., Philadelphia.

Professor of the Practice of Medicine and of Clinical Medicine in the Medico-Chirurgical College, Philadelphia.

EDWARD R. BALDWIN, M. D., Saranac, N. Y.

Physician in Charge, Reception Hospital for Tuberculosis, Saranac Lake, N. Y.

C. R. BARDEEN, M. D., Madison.

Professor of Anatomy, University of Wisconsin, Madison.

LEWELLYS F. BARKER, M. D., Baltimore.

Professor of Clinical Medicine, Johns Hopkins University, Baltimore.

JOHN FAIRBAIRN BINNIE, A. M., C. M. (Aberdeen), Kansas City, Mo.

Fellow of American College of Surgeons; Surgeon to German and Kansas City General Hospitals; Formerly Professor of Surgery, University of Kansas.

CHARLES W. BONNEY, B. L., M. D., Philadelphia.

Demonstrator of Anatomy, Jefferson Medical College, Philadelphia.

NATHAN E. BRILL, M. D., New York City.

Visiting Physician, Mount Sinai Hospital, New York.

ARCHIBALD CHURCH, M. D., Chicago.

Professor of Clinical Neurology, Mental Diseases, and Medical Jurisprudence, Northwestern University Medical School, Chicago.

L. PIERCE CLARK, M. D., New York City.

Formerly Assistant Physician, Craig Colony for Epileptics, Sonyea, N. Y.; Fellow of the New York Neurological Society; Fellow of New York Academy of Medicine.

SOLOMON SOLIS-COHEN, M. D., Philadelphia.

Professor of Clinical Medicine at Jefferson Medical College, Philadelphia.

WARREN COLEMAN, M. D., New York City.

Professor of Clinical Medicine and Applied Pharmacology, Cornell University Medical College; Visiting Physician to Bellevue Hospital, New York.

W. M. LATE COPLIN, M. D., Philadelphia.

Professor of Pathology; Pathologist and Director of Clinical Laboratories, Jefferson Medical College Hospital; Pathologist to the Philadelphia Hospital, etc.

NATHAN S. DAVIS, Jr., M. D., Chicago.

Professor of Principles and Practice of Medicine in Northwestern University Medical School, Chicago.

THEODORE DILLER, M. D., Pittsburg.

Associate Professor of Neurology, University of Pittsburg; Visiting Physician to the Insane Department of St. Francis Hospital, Pittsburg; Member American Neurological Association.

CHARLES HUNTER DUNN, M. D., Boston.

Clinical Instructor in Pediatrics, Harvard Medical School; Assistant Physician at the Children's Hospital; Assistant Physician and Pathologist at the Infant's Hospital, Boston.

J. CLIFTON EDGAR, M. D., New York City.

Fellow of American College of Surgeons; Professor of Obstetrics and Clinical Midwifery, Cornell University Medical College, New York City; Attending Obstetrician, Bellevue Hospital; Obstetric Surgeon, Manhattan Maternity Hospital and Dispensary.

CHARLES P. EMERSON, M. D., INDIANAPOLIS.
Dean and Professor of Medicine of Indiana University, Indianapolis.

AUGUSTUS A. ESHNER, M. D., PHILADELPHIA.
Professor of Clinical Medicine in the Philadelphia Polyclinic.

FRANCIS ASHLEY FAUGHT, M. D., PHILADELPHIA.
Instructor in Medicine and Director of the Laboratory of the Department of Clinical Medicine, Medico-Chirurgical College, Philadelphia.

B. A. FEDDE, M. D., BROOKLYN, N. Y.

VIRGIL P. GIBNEY, M. D., NEW YORK CITY.
Fellow of American College of Surgeons; Professor of Orthopedic Surgery, College of Physicians and Surgeons, New York City.

R. MAX GOEPP, M. D., PHILADELPHIA.
Professor of Clinical Medicine, Philadelphia, Polyclinic; Assistant Visiting Physician, Philadelphia Hospital; Assistant in Clinical Medicine, Jefferson Medical College, Philadelphia.

EDWARD H. GOODMAN, M. D., PHILADELPHIA.
Associate in Medicine, University of Pennsylvania; Assistant Visiting Physician, University and Philadelphia General Hospitals; Dispensary Physician, Presbyterian Hospital, Philadelphia.

GEORGE M. GOULD, A. M., M. D., ATLANTIC CITY.
Ex-President of the American Academy of Medicine; Formerly Editor of "American Medicine"; Author of Gould's Dictionaries.

CHARLES LYMAN GREENE, M. D., MINNEAPOLIS.
Professor of Medicine, University of Minnesota, Minneapolis.

W. A. HARDAWAY, A. M., M. D., ST. LOUIS.
Formerly Professor of Diseases of the Skin and Syphilis, St. Louis Medical College, St. Louis.

H. F. HARRIS, M. D., ATLANTA.
Professor of Anatomy, Eclectic Hospital Medical College; Secretary and Director of Laboratories Georgia State Board of Health, Atlanta.

JOHN C. HEMMETER, M. B., M. D., BALTIMORE.
Professor of Physiology and Clinical Medicine, University of Maryland, Baltimore.

BARTON COOKE HIRST, M. D., PHILADELPHIA.
Fellow of American College of Surgeons; Professor of Obstetrics in the University of Pennsylvania, Philadelphia.

BAYARD HOLMES, M. D., CHICAGO.
Formerly Professor of Principles of Surgery, College of Physicians and Surgeons, Chicago.

E. FLETCHER INGALS, A. M., M. D., CHICAGO.
Fellow of American College of Surgeons; Professor and Head of Department of Diseases of the Chest, Throat and Nose, Rush Medical College, Chicago.

ABRAHAM JACOBI, M. D., NEW YORK CITY.
Formerly President, American Medical Association; Emeritus Professor of Pediatrics, Columbia University; Consulting Physician, Bellevue and German Hospitals, New York.

ALLEN A. JONES, M. D., BUFFALO.
Adjunct Professor of Principles and Practice of Medicine, Medical Department, University of Buffalo.

WILLIAM W. KEEN, M. D., HON. F. R. C. S., PHILADELPHIA.
Fellow of American College of Surgeons; Emeritus Professor of the Principles of Surgery and Clinical Surgery, Jefferson Medical College, Philadelphia.

HOWARD S. KINNE, M. D., LOGANTON, PA.
Formerly Instructor in Children's Diseases, Medico-Chirurgical College and Chief of the Outpatient Departments for Diseases of Children, Medico-Chirurgical and St. Joseph's Hospitals, Loganton, Pa.

ALEXANDER LAMBERT, M. D., NEW YORK CITY.
Visiting Physician to Bellevue Hospital; Professor of Clinical Medicine, Cornell University, New York.

ERNEST LAPLACE, M. D., Philadelphia.

Professor of Surgery and Clinical Surgery, Medico-Chirurgical College, Philadelphia.

JAMES HENDRIE LLOYD, A. M., M. D., Philadelphia.

Neurologist to the Philadelphia Hospital; Physician to the Methodist Episcopal Hospital.

WILLIAM H. G. LOGAN, M. D., D. D. S., Chicago.

Fellow of American College of Surgeons; Professor of Oral Pathology and Associate Professor of Surgery at the Chicago College of Dental Surgery, Dental Department of Valparaiso University; Professor of Dental Pathology at the Chicago College of Medicine and Surgery, Medical Department of the Valparaiso University.

WILLIAM PALMER LUCAS, M. D., San Francisco.

Professor of Pediatrics, University of California.

L. S. McMURTRY, M. D., Louisville.

Professor of Gynecology and Abdominal Surgery, University of Louisville.

G. HUDSON MAKUEN, M. D., Philadelphia.

Fellow of American College of Surgeons; Professor of Defects of Speech, Philadelphia Polyclinic.

MATTHEW D. MANN, M. D., Buffalo.

Fellow of American College of Surgeons; Emeritus Professor of Obstetrics and Gynecology, Medical Department University of Buffalo.

HENRY O. MARCY, A. M., M. D., Boston.

Fellow of American College of Surgeons; Formerly Surgeon to the Cambridge Hospital for Women; President of the Section on Gynecology Ninth International Medical Congress; late President of the American Academy of Medicine; Member of the British Medical Association; Corresponding Member of the Medicochirurgical Society of Bologna, Italy; late Surgeon U. S. A.

RUDOLPH MATAS, M. D., New Orleans.

Fellow of American College of Surgeons; Professor of General and Clinical Surgery, Medical Department, Tulane University.

JOSEPH M. MATHEWS, M. D., Louisville.

Formerly Professor of Surgery, and Clinical Lecturer on Diseases of the Rectum. Hospital College of Medicine.

JOHN K. MITCHELL, M. D., Philadelphia.

Physician to the Orthopedic Hospital and Infirmary for Nervous Diseases; Consulting Neurologist Widener Memorial Training School for Crippled Children, Philadelphia.

E. E. MONTGOMERY, M. D., Philadelphia.

Fellow of American College of Surgeons; Professor of Gynecology, Jefferson Medical College.

HAROLD N. MOYER, M. D., Chicago.

Formerly Assistant Professor of Medicine, Rush Medical College; Ex-president American Neurological Society.

A. G. NICHOLLS, M. D., Montreal.

Assistant Professor of Pathology and Lecturer in Clinical Medicine, McGill University.

ALBERT J. OCHSNER, M. D., Chicago.

Fellow of American College of Surgeons; Professor of Clinical Surgery, College of Physicians and Surgeons, Medical Department of University of Illinois.

A. H. OHMANN-DUSMESNIL, M. D., St. Louis.

Professor of Dermatology and Syphiology in the St. Louis College of Physicians and Surgeons.

SIR WILLIAM OSLER, Bt., F. R. S., M. D., University of Oxford, England.

Regius Professor of Medicine, Oxford, England; Hon. Professor of the Principles and Practice of Medicine, Johns Hopkins University.

GEORGE E. PFAHLER, M. D., Philadelphia.

Clinical Professor of Roentgenology, Medico-Chirurgical College.

CLEMENS F. von PIRQUET, M. D.

Formerly Professor of Pediatrics, Johns Hopkins University.

EDWARD PREBLE, M. D., New York.

WALTER L. PYLE, A. M., M. D., Philadelphia.

Formerly Assistant Surgeon to Wills Eye Hospital; Editor of an "International System of Ophthalmic Practice."

B. ALEXANDER RANDALL, A. M., M. D., PHILADELPHIA.

Clinical Professor of Diseases of the Ear, University of Pennsylvania; Professor of Diseases o the Ear, Philadelphia Polyclinic.

JOSEPH RANSOHOFF, M. D., F. R. C. S., CINCINNATI.

Fellow of American College of Surgeons; Professor of Surgery, University of Cincinnati, Ohio.

WILLIAM L. RODMAN, M. D., PHILADELPHIA.

Fellow of American College of Surgeons; President, American Medical Association; Professor of the Principles of Surgery and Clinical Surgery, Medico-Chirurgical College.

R. C. ROSENBERGER, M. D., PHILADELPHIA.

Professor of Hygiene and Bacteriology, Jefferson Medical College.

J. T. RUGH, M. D., PHILADELPHIA.

Associate in Orthopedics in the Jefferson Medical College; Orthopedic Surgeon to the Methodist Hospital.

JAY F. SCHAMBERG, A. M., M. D., PHILADELPHIA.

Professor of Skin Diseases, Philadelphia Polyclinic.

R. J. E. SCOTT, M. A., B. C. L., M. D. NEW YORK.

Fellow of the New York Academy of Medicine; Formerly Attending Physician to the Demilt and Bellevue Dispensaries. Author of "The State Board Examination Series"; Editor of "Witthaus' Essentials of Chemistry and Toxicology"; "Hughes' Practice of Medicine," and "The Practitioners Medical Dictionary," etc., etc.

F. M. SHOOK, M. D., LIEUT. U. S. N., NEW YORK.

JOSEPH F. SILER, M. D., WASHINGTON, D. C.

Captain Medical Corps, U. S. A., Lecturer on Tropical Medicine, New York Post-Graduate Medical School and Hospital, Member Field Commission of the Pellagra Investigation, London, 1910.

RICHARD SLEE, M. D., SWIFTWATER, PA.

Formerly Assistant Bacteriologist and Deputy Inspector of the Pennsylvania State Board of Health and Pathologist to the Post-Graduate and Polyclinic Dispensary, Philadelphia.

FREDERIC E. SONDERN, M. D., NEW YORK.

Professor of Clinical Pathology, New York Post-Graduate Medical School; Director of Laboratories, N. Y. Lying-In Hospital, New York.

EDMOND SOUCHON, M. D., NEW ORLEANS.

Fellow of American College of Surgeons; Emeritus Professor of Anatomy and Clinical Surgery, Medical Department, Tulane University.

WARD F. SPRENKEL, M. D., PHILADELPHIA.

Formerly Assistant Demonstrator of Obstetrics, University of Pennsylvania.

FRANCIS T. STEWART, M. D., PHILADELPHIA.

Professor of Clinical Surgery, Jefferson Medical College; Surgeon, Germantown Hospital and Out-Patient Surgeon, Pennsylvania Hospital.

CHARLES G. STOCKTON, M. D., BUFFALO.

Professor of Principles and Practice of Medicine and Clinical Medicine, Medical Department, University of Buffalo.

JOHN MADISON TAYLOR, A. M., M. D., PHILADELPHIA.

Associate Professor of Non-Pharmaceutic Therapeutics, Temple University.

WILLIAM S. THAYER, M. D., BALTIMORE.

Professor of Clinical Medicine, Johns Hopkins Medical School.

J. ASHBURTON THOMPSON, M. D., SYDNEY, N. S. W.

Chief Medical Officer of the Government; President of the Board of Health; Permanent Head of the Department of Public Health, etc.

JAMES THORINGTON, A. M., M. D., PHILADELPHIA.

Emeritus Professor of Ophthalmology in the Philadelphia Polyclinic; Ophthalmic Surgeon, Presbyterian Hospital, Philadelphia.

MARTIN B. TINKER, M. D., Ithaca, N. Y.

Fellow of American College of Surgeons; Formerly Assistant Professor of Surgery, Cornell University.

JAMES TYSON, M. D., Philadelphia.

Emeritus Professor of the Theory and Practice of Medicine and of Clinical Medicine in the University of Pennsylvania; Physician to the Pennsylvania and University Hospitals.

J. WILLIAM WHITE, M. D., Ph. D., Philadelphia.

Fellow of American College of Surgeons; Emeritus Professor of Surgery, University of Pennsylvania; Surgeon to the University Hospital.

REYNOLD W. WILCOX, M. A., M. D., New York.

Formerly Professor of Medicine and Therapeutics at the New York Post-Graduate Medical School.

HARVEY W. WILEY, M. D., Washington.

Formerly Chief Chemist U. S. Department of Agriculture, Washington, D. C.

GEORGE WILKINS, M. D., Montreal.

Emeritus Professor of Medical Jurisprudence, Medical Department, McGill University.

ALBERT WOLDERT, Ph. G., M. D., Tyler, Texas.

Formerly Physician to the Out-patient Department for Diseases of Children, St. Joseph's Hospital, Philadelphia.

ALFRED C. WOOD, M. D., Philadelphia.

Assistant Professor of Surgery, University of Pennsylvania.

HORATIO C. WOOD, M. D., Philadelphia.

Emeritus Professor of Materia Medica and Therapeutics, University of Pennsylvania.

JAMES K. YOUNG, M. D., Philadelphia.

Fellow of American College of Surgeons; Associate Professor in Orthopedic Surgery, University of Pennsylvania; Professor of Orthopedic Surgery in the Philadelphia Polyclinic; Clinical Professor of Orthopedic Surgery in Woman's Medical College.

PREFACE TO THE FOURTH EDITION

The present revision will be found to include many new articles as well as a large number of changes. New material will be found under the following headings: Acidosis; Anthrax; Antinarcotic Legislation; Atophan; Baseball Finger; Benedict's Test for Sugar; Benedikt's Syndrome; Blood Pressure; Bronchoscopy; Carrel-Dakin Solution and Treatment of Wounds; Macewen's Sign and Brudzinski's Sign in Cerebrospinal Meningitis; Chauffeur's Fracture; Affections of Cicatrices; Dietetic (Starvation) Treatment of Diabetes; Schick's Reaction in Diphtheria; Emetine Treatment of Dysentery; Erythremia; Garrod's Thread Test; Gas Gangrene; Treatment of Gonorrhea; Treatment of Gout; Intraspinal Therapy in Locomotor Ataxia; Treatment of Malaria; Calcium Sulfid Treatment of Poisoning by Corrosive Sublimate; Fischer's Treatment of Nephritis; Karell's Treatment of Nephritis; Optochin; Infantile Paralysis; Pellagra; Liquid Petrolatum; Phenolsulphonepthalein Test; Parresine; Rickets; Rocky Mountain Spotted Fever; Coley's Treatment of Sarcoma; Staphylococcus and Streptococcus Infections; Sickroom; Tennis Leg; Russo's Test in Typhoid Fever; Typhoid State; Trench Feet; Trench Fever; Vincent's Angina; War Surgery; Weil's Disease.

A few articles have been omitted; condensation has been effected wherever possible; and the needs and requirements of the busy practitioner have ever been kept in mind.

New York. R. J. E. SCOTT.

PREFACE TO THE THIRD EDITION

In spite of the very thorough revision to which this work was subjected three years ago, the call for a new edition has made it possible to include several new sections as well as to make such changes in some of the articles as are necessary to bring them into accord with recently established facts. The number of cross references has been materially increased; and it is hoped that this work, in its revised form, will prove even more useful than before.

New articles will be found on: Accommodation; Adalin; Schaefer's Method of Artificial Respiration; Ulcer of the Bladder; Fracture of the Carpal Bones; Cervical Ribs; Coleman-Shaffer Diet in Typhoid and Other Fevers; Cysts; Dementia Præcox; Emetin in Dysentery, and in Pyorrhæa Alveolaris; Removal of Gunpowder Stains; the Harrison Law; Hibbs' Method of Treating Congenital Dislocation of the Hip, and Osteoplastic Operation for Pott's Disease of the Spine; Hirschsprung's Disease; Kraepelin's Classification of Mental Diseases; Idiocy and Imbecility; Intratracheal Insufflation of Ether; the Luetin Reaction; Madelung's Deformity; Mesenteric Cysts; Narcophin; Omentum; Pantopon; Pulmotor; Retroperitoneal Tumors; Achromatic Bifocals, and Fused Bifocals; Care of Spectacles; Splenectomy; Sprengel's Shoulder; Trigger Finger; and Twilight Sleep.

New York. R. J. E. SCOTT.

PREFACE TO THE SECOND EDITION

The general plan of this book, so skilfully outlined by the previous editors, has been maintained. At the same time every part of it has been thoroughly revised, much of it has been rewritten, a number of new articles have been incorporated, and a few of the old ones have been omitted.

In the new material will be found articles on: Anatomic Age; Appendicitis; Autointoxication; Bier's Hyperemic Treatment; Blood-pressure; Breast (Tumors); Brill's Disease; Cerebrospinal Meningitis (Treatment); Colon Bacillus Infection; Craniectomy; Cryoscopy; Cytology; Eclampsia; Feces; Food-adulteration; Fourth-of-July Accidents; Glandular Fever; Hand (Palmar Abscess); Heart-block; Hookworm Disease; Immunity; Inoscopy; Lambert's Treatment for Narcotic Addiction; Laryngeal Muscles (Paralysis); Modified Milk in Infant Feeding; Mosquitos; Nose (Diseases of the Accessory Sinuses); Opsonin Therapy; Parasites; Paratyphoid Fever; Pellagra; Pyorrhea Alveolaris; Radium; Roentgen Rays; Sepsis; Serum Therapy; Sleeping Sickness; Teeth (Extraction); Tuberculin; Tuberculosis (Treatment); Uterus (Retrodisplacements); Vaccine Therapy; and Vaginal Douche.

The following articles (among others) have been largely rewritten or added to: Alcohol; Anemias; Antiseptics and Disinfectants; Blood (Examination); Caisson Disease; Carcinoma; Cystoscope; Hernia; Intestinal Surgery; Lungs (Surgery); Malarial Fevers; Pain; Phototherapy; Prostate Gland (Hypertrophy); Rape; Sewage Disposal; Stomach (Surgery); Syphilis (Salvarsan); and Worms.

These lists by no means represent all the changes in the work. Indeed, it is safe to say that very few articles remain exactly as they were in the former edition. This is not due to any desire for change or love of unnecessary work on the part of the present editor but was necessitated by the advances made in every branch of medical science during the past decade.

There are more than two hundred additional illustrations besides the large number of old figures that have been replaced by better ones.

Special provision has been made for the reader in need of immediate information on diagnosis and treatment. In furtherance of this object, cross-references have been very freely inserted. Catch words are placed at the top of each page; the first title indicates the first topic in the left-hand column, and the second one the last topic in the right-hand column. The prescriptions, which are very numerous, are written in English, and without abbreviations; and the scruple sign has been eliminated as being both confusing and unnecessary.

Attention is directed to the information in tabular form; not only is there a great increase in the number of tables presented, but they are all so arranged that they can be read without the book being turned round.

Readers of the first edition will miss from the list of contributors such names as Senn, Bullitt, Burnett, Hughes, Solly, DeForest Willard, and others now deceased.

Throughout the whole period of the preparation of this new edition, the interests of the general practitioner have been kept in mind. While we have been fortunate in se-

curing the services of eminent specialists, and are very thankful to them for their valuable contributions, it is for the practitioner and not for the specialist that the volume is mainly intended. In a word, the purpose of the present edition of this Cyclopedia is to provide the general medical reader with a source of information *on every medical subject except his own specialty.* It is hoped, and believed, that the busy practitioner or family doctor will find this volume to be a ready helper in every emergency that may confront him, and a trustworthy guide in his daily practice.

NEW YORK. R. J. E. SCOTT.

PREFACE TO THE FIRST EDITION

It has been our object to present in one handy volume, concisely and authoritatively, the most important facts in all branches of medicine and surgery that are of working value to the active practitioner. At the same time we have endeavored to provide a trustworthy handbook for easy and rapid reference in physical and clinical diagnosis, general therapeutics, operative technic, materia medica, toxicology, and other subjects, concerning which information is constantly needed in undergraduate study and in daily practice. Diagnosis and treatment have received particular attention. Many minor subjects of genuine value to the practitioner, but usually held of too little importance for discussion in the text-books, are here given proper consideration. Numerous well-tried and valuable formulas are distributed through the volume. When it has been possible, the information has been presented in tabular form or arranged in convenient parallel columns.

Besides the multitude of original contributions, there has been frequent recourse to the latest medical periodicals and text-books and the standard medical dictionaries and cyclopedias of all languages; and we are under especial obligation to the works of Potter, Moullin, Walsham, Tyson, and Hughes.

A striking criticism of many large collaboration books is that as each contributor is held personally responsible for his work, he must necessarily be allowed to preserve his distinct and separate individuality, not infrequently dissenting from teachings elsewhere in the same volume; the reader is thus left bewildered by a mass of heterogeneous and undigested material. To avoid this and other disadvantages, and to secure the desired homogeneity in this cyclopedia, we have asked permission of our contributors to merge their work anonymously in proper subordination and under the free control of the editors. By this arrangement the separate contributions have been wrought over, supplemented, and rendered organically unitary with the rest.

As to the practical use of the book: To become perfectly familiar with such a reference work the owner should look through it carefully to fix the general style of classification in his mind. Although the subjects are generally introduced under the most common title, an attempt has been made to classify disease and injury according to the part involved. Numerous cross-references render a general index unnecessary. Further to facilitate reference, frequent subdivision and a uniform system of bold-face headings have been adopted, so that the subject-matter of a page may be seen at a glance. Throughout the book English generally has been preferred to Latin.

GEORGE M. GOULD,
WALTER L. PYLE.

A CYCLOPEDIA

OF

PRACTICAL MEDICINE AND SURGERY

A

ABASIA.—Motor incoordination in walking. See Astasia.

ABDOMEN, DISEASES. Classification.—(1) Diseases of the anterior abdominal walls; (2) diseases of the peritoneum; (3) diseases of the organs contained in the abdominal cavity; (4) diseases of the abdominal vessels; (5) diseases of the sympathetic or other nerves; (6) diseases of the cellular tissue, abscess, etc.; (7) diseases of the posterior abdominal wall, pelvis, diaphragm, etc.; (8) diseases of the parts adjacent to the abdominal region. The different diseases are described under their separate headings.

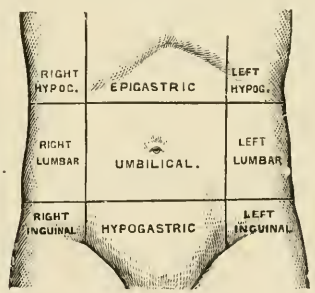
ABDOMEN, EXAMINATION, IN THE FEMALE.—Let the patient lie upon her back on a bed or table, with no clothing except a night-dress. The lower extremities and pubes should be covered with a sheet, while the abdomen is exposed by drawing the night-dress well up to the costal margin. As in examination of the chest, we use the senses of sight, touch, and hearing.

Inspection reveals the presence of dilated veins, of areas of pigmentation, and of the *lineæ albicantes*. These lines indicate that the abdomen has been greatly distended from some cause—probably, although not necessarily, by pregnancy. By inspection may also be determined the size and shape of the abdomen, and the presence of any localized bulging or prominence. The latter may be indicative of an intraabdominal mass, or it may be the result of displacement of one or more of the abdominal organs. Abdominal movements can also be distinguished.

Palpation should be practised very gently at first, and with a warm hand, so that contraction and rigidity of the abdominal muscles may be avoided. As the examiner proceeds, the fingers may be pressed more deeply into the abdomen. The various abdominal regions should be palpated, and the presence of any mass, or enlargement or displacement of organs noted. By this means fluctuation in an encysted fluid-accumulation is readily determined. The kidneys, especially the right, may be palpated, and in favorable cases the vermiform appendix may be felt.

Percussion is performed in the usual manner, the patient lying upon her back. If the presence of free fluid in the abdomen is suspected, percussion should be performed with the patient in different positions, so that the change in percussion-note may be perceived.

ABDOMEN, GENERAL PHYSICAL DIAGNOSIS. Topography.—The abdomen may be divided into 9 regions by 4 lines, 2 horizontal and 2 vertical, as in the accompanying illustration and in the table on the following page; the names of the regions and their contents are also shown there. Unfortunately, different authors draw these lines through different points, and so there is no uniformity. A more practical method is that which



Abdominal Regions.

divides the abdomen into four quadrants by a vertical line and a horizontal line which intersect at the umbilicus.

Right Upper Quadrant	Left Upper Quadrant
Liver and gall-bladder.	Left extremity of liver.
Head of pancreas.	Spleen.
Right kidney.	Splenic flexure of colon.
Colon, hepatic flexure.	Left kidney.
Pyloric end of stomach.	Pancreas.
	Fundus of stomach.

Right Lower Quadrant	Left Lower Quadrant
Colon. Cecum. Appendix.	Colon. Sigmoid flexure.

General enlargement of the abdomen may be caused normally by an accumulation of food or drink after a hearty meal, or by pregnancy. Pathologic distention is due to gases, dropsical effusions, morbid growths, and enlarged viscera. The "pot-belly" of children is seen in cases of scrofulous affection of the mesenteric glands, and sometimes in chronic gastrointestinal catarrh.

When the abdomen is distended with gas, there is a high-pitched note on percussion. In fluid distention there is fluctuation and a characteristic dulness. In general effusion the fluid changes position with change of the patient's posture. If the effusion is circumscribed, it indicates special visceral diseases, particularly of the liver, ovary, or kidney, according to the location. In tympanites the epigastrium is quite prominent, while in ascites it is moderately flat.

THE ABDOMINAL VISCERA REGIONALLY ARRANGED

Right.	Middle.	Left.
Hypochondriac.	*Epigastric.*	*Hypochondriac.*
Liver: portion of right lobe (gall-bladder, usually cut by longitudinal line). *Kidney:* upper and outer part. *Colon:* hepatic flexure and part of ascending colon.	*Liver:* quadrate, caudate, Spigelian, and greater part of left lobes (gall-bladder usually cut by longitudinal line). *Pancreas:* head and body. *Spleen:* upper and inner part. *Kidneys:* upper and inner part, with pelvis renalis. *Suprarenal bodies.* *Stomach:* middle and pyloric regions, cardiac and pyloric orifices. *Duodenum:* first and second portions and termination of third portion. *Large intestine:* transverse colon, variable portion.	*Liver:* portion of left lobe. *Spleen:* lower and outer part. *Pancreas:* tail. *Kidney:* upper and outer part. *Stomach:* great culdesac. *Colon:* splenic flexure.

Longitudinal plane along outer border of rectus.

Upper horizontal plane at level of lowest point of costal border.

Lumbar.	*Umbilical.*	*Lumbar.*
Kidney: lower and outer part *Ascending colon* and portion or whole of *cecum.* *Small intestine:* chiefly ileum.	*Kidneys:* lower and inner portions with ureters. *Duodenum:* lower flexure and part of third portion. *Jejunum* and *ileum.* *Transverse colon:* portion. *Sigmoid flexure* and commencement of *rectum.*	*Kidney:* lower and outer part. *Small intestine:* chiefly jejunum. *Descending colon* and portion of *sigmoid flexure.*

Lower horizontal plane at level of anterior superior iliac spines carried into true pelvis.

Inguinal.	*Hypogastric.*	*Inguinal.*
Small intestines. *Cecum:* lower portion, occasionally. *Inguinal canal.*	*Small intestines.* *Sigmoid flexure* and *rectum* (portion). *Cecum:* occasionally. *Ureters.* *Bladder:* in children; and if distended, in adults. *Fundus uteri* and appendages.	*Small intestines.* *Sigmoid flexure:* portion. *Inguinal canal.*

Enlargement of the right hypochondrium is most frequently due to disease of the liver or gall-bladder. Occasionally, tumors of the kidney or hydronephrosis cause swelling in this location. Such tumors lie behind the ascending colon, and their dulness is thus obscured by superficial tympany. Examination of the urine is of value in these cases.

Enlargement of the lumbar regions may be due to tumor, cyst, or abscess of the kidney.

Enlargement of the right inguinal region may be due to diseases of the cecum and appendix, to fecal impaction, to tumors of the ovary, to pelvic abscesses, and to enlarged or movable kidney.

Enlargement of the epigastrium may be due to distention of the stomach, to dilatation or morbid

growth of this organ, to cancer or cyst of the pancreas, to cancer of the large intestine, to tumor of the left lobe of the liver, or to aneurysm.

Enlargement of the umbilical region may be due to umbilical hernia; to rupture of the abdominal muscles; to a floating spleen, kidney, or liver; to tuberculous disease of the omentum or mesenteric glands; to dilatation after a full meal; to cancer of the stomach, liver, or gall-bladder, particularly on the right side. Disease of the pancreas and spleen, and effusions into the lesser peritoneal cavity may cause swelling, beginning at the left side. The vertebræ may project and cause tumors in this location.

Enlargement in the hypogastric region may be caused by distention of the bladder, by pregnancy, and by tumors and cysts of the uterus. It is also common in dilatation and prolapse of the stomach, in which conditions the lesser curvature of the stomach can be readily outlined.

Enlargement of the left hypochondrium may be due to enlargement of the spleen, to movable kidney or tumors of the kidney, to effusions into the lesser peritoneal cavity, and to dilatation or carcinoma of the stomach.

Enlargement of the left inguinal region may be due to malignant tumor of the sigmoid flexure, to volvulus, to fecal impaction, and to the causes of enlargement on the right side that are anatomically possible in this location.

The movements of abdominal swellings with the movements of respiration indicate that they are probably connected with the diaphragm, and depend on disease of the liver or spleen, as the other organs have no normal attachment to the diaphragm.

Pulsation of the abdominal aorta sometimes indicates aneurysm; but in most instances it is merely a nervous symptom of no clinical significance. It is common in neurasthenic women and in the subjects of hyperthyroidism. Pulsation of the liver, usually in association with jugular pulsation, is occasionally seen in tricuspid regurgitation.

The skin of the abdomen is wrinkled and atrophied in senility, emaciation and cachexia due to any cause. *Lineæ albicantes* indicate previous stretching of the abdominal walls by pregnancy, obesity or pathologic enlargement; they are constantly seen in multiparæ. Dilated veins and areas of pigmentation result from portal obstruction and are observed in cases of hepatic cirrhosis. The term *caput medusæ* is used to describe the characteristic radiation from the umbilicus of a mass of dilated veins. It is on the abdomen that the characteristic rose-spots of typhoid fever are found.

The movements of the abdomen are increased during dyspnea and there may be pronounced retraction of the epigastric and hypochondriac regions. The movements are restricted by tight lacing, or tight clothing; by enlargement or distention; by ascites, or abdominal tumor; and especially by paralysis of the diaphragm, generally unilateral, which causes retraction of the abdomen during inspiration. **Retraction** is also seen in extremely thin and emaciated persons. It may be the result of prolonged abstinence, of extreme purging and vomiting, as in cholera, dysentery, and similar diseases, and of many prolonged and wasting diseases. If the retraction is associated with marked rigidity and pain, we may suspect hepatic, renal, or metallic colic, or the beginning of peritonitis. In the second stage of tuberculous meningitis of children there is retraction of the abdomen.

Palpation of Abdomen.—By this method of diagnosis we detect the size, form, position, attachment, and condition of the internal organs, as well as the degree of fluctuation. In applying this method the tissues should be relaxed as much as possible by having the patient lie on his back, with the thighs flexed on the body. In many instances the patient should be turned from one side to the other while the examination is being made, in order that the internal organs may gravitate from the part. In palpation the **character of the pain** is an important factor: the pain of an inflammatory condition of a serous membrane is sharp and cutting, while if the mucous membrane is involved, it is usually dull. Pain due to involvement of the nervous mechanism, as in colic, is sharp and is relieved by pressure, while in acute inflammatory processes pain is usually increased on pressure. See ABDOMEN (Pain in).

Percussion of Abdomen.—This method of diagnosis reveals: (1) The condition of an organ, whether solid or filled with air; (2) the boundaries of the organ. To apply percussion, the patient should be in the same position as for palpation. Mediate percussion is best. To obtain the accurate boundary of an organ that is of denser medium than the surrounding parts, the first few strokes should be made over the one that has a more resonant or tympanitic note; as, for instance, to find the upper border of the liver, the first few strokes should be made over the lung, gradually going downward; and to find the lower border, begin over the region of the ascending colon, gradually percussing upward. The character of the note should be considered, whether *dull*, *flat* or *tympanitic*.

Auscultation of Abdomen.—Either the mediate or immediate method may be used. In mediate auscultation the stethoscope is used; in immediate auscultation the ear is applied to the bare surface. In applying this method the patient should be in the recumbent posture. It is particularly applicable as a diagnostic measure in aneurysms of the abdominal aorta and in detecting the fetal heart-sound. The examinations of the viscera are discussed under their separate headings. See STOMACH, LIVER, KIDNEY, SPLEEN, etc.

ABDOMEN, PAIN IN.—**Diffuse abdominal pain** generally means peritonitis. Rheumatism of the abdominal muscles may be so severe as to lead to a mistaken diagnosis. The presence of rheumatism elsewhere and the associated symptoms lead to a correct diagnosis. There is sometimes diffuse abdominal pain in hysteria.

Localized abdominal pain is a valuable guide to the focus of injury or disease: as, for instance, appendicitis is characterized by a pain in the

right iliac region. However, abdominal pain is often referred, and it is sometimes very difficult for the patient to locate the exact point of pain. It is always best to call to our aid the pain elicited by pressure. Neuralgia is recognized by the intermittent character of the pain and the well-known points of tenderness, and by the associated anemia. The seat of abdominal pain is further discussed under the different organs and their injuries and diseases.

Acute abdominal pain points to inflammation, perforation, gastralgia, enteralgia, or occlusion of some of the numerous abdominal channels. **Sudden and severe pain** is usually due to traumatism, perforation, or colic Traumatism is diagnosed by the history and signs of injury. Perforation is indicated by the history and location of the diseased part and by the character of the associated symptoms. **Colic** is a spasm of the mucous canal. We may have intestinal, hepatic, renal, uterine, and vesical colic. In colic the pain is paroxysmal, and each spasm may be attended by vomiting, rapid pulse, cold sweat, and more or less collapse. The history and the associated symptoms must determine the variety of colic. Lead colic is often difficult to diagnose. See Colic.

Persistent abdominal pain results from various visceral diseases, chronic peritonitis, ulcers, gastrointestinal neuroses, diseases of the vertebræ, or abdominal aneurysm. In vertebral disease there is pressure on the peripheral nerves as they emerge from the spinal column, and the pain is intermittent and located about the navel. Abdominal aneurysm, causing pressure on the spine or erosion, produces a similar pain.

ABDOMEN, WOUNDS AND INJURIES.—The abdominal walls, or the viscera, or both may be affected. It is impossible to estimate immediately the extent of injury, because death has ensued without any apparent injury, and without the discovery of any structural lesion, even after autopsy. Shock may pass off within a few hours or even minutes, or it may prove fatal or be followed, without break or interruption, by internal hemorrhage or rupture of hollow viscera. The viscera may be reduced to pulp with no evidence of external injury. For this reason prognosis in wounds and injuries of the abdomen must be very guarded.

Contusion without Injury to the Viscera.—There may be hematoma of the subcutaneous tissue or in the sheath of the recti muscles, abscess of the abdominal wall, laceration of muscles, such as the recti, or of the diaphragm, and rupture of the parietal peritoneum, or subsequent peritonitis.

Hematoma of the abdominal wall is usually absorbed, although suppuration may ensue. Abscesses are characterized by the great amount of induration that surrounds them, and by the fetid nature of their contents. Lacerations of muscles are not rare. They may be caused by sudden effort in parturition or in lifting, or by a blow, and they are frequent in tetanus and sometimes follow typhoid fever.

Rupture of the recti muscles is diagnosed by sudden pain and swelling, increased pain on movement, and sometimes a sulcus may be felt between the torn ends. Nothing can be done to secure the ends. Rest on the back, with the shoulders raised and the thighs flexed on the abdomen, is advised. A large concave pad should be placed over the protrusion, and retained by a broad roller or an elastic bandage. As the opening is large, there is little danger of intestinal strangulation.

Rupture of the diaphragm, if the patient lives, may be recognized by the presence of a traumatic phrenic hernia. The parietal peritoneum sometimes gives way from its own want of elasticity. Peritonitis ensuing must be treated on general principles.

General treatment consists in placing the patient on the back and securing reaction from the shock. Alleviate the pain by morphin or another analgesic. Apply ice and lead-water and laudanum at varying intervals. Give but little ice by the mouth. Food is inadvisable for 48 hours. After 24 hours the intermittent application of heat by fomentations or poultices is advisable, and the bowels should be kept open by salines.

Contusion with Visceral Injury.—The first symptoms are marked shock and acute pain. Persistence of collapse and intense coldness of the extremities would lead us to suspect internal hemorrhage. The immediate development of peritonitis points to injury of the peritoneum itself, or to injury of one of the hollow viscera.

Rigidity of the abdominal muscles, with marked restlessness and pallor, though variable in degree, are strong diagnostic indications of visceral rupture, more especially of the stomach and liver. Constipation, though usually present in bowel rupture, is not to be relied on, and is practically worthless as a symptom when a diagnosis must be arrived at within a few hours.

The symptoms of injury to the various viscera are as follows:

Liver.—Pain and dulness over the hepatic region, great collapse, bilious vomiting, and clay-colored stools.

Kidney.—Bloody urine, frequent urination, pain in the lumbar region, and possibly retraction of the testicle.

Spleen.—Symptoms of profuse internal hemorrhage, with extreme shock and collapse, pain and dulness over the splenic region.

Stomach.—Bloody vomiting and great collapse. However, the stomach may be injured without hematemesis.

Intestines.—Bloody stools, great shock, tympanites, and possibly emphysema, owing to the escape of flatus into the subperitoneal tissue, and thence into the superficial structures.

The treatment is expectant, and consists, in many cases, of simply relieving the pain and obtaining reaction from the shock. The patient should be placed at perfect rest in a recumbent position. Unless it is absolutely necessary to have the symptoms unmasked, opium should be administered. External warmth and stimulants are indicated. The local treatment consists in cold applications to the abdomen. The diet should be mild and unirritating, and if there is reason to suspect rupture of any part of the gastrointestinal

canal, the patient should be nourished by nutrient enemata. The patient should be catheterized, particularly if there is any sign of injury to the bladder or kidney; at all events, to prevent undue retention of urine. Purgatives should be avoided. If there are unmistakable signs of persistent internal hemorrhage, and the patient is sinking rapidly, an Abdominal Section (*q. v.*) is peremptorily demanded. If there is great suffering from gaseous distention, the surgeon is justified in puncturing the bowel through the linea alba with a trocar. Operative interference is contraindicated in traumatisms of the abdominal cavity, in severe shock, unless to control hemorrhage. Never operate when the patient is in a condition of collapse or cyanotic from peritonitis and heart failure. General peritonitis from bowel rupture is nearly always fatal, but a few recoveries after operation have been reported.

The earlier rupture of the alimentary canal or urinary bladder is operated upon, the better. The chance of recovery decreases rapidly after 6 hours and the case is usually hopeless after 24 hours. Indeed, most of the cases succumb in from 12 to 48 hours.

Nonpenetrating wounds of the abdominal parietes should be thoroughly cleansed, and any foreign bodies removed. If there is much hemorrhage, the wound should be enlarged, if necessary, to find the bleeding vessel, which should be promptly ligated. If it is found impossible to secure the bleeding point, the wound should be packed with sterilized gauze, and under no circumstances immediately closed. If the wound shows a tendency to gape, it should be united with several sutures. If the muscles are severed, they should be united by a separate buried catgut suture.

Penetrating wounds of the abdomen should be treated from the beginning by absolute rest and the use of opium. The shock should be met in the ordinary manner, and the wound should be covered with a temporary antiseptic dressing. If any of the viscera are seriously wounded, there will be collapse, severe local pain, and possibly local swelling, although there is usually rapid abdominal distention. There may be vomiting of blood. If there is extensive internal hemorrhage, the characteristic signs of progressive hemorrhage will be present. Protruded viscera should be carefully examined, and if uninjured, should be cleansed with either sterilized water or some weak antiseptic solution. If there is constriction of the bowel, the wound should be enlarged and the obstruction to the return removed. If gaseous distention prevents the return of the bowel, it should be aspirated and the gas removed. If the bowel is seriously injured or gangrenous, it is always best to open it and allow its contents to escape and to suture it to the edge of the wound, forming an artificial anus; any further surgical procedure can be effected later, when complete reaction has been established. Lacerated or gangrenous omentum should be ligated with silk, and removed. Small punctured wounds of the intestine may be held together by a fine pair of forceps, and a silk or gut ligature passed around the wound. The ends are then cut off close, and the intestine is returned. Incised wounds involving a considerable portion of the caliber of the bowel should be sutured by one of the methods having for its object the inversion of the edges of the wound and the consequent coaptation of the serous surfaces. See Intestines (Surgery of).

If there is reason to believe there is much blood-clot in the abdomen, or that septic matter has entered, the cavity should be carefully cleansed by persistent sponging and flushing with a warm saline solution or a weak sterile solution of boric acid (1 : 20), at a temperature of about 110° F. As the fluid is poured in, the hand should be introduced and moved about so as to free all the clots. When the clots no longer float out, the residue should be carefully mopped out with sponges. The wound may then be sutured and dressed.

The injuries to the abdominal viscera are discussed under their special heads, as Stomach, Kidney, Peritonitis, etc. Special attention is called to the article on certain abdominal wounds under the heading Gunshot Wounds (*q. v.*).

ABDOMINAL ANEURYSM.—See Aorta (Aneurysm).

ABDOMINAL SECTION. Preparatory Treatment of the Patient. General.—Before subjecting the patient to a major operation, it is unquestionably very important that the heart should be in the best possible condition to withstand the shock. To this end, if there is any cardiac weakness or valvular insufficiency, a course of heart tonics—such as strychnin and digitalis—should precede the operation. If there is no time for such a course of treatment, then before the anesthetic is given the heart should be stimulated by a hypodermic injection of 1/20 of a grain of strychnin. Minor valvular lesions are not a contraindication to operation. Many cases with mitral murmurs have been operated on successfully. It is probable that aortic lesions are the more serious; but, unless very bad, they do not contraindicate operation.

As cases have been reported in which death has followed abdominal sections from suppression of urine or from nephritis, as shown by the presence of albumin and casts, it is very necessary that the condition of the kidneys be thoroughly investigated and any abnormalities corrected beforehand. In a large proportion of gynecologic cases demanding abdominal section, renal insufficiency, to a greater or less degree, is found. The kidneys may be put in a healthier condition and made to do their work properly by administering large quantities of water, by the use of hot-water baths daily, and by the administration of diuretics such as the salts of potassium or diuretin. The choice of the anesthetic must also be made somewhat according to the condition of the kidneys, it being generally held that ether is more dangerous than chloroform in its action on these organs. The same may be said to be true of the respiratory tract. Bronchitis with cough following celiotomy is, to say the least, a very annoying complication, and, if severe, may be serious. It is, therefore, advisable to defer an operation should an acute bronchitis exist.

The intestinal tract should be thoroughly cleared out, and the patient kept upon a diet which will not leave much residuum for 48 hours before the operation. The advantage of this is that there is very little food left to ferment within the intestines and produce gas. This is one of the most annoying symptoms after operation, and everything that is possible should be done to avoid it. Distended intestines are also greatly in the way during the operation. Autointoxication by retained excretions is often productive of serious consequences. By the treatment suggested for the kidneys and intestines, this condition may be overcome. Its existence should be carefully inquired into in every case, and, if found, should be thoroughly treated before operation. Undoubtedly, much suffering can thus be avoided, as well as some fatal results.

Local Preparation.—The patient is given a warm tub bath after which the skin is shaved, thoroughly washed with green soap and warm water, then with alcohol and finally with bichlorid of mercury solution, 1 : 1000. Many eminent surgeons consider it sufficient to prepare the field of the operation in this manner after the patient has been placed upon the operating table. If, however, the preparation be made the day before the operation, as others prefer, a towel wet with the same solution may be placed over the abdomen, fastened by a binder, and left until the patient is placed upon the table; or a dressing of dry sterile gauze may be used instead of this wet dressing. The preparation is repeated after the patient is placed upon the table. Many have discarded the brush, merely washing the skin thoroughly with gauze. Sterilization of the skin with tincture of iodin is a new method which has given excellent results. Grossich reports 2284 operations in which it was employed without a single case of infection. He merely paints the *dry* skin, which has been previously shaved. Other surgeons, however, wash the skin with the usual solution before applying the iodin.

The Operating Room.—In all modern hospitals appropriate operating rooms are provided. In private houses the operating room should always be chosen beforehand, and, if possible, properly prepared. The first point is to secure a good light. A northern exposure is better than one in which the sun shines directly into the room. A high window, unobstructed by veranda, trees, or intervening buildings is desirable. If time allows, the carpet should be removed from the floor. The draperies over the window nearest the operating table should be removed some time previously, so that all dust will have time to settle and be wiped up. The floor should be thoroughly scrubbed; and if it is dampened at the time of the operation, the dust will be prevented from rising. It is not necessary to wash the walls and ceiling, as has been sometimes recommended, because if they are untouched, no dust will be given off from them.

The temperature of the room should be between 70° and 80° F. Too warm a room is annoying to the operator, and does no good to the patient. There should also be some provision for ventilation, to allow of the escape of the fumes of the anesthetic, and to supply plenty of oxygen to the patient, whose respiratory function is necessarily somewhat impeded.

The Table.—There are many good operating tables at present supplied for hospital use. Most of them are too heavy to make transportation possible. In a private house a table may generally be found that will do. It should be 6 feet long, 2 feet wide, and from 30 to 34 inches high. If no such table can be secured, 2 or 3 stands placed end to end will answer the purpose, provided they are strong enough; or a board may be set upon two horses or the backs of chairs, the seats of the chairs facing each other, and fastened together by a stick, to prevent their tipping.

A table especially designed for securing the Trendelenburg posture is in many cases indispensable. There are several frames made that may be adapted to any table. That designed by Krug is very satisfactory. It can be adjusted to any ordinary wooden table by clamps, and is easily transported. If no such appliance is at hand, a chair may be used, resting upon its top and the front edge of the seat; or one end of the table may be raised by chairs or blocks, the legs of the patient being allowed to hang over the edge of the table. Before use, the table should be thoroughly scrubbed with an antiseptic solution.

Water.—As large quantities of sterilized water are generally needed, it is always desirable that this should be prepared beforehand. The water may be boiled in a clothes-boiler, and put in clean pails to cool over night, covering the pails with sterilized towels tied over the tops. The morning of the operation a fresh supply of boiled hot water should also be provided.

Towels.—As many towels are useful in operations it is generally well for the surgeon to supply himself beforehand. He can then have his towels put into a sterilizer and carefully done up ready for use. This is quite necessary, as in many households of the poorer class enough towels cannot be procured. If the towels have not been previously sterilized, they can be rendered sterile at the time of the operation by wetting them in a 1‰ : 1000 sublimate solution. Two or three sterilized sheets should also be provided.

Sponges.—Marine sponges are now seldom employed, gauze sponges having come into almost universal use during the last few years. These latter should, of course, be made beforehand, carefully sterilized, and put up in packages, each package containing a certain definite number, as 9 or 12. In this way tally can be more easily kept of the number of pads used.

If sea sponges are used, they should be thoroughly prepared beforehand by the following method: After being pounded and beaten to get out as much sand and grit as possible, they should be washed in clear water many times, until no more sand washes out. They should then be placed in a solution of hydrochloric acid, 1 : 10, for 24 hours. They can then be placed in a 1 : 20 solution of carbolic acid; or, if it is desired to make the sterilization very complete, they may be put in a strong

warm solution of permanganate of potassium, and decolorized in oxalic or sulphurous acid solution. They should then be rinsed thoroughly in warm sterilized water, and tied up tightly in a sterilized cotton bag to dry. After sponges have been used, even though they have been infected with pus or other septic material, it is not necessary to throw them away. The same sponges have been used for many operations without any bad results. The method of cleansing these sponges is as follows: They are soaked in strong, hot soapsuds, made with pearline or some other powdered soap, for 24 hours. They are then thoroughly washed in a succession of hot baths until all the soap is washed away, and then left under the running water for several hours to get out the remainder of soap that may be left. After this they are put while wet in the 1 : 20 carbolic acid solution, and left for at least 24 hours; or they may be sterilized with formaldehyd gas in the formalin sterilizer, or subjected to steam sterilization in the autoclave. They should be placed damp in the sterilizer. They should afterward be preserved in tightly closed cotton bags. A convenient number of sponges for the operator to carry with him for a celiotomy is 12,—3 large flat sponges and 9 round ones.

Ligatures.—The ligatures recommended to be used are catgut, silkworm-gut, and very fine silk. Catgut should be used for most purposes, such as tying adhesions and pedicles, sewing together flaps of peritoneum, sewing under oozing surfaces, as well as sewing up the fascia and skin in closing the abdominal wound. If properly prepared, catgut is absolutely reliable, as has been proved in many hundreds of cases. Many methods have been advocated for preparing catgut. Undoubtedly, the kumol method is very satisfactory, but it is somewhat difficult, and is not generally used outside of hospitals. By this method the catgut is sterilized at a temperature of 165° C.

The following method is simple, and has answered well in practice. The catgut is obtained from the dealers in jewelers' supplies, in skeins of 5 meters each. It is impregnated with a considerable quantity of oil. In order to remove this, and at the same time to sterilize it, the catgut is soaked in a 1 : 1000 solution of corrosive sublimate and ether. It is left in this for periods varying from 4 to 8 hours, according to the size of the catgut. Afterward it is boiled in alcohol for 20 minutes, to extract all the sublimate, and is then preserved in alcohol until it is used. Careful bacteriologic experiments show that catgut prepared in this way is perfectly sterile. It is not irritating to the tissues, nor are its strength and its elasticity diminished.

Recently, several methods have been described of preparing catgut by the aid of formalin. The following method can be recommended; and the catgut thus prepared is more enduring within the tissues than that prepared by the former method: Place the rolls of catgut in a 2 percent solution of the commercial formalin. Let it remain for from 12 to 24 hours, according to the size. Wash in running water for 4 hours, to remove the formalin; then in salt solution, and preserve dry or in alcohol.

Iodin catgut may be prepared by immersing the catgut in a 1 percent solution of iodin and potassium iodid for at least 8 days. It may be kept in the solution for several months without injury. A very convenient method is that of Salkindsohn, who uses a solution of 1 part of tincture of iodin and 15 parts of proof spirit.

Silverized catgut, used by Blake, is prepared by immersing the catgut in a 2 percent solution of collargol for one week, and then soaking it in 95 percent alcohol for 30 minutes, after which it is wound on glass spools and transferred to fresh alcohol of the same strength.

Silkworm-gut is very generally recommended for closing the abdominal wound. This can be sterilized by boiling in water, and preserved dry in hermetically sealed tubes, or in alcohol. Another method recommended is to place the strands of silkworm-gut in a test-tube which is plugged with absorbent cotton. The tube should then be placed in a steam sterilizer for 1 hour the first day, and for 30 minutes each of the two following days. As the steam penetrates the plug, the silkworm-gut is perfectly sterilized, and may be preserved without removing the cotton.

Silk is only useful, in abdominal surgery, for closing wounds of the intestine. Fine white sewing silk may be used for this purpose, and may be sterilized in the same manner as the silkworm-gut. Should the operator fear the use of catgut and desire to use silk for tying pedicles and for other similar purposes, larger strands can be provided. Nos. 3 and 4 surgeons' silk are generally useful for such purposes. The great objection to the use of silk in the abdomen is that, if placed deep within the abdominal cavity, should a sinus form and the piece of silk at the bottom of it become infected, the sinus will remain open for years, or until the silk is expelled. An experience of this kind will teach a useful lesson, and as catgut has served its purpose so well, we unhesitatingly advise its use to the exclusion of the former.

Iodoform Gauze.—It is well for the surgeon to be supplied with iodoform gauze. It should be in strips of different widths. Strips 1 and 2 inches wide respectively will be found useful. For leaving within the abdominal cavity, the frayed edges should be turned in and sewed together. Four thicknesses are better than two. The gauze may be purchased ready-made. or, better, prepared according to the following plan: Mix together equal parts of alcohol, ether, and glycerin. Mix with this 1 part of iodoform. When the iodoform is dissolved, dip the gauze in the mixture and squeeze dry. Pack in glass jars until used.

Drainage Pad.—For ovariotomy and operations when it is possible that it may become necessary to wash out the abdomen, a rubber drainage pad is very useful, unless a special table with arrangements for drainage is in use. This pad (called the Kelly pad) should be 25 inches in diameter, with an inflatable rim and an apron extending over the edge of the table to carry away the waste. A smaller perineal pad may also be needed for

cleansing the vagina previous to the operation. The pads should be thoroughly scrubbed with soap and water and sterilized with sublimate solution beforehand.

Dressings.—For dressing the abdominal wound various materials have been used. Formerly, dusting powders and antiseptic gauze or wool were much in vogue, but at present they are rarely seen in the best clinics.

All that is necessary is a narrow piece of sterile gauze several layers thick, fastened over the line of incision with narrow sterile adhesive strips, over which a pad of gauze or gauze and cotton is fastened by means of broader strips of plaster. If desired a scultetus bandage may be applied after the gauze dressing has been put on.

The important thing about an abdominal dressing is to have it so adjusted that it will not slip out of place and expose the incision. It should not be cumbersome, nor should it be applied so tightly as to render the patient uncomfortable. The double gauze dressing above recommended fulfills its purpose admirably, as the first piece protects the incision throughout its entire length, and cannot slip beneath the superjacent pad.

In addition to the materials thus provided there should be a small table for instruments, 3 clean pails, a foot-bath tub, 2 china basins and 2 pitchers, a saucer, a tray for instruments, or, if that cannot be obtained, a large meat-platter, and a china bowl holding about a quart. Two granite-ironware basins will also be found convenient. If no sink or closet is handy, a large tub for dirty water should be provided. In the case of a large ovarian cyst, an empty clothes-boiler will also be necessary to receive its contents.

Instruments.—The instruments must be chosen according to the operation to be performed. As a general rule, the fewer the instruments the better, if everything absolutely necessary is provided. At the same time, in some unexpected emergency some little-used instrument may serve a good purpose. For the average abdominal section the following instruments will be found all that are necessary:

A scalpel with a broad-ended handle, that can be used for separating adhesions.

One pair of small straight scissors.

One pair of long scissors curved on the flat.

One pair of short scissors curved on the flat.

Two needle-holders—one large (Sims'), one small (Wyeth's).

Four long hemostatic forceps.

Twelve short hemostatic forceps.

Two Jacob's traction forceps.

Two pedicle needles, right and left.

Two Nélaton's cyst forceps. } (In case of a cyst.)
One trocar—Emmet's or Tait's. }

One strong volsellum forceps.

One dissecting forceps with broad tips.

Three glass drainage-tubes, different lengths.

Needles. The needles useful are:

The largest size half-curved surgical needles, for closing the abdominal incision.

A small, fine needle, for closing the skin.

A short, round (without cutting-edges) needle, curved near the tip, for sewing in the pelvis. The eye should be large enough to admit No. 2 catgut (Emmet's vesicovaginal fistula needle).

A strong curved needle with large eye, to sew the fascia.

Several straight cambric needles, for sewing intestine or bladder.

Sterilization of Instruments.—There are several methods in use for sterilizing instruments. Some of them are more or less destructive to the instruments, while others do not affect them at all. The placing of an instrument in a steam sterilizer, while it may effectually destroy all disease germs, certainly injures exposed steel or iron, so that knife- and scissor-edges that are not protected by nickel plate are quickly corroded. A boiling alkaline solution, while very strongly antiseptic, will not injure the instruments so much as steam. For ordinary sterilization in private houses the method recommended is to boil the instruments in such a solution for 10 minutes. Washing soda may be used for this purpose, and can generally be obtained. In default of this, a very strong solution of bicarbonate of sodium will do.

A very convenient form of sterilization has now been placed in our hands in the formalin sterilizer. Formaldehyd gas is set free in a tightly closed tin box, by an alcohol lamp, there being placed in a cup over it paraldehyd pastils. Sponges and dressings may be sterilized in the same way, but take longer.

It is a good custom to place the instruments in the sterilizer about the time the administration of the anesthetic is begun. They may then be removed at the beginning of the operation, when they will be found perfectly sterile. This method has been found very efficient and practical.

Preparation of the Operator and His Assistants.—Careful preparation of the persons and clothing of the operator and his assistants is of the utmost importance. Undoubtedly, the hands of the operator are the most common source of infection, and the utmost care should be taken to render them as sterile as possible. The careful avoidance of contact with septic material is, therefore, desirable, although often impossible. The most exact habits of personal cleanliness, both as regards person and dress, are a necessity for both operator and all those directly concerned with operations. At the time of the operation, all taking part should be clothed in carefully sterilized operating gowns. In this way all contact of hands or instruments with ordinary clothing is avoided.

The hands and the forearms, to above the elbows, should be cleansed with the most scrupulous care. The cleansing should be done with hot soapsuds and a nail-brush. With this the hands should be scrubbed for several minutes, and then kept immersed in the suds for an equal length of time. After this the soap may be washed off in clean water, and then the finger-nails should be carefully cleaned with a nail-file, both the parts under the nail and around the matrix. After this the hands should be again well scrubbed with soap and water, to remove all the partly loosened particles, and then well washed with alcohol.

Special attention should be given to the finger-tips and nails, and to the parts between the fingers. Then, while still wet, the hands should be immersed in a 1:1000 mercuric chlorid solution for 2 or 3 minutes. Merely dipping the hands into the solution is not sufficient; they, as well as the forearms, must be well washed with it. While this method may not render the hands, as tested by the bacteriologists, absolutely sterile, it has proved satisfactory in practice, and is now adopted by many operators. This method will apply to the hands of the operator and of all assistants and nurses.

The bichlorid solution should be washed off with sterile water, and sterile rubber gloves put on. The sleeves of the operating gown should be long, so that they may be tucked into the gloves at the wrist, thus completely covering the skin. The surgeon and assistant should wear linen masks which cover both head and face.

After the hands have once been rendered aseptic, great care must be taken not to touch any unsterilized objects, such as articles of furniture, clothing, the head and face of the individual, or unsterilized portions of the patient's body. If it should become necessary to do this, the hands should be again thoroughly immersed in the sublimate solution.

Anesthetics.—Ether has unquestioned advantages over chloroform in the greater degree of muscular relaxation which it induces. Its irritating effect on the kidneys renders it dangerous where there has been any previous trouble with those organs; and in cases of this kind, or where bronchitis or other pulmonary disorders exist, chloroform may be substituted. The anesthetic should be in the hands of a skilled administrator. See ANESTHETICS.

Technic of Operation.—All the preparations having been made, as already indicated, the patient, being thoroughly anesthetized, is placed upon the operating table. The lower extremities should be enveloped in warm flannel drawers or stockings.

If any operation is to be done that will involve opening the vagina—such as total extirpation of the uterus—the patient should be placed upon the perineal pad, and the vagina should be thoroughly scrubbed with a piece of gauze held in a dressing forceps, previously dipped in green soap. After the scrubbing the soap should be washed out and the vagina syringed with a 1:2000 sublimate solution. If there is any septic material coming from the uterus, as in cancer of the body, the uterus should be first thoroughly curetted and packed with iodoform gauze. A cancerous cervix should also be curetted, disinfected, and the vagina lightly packed with iodoform gauze.

These steps completed, the patient is placed full length upon the table, and the lower extremities firmly fastened to the table. Over the legs and thighs, as far as the symphysis, should be placed a heavy blanket inclosed in a sterilized sheet, the legs being wrapped in this as much as possible. The night-dress of the patient should be pushed up nearly to the armpits, and a folded sheet placed around the body below it, just below the breasts, to prevent the soiling of the patient's clothing.

If the abdomen has been properly prepared, no steps in this direction need be taken; but if the preparation has not been made, the abdomen should now be shaved, scrubbed with green soap and water, followed by a mixture of equal parts of alcohol and ether, and then scrubbed with the mercuric chlorid solution, 1:1000.

It is a good custom to place a rubber sheet (rubber on both sides) over the patient, reaching nearly from the clavicles to the knees, in which an opening about a foot long has been made. This must be carefully sterilized. Towels dipped in 1:1000 sublimate solution and wrung out are folded over the edges of the opening in the rubber sheet on each side, and a similar towel is laid across the chest and another across the thighs of the patient. In this way the patient's skin is protected and is not too much cooled by the dampness. The rubber sheet prevents evaporation, and unquestionably tends to prevent shock and depression from undue cooling of the surface.

The operator then takes his stand at the left side of the patient. Immediately beside the operator should be placed the table containing the tray with instruments, the bowl with the short hemostats, and the saucer with the needles. The jars of catgut and silk should also be arranged upon this table, a nurse standing behind it ready to thread needles, cut catgut, and pass instruments. Opposite the operator should be the assistant, and behind him and to his right should be another nurse, whose duty it is to take care of the sponges. She should have 2 pails of hot sterilized water, placed upon chairs or a bench, one for washing out the blood from the sponges, and the other for rinsing them before handing them back to the assistant. Two granite-ironware basins may be placed upon the legs of the patient, one for holding clean sponges, and the other for receiving the soiled ones. The nurse may thus take the soiled sponges from one basin, wash them, and return them to the other.

The **first step** of the operation consists in incising the abdominal wall. The site of the incision must depend on the organ to be operated upon. As all operations are, in a sense, exploratory, the first incision should be quite small—barely large enough to admit one or two fingers. It may be enlarged later, according to circumstances. The incision through the skin is made with a scalpel, after which the different layers are picked up and held tense between two hemostatic forceps, and cut with the scissors. If the peritoneum is opened in this way, air will enter the moment it is nicked, and it will balloon open, allowing the intestines or omentum to fall back into the abdominal cavity. In this way it can be incised with perfect safety.

The abdomen being opened, two fingers, or the whole hand, as may be necessary, are introduced for exploratory purposes. An exact diagnosis of the condition having been made, the operation is then either abandoned or proceeded with, according to circumstances. If dense adhesions are encountered, as in the case of large growths, they can usually be broken up with the hand; it is generally recommended that this should be done before the tumor is reduced in size in any way. In case of in-

flammatory exudates in the pelvis, a line of cleavage can generally be found between the different adhering organs. In this way ovarian abscesses and pus-tubes can be gently and carefully separated by the finger-tips and freed from adhesions to surrounding organs. The greatest care should be taken not to injure the intestines. If the intestines are found to be adherent, it is well to place the patient in the Trendelenburg posture, and to try to dissect them loose, sight being relied on rather than touch.

All bleeding points should be tied as soon as possible, and all bands of adhesion should be tied on both sides before cutting. Pedicles may best be tied by the Bantock knot. This prevents the slipping of the ligature.

In cases of hysterectomy the arteries supplying the uterus may be tied before they are cut, thus preventing nearly all hemorrhage. In the case of large cystic tumors, after the cyst has been emptied with the trocar it should be removed from the abdomen and the pedicle carefully ligated. If the hemorrhage from the tumor is severe, the pedicle can be clamped until it is tied, the clamps being removed at the moment that the ligature is tightened.

After the diseased parts are removed or the operation is completed, the toilet of the peritoneum should be most carefully made. All oozing should be checked by pressure, by tying bleeding places, or by sewing under the bleeding area with catgut. Adhesions or injured spots on the omentum that continue to bleed should be carefully tied. All clots, débris from tumors, pus, or other extraneous matter should be carefully sponged out. If this proves difficult or impossible, the abdomen may be flooded with hot normal salt solution (about a dram to the pint). This may be poured in from a pitcher. The patient should lie on a pad to carry off the water. Small dram bottles of sterilized salt may be prepared beforehand.

After the operation is completed and the peritoneal cavity thoroughly cleansed, the omentum should be carefully placed over the intestines, and on top of it a flat sponge or pad, when the operator may proceed to close the abdominal incision. There are many ways of doing this. A very satisfactory method is to close the peritoneum with a continuous suture of fine catgut, either plain or chromicized, then to suture the fascia and muscle with chromicized catgut No. 2, and finally to close the skin with interrupted sutures of silkworm-gut. But before the suture is completed, the flat sponge should be withdrawn from the abdomen, and the nurse directed to count the sponges. This she must do aloud, counting the sponges separately from one basin into another. If pads have been used, the exact number should be known beforehand, and every one must be accounted for at this time. The difficulty of keeping an accurate count of pads is an objection to their use. By having them done up in packages containing an equal and definite number a better count can be kept, as the opening of each new package adds a definite known number to those already in use. Many cases have occurred in which sponges and instruments have been left in the abdomen, hence the necessity for extreme care. Through-and-through sutures of silkworm-gut are not used as much as formerly, most operators believing that tier suturing is preferable. In closing long incisions three or more silkworm-gut sutures may be passed through muscle, fascia and skin after the peritoneum has been closed, if the operator thinks they will afford additional protection against reopening of the wound. They are clamped with hemostats and tied after the fascia has been sutured in its continuity. There is ample experience to show that this procedure is unnecessary.

After the incision has been closed, the abdomen should be washed and dried and the dressing applied in the manner above described.

The patient should then be placed in bed, surrounded by hot-water bags or bottles, the greatest care being taken that the water is not hot enough to burn her.

Drainage.—Drainage has fallen into disuse, and is now used only in very particular instances. It has been found that the peritoneum can resist the invasion of a very large number of pyogenic bacteria, and that patients do better without drainage than with it. In pelvic surgery, particularly in pus cases, drainage has been extensively used; but of late long series of cases have been reported without drainage, and with an exceedingly low rate of morbidity and mortality. Some of the objections to the drain are that the drainage-tube tract is likely to become infected, with a resulting sinus; the greater tendency to suppuration of the abdominal wound; and the far greater frequency of ventral hernias following. In pelvic surgery the glass drainage-tube may be used, but it is not applicable in other cases. In operations in the upper part of the abdomen the drainage-tube can seldom be used, and here we must substitute gauze drains.

The cases that should be drained are abscesses within the peritoneal cavity that are walled off, and whose walls cannot be removed; extensive peritoneal suppuration; tubercular peritonitis; and when the intestine, bladder, or gall-bladder has been sutured and there is fear that the suturing will not be tight. With these, and possibly a few other very rare exceptions, drainage within the abdominal cavity may be entirely dispensed with.

Should the glass drainage-tube be used, its contents should be emptied by a long-nozzled uterine syringe, the greatest care being taken that the syringe and all the surroundings are entirely aseptic. Even with the utmost care, infection is likely to occur. The tube should be emptied at first every 10 or 15 minutes, the intervals being increased as the amount of effusion diminishes. The tubes may be removed in from 24 to 48 hours, or when the discharge ceases. Gauze drains may be left in for periods varying from 2 to 6 days. Their removal causes intense pain, which makes it advisable to use them as rarely as possible.

The pelvis is sometimes packed with gauze to check oozing. This is very rarely necessary, but is an efficient means of saving life in exceptional cases. This can hardly be called drainage.

In a small proportion of cases in the pelvis

drainage may be effected by opening into the posterior culdesac of the vagina. A gauze drain should then be placed in Douglas' pouch, a portion of it being pushed through into the vagina. It may be removed in from 2 to 4 days. Such drainage is very rarely necessary.

After-treatment.—The after-treatment of a person on whom abdominal section has been done can best be carried out if we will remember that the less we do the better. The work of the surgeon having been performed, the natural recuperative powers of the patient must be relied on to complete the processes of repair. For the first 24 hours the patient's diet should be restricted to water. This, in most cases, may be allowed in large quantities. If vomiting exists, the water will do no harm, even if it is rejected, as it thus washes out the stomach; at the same time, a certain amount of it is absorbed. Morphin should be used as sparingly as possible. The great majority of cases require none. Occasionally, in very sensitive individuals, morphin will be needed in small doses for the first 24 or 36 hours. It should be dispensed with as early as possible. Codein may often be substituted with advantage.

Patients probably suffer more from intestinal colic due to gas than from any other one thing. This may be avoided in part by having the intestinal tract thoroughly cleared out before the operation, and by avoiding all foods that ferment until the digestive processes are resumed. The anesthetic, as well as the handling of the intestine and the shock of the operation, seem to check the digestive function, and it is only resumed after several days, and then slowly. Food, therefore, is of no use to the patient.

On the third day after operation small quantities of broth may be administered, and if retained and digested, the patient may soon receive solid food. The juice of oranges or other fruit is often acceptable at an early day, relieving the dryness of the mouth and throat.

In case of extreme vomiting, the usual remedies may be applied. The smelling of vinegar, drinks of very hot tea or water, the use of bismuth, oxalate of cerium, carbolic acid in drop doses, and similar agents may be tried. The washing out of the stomach will often prove beneficial, especially with patients who are familiar with the procedure.

The bowels may be moved on the third or fourth day by means of fractional doses of calomel, followed in 12 hours by a saline laxative and an enema. If the intestinal tract has been thoroughly cleaned out before the operation, there is no need of administering laxatives so early as was formerly the practice, for instance 24 hours after the operation.

Distention may be relieved by the use of the rectal tube, small high enemata of emulsion of asafetida, and the internal administration of salol and chloroform, according to the method of Wm. H. Teller, who mixes equal parts of the two drugs and gives 3 drops in a teaspoonful of brandy every 3 or 4 hours. The chloroform completely dissolves the salol, forming a thick heavy liquid, which is held in solution in brandy or whiskey, but not in water, as the latter precipitates the salol. This mixture may be given any time after the first 24 hours.

The skin sutures may be removed on the eighth to tenth day, the wound being supported by 2 or 3 long strips of adhesive plaster for a few days longer. The bursting open of the wound after the removal of the stitches has occurred; but usually, in this event, a prompt reclosing of the abdomen is followed by no injury.

The patient may be allowed to sit up after the fourteenth or fifteenth day, and thereafter to gradually resume her usual mode of life. In most instances it is well for the patient to wear a well-fitting abdominal supporter for 6 months after the operation, in order to remove all strain from the newly formed cicatrix, and thus to diminish the danger of a ventral hernia.

ABDOMINAL TUMORS.—These are best classified as follows:

1. **Tumors of the parietes,** including inflammations, abscesses, cysts, fatty and fibrous growths, sarcoma, carcinoma, obesity, edema, elephantiasis, ventral and umbilical hernias, and spasmodic contraction of an abdominal muscle.

2. **Intraperitoneal tumors,** which may arise from the peritoneum, liver, gall-bladder, pancreas, spleen, stomach, intestine, omentum, mesentery, bladder, uterus, round ligaments, broad ligaments, Fallopian tubes, or ovaries, subperitoneal cysts, peritoneal effusion, peritoneal hematocele, tympanites, ascites, phantom tumors, and extrauterine pregnancy.

3. **Retroperitoneal tumors,** including aortic aneurysms, abscesses, cysts, fibroma, sarcoma, carcinoma, kidney tumors, and hematocele. See Abdomen (General Physical Diagnosis), Liver, Kidney, Stomach, Uterus, Hernia, Ascites, etc.

ABDUCTION OF THE EYE.—The power of the external recti, measured by the maximum ability to preserve singleness of vision with prisms placed bases toward the nose. It is commonly from 6 to 8 degrees. See Eye-muscles (Anomalies).

ABORTIFACIENTS.—Drugs or agents causing the expulsion of the fetus or ovum. Their mode of action is not clearly understood, but it is generally regarded as due to direct stimulation of the uterine center in the cord or to congestion of the uterus that produces reflex stimulation thereof. Any drastic purgative or gastrointestinal irritant may produce this reflex action. Most volatile oils act thus, as do colocynth, tansy, pennyroyal, and many other vegetable agents used by women to produce abortion. All abortifacients are dangerous to life in doses sufficient to excite action of the gravid uterus. If abortion is indicated, it should be effected by instrumental means. The principal drugs used as abortifacients are borax, cotton-root bark, ergot, hydrastis, oil of rue, pilocarpin, potassium permanganate, quinin, savin, ustilago, viscum flavescens (mistletoe), and strong purgatives. Injections of glycerin are a dangerous means of inducing abortion. See Emmenagogs, Oxytocics, Abortion, Abortion (Induction).

ABORTION.—The expulsion of the ovum before the fourth month.

Frequency.—The frequency of abortion is very

difficult to estimate; it is probable, however, that it occurs once in every four or five pregnancies.

Causes.—The causes of abortion may be briefly enumerated as follows:

1. Any pathologic condition of the ovum, membranes, or placenta, such as apoplexies, cystic degeneration of the chorionic villi, and cellular infiltration of the placenta.

2. Certain general diseases of the mother, including syphilis; typhoid fever; the exanthems; conditions interfering with proper aeration of the blood, as pneumonia and valvular heart-disease; various systemic poisons, as malaria, lead, and arsenic; certain blood-diseases, as grave anemia and leukocythemia; various local conditions, such as metritis, salpingitis, and ovaritis, cystitis, appendicitis, and placenta prævia.

3. Diseases of the father, such as syphilis, phthisis, and nephritis, in which the spermatozoa are diseased or of lessened vitality.

4. Death of the fetus from any cause.

5. Traumatism, as from a fall, a blow, or a kick on the abdomen.

6. Spasmodic muscular action, as in chorea, uncontrollable vomiting or coughing, convulsions of any kind.

7. Reflex causes, as violent emotion or mental shock. When the uterus shows a tendency to contract under the slightest stimulus (irritable uterus), any trivial cause, such as a long walk, a hot bath, or even the sight of another woman in labor, may result in abortion.

8. Criminal abortion, caused by the use of drugs, vaginal and uterine injections, and the introduction of an instrument into the uterus.

Symptoms.—The symptoms of abortion vary with the duration of pregnancy. Occurring during the first few weeks of gestation (**ovular abortion**), there will be hemorrhage, more or less profuse, intermingled with which there will be dark, fleshy masses (*decidua*). To these symptoms there may be added a sense of vague pain and discomfort in the sacral region. During the second and third months (**embryonic abortion**) the clinical phenomena will be more pronounced. There are continued and increasing hemorrhage, cramp-like bearing-down pain of a pronounced character, and finally expulsion of all or a part of the ovum. The physical signs at this period are well marked: at first the cervix will be found soft and the os slightly dilated; the uterus will be felt enlarged and soft behind the symphysis; later, the angle of anteflexion between the upper and lower uterine segments will be effaced (*Tarnier's sign*); and, finally, portions of, or the entire, ovum may be felt presenting. Occurring during the fourth, fifth, and sixth months (**miscarriage**), the symptoms will be still more pronounced; the hemorrhage is likely to be profuse, and may even be fatal; the pain will be severe, intermittent, and cramp-like, resembling labor pains at term; the membranes will rupture, with discharge of liquor amnii, and the fetal parts presenting may be distinctly felt by the examining finger. Occurring after the sixth month (**premature labor**), the clinical phenomena are in nowise different from those of labor at term.

Duration.—The time consumed in the expulsion of an ovum varies considerably. It may extend over a period of days, or even months, and it may occur almost instantaneously (**instantaneous abortion**). Usually the duration of a spontaneous abortion is from 24 to 48 hours.

Diagnosis.—The following table shows the main diagnostic points in the various forms of abortion:

Threatened Abortion.	Inevitable Abortion.	Incomplete Abortion.	Complete Abortion.
Hemorrhage slight and usually free from clots.	Hemorrhage profuse and continuous, clotted and dark colored.	Hemorrhage persistent, at times profuse, at others scanty, dark colored and offensive.	Entire cessation of hemorrhage.
Pain not marked.	Pain cramp-like and severe.	Occasional attacks of pain may be present.	Entire cessation of pain.
Os slightly patulous.	Cervical canal dilated.	Cervical canal dilated: admits finger, which feels portions of decidua, membranes, and blood-clot.	Os retracted.
Uterus soft, enlarged showing angle of anteflexion between upper and lower uterine segment.	Uterus soft, enlarged angle between upper and lower uterine segment effaced.	Uterus large, soft, and baggy; not involuting.	Uterus large, but retracted and firm; involution proceeding normally.
Discharge is bright colored blood.	Discharge consists of dark blood, clots, and portions of ovum.	Examination of discharged material shows only portions of the ovum.	Discharge is the ordinary lochia, which gradually ceases.
All signs of pregnancy present except amenorrhea.	Signs of pregnancy present except amenorrhea.	Signs of pregnancy arrested.	Subsidence of the signs of pregnancy with possibly the establishment of the milk secretion.

The diagnosis of miscarriage may be made by the history of the duration of pregnancy, fourth to sixth month inclusive; by discharge of the liquor amnii; by the greater pain and hemorrhage; by the stage of development of the fetus; and probably by the establishment of the milk secretion and lochial flow.

Prognosis.—The ovum is inevitably destroyed. The immediate dangers to the mother are hemorrhage and sepsis. During the first 3 months the ovum is likely to be expelled entire, and these dangers are therefore slight; from the fourth to the seventh month, however (**miscarriage**), the

placenta is intimately adherent to the uterine wall, portions of which, remaining in the uterine cavity, give rise to continued hemorrhage and septic infection. The remote dangers are subinvelution, endometritis and metritis, displacements, menorrhagia and metrorrhagia, salpingitis and ovaritis, and sterility.

Mortality.—The death-rate of spontaneous abortion and miscarriage is about 1.5 percent. The mortality of criminal abortion cannot be definitely computed; it is probably from 5 to 20 percent.

Prophylactic treatment comprises the correction of any ascertainable cause of abortion. If the patient has aborted a number of times previously (**habitual abortion**), or if there exists any other reason for suspecting premature expulsion of the ovum, a definite line of treatment should be instituted. Active exercise, such as the lifting of heavy weights, reaching for objects far above the head, bicycle or horseback riding, should be interdicted. Excessive sexual intercourse or other source of pelvic congestion should be avoided. Rest in bed at the periods corresponding to the normal menstrual epoch will be found beneficial. Local conditions, such as displacements, laceration of the cervix, and inflammatory pelvic disease, should be treated prior to pregnancy. If there is a history of syphilis in either parent, active antisyphilitic treatment should be instituted throughout the entire course of pregnancy.

Treatment of Threatened Abortion.—This includes rest in bed, with absolute quiet; the administration of nerve sedatives, preferably suppositories of opium—1 grain of the extract morning and evening; this may be supplemented by teaspoonful doses of the fluidextract of viburnum prunifolium 4 times daily.

If the abortion is due to general disease, such as typhoid fever, pneumonia, phthisis, or valvular heart-disease, no attempt should be made to prevent it.

Treatment of Inevitable Abortion.—If the preceding plan of treatment fails to control the symptoms, and if, in addition to pain and hemorrhage, there is dilatation of the os with expulsion of portions of decidua, treatment to prevent abortion will be of no avail, and appropriate measures must be instituted to hasten the emptying of the uterus.

Two methods of treatment have been advised for these cases. The first is **the expectant plan,** which may be described briefly as follows: Place the patient in bed, and if the bleeding is profuse, insert a tampon of iodoform gauze (1 yard) well up against the cervix. If this fails to control the hemorrhage, reinforce it by another yard or two of gauze and a perineal pad and binder. Small doses (1/2 of a dram) of the fluidextract of ergot should now be given every 2 or 3 hours. At the end of from 8 to 12 hours remove the tampon, when the ovum may be found extruded from the cervix; if not, a vaginal douche of mercuric chlorid (1 : 4000) must be given, and another tampon introduced. If upon the removal of this second tampon at the end of 10 or 12 hours the ovum is not discharged, then more vigorous methods to secure its expulsion must be adopted; these will be described under the active and better method of treatment.

The active plan comprises the following: (1) The physician's hands and instruments are sterilized; (2) the patient is etherized and placed on an appropriate table, or across the edge of the bed, her buttocks resting upon a Kelly pad; (3) the perineum, inner part of thighs, pubes, vulva, and vagina are thoroughly scrubbed with equal parts of tincture of green soap and water, using a soft nail-brush or pledgets of cotton, followed by a vaginal douche of mercuric chlorid (1 : 4000); (4) the anterior lip of the cervix is grasped with a double tenaculum and drawn well down to the vulvar orifice; (5) if necessary, the cervix is now dilated with a branched steel dilator (Wathen's) up to 1 1/2 inches; (6) placental forceps (Thomas') are now passed carefully into the uterus, and the ovum and greater part of the decidua quickly removed; (7) this is followed by thorough but careful curettage, leaving the uterine cavity free from any deciduous membrane or blood-clot; (8) an intrauterine douche of sterile water should now be given, preferably with a fountain syringe and a two-way metal catheter; (9) a light tampon of iodoform gauze is now placed in the vagina and the patient returned to bed.

A strip of gauze may be placed in the uterus in cases of sharp retroflexion, to secure free drainage, and occasionally an intrauterine tampon will be necessary when the uterus refuses to contract and hemorrhage persists after the use of the curet.

After-treatment.—The after-treatment of abortion comprises rest in bed for 10 days or 2 weeks, removal of tampon at the end of 24 hours, followed by a vaginal douche of mercuric chlorid (1:4000). The diet should be light and easily digested, and the bowels should be evacuated at the end of the second day. Later, a normal involution and return to perfect health will be favored by the administration of nutritious food and tonics.

The foregoing treatment is applicable to those cases occurring before the fourth month of gestation; after this time (**miscarriage**) the treatment is the same as for labor at term. See LABOR.

ABORTION, INDUCTION.—Emptying the pregnant uterus of its contents before the viability of the child (one hundred and eightieth day).

Indications for the Induction of Abortion.—(1) Pathologic vomiting, vomiting resisting all other treatment, particularly rectal alimentation; (2) albuminuria accompanied by casts, edema, excessive blood-pressure, persistent headache, and failing vision; (3) profuse uterine hemorrhage from premature separation of the membranes, or placenta prævia; (4) rarely, certain nervous diseases, such as chorea, acute mania, and melancholia; (5) blood-diseases, as pernicious anemia and leukocythemia; (6) certain local conditions, as retroflexion, prolapse, hernia of the uterus; (7) death of the embryo, as evidenced by a foul discharge and the disappearance of the presumptive signs of pregnancy; (8) intrauterine disease, as cystic degeneration of the chorionic villi, and hydramnios.

In general, it may be said that abortion should be induced if the mother's life is endangered by any condition or disease originating in or aggravated by pregnancy.

Method of Inducing Abortion.—The quickest, easiest, and best method of inducing abortion, applicable until the beginning of the fourth month, is as follows: (1) Disinfect the cervical canal, vagina, vulva, pubes, and inner part of thighs by scrubbing thoroughly with tincture of green soap and pledgets of cotton, followed by a vaginal douche of mercuric chlorid (1:4000); (2) seize the anterior lip of the cervix with a double tenaculum and draw it well down to the vulva, thus fully exposing the external os and straightening the cervical canal; (3) dilate the cervical canal with branched dilators (Wathen's) up to 1 1/2 inches, using first the smaller, then the larger, instrument; (4) remove the embryo and decidua with placental forceps (Thomas'), followed by thorough curetting with a sharp curet (Sims'); (5) irrigate the uterine cavity with warm sterile water, using a fountain syringe and a two-way metal catheter; (6) place a light tampon of iodoform gauze in the vagina, which may be removed at the end of 24 hours.

After the end of the third month of gestation the method of inducing abortion is the same as for the induction of premature labor. See Labor (Premature).

Medicolegal Aspect of the Induction of Abortion.—The following points relate only to criminal abortion:

1. It is a felony for any woman to take any drugs, use any instrument or any means whatsoever, for the purpose of producing an abortion upon herself.

2. It is a felony for any person to administer or cause to be administered to any woman any drugs, or cause to be used any instrument or other means whatsoever, for the purpose of producing an abortion upon her.

3. It is a misdemeanor to supply or cause to be supplied to any woman or any other person the means whereby abortion may be produced.

4. If the attempt is made to produce abortion, it makes no difference whether the woman is pregnant or not.

5. It makes no difference whether an injury is inflicted or not.

6. It makes no difference whether the attempt to commit abortion is successful or not.

7. It makes no difference what stage of pregnancy the woman is in at the time the attempt is made.

8. If death takes place from an attempt to produce abortion, the agent is indictable for wilful murder.

9. It makes no difference if the woman consent to, or even solicit, the attempt to produce abortion.

10. The victim is always considered an accomplice, and her evidence against the agent must be corroborated by other testimony.

ABRASION.—Excoriation of a mucous or cutaneous surface by mechanic means. The treatment consists generally in cleanliness, protection, and rest of the part. If the abrasion is extensive, sedative lotions and protective and emollient ointments may be employed, such as solutions of tannic acid, rose water, lead-water, zinc ointment, vaselin, etc.

ABSCESS.—See Suppuration.

ABSCISSION.—Removal of a part, as the prepuce, or a fractured bone, by cutting. Applied particularly to a surgical operation upon a staphylomatous cornea, in which the bulging portion is excised and the parts are brought together so that the posterior and chief part of the globe forms a "stump" for an artificial eye.

ABSINTHE.—A French liqueur; it is an alcoholic solution of the oil of absinthium (wormwood) exhibited with extract of anise, marjoram, and angelica.

ABSINTHISM.—Excessive drinking of absinthe induces marked symptoms earlier than those caused by the persistent use of other forms of alcohol. Besides epileptiform convulsions and tremors, especially of the upper extremities since the cervical part of the spinal cord is especially affected, there are observed hallucinations and vertigo.

ABSORBENT.—A drug or medicine that produces absorption or exudation of diseased tissue: as, *e. g.*, the iodids and mercurials. In surgery, a substance that mechanically takes up excreted matter, such as cotton, sponge, charcoal, magnesia, chalk, etc.

ACACIA (Gum Arabic).—A gummy exudation from *Acacia Senegal.* It occurs in roundish tears of various sizes, or broken into angular fragments, whitish or yellowish-white, translucent, very brittle; insoluble in alcohol, but soluble in water, forming a thick and mucilaginous liquid. It consists of *Arabin*, combined with calcium, magnesium, and potassium. Incompatible with acacia, are: Alcohol, ammonia, ether, ferric salts, lead subacetate, mineral acids, potassium tartrates, syrup of squill. Acacia has no physiological activity but that of a demulcent; it is chiefly used in coughs, sore throat, inflamed conditions of the stomach or intestines, in irritant poisonings, and as an external protective for burns, ulcers, and excoriations.

There are two special preparations: **Mucilage of A.**, containing acacia 34, lime-water 33, and water to 100. Dose, 4 drams. **Syrup of A.**, containing acacia 10, sugar 80, and water to 100.

ACANTHOSIS NIGRICANS.—A rare cutaneous disease characterized by increase of pigmentation associated with papillary hypertrophy developing even into verrucous nevus-like excrescences. The most common sites are the axillary, genitocrural, anal, and abdominal regions; also the neck and face. Epitheliomatous degeneration is sometimes observed in the lesions. In most cases, carcinoma is discovered in one of the abdominal organs. If a malignant growth is not present, the course of the disease is slow. Treatment is simply hygienic and expectant.

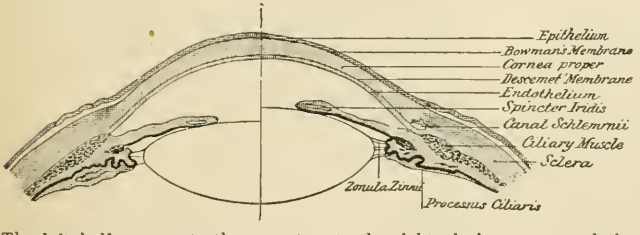
ACARUS SCABIEI.—See Scabies.

ACCESSORY SINUSES OF NOSE.—See Nose (Accessory Sinuses).

ACCOMMODATION.—Rays coming from a distant object—that is, beyond six meters—may be considered, for practical purposes, as parallel, and the normal eye at rest gives them such convergence that they are brought to an exact focus on the layer of rods and cones of the retina. Rays from any given point of a nearer object approach the eye with a divergence so considerable that they cannot be focused on the retina by the simple refractive properties of the dioptric system of a normal eye. However, to obviate this difficulty the eye has the faculty of increasing its refractive power in order to give increased convergence to the rays coming from a near object, and this change in the eye is called accommodation.

The Mechanism of Accommodation.—Optically considered, the extra divergence might be neutralized in two ways: by displacement of the retina backward, or by a shortening of the focal distance of the dioptric apparatus of the eye. Investigations have proved that accommodation is effected through the dioptric apparatus, the increased refractive power being due to a change of the curvature of the refractive surfaces of the lens. It is commonly believed that this is effected in the following manner: The ciliary muscle contracts, thus relaxing the suspensory ligament of the lens, allowing the inherent elasticity of the lens to act and push forward the anterior surface, which, by becoming more convex, increases its refractive power. The posterior surface of the lens scarcely alters in shape. This view is not accepted by Tscherning, who maintains that the ciliary muscle in contracting increases the tension of the suspensory ligament, and thus induces bulging of the lens anteriorly outward, and hardly at all toward the periphery. However, all theorists believe that ciliary contraction is the important factor in accommodation, although they differ as to how it acts. Associated with the act of accommodation is a simultaneous contraction of the pupil. The elastic power of the lens is due to a peculiar watch-spring arrangement of its fibers.

The Far and Near Points.—When the ciliary muscle is entirely relaxed and the eye is completely



The left half represents the eye at rest; the right, during accommodation.

at rest, distant objects are received at an accurate focus on the retina, and the eye is said to be adapted for its **far point**, or **punctum remotum**. When, however, the ciliary muscle has contracted to its fullest extent, the lens becomes convex to its greatest degree, and the nearest point from which rays may diverge and yet focus on the retina is called the **near point**, or **punctum proximum**. This is found by directing the patient to look at some fine print of a definite measurement, and bringing it slowly closer and closer to the eye until it becomes blurred and illegible, and noting the distance from the eye of the point where the print is still distinct. The print may be brought up close to the eye, and carried slowly away until it is first legible; the distance of this point from the eye gives an equally accurate result.

The distance between the far and near points is called the **range** or **amplitude of accommodation.** This range is dependent on the elasticity of the lens and lessens with advancing age, until about seventy or seventy-five years, when it becomes *nil* and the eye is incapable of adjusting itself for objects nearer than infinity. The range of accommodation is usually expressed in diopters, and is represented by that convex lens which, placed closely in front of the eye, would take the place of the increased convexity of the lens in giving rays from a near point a direction as if they came from infinity. The table in the article on PRESBYOPIA gives the range of accommodative power which an emmetropic eye at different ages is found to possess.

In hyperopia the range of accommodation is diminished to an extent expressed by the number of a lens which will enable the eye to see distant objects without accommodation.

The Association between Accommodation and Convergence.—**Convergence** is the power of directing the visual axes of two eyes to a near point, and is effected chiefly by the action of the internal recti. The nearer an object, the more convergence is necessary, and usually for every increase of the convergence there is a certain increase in accommodation, the internal recti and ciliary muscles acting in unison. Although accommodation and convergence are usually harmonious in action, they may take place separately and independently. If we paralyze the accommodation with a mydriatic, convergence is not interfered with, and also in advancing life, when greater contraction of the ciliary muscles is necessary to produce the requisite change in the convexity of the lens, the amount of convergence remains the same. It must be remembered that the relations between accommodation and convergence are necessarily very different in ametropia. See PRESBYOPIA.

ACCOMMODATION, AGENTS AFFECTING.—See MIOTICS, MYDRIATICS.

ACCOMMODATION, FAILURE.—See PRESBYOPIA.

A. C. E. MIXTURE.—An anesthetic mixture composed of alcohol 1 part, chloroform 2 parts, ether 3 parts. See ANESTHETICS.

ACETANILID (Antifebrin).—Phenyl-acetamid. A synthetic compound obtained by the interaction of aniline and glacial acetic acid. The trade name *Antifebrin* is copyrighted, and should be dropped from professional usage.

Acetanilid occurs in colorless, inodorous, glistening, lamellar crystals, of slightly pungent taste, soluble in 200 of cold water, 18 of boiling water, 4 of alcohol, freely in ether and in chloroform. Aver-

age dose, 4 grains; death has occurred from 5 grains, and recovery has taken place after a dram.

Incompatibles are: Alkaline bromids and iodids, chloroform, hydrated chloral, phenol, potassium and sodium hydroxids, resorcinol, spirit of nitrous ether, thymol.

Action.—Antiseptic, hemostatic; antipyretic; analgesic; diuretic; diaphoretic; depresses the heart, causes formation of methemoglobin, and disintegration of red blood-corpuscles; may induce skin eruptions. It is believed that acetanilid and other antipyretics of its class act through alterations produced in the heat-regulating mechanism which result in lowering the point at which the temperature is maintained. Consequently, a great increase in the dissipation of heat must take place in order to get rid of the warmth that has accumulated in the body, and this augmented output is attained by dilatation of the cutaneous blood-vessels. Their principal action practically, therefore, is by causing an increased heat loss through this vascular effect, by reason of which a large amount of blood is exposed to the cold air.

Therapeutics.—Externally, for venereal and other ulcerations, urticaria, eczema, erysipelas and other affections associated with considerable irritation, and as an antiseptic for wounds; internally, for the reduction of pyrexia and as an analgesic for neuralgias, dysmenorrhea, locomotor ataxia, migraine, and various headaches. Several proprietary remedies containing acetanilid are used to a considerable extent. On account of the danger of collapse effects, it is now generally considered preferable to reduce the temperature in fevers, when this is desired, by cold baths and other means.

There is one preparation: **Pulvis acetanilidi Compositus,** compound acetanilid powder; containing acetanilid 70, caffein 10, sodium bicarbonate 20. Average dose, 7 1/2 grains.

For neuralgias:

℞. Acetanilid, gr. x
Monobromated camphor, gr. v.
Make into 10 pills.
One pill every 2 hours.

℞. Acetanilid, gr. x
Quinin salicylate, gr. x.
Make into 10 powders.
One powder 3 times daily.

In such dermal diseases as eczema and in burns it may be used as an external application:

℞. Acetanilid, gr. xl to lx
Cold cream, ℥ j.
Make into an ointment and apply locally.

Poisoning by this drug is manifested by cyanosis, expressionless or anxious face, sweating, a soft, compressible, slow, and weak pulse, and shallow, slow respiration. Secondary anemia is present in a variable degree and the spleen is enlarged.

The blood has the characteristic chocolate-color normethemoglobinemia and does not regain its formal color on exposure to the air. The urine is dark in color and contains paramidophenol and an increased amount of ethereal sulphates, sometimes methemoglobin. Acetanilid poisoning results from ingestion of a toxic dose, from prolonged addiction or the external application of the drug to burns, ulcers, etc., where the absorbing surface is extensive. Stimulants, external heat, belladonna to maintain blood pressure, cardiac stimulants, such as strychnin, and oxygen inhalations are indicated.

Acetanilid habit is occasionally observed from the use of "headache powders," the chief ingredient of which is acetanilid. The victims present albuminuria, circulatory disturbances, as blue mucous membranes, weak irregular heart, and edema of feet and ankles, in conjunction with a total loss of moral sense.

ACETIC ACID.—A clear liquid, made up of 36 percent of absolute acetic acid ($CH_3.COOH$) and 64 percent of water, of acid taste, and miscible with water and alcohol. Dilute acetic acid contains 6 percent of the absolute acid and is the equivalent of vinegar. The glacial acetic acid is almost absolute acetic acid and is a powerful escharotic, and may be used to remove warts and other growths, and to apply to old sores where granulations are profuse and slow to heal. Dilute acetic acid is useful in various superficial skin-inflammations, such as sunburn, and in sprains. As an injection to expel seatworms, it should be diluted to 3 or 4 times its bulk with water. A lotion of acetic acid may be useful in night-sweats and to arrest epistaxis. It is a harmful remedy in obesity. It should not be taken by nursing mothers, as it may produce diarrhea in the child. Chemically pure acetic acid is commonly used to acidulate urine before examination.

In **poisoning** by acetic acid large quantities of milk should be given, besides alkaline liquids, such as lime-water, soap-water, etc., followed by the treatment of gastroenteritis.

For removal of vegetations about the external genitals:

℞. Salicylic acid, gr. xxx
Acetic acid, ℥ j.
Apply with a camel's hair brush.
Little pain is caused by this application.

For sponging the body in fever:

℞. Dilute acetic acid (or vinegar), ℥ j
Water, ℥ ij to iv.

ACETONE.—$CO\langle^{CH_3}_{CH_3}$ Dimethyl ketone. A colorless, mobile and volatile liquid, of peculiar odor and burning taste, present in crude wood-spirit. It occurs in small quantities in the blood and in normal urine, and in considerable quantities in the urine of diabetics; it is often a forerunner of diabetic coma, and is sometimes found in cases of carcinoma and cerebral lesion. Like methyl alcohol, it is miscible in all proportions with ether, alcohol, and water. It is an excellent solvent for

resins, gums, camphor, fats, and gun-cotton. It has anesthetic, hypnotic, and anthelmintic properties; and it has been used in cases of rheumatism and gout. The test for acetone is described under URINE (Examination).

ACETONURIA.—This is found in autointoxication of intestinal origin, after chloroform anesthesia, in cancerous cachexia, states of inanition and febrile, infectious and septicemic conditions, and certain nervous diseases such as tabes dorsalis and melancholia. The combination of acetone and sugar in the urine is good evidence of diabetes. See ANESTHESIA (Sequels); URINE (Examination).

ACETOZONE.—Benzozone, benzoyl-acetyl peroxid. An intense germicide, though practically not injurious to animal tissue. It has been used with great satisfaction in typhoid fever, cholera, amebic dysentery, urethritis, etc. Externally it is employed in abscesses, etc. Dose of the powder, 3 to 5 grains, with sugar of milk, in capsule; or 4 ounces of a solution of 15 grains in a quart of water.

ACETPHENETIDIN.—See PHENACETIN.

ACETUM.—Vinegar. See ACETIC ACID; VINEGAR.

ACETYL-SALICYLIC ACID.—See ASPIRIN.

ACHILLODYNIA.—Inflammation of the retrocalcanean bursa, causing severe, persistent pain in the heel. It may be caused by gout or by gonorrheal infection. The bursa may become so distended as to make incision and erasion necessary.

ACHOLIA.—The synonyms are cholemia and cholesteremia. (It may be classed under the head of Autointoxication.) A retention in the system of certain products that should have been eliminated by the liver. It is usually dependent upon rapid destruction of the liver cells, as seen in carcinoma, yellow atrophy, and hypertrophic cirrhosis of the liver. See AUTOINTOXICATION, JAUNDICE, LIVER, etc.

ACHONDROPLASIA.—Lack of the normal development of cartilage. Parrot's term for a form of fetal rickets in which the limbs are short, the curves of the bones exaggerated and there is an absence of the proliferating zone of cartilage at the junction of the epiphyses. The children are generally still-born. This condition resembles a fetal cretinism.

ACHORION.—A genus including several species of fungus (or fungoid) organisms found in the skin, especially the hair follicles. See FAVUS, RINGWORM, etc.

ACHYLIA GASTRICA.—A condition in which there is entire absence of hydrochloric acid in the gastric juice; it occurs in hysteria, neurasthenia, carcinoma, and atrophy of the gastric glands due to chronic inflammation. See GASTRIC NEUROSES (Hypochlorhydria).

ACIDITY.—During normal metabolic activity certain acids are constantly being formed throughout the system, which are eliminated through the emunctories of the body—skin, kidneys, lungs, and bowel. Not only are acids formed within the living body, but they are also introduced through the medium of certain articles of food. The acids formed belong to the organic compounds, generally lactic, oxalic, and uric acids; when the end-products of normal metabolism (urea, carbonic acid, etc.) are not formed, these organic acids may accumulate in the blood and tissues, either through excessive formation or defective elimination, giving rise to certain effects.

Effects of Acidity.—When the emunctories fail to eliminate these acids, the irritant action seems to be exerted upon the skin and mucous membrane, giving rise to nasal catarrh, bronchitis, and gastro-intestinal irritation. The excessive accumulation of uric acid may lead to the formation of uric acid calculi or to inflammation of the serous membranes (rheumatism). The skin may be affected, and herpes, eczema, and urticaria are common.

Estimation of Acidity.—The amount of acidity of the system may be approximately obtained by the amount of acid excreted in the urine. For this purpose Ralfe advises the following process: "Collect the urine during 24 hours, placing 100 c.c. in a beaker, and then adding a solution of sodium hydrate (standardized so that 1 c.c. = 0.01 gm. of crystallized oxalic acid) from a Mohr's buret until the fluid is neutralized. The number of cubic centimeters of the standard solution required to effect this is multiplied by 0.01, which gives the percentage acidity in terms of oxalic acid. To ascertain from this the total amount of acid in the 24 hours' urine is only a matter of calculation." These results are, however, only approximate, as may well be supposed. See also STOMACH CONTENTS (Examination), URINE (Examination).

Treatment.—The diet must be judiciously regulated, eliminating such articles as rich desserts, acid fruits and vegetables, and starchy foods. Soerensen and Metzger state that persons with gastric hyperacidity tolerate fats exceptionally well, and that a diet rich in easily melting fats, such as butter, oil, and especially milk and cream, is indicated. They also mention that oatmeal broth vanishes from the stomach with remarkable rapidity, even in cases of great motor insufficiency, with normal increased acidity. Alcohol, and especially wines, should be positively forbidden. Meats, such as beefsteak, and the excessive use of tea, coffee, and tobacco, lead to formation of uric acid, and should be restricted. Fish, eggs, and wild fowl may be allowed. Active exercise in the open air should be encouraged, in order to keep the digestion in as good condition as possible and to aid the skin in eliminating excrementitious material. The state of the bowels requires especial attention, constipation being carefully avoided by the administration of alkaline mineral waters, as the Friedrichshall and Hunyadi.

Dilute nitric (5 minims) and hydrochloric (5 minims) acid, taken an hour before meals, is thought to diminish the quantity of acid.

Should there be symptoms of dyspepsia, with eructation of sour material, the bicarbonate of sodium or potassium may be given. If the former drug is used (1/2 of a dram), it may be taken immediately before meals in one-fourth of a glass of water.

It should be remembered that the bicarbonate

of potassium has an irritant effect upon the kidneys if continuously administered over long periods, but from 4 to 8 grains can be taken for periods of a week or two without injury. The following prescription may be of service:

℞.	Lithium carbonate,	ʒ jss
	Wine of colchicum seed,	ʒ ijss
	Elixir of orange,	ʒ iv
	Solution citrate of potassium, enough to make	ʒ iv.

Two teaspoonfuls every 4 hours.

See Gout, Rheumatism, Uricacidemia.

ACIDOSIS.—This term was first introduced into pathology in connection with certain manifestations of diabetes which were believed to explain the development of coma in that disease. Around this concept as a nucleus has been built up such a mass of vague and contradictory doctrine that it would, perhaps, in some respects be well if it could be banished from pathology altogether; nevertheless in as far as the entity of a morbid process can be revealed by the criterion of treatment it has probably come to stay. In *American Medicine* for June, 1916, will be found a symposium of seventeen articles by prominent clinicians in which acidosis is discussed from every conceivable angle.

In its most restricted sense acidosis refers to the appearance in the urine of the so-called acetone bodies—acetone, diacetic acid and oxybutyric acid; but this phenomenon can occur in the normal subject, and, moreover, is present in the greatest variety of abnormal conditions. Although the bodies appear in the urine in the order named, oxybutyric acid is really the parent substance of the other two.

Acidosis has been defined as an accumulation of acid metabolic products in the body, the result either of excessive formation or defective elimination, or both. The claim is heard, however, that not the excess of acid but the coincident loss of alkali, or rather of bases, constitutes the pathological condition. Hence, at least in theory, if the body should be starved in regard to alkaline and earthy bases, what is known as acidosis would develop. From this viewpoint the accumulated acids are not necessarily toxic. The majority of writers, however, believe in the existence of an acid intoxication not unlike that produced by the ingestion of inorganic acids. In passing, it is worth while to call attention to the fact that in the general intoxication caused by oxalic acid there is little resemblance to acidosis.

It is commonly taught that the acetone bodies are formed at the expense of the protein and fat of the diet and not at all from the carbohydrate. Their appearance in diabetes is therefore readily explained by carbohydrate intolerance and defective utilization. Acidosis is an integral part of diabetes.

The phenomenon of acidosis is intimately bound up with starvation and in some of the conditions under which it occurs inanition is actually present, as in pernicious vomiting of pregnancy and intestinal obstruction. Moreover as a result of acidosis persistent vomiting may result and a vicious circle be set up.

Most writers describe a syndrome of acid intoxication characterized by drowsiness, thirst, restlessness, air hunger and acetone breath. For some reason vomiting is not enumerated in this syndrome although it is the principal symptom of cyclic vomiting—one of the best known forms of acidosis.

Save for its diabetic manifestations acidosis is best known clinically in association with **childhood.** For a considerable period the chief expression of this clinical condition was cyclical vomiting. More recently much has been written by pediatrists on a form of acidosis in young infants which appears to be due to base starvation. In this form the child may seem to be suffering from severe pneumonia—an affection, by the way, in which acidosis is known to occur. As a result of deprivation of mineral bases the blood becomes profoundly modified. There is destruction of the red cells with resulting air hunger expressed as rapid pulse and respiration. Cyanosis does not develop but the face is notably flushed and the resemblance to the picture of pneumonia startling. Such cases yield rapidly to the rational treatment of acidosis.

Certain eminent pediatrists make acidosis responsible for much of the pathology of childhood. Rickets they ascribe to lime deprivation due primarily to this condition. Pyelitis develops readily in the very acid urine. While most writers are at much pains to differentiate cyclic vomiting from conditions which greatly resemble it, others boldly attribute to acidosis most of the so-called bilious and nervous vomiting and even cases which would ordinarily be termed migraine.

Of especial interest to the surgeon is the acidosis of so-called delayed chloroform poisoning which much resembles cyclical vomiting; and the obstetrician is familiar with acidosis as seen in certain forms of pregnancy toxemia (it does not occur in ordinary eclampsia).

The best evidence of the existence of acidosis as an entity is the nature and result of treatment which is largely the same for all well defined and recognized forms of the condition. First to be considered is the **diet** in which protein consumption is not only to be cut to the minimum but limited to certain forms of protein which are least apt to form the acetone bodies, as casein and such protein as is obtainable from a vegetable diet. In cases with threatening symptoms forced carbohydrate feeding is recommended in the shape of solutions of glucose by the mouth or by enema or subcutaneous infusion. Fats should be left out of the diet entirely. Of remedies sodium bicarbonate is the main-stay and in certain cases of cyclical vomiting with alarming symptoms it may be advisable to administer it by intravenous injection since in quite a number of these cases the disease has proved fatal. In order to push the treatment of acidosis when the child is an adynamic condition Fischer recommends the citrates of sodium and potassium alone or with the bicarbonate.

The well-known Allen treatment for diabetes is

designed to prevent the development of acidosis in that disease but is not quite adapted to the treatment of acidosis in general. Glucose is of course contraindicated here and the patient receives in addition to vegetable diet a certain amount of alcohol as an oxidizable carbohydrate.

In regard to the **diagnosis** of acidosis the reader should consult works on biological chemistry for information in regard to the detection of the acetone bodies in the urine; further in reference to the details of treatment and the dosage the limits of this article forbid entering into them. See Diabetes Anesthetic (Anesthesia Sequels), Urine (Examination), Garrod's Thread Test.

ACIDS.—A compound of an electronegative element, or radical, with one or more atoms of hydrogen which latter can be replaced by electropositive or basic atoms without the formation of a base. The name acid is loosely applied to any substance having a sour taste. Acids vary in their terminations according to the quantity of hydrogen or other electronegative constituent. Those having the maximum of oxygen end in *-ic;* those of a lower degree in *-ous.* When there are more than two combinations, the prefix *hyper-* or *per-* is prefixed to the highest, and *hypo-* to the lowest. Acids that end in *-ic,* as sulphur*ic* acid, form salts terminating in *-ate;* those ending in *-ous* form salts terminating in *-ite.* A few acids (as hydrochloric) contains no oxygen, but all contain hydrogen. They change the color of litmus from blue to red, and unite with bases to form salts. Their physiological actions are chiefly due to their powers of neutralizing alkalies, withdrawing water from the tissues, and precipitating the globulins and some other proteids. They are poisonous to protoplasm, somewhat antiseptic, and many of them are powerfully corrosive to the tissues. Taken internally in dilute solution they have a sour taste, and cause an astringent sensation in the mouth and throat, induce a reflex flow of saliva, and in the stomach displace weaker acids from their combinations. Applied to the mouths of ducts from glands having an alkaline secretion they stimulate the latter, but check the secretion of glands producing acid secretions. In the blood and tissues they exist as salts by combination with the alkalies of the body, and if administered in sufficient quantity to neutralize the latter the animal dies, its blood being unable to carry carbon dioxid from the tissues to the lungs. They are rapidly excreted by the kidneys as acid salts, increasing the acidity of the urine. Therapeutically they are employed locally as caustics, styptics and anhydrotics, and internally in very dilute form as refrigerants, stomachics, astringents, ehmostatics, and antidotes in poisoning by alkalies. *Incompatible* with acids generally are: Alcohol with strong acids; alkalies, alkaloids; benzoates and borates with strong acids; bismuth and ammonium citrate, bicarbonates, bromids of weak bases, carbonates, chlorids of weak bases, glucosids, iodids of weak bases, metallic salts with organic acids, pancreatin, potassium and sodium tartrate, potassium tartrate, salicylates, silicates.

ACIDS, SWALLOWING.—Of the corrosive acids, sulphuric, nitric, and hydrochloric are the most frequently swallowed. Carbolic and oxalic acids are of more import from their toxic effects than from their corrosive action. Oil of vitriol, or strong sulphuric acid, is sometimes mistaken for other substances, and swallowed. It has been administered with murderous intent. It is much more disastrous than the diluted acid.

The symptoms are very prominent. Marks of the corrosive may be seen about the mouth, and white spots may be seen on the mucous membranes. There is agonizing pain in the stomach, heat, and great thirst. Vomiting may ensue, and it will be acid. The patient soon sinks into collapse, which becomes great if perforation of the stomach has taken place.

The prognosis is grave, and depends greatly on the amount of fluid in the stomach at the time of swallowing the acid.

Treatment.—No violence, as the stomach-pump, or emetics must be used. Any alkali but a carbonate must be administered at once. Large quantities of water, milk, and mucilaginous drinks should be given. The plaster from the wall or ceiling, pulverized and suspended in water, is a ready antidote when magnesia or lime-water is not obtainable. If there is much collapse, stimulating measures are indicated. Rectal administration of stimulants is of great value. Perforation is serious, and often does not occur for several days. Operation is of little avail. See Poisoning.

ACNE (Acne Vulgaris; Pimples). Definition.—Acne is an inflammatory disease occurring in and around the sebaceous glands, characterized by papules, tubercles, or pustules, affecting chiefly the face, and running a more or less chronic course.

Acne is an extremely common disease, comprising over 7 percent of all dermatoses.

Symptoms.—The forehead, cheeks, and chin are the regions usually affected, although the chest, shoulders, and back are not infrequently involved. The lesions are papular, pustular, or nodular, or a combination of these may be present. Comedones, or black-heads, and oily seborrhea often coexist, the former frequently giving rise to acne lesions. The primary manifestations are the size of a pinhead or of a pea, bright or dark red, discrete papules appearing at the orifices of the sebaceous glands and hair follicles. These vary in number from 2 or 3 to several dozen. After a period of a few days or weeks the lesions become pustular and discharge or undergo absorption, being followed by reddish stains or, in some cases, by scars. A new crop succeeds the old, the affection continuing thus for months or years.

According to the predominating lesions, various forms of acne are distinguished:

Acne punctata is represented by small conic elevations with central sebaceous openings filled with dark-colored points.

Acne papulosa consists of small, reddish, acuminate papules.

Acne pustulosa is characterized by pustules resulting from suppuration of the papular lesions.

Acne indurata is a pustular acne in which the lesions are large and have markedly infiltrated

bases. They are nodular, deep-seated, and often painful.

Acne artificialis is a papular or pustular eruption produced by the internal administration of the iodids and bromids or the external use of tar (**tar acne**).

Acne cachecticorum is an acne occurring usually upon the trunk and extremities of strumous and cachectic individuals. The lesions are large, indolent, violaceous, scar-leaving pustules.

The subjective symptoms in acne are extremely mild. Itching and burning are usually absent, but in some cases exist in a mild degree. The large indurated lesions are often painful, or, rather, tender to the touch.

The course of acne is chronic, the disease, untreated, tending to continue for months and years. In girls periodic aggravation occurs with great constancy before, during or after each menstruation. Spontaneous improvement takes place between the ages of 25 and 30.

Etiology.—Puberty is the most potent predisposing cause, the vast majority of cases of acne occurring between the ages of 15 and 25; after 30 acne is uncommon. The great glandular activity occurring at this period is easily subjected to pathologic perversion.

Dyspepsia and constipation play an important rôle in the causation of this disease; uterine disease, menstrual irregularities, anemia, and general debility are also provocative in many cases. The bromids, iodids, and tar may call forth an acne.

Pathology.—An acne lesion consists of a perifolliculitis and a folliculitis due to the irritation of retained and decomposed sebum. Recent experiments by Fleming have shown that the primary lesion is not due to the staphylococcus but to a bacillus. There is engorgement of the surrounding vessels and an intense cell-infiltration. The process ends in resorption or suppuration, with or without destruction of the follicle.

Diagnosis.—The diagnosis of acne is, as a rule, unattended with difficulty. It may in some cases be confounded with the papular or pustular syphiloderm. Herewith is appended the differential diagnosis:

Acne.	Papulopustular Syphiloderm.
1. Often with associated comedones and oily seborrhea.	1. Concomitant signs of syphilis present.
2. Occurs at age of puberty.	2. Occurs usually later.
3. Limitation of lesions to face.	3. Distribution general.
4. Course chronic, with exacerbations.	4. Course acute.
5. Lesions acutely inflammatory.	5. Lesions are new growths.
6. Lesions light or dark red.	6. Lesions brownish-red or ham-colored.
7. No tendency to ulceration.	7. Tendency to ulceration.

Prognosis.—Some cases respond rapidly to treatment; others are refractory. Very few cases are incurable. Success depends upon the detection and removal of the cause. The average case requires months for a cure. Severe cases may be followed by scarring.

Treatment.—Constitutional and local remedies are both of importance—the former to prevent the formation of new lesions, and the latter to cause the disappearance of the old.

Vaccine Therapy.—Acne offers one of the most promising fields for vaccine therapy, preferably with autogenous vaccine. See Vaccine Therapy (Staphylococcus). A mixed vaccine of polyvalent staphylococci and acne bacilli has been used with marked success in some cases.

Constitutional Treatment.—There are no specifics. Treatment must be directed toward the correction of systemic errors.

Dyspepsia and constipation frequently call for treatment. For the former, the bitter tonics, mineral acids, and alkalies may be used, according to the exigencies of the case. Constipation may be overcome by diet, abdominal massage, and the various laxatives. A pill of aloin, strychnin, and belladonna, blue mass or calomel, cascara sagrada, the salines, etc., are all useful.

The following is an admirable combination for coexisting anemia and constipation (Startin):

℞.	Iron sulphate,	gr. xvj
	Magnesium sulphate,	ʒ j
	Dilute sulphuric acid,	♏ j
	Peppermint water,	ʒ iv.

Tablespoonful in a goblet of water a half hour before breakfast.

The laxative mineral waters, such as Hunyadi Janos, Friedrichshall, and Saratoga waters, may also be employed.

In cases attended with much pustulation, the sulphid of calcium, in 1/10 to 1/2 grain doses, 4 times daily, is said to be serviceable. Iron preparations are of value in cases complicated by chloranemia. Cod-liver oil and the hypophosphites are indicated in strumous and rachitic patients. Small doses of arsenic, strychnin, and bichlorid or mercury are of value in individuals with lowered nerve-tone.

Hygienic measures, such as cold baths, outdoor exercises, and regular life are, of course, not to be neglected.

In many cases dietary restriction is necessary. Highly seasoned foods, pastries, candy, ice cream, salt meats, and alcoholic beverages are to be avoided; nothing should be eaten between meals.

Local Treatment.—The object of local treatment is to hasten the disappearance of existing lesions and to stimulate the sebaceous glands to healthy action.

The nature of the remedies to be employed depends upon the degree of inflammatory reaction present. In the vast majority of cases stimulating applications are indicated. Occasionally, however, the face is hyperemic and tender, and requires the use of sedative lotions and salves.

Before the local remedies are applied, the face should be thoroughly washed with soap and hot

water, with a view to opening up the follicles. For this purpose ordinary soap may be employed, or, in sluggish cases, soft soap or the tincture of green soap. This is advantageously followed by mopping the face for 5 minutes with very hot water. Comedones are to be removed either by pressure of the fingers or the use of the comedo expressor or a watch-key.

Salves and pastes are most conveniently applied at night. Lotions, used alone or in conjunction with ointments, may be sopped on frequently during the day.

Sulphur is by far the most generally useful and efficient remedy. It may be used in the form of a powder, ointment, paste, or lotion. When the lesions are deep-seated and the face is dry, ointments are to be preferred; when superficial and the face is oily, lotions are indicated.

Incorporated in a paste, sulphur may be used as in the following formula:

℞. Precipitated sulphur, ℥ j to ij
Lassar's Paste { Starch, Zinc oxid, Petrolatum, } each, ℥ ij ℥ iv.
Rub in at night.

One of the most efficient lotions is known as the "compound zinc sulphid lotion." Its formula is as follows:

℞. Zinc sulphate, Potassium sulphid, } each, ℥ j
Rose-water, q. s. ad ℨ iv.

(The ingredients are to be dissolved separately, heated, and then mixed. A double decomposition takes place, with the precipitation of a whitish powder. The potassium sulphid should always be fresh.)

Another useful formula is that devised by Kummerfeld:

℞. Precipitated sulphur, ℥ iv
Pulverized camphor, gr. x
Pulverized tragacanth, gr. xx
Lime-water, ℥ ij
Rose-water, ℥ ij.

When oily seborrhea coexists, the following may be employed:

℞. Precipitated sulphur, ℥ j
Ether, ℥ iv
Alcohol, ℥ iijss.

The *mercurials* are often serviceable in the treatment of acne. Care must be taken in changing from the sulphur to the mercurial treatment, or vice versa, that there is an intermission of a few days, and that the face is thoroughly cleansed, to avoid the disagreeable though temporary blackish discoloration resulting from the formation of the sulphid of mercury. The following is a much used formula:

℞. Mercuric chlorid, gr. ss to ij
Emulsion of almonds, ℥ iv
Compound tincture of benzoin, ℥ j.

In addition to the above remedies, resorcin (20 to 40 grains to 1 ounce), beta-naphthol (10 to 30 grains to 1 ounce), and ichthyol (1 to 2 drams to 1 ounce) may all be found useful.

In indurated acne benefit will often accrue from the use of mercurial or ichthyol plaster worn during the night. In obstinate cases incision of the lesions with expression of their contents may be resorted to.

ACNE ROSACEA. Definition.—Acne rosacea consists of two processes—an acne and a rosacea. The latter is a chronic hyperemic disorder of the face, particularly of the nose and cheeks, characterized by redness, dilatation of blood-vessels, and in some cases connective-tissue hypertrophy. The acne lesions are secondary.

Symptoms.—The disease has three stages. In the first stage there is simply a diffuse hyperemia of the part, coming on after meals, after drinking hot beverages, on exposure to cold or heat, and at the menstrual period. Oily seborrhea is often present. After some months or years the second stage develops. In this the redness is more permanent, due to enlarged capillaries and venules, which are visible coursing through the skin. At the same time papular and pustular acne lesions appear. This is the usual clinical picture of acne rosacea.

In exceptional cases the disease progresses to a third stage, which is characterized by further capillary enlargement, and hypertrophy of the sebaceous glands and connective tissue. A lobulated or bulbous enlargement of the nose takes place, sometimes reaching the size of a fist (**Rhinophyma**; **Acne hypertrophica**).

The course of the disease is chronic, lasting over a period of years.

Etiology.—The disease occurs in both sexes, but is usually worse in men. The most frequent causes are chronic gastrointestinal disturbances, anemia, menstrual and uterine disorders, continued exposure to cold winds, and the excessive use of alcoholic beverages, tea, etc. The inordinate use of tea is as fertile a cause in women as is the abuse of alcohol in men.

Pathology.—There is at first a dilatation of vessels, followed by permanent enlargement, and ultimately connective-tissue overgrowth. In hypertrophic cases the corium is greatly thickened and the sebaceous glands somewhat enlarged.

Diagnosis.—The tubular syphiloderm and lupus vulgaris may in some cases simulate acne rosacea, but the presence of hyperemia, with enlargement of vessels, and acne papules and pustules occurring upon the nose and cheeks and running a chronic course, renders the diagnosis easy. Both syphilis and lupus tend to ulcerate.

Prognosis.—Cases of modern severity may be much benefited, or even cured, by judicious treatment. When connective-tissue hypertrophy has

taken place, the prognosis is more guarded. The disease exhibits no tendency to spontaneous improvement, as is seen in simple acne.

Treatment.—Internal and external remedies are both of importance. The cause or causes of the disease must be assiduously investigated. When the stomach is at fault, the diet should be carefully regulated. Condiments, alcohol, tea, and all sorts of stimulating articles are to be prohibited.

Due attention must be paid to the condition of the bowels. In the various forms of dyspepsia, nux vomica, the stomachic bitters, mineral acids, alkalies, etc., are to be prescribed.

Some cases require the use of iron, strychnin, cod-liver oil, and similar tonics.

Local Treatment.—The sulphur preparations used in the treatment of simple acne are valuable also in rosacea. Excellent results often follow the use of the compound zinc sulphid lotion and Kummerfeld's solution. See ACNE.

When permanent dilatation of blood-vessels has taken place, it may be necessary to resort to the use of electrolysis, scarification, or slitting with a knife. In acne hypertrophica the thickened tissues may be pared off with a knife.

ACONITE.—Aconite root is also called "monkshood" or "wolfsbane." It possesses a bitter, pungent taste, and causes numbness and tingling when applied to tongue and lips. The aconite of the U. S. P. is derived entirely from the root.

Action.—It first stimulates and then paralyzes the sensory nerves, causing tingling, burning, numbness and finally anesthesia; also successively stimulates and paralyzes all the parts of the heart's organism, and there is always in the end a complete fall of blood-pressure from paralysis of the heart and vessels. The peripheral vessels and the pupil are dilated. Clonic convulsions may be excited, but the motor nerves are not affected until after the sensory nerves. Moderate doses usually have the effect of quieting the respiratory movements, but large amounts paralyze the respiratory center in the medulla, and this paralysis begins early and progresses rapidly. The temperature is markedly reduced by aconite. Profuse diaphoresis is commonly caused by it, but it has only a moderate diuretic effect.

Therapeutics.—Externally, neuralgia; myalgia; gout; chronic rheumatism; prurigo; pruritus; papular eczema; herpes zoster; chilblains. Internally, in fevers and in the early stages of acute inflammatory affections, especially of the organs of respiration, when the type of the disease is not adynamic. It is contraindicated in typhoid and other continued fevers of an asthenic character and also in inflammatory conditions of the gastro-intestinal mucous membrane. In conditions in which there is high arterial tension, chiefly of cardiac origin, aconite is a remedy of great value; it may also be of service in simple nervous palpitation of the heart, epistaxis and congestive dysmenorrhea, and to relieve the pain of aneurysm.

Small divided doses (1 minim every 15 minutes) of the tincture act better than a full dose given at once. The dose of the root is from 1/2 to 2 grains.

In simple fever:

℞.	Tincture of aconite,	ʒ iij
	Spirit of nitrous ether,	ʒ iv
	Solution of ammonium acetate,	ʒ vj
	Syrup of lemon,	q. s. ad ʒ iij.

Mix into solution and take 1 teaspoonful every 3 hours. Water may be added.

In threatened abortion:

℞.	Tincture of aconite,	ʒ vj
	Tincture of belladonna,	ʒ ij
	Rose-water,	ʒ iv.

Rub 2 drams over the groins, sacrum, etc.

Externally, aconite is useful in the treatment of myalgia, neuralgia, rheumatism, and other painful affections.

℞.	Tincture of aconite,	ʒ iij
	Essential oil of mustard,	ʒ j
	Glycerin,	ʒ j
	Rectified spirits,	q. s. ad ʒ vj.

Two teaspoonfuls should be rubbed into the affected parts night and morning.

	Tincture of aconite,	ʒ iij
	Camphor,	ʒ ij
	Chloroform,	♏. xl
	Oil of cajuput,	ʒ ij
	Tincture of capsicum,	ʒ ij
	Rectified spirits,	q. s. ad ʒ vj.

Apply locally. Oil of origanum may be added as a scent.

Poisoning.—The root is sometimes mistaken for horseradish root and eaten. Aconite root does not emit the pungent odor of horseradish when scraped or broken, and the scraped surface of horseradish retains its white appearance, whereas aconite root is brown, is more conic in shape, is destitute of the pungent odor, and speedily acquires a pink color when scraped or exposed to the air. When liniments containing aconite are swallowed, the symptoms of poisoning occur.

The general symptoms of poisoning are weakening of the heart's action, disturbances of respiration, paralysis of sensation on the surface of the body, and a numbness or drawing of the skin. The great cardiac depression, the difficulty of respiration, the numbness, tingling, and burning in the mouth usually serve to distinguish the nature of the case. If 12 hours are passed and life remains, recovery is generally rapid and complete, as death usually occurs in from 4 to 5 hours. The fatal dose of the root is about 60 grains.

The treatment of poisoning by aconite consists in placing the patient prone, with the feet higher than the head, to promote circulation in the base of the brain; the maintenance of bodily heat by warm blankets, hot bottles, or bricks; hypodermic injections of ether, alcohol, and digitalis, the last

named of which is the physiologic antagonist of aconite, but is slow in its action. Artificial respiration may be employed if breathing fails, or 3 to 5 drops of amyl nitrite may be inhaled from a kerchief or cloth a few times, since large amounts depress the heart. From 1/20 to 1/10 grain of strychnin will stimulate the heart and respiration. Emetics should not be used when the symptoms are severe, for vomiting may arrest cardiac action. If vomiting does occur, the head should be turned to the side. The stomach should be washed out with a siphon rubber tubing. Strong black coffee or tea, and brandy or whisky are serviceable.

Preparations. Fluidextractum A.—An alcoholic preparation of which each drop represents nearly 1 grain of the powdered drug. Dose, 1 minim.

Tinctura A.—Has of aconite 10, alcohol and water to 100. Average dose, 10 minims.

Tinctures of aconite-root vary greatly in strength. In Fleming's tincture 79 parts of aconite are used in preparing 100 of the tincture, in that of the B. P. 5, in the French 20, the German 10, while the Linimentum Aconiti (B. P.) is really a very strong tincture, of the strength of 1 to 1 1/2. Probably the best and safest preparation for ordinary use is a 10 percent tincture, of which the maximum single dose for an adult is stated in the German Pharmacopeia at 9 minims, and the maximum daily dose at 35 minims.

The best rule for the administration of aconite is to give minim doses of the official tincture every 15 minutes until the desired effect is produced.

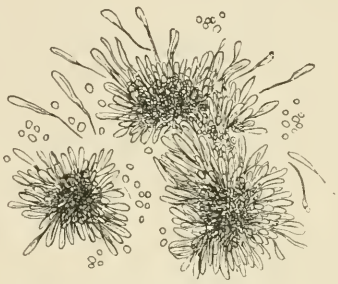
Aconitina, *Aconitine,* is a white, prismatic powder, readily soluble in alcohol or chloroform, nearly insoluble in water. It is difficult to obtain it of constant strength, some samples being nearly inert, others extremely active. As it occurs commercially it is a mixture of several alkaloids and should not be used internally in practical medicine (Wood). The *Aconitine Crystalisée* of Duquesnel is a nitrate of aconitine, and is probably the most active preparation on the market (Squibb). Average dose, 1/400 of a grain.

ACRODYNIA.—This disease is also called epidemic erythema; it is a rare disease, characterized by gastrointestinal symptoms, redness of the conjunctiva, edema of the face, formication, pricking pains in the palms and soles, hyperesthesia followed by anesthesia of these parts, and an erythematous eruption preceded by blebs, chiefly on the hands and feet, but spreading over the limbs and trunk. This is followed by exfoliation and dark brown or black pigmentation, greatest in the warm regions of the body. Wasting of the limbs, with edema, cramps, pareses, and spasms, may be present, and in the old or feeble death may follow. The disease is probably due to some noxious constituent of, or defect in, the diet. The treatment should be directed to the regulation of the digestive and assimilative organs, and to the relief of the local inflammations by soothing lotions and ointments.

ACROMEGALY.—See Akromegaly.

ACTINOMYCOSIS (Lumpy Jaw).—Actinomycosis is a parasitic disease occurring in the lower animals and in man, due to the ray fungus, and characterized by deep subcutaneous tumors or swellings that break down and suppurate.

The face and neck are the parts usually involved, the parasite gaining entrance to the tissues around carious teeth. The onset of the disease is insidious, weeks or months elapsing before the appearance of cutaneous manifestations. The lesions consist of deep-seated tumors or swellings that, approaching the surface, become red or livid in color, and, breaking down, discharge a bloody sero-pus containing characteristic yellow granules. These granules are made up almost exclusively of fungus. Sinuses with uneven nodular edges persist for an indefinite period. The disease is due to the presence of a characteristic microparasite, the *ray fungus* (*Actinomyces bovis*), which is composed of fine mycelial threads and club-shaped bodies. The most frequent and most curable form is that in which the abscesses form about the jaws and teeth. The best mode of staining the threads is by Gram's method. To stain the clubs as found in man is difficult; the best results have been obtained with orange rubin or eosin.



Actinomyces—The Ray Fungus.]

Treatment.—The administration of large doses of potassium iodid has proved successful in many cases, and should be given thorough trial. Locally, irrigation with corrosive sublimate solutions are advised. The X-ray has proved of value, both when used alone and also when used in conjunction with the administration of the iodids. In obstinate cases the parts should be thoroughly curetted. When the parasite has found a nidus in the lungs or digestive tract, all treatment has proved useless.

ACTOL. Silver Lactate.—A white, inodorous and tasteless powder, which coagulates albumin and is soluble in 20 of water. It lessens putrefaction in the bowel and constipates to some extent. A solution of 1 in 1000 destroys pathogenic microbes within 5 minutes. For gargles, mouthwashes, etc., solutions of 1 in 8000 to 1 in 4000 are used, though stronger ones do not irritate.

ACUPRESSURE.—An operation formerly used to stop hemorrhage or aneurysm by a needle compressing the tissues, on each side, above or below the vessel. For an aneurysm it presents no advantage over ligature, and the method has become almost obsolete. In wounds of the scalp and in

bursting of varicose veins, acupressure is of particular value.

ACUPUNCTURE.—Puncture of the skin or tissues by one or more needles for relief of pain, the exit of fluid or of coagulated blood in an aneurysm, etc. It is now chiefly employed in lumbago and sciatica, and has been used as a means of counter-irritation in neuralgia; as a stimulant, to evacuate or disperse fluids from various parts of the body; for the relief of chronic muscular pains and stiffness of the joints; in the treatment of ununited fracture; in the treatment of aneurysm; for the radical cure of hernia of the bowel. The spleen has been acupunctured for malarial hypertrophy.

In lumbago acupuncture is made over the erector spinæ muscles, and in sciatica along the course of the nerve; it is performed thus: The patient is placed prone on his face, the tender spots are found, and from 1 to 6 needles are pushed vertically to the depth of from 1 1/2 to 2 inches, and allowed to remain for from 1/2 of an hour to 2 hours. The needle should actually penetrate the nerve in sciatica.

The beneficial effect is supposed to be due to the escape of the fluid from the nerve-sheath.

The ordinary acupuncture needle is a three-cornered pyramidal instrument, and this form is more convenient than a round-pointed, conic one, as it permits the escape of fluids more readily. The punctures should be made in rapid succession, and be sufficiently deep to allow a free escape of the fluid.

ADALIN.—A hypnotic belonging to the same class as Veronal; it is soluble in alcohol, but not in water, and is almost tasteless. Dose 15 grains.

ADAMS-STOKES SYNDROME.—See Heart Block.

ADDICTION PSYCHOSES.—See Drug Addiction.

ADDISON'S DISEASE.—See Suprarenal Disease.

ADDUCTION OF THE EYES.—The power of the internal recti muscles, measured by the maximum ability to preserve singleness of the image with prisms placed bases toward the temples. It varies from 15° to 40°. See Eye-muscles (Anomalies).

ADENITIS.—Inflammation of a (lymphatic) gland. See Lymphatics (Diseases).

ADENOIDS.—A term applied to a hypertrophy of the adenoid tissue that normally exists in the nasopharynx. It is diagnosed by anterior or posterior rhinoscopy or by palpation with the forefinger behind the palate. Adenoid growths bleed easily, and the examining finger will be found covered with blood. This hypertrophy is associated with the following characteristic symptoms: Vacant expression of the child (see Face in Diagnosis), aprosexia, open mouth, noisy breathing, more or less impairment of the hearing, a hacking cough, a peculiar muffling of the voice, and an enlargement of the tonsils. The vegetations exert an injurious influence on physical development. The most important predisposing cause is youth. Adenoids are met with in all classes of life and in all climates.

Treatment consists in the early and complete removal of the growths.

In adults the operation may be done under cocain anesthesia. A general anesthetic allows more thorough manipulation.

When performed under an anesthetic, these operations should never be undertaken without ample assistance. The instruments devised for this operation are many. Each instrument has some merit, and there is no one suitable to every case; hence it is well to have various-shaped instruments at hand. The forceps most used are the Hooper, Gradle, Quinlan, and Lowenberg; the curets, Gottstein and Hartmann. The head being dependent over the edge of the table and supported by the assistant, the jaws are held open with a mouth-gag, the forceps is introduced, and all tissue within its grasp is removed. A smaller forceps follows this one; then the curet is used, followed by the forceps, to detach any tissue loosened by the curet, and the finger now sweeps all over the postnasal space to ascertain if it is clear. The patient is turned over on his face and the blood allowed to flow out, and the nose and throat are well sprayed with the iced antiseptic solution.

Gottstein Curet.

The patient is now placed in bed, the directions are given for a low diet, and a spray of the iced antiseptic solution in the nose and throat used once every hour. Every case operated upon should be kept in bed and under observation for 24 hours, but this rule is not usually followed in clinics. After the first 24 hours the spray is used less frequently and no longer iced. After the third day warm saline washes with some antiseptic added may be used by means of a nose-cup.

The operation may be performed upon children without anesthesia, and even without an instrument, the index-finger of the right hand being used instead.

The child sits in the lap of an assistant with its head leaning against his right shoulder; he embraces the child with his arms, holding its body and its hands firmly, while its feet are grasped and the knees secured by the assistant. Then, passing his left arm around the head of the child, the operator holds the mouth-gag in place with his left hand, while his right hand remains free to remove the growths, which, together with the blood, fall into a basin held in the hands of a second assistant. Some of the most satisfactory cases require no treatment beyond the operation itself, which may not consume more than 30 seconds.

ADENOMA.—A tumor that has sprung from a gland or is formed after the type of a secreting gland. See Tumors.

ADEPS.—See Lard.

ADIPOSIS DOLOROSA (Dercum's Disease).—A chronic condition characterized by painful and tender masses of fat irregularly distributed throughout the body; the hands and feet are not involved.

It attacks mostly women. It is probably a neuritis accompanied by fat deposition. Atrophy with sclerosis of the thyroid gland has been found, and in one instance a tumor of the pituitary body. There may be mental weakness, and increasing muscular weakness is observed. Hyperesthesia alternating with anesthesia may be noted in various areas. The fatty areas increase in size, soften, but do not pit on pressure.

Treatment.—Thyroid extract may prove of value. For the pain, aspirin, phenacetin and salipyrin may be used.

ADOLESCENCE.—Youth, or the period between puberty and maturity, usually reckoned as extending in males from 14 to 25 years, and in females from 12 to 21 years.

At puberty, which usually occurs at about the fourteenth year, certain characteristics develop in both the male and female. In the male, the voice becomes stronger and has a lower note while the sexual organs undergo a marked increase in development. The mental faculties are very alert and in the receptive stage for the acquisition of knowledge. As adolescence comes on, these transformations are more rapid, instability and frivolity giving place to determination and reflection.

In the female care should be exercised in properly instructing the girl in regard to the menstrual period, which makes its appearance at this time. Overwork and nervous excitability must be avoided. School-life requires regulation, and the best hygienic conditions should be enjoyed. Constipation is prone to occur, and may lead to a high grade of anemia if allowed to persist. A sufficient amount of outdoor exercise is absolutely essential in both sexes, as well as wholesome food in proper amount and at the proper intervals. See PUBERTY.

ADRENAL DISEASE.—See SUPRARENAL DISEASE.

ADRENALIN (Adnephrin, Adrin, Epinephrin, Suprarenalin).—The chief active principle of the suprarenal gland and the most powerful hemostatic and astringent known. It has been found to be of great value in all conditions in which adrenal extract is indicated. It is generally used in the form of the chlorid which is marketed in a 1 to 1000 solution. This solution is diluted for local medication to 1 in 5000, or 1 in 10,000. In the production of local anesthesia it is often added to cocain (or holocain, etc.) to increase the effect of the latter and to prevent intoxication. Its powerful angiostenotic properties are utilized for bloodless operations on the nose and throat, in epistaxis, menorrhagia, and other forms of hemorrhage, in asthma, laryngitis, conjunctivitis, coryza, etc. Its prompt and powerful stimulation of the heart and vasomotor system will be found invaluable in collapse during anesthesia and surgical shock, in opium and morphin poisoning, and in sudden failure of the circulation. Dose, internally, 5 to 10 minims of the solution. See SUPRARENAL EXTRACT.

ADVANCEMENT.—See EYE-MUSCLES (Operations).

AEROPHAGIA.—Swallowing of air occurs as a symptom of various gastric neuroses associated with atony of the stomach walls, and especially in hysteria. It must be differentiated from belching of gas resulting from fermentation of stomach contents which, however, rarely produces any considerable quantity of gas. Aerophagia, when not due to organic disease or reflex causes, readily yields to simple therapeutic measures tending to improve the general condition.

AEROTHERAPY.—See PNEUMOTHERAPY under TUBERCULOSIS (Pulmonary).

AFRICAN LETHARGY.—See SLEEPING SICKNESS.

AFTER-BIRTH.—The popular designation of the placenta, cord, and membranes; also called the secundines. See PLACENTA.

AFTER-COMING HEAD.—See FETUS (Breech Presentation, Version).

AFTER-MILK.—The last milk taken from the breast at any one milking; also called strippings. It has a high specific gravity compared with foremilk, and is particularly rich in fat.

AFTER-PAINS.—Intermittent and painful contractions of the uterus, caused by efforts to expel portions of membranes, placenta, and blood-clots retained in its cavity after miscarriage or labor. They rarely occur except in multiparæ, and usually disappear after the first 3 or 4 days of the puerperium.

Diagnosis.—They may be confounded with the beginning pain of pelvic inflammation. The following table will enable one to make a differential diagnosis:

AFTER-PAINS.	PAIN OF PELVIC INFLAMMATION.
Cramp-like and intermittent.	Constant; as a rule, localized to one side of the pelvis.
Not affected by pressure.	Intensified by pressure.
Attended by discharge of blood-clots or portions of membranes.	Lochial discharge lessened or suppressed.
Uterus becomes hard at time of pain.	Uterus boggy, tender, and subinvoluted.
Pulse normal.	Pulse rapid.
Temperature normal.	Temperature elevated.

Treatment.—If the pains are severe enough to make the patient distinctly uncomfortable, they can usually be readily relieved by the administration of 1 dram of the camphorated tincture of opium combined with 1/2 of a dram of the fluid extract of ergot. If this mixture, given every 2 or 3 hours, fails to relieve the patient, a hypodermic injection of morphin acetate (1/4 of a grain) should be substituted.

AGALACTIA.—See BREAST (Defective Secretion of); MILK (Mother's).

AGAR-AGAR.—A substance derived from sea weeds in the East Indies. It is used as a demulcent and in constipation. In the stomach and intestines, by absorption of water, it is converted into an indigestible jelly which increases the bulk of the feces. Dose, 75 to 240 grains mixed with food. See BACTERIOLOGY.

AGARIC ACID.—An odorless powder. It is used to arrest colliquative sweats. It is one-

twentieth as active as atropin and does not influence other secretions. Dose, 1/12 to 1/3 grain; it should not be given hypodermically.

AGE.—The length of time a being has existed; also a certain stage in life. The period of life is divided into a succession of ages, as follows: (1) *Infancy*, from birth to the appearance of the temporary teeth; (2) *childhood*, from the cutting of the first permanent teeth to puberty; (3) *youth*, from puberty to the attainment of the full stature—that is, 18 or 19 for girls, 21 to 22 for boys; (4) *maturity*, covering the interval from youth to the climacteric; (5) *old age*, or period of decline. Other divisions may be made: as, *e. g.*, those of embryonic life, of immaturity, of maturity, of senility, etc. See Adolescence, Anatomic Age, Infant, Old Age, Puberty, etc.

AGE OF CONSENT.—See Rape.

AGORAPHOBIA.—A fear of open places, usually associated with symptoms of greater importance in neurasthenia and in persons of neurotic inheritance. The condition may be developed rapidly or gradually. It is characterized by a feeling of alarm or terror that the individual experiences when in a certain space—upon the street, especially when the stores are shut, in a church, theater, vehicle, on a bridge, or in looking at an extended façade or flying perspective. Such persons feel better when with some one, or when they are near some object, as a carriage, or when carrying an umbrella or a stick.

The treatment should regard the general health in the broadest sense, and particularly strengthen the nervous system. Active mental employment and pleasing social and moral surroundings will do much to relieve and finally cure the malady.

AGRAPHIA.—Inability to express ideas in writing. In some cases not a single letter can be formed; in others, words, and a number of words—without meaning however—can be written. This defect may occur alone or associated with defects of speech. It is a disease of the motor speech-center whereby the power of writing is abolished, even when the hand-center is intact and the movements of the arm are unimpaired. See Aphasia.

AGUE.—See Malarial Fever.

AGUE-CAKE.—Enlargement of the spleen due to malaria.

AGURIN.—Theobromin sodium acetate, said to contain 60 per cent. of theobromin; it is equally as active a diuretic as diuretin though more soluble, and is well tolerated by the stomach. It is said to have greater power of sustaining the diuresis produced than theophyllin though inferior to the latter in diuretic power. Excellent results are recorded in dropsies and engorgements. It is said to be an efficient antistenocardiac remedy. Dose, 5 to 15 grains in wafers.

AINHUM.—A disease occurring in the tropics, chiefly affecting negroes, in which the little toes are slowly and spontaneously amputated at about the digitoplantar fold. The process is very slow, does not affect other toes or parts, is unaccompanied by any constitutional symptoms, and its cause is unknown. It sometimes attacks the great toe. Called also "dactylolysis spontanea."

AIR.—Atmospheric air consists of a mixture of 77 parts by weight, or 79.19 by volume, of nitrogen, and 23 parts by weight, or 20.81 by volume, of oxygen; with 3.7 to 6.2 parts by volume of CO_2 in 10,000 parts. One hundred cubic inches weigh 39,935 grains. The pressure of the air at sea-level is about 14 3/4 pounds upon the square inch.

AIR-BATH.—Therapeutic exposure to air that may be heated, condensed, or variously medicated. See Bath.

AIR, COMPRESSED.—See Pneumotherapy under Tuberculosis, Pulmonary; and Lungs, (Surgery).

AIR-EMBOLISM.—See Veins (Injuries).

AIR, LIQUID.—Liquefaction occurs at − 140° C. (− 220° F.) at a pressure of 39 atmospheres, but may be brought about at a higher pressure by lowering the temperature beyond the above-mentioned level. Liquid air is now manufactured commercially and has been employed in medical practice.

Physiologic Action.—Aside from a slight antibacterial power, manifested in a reduction of the virulence of bacterial colonies rather than actual destruction, liquefied air acts (1) as a cold application, (2) as a counterirritant, (3) by virtue of the hyperemia which follows its application, and (4) as an escharotic.

Clinical Uses.—As a cold application to freeze the tissues for the purpose of inducing local anesthesia and analgesia (application to the spinal extremity of a nerve in neuralgia and herpes zoster). The hyperemic effects are utilized in the treatment of furuncles and carbuncles. One application of liquid air is said to abort a boil. Lupus vulgaris and lupus erythematosus, as well as epithelioma, have been treated in this way with some success though it is not as satisfactory as carbon dioxid snow (*g. v.*). It is also said to be an effective means of removing nævi without pain and without leaving a scar. For the destruction of polypi and other benign growths it may be used in the same way as other cauterizing agents.

The fluid is supplied in Dewar's bulbs and, according to White, is applied with a certain amount of pressure on a swab of wool. See Carbon Dioxid Snow.

AIROL.—Bismuth oxyiodogallate, or, practically, dermatol with the addition of iodin. It is employed as a substitute for iodoform in similar doses and preparations. It is not without toxic effect in large doses. Calomel is incompatible with it.

AIR-PASSAGES, FOREIGN BODIES IN.—See Larynx.

AKROMEGALY. Definition.—A disease characterized by abnormally large development of the extremities and of the face, the bony as well as the soft parts being involved.

Etiology.—It is a disease of early adult life, usually commencing before 30. Heredity need not be considered, for although it is slightly more frequent in women, they are likely to become sterile early. Various diseases have preceded, but none have been proved to cause, its appearance.

Morbid Anatomy.—Akromegaly is a true hypertrophy of the bones. In well-marked cases nearly

all bones may be affected, although the enlargement of the bones of the extremities and of the face is more evident. In the long bones the greatest growth is at the ends and at the points of insertion of muscles and tendons. The spongy bones are all more or less thickened, while flat, thin bones, the cranial excepted, may become thinner in their plates. The spongy ends of long bones may show a condensing osteitis, and ossification may be found in articular cartilages and tendons, and by this process cranial sutures may be obliterated. The dilatation of the antrum is believed to be the cause of the apparent enlargement of the superior maxilla. The marked growth of the lower jaw, which is lengthened and widened, particularly at the symphysis, favoring a prominent mental process, gives rise to a prognathous outline that is quite pathognomonic of the disease. The features gradually assume the type characteristic of the disease, obliterating racial distinctions. Inasmuch as the blood-vessels are usually changed—either narrowed, from a thickening of the intima, or dilated, from thinning of the remaining coats—thus modifying the nutrition of the tissues, various degenerations are found. There may be enlargement of the brain and nerves and thickening of the endocardium and pericardium. There may be increase of connective tissue in the liver, or sclerosis and fatty change in the nerves. The heart is generally enlarged. Chronic nephritis and renal cysts have been observed. The liver, kidneys, and suprarenal capsules are often increased in size. A very constant finding is a diseased pituitary body, which may be enlarged, diseased, or the seat of a cyst, glioma, adenoma, or small-celled sarcomatoid growth. There may also be enlargement of the thyroid and thymus glands, or atrophy of the former.

Pathology.—Since the pituitary body is so constantly found to be diseased, the disease is inferentially one of the ductless gland system, and not of neurotic origin (von Recklinghausen), nor a trophoneurosis (Lancereaux), nor of the vascular system (Klebs). The secretion of the pituitary body is qualitatively changed.

Symptoms.—These are due to local changes in the pituitary body or around the sella turcica, or to connective-tissue changes in the organs of the body, to the resulting vascular and nervous degenerations, and to growth in the bones. Kyphosis is common, resulting from involvement of the spinal column. There may be atrophy of the muscles. The eyeballs are often prominent and exophthalmos may be observed. Of the special symptoms, headache occurs very frequently, also pain in the extremities. The voice becomes altered by reason of changes in the tongue and larynx. The special senses are often impaired. Visual impairment is nearly always present and may progress to total blindness from optic atrophy; narrowing of the visual fields in all degrees, or hemianopsia and optic neuritis due to pressure, are frequent. In a number of cases bitemporal hemianopsia, due to pressure of the hypertrophied pituitary body on the chiasm, has been noted. Various cutaneous manifestations (as hyperhidrosis, anesthesia, trophic disturbances), symptoms referable to the circulation (as dyspnea, asthmatic attacks, hypertrophy and dilatation of the heart, palpitation), modifications of the urine (as polyuria, albuminuria, and glycosuria), are not infrequent. Mentally, the patients are dull, and they often suffer from a sense of fatigue. There is diminution of sexual desire, and in women menstrual disorders and early cessation of the menses.

Diagnosis.—This presents no difficulties. It is distinguished from progressive hyperplasia, which is congenital and usually unilateral, and involves the shaft of the bone. For its relation to giantism, see GIGANTISM. From osteitis deformans (Paget's disease) the distinction is simple. In hypertrophic pulmonary osteoarthropathy (Marie) the jaw is not enlarged, the articular surfaces of long bones are markedly thickened, kyphosis is not constant, and lesions of the respiratory organs are associated.

The earlier period of its onset, the oval face, the sausage-shaped fingers, and the yellow and wrinkled skin differentiate akromegaly from myxedema.

Prognosis.—The disease is of long duration and generally fatal. The symptoms may be stationary as regards severity. Death is usually unexpected. Considering the number of instances in which metabolism is disturbed, the patient's resistance to intercurrent febrile diseases is lessened.

Treatment.—As it is likely that the primary cause of the disease lies in the disordered secretion of the pituitary body, the hypodermic injection of extracts of this body is indicated. Marinesco reports that in 3 instances the headache diminished considerably, but not the pains in, nor the size of, the limbs.

Inasmuch as Osborne found evidence that the thyroid had attempted to furnish a new secretion, and at the same time a large amount of its own, to assist the pituitary body, thyroid extract is theoretically useful. Certainly, in a considerable number of cases the thyroid has been found to be atrophied—it may be from its hypertrophy by connective-tissue formation—which prevents it from performing its functions. Bramwell obtained success in one instance, but in a second, possibly a case of gigantism, great improvement followed the use of the pituitary after the failure of the thyroid extract.

Observing the diminution of red blood-corpuscles and hemoglobin, and the leukocytosis of the late stages, in addition to the thyroid extract Brown-Séquard recommended the simultaneous administration of extracts of spleen and bone-marrow, equal parts, daily injections. Of particular importance is the maintenance of as high a degree of nutrition as is possible.

The various symptoms must be treated as they arise with a view to relief only.

ALBARGIN.—A compound of silver nitrate with gelatin, containing from 13 to 15 percent of silver. It is used as a substitute for silver nitrate.

ALBINISM (Congenital Achroma; Congenital Leukoderma).—That condition of the skin in which there is a congenital absence of pigment, unaccompanied by textural changes in the skin, and involving its entire surface, including the pilary

filaments and the choroidal coats and irides of the eyes. It is usually associated with nystagmus, photophobia, and astigmatism.

ALBUMIN.—A proteid substance, the chief constituent of the body. Its molecule is highly complex, and varies widely, within certain limits, in different organs and conditions. It contains approximately the following percentages: Carbon, 51.5 to 54.5; hydrogen, 6.9 to 7.3; nitrogen, 15.2 to 17.0; oxygen, 20.9 to 23.5; sulphur, 0.3 to 2.0. Its exact composition and constitution are still unknown. Albumen (white of egg, often called albumin) is largely composed of it. Other varieties are called after their sources or characteristic reactions, as acid albumin, alkali albumin, muscle albumin, serum albumin, ovum albumin, vegetable albumin, etc. Normal albumin is the type of a group of proteids known as albumins. For the various tests for albumin see URINE (Examination). See also ALBUMINURIA.

ALBUMINOID DISEASE.—It is also known as **Lardaceous, Waxy, or Amyloid Degeneration.** A form of degeneration usually affecting simultaneously a number of the viscera, and occurring secondarily to some preexisting disease. Those viscera, most usually the seat of the change are, in the order of frequency, the spleen, liver, kidneys, intestine, and lymph-glands. (See SPLEEN, LIVER, NEPHRITIS.) The tissues around the capillary vessels are first affected; from these centers it spreads until the whole organ on section presents a pale, glistening, waxy, or bacon-like appearance. This is due to the infiltration of a peculiar proteid substance, lardacein, which, with iodin, gives a deep mahogany brown color, the characteristic test for the disease. The preexisting disorder is either some chronic suppuration, as in diseases of the bones or joints, or some wasting disease, like pulmonary tuberculosis, syphilis, etc. The only way in which the disease may be arrested is by thorough removal of the cause.

ALBUMINURIA.—The presence in the urine of albumin, a mixture of serum albumin and serum globulin in various proportions. True albuminuria must be distinguished from the presence of albumin due to an admixture with the urine of blood, pus, or other albuminous fluid. However, even under these circumstances it must be remembered that true albuminuria may be coexistent. Albumin in the urine may result from a number of causes: *e. g.*, from mechanic interference with the renal circulation; from congestion, lesions, and organic diseases of the kidneys themselves; from toxic substances in the blood, such as lead, in which case there is a granular form of nephritis; from changes in the blood due to various diseases, as anemia, purpura, scurvy, and sepsis; in pyrexia; in certain nervous disorders, such as tetanus, delirium tremens, apoplexy, Graves' disease, and epilepsy; in various functional disorders, as dyspepsia, high living, great exertion, etc., and during pregnancy. The etiology of albuminuria is still undetermined, but it is now recognized that it will be produced by any condition that interferes with the nutrition of the glomeruli or renal epithelium. **Cyclic albuminuria,** a condition also known as physiologic, simple, functional, or transient albuminuria, or the albuminuria of adolescence, in which a small quantity of albumin appears in the urine, especially of the young, at stated times of the day; hence the term "cyclic." The nature of this phenomenon is not positively known, but it is probably the result of some changes in the renal circulation. See NEPHRITIS, KIDNEY, URINE (Examination).

ALCOHOL.—Ethyl alcohol, C_2H_5OH. A liquid obtained by the distillation of fermented grain or starchy substance. It is used in pharmacy as a solvent for resins, and as a base for all tinctures. Commercial alcohol contains 91 percent of absolute alcohol, with 9 percent of water.

Action.—Alcohol is both refrigerant and rubefacient, and is also astringent, anhidrotic and slightly anesthetic. While it is antiseptic and disinfectant, it has comparatively little bactericidal action at the temperature of the body, and alcoholization actually predisposes to bacterial infection. It generally tends to promote digestion, sharpening the appetite and increasing the flow of gastric juice, but large quantities give rise to so much local irritation that nausea and vomiting result. In concentrated form it reflexly stimulates the heart and respiration and causes dilatation of the blood-vessels, particularly those of the skin. About 90 percent of the alcohol absorbed from the alimentary tract undergoes combustion. In doing so it gives up energy to the body, and is therefore to be considered as a food. Alcohol is generally regarded as a central nervous stimulant, which first excites and then depresses the cerebral and other cells. Narcotic doses usually cause a considerable reduction of temperature. Alcohol is somewhat diaphoretic and diuretic. The small percentage of it which is not oxidized in the tissues is excreted unchanged, principally by the lungs and kidneys, and to a slight extent in the sweat and milk.

Therapeutics.—Alcohol is employed as an evaporating lotion for sprains, bruises and local inflammations, and its rubefacient and astringent effects are also made use of in various conditions. Given internally, it may relieve gastric pain and is sometimes of service, especially in the form of champagne or of brandy, in small doses with ice or effervescent mineral waters, in checking nausea and vomiting. It is useful in diarrheal affections and in intestinal as well as gastric colic. Alcohol is of immense advantage in many cases of febrile disease, when during critical periods it sustains the vital powers by supplementing the insufficient quantity of nutriment which the system is capable of appropriating and at the same time stimulating the digestion, thus enabling the patient to dispose of an increased amount of food. It is also highly useful in arousing and supporting the flagging powers in sudden depression of the system, as in shock, syncope, severe hemorrhage, and poisoning by various drugs. In phenol poisoning and snake-bite it likewise has a direct antidotal effect. In certain chronic conditions it is of undoubted benefit, but the danger of the patient's contracting the alcoholic habit must always be taken into consideration (Wilcox).

Alcohol and Food.—W. S. Hall of Chicago gives the following table showing the differences between foods and alcohol:

Food.	Alcohol.
1. A certain quantity will produce a certain effect at first; the same quantity will always produce the same effect in the healthy body.	1. A certain quantity will produce a certain effect at first but it requires more and more to produce the same effect when the drug is used habitually.
2. The habitual use of food never induces an uncontrollable desire for it in ever-increasing amount.	2. When used habitually it is likely to induce an uncontrollable desire for more, in ever-increasing amounts.
3. After its habitual use a sudden total abstinence never causes any derangements of the central nervous system.	3. After its habitual use a sudden total abstinence is likely to cause a serious derangement of the central nervous system.
4. Foods are oxidized slowly in the body.	4. Alcohol is oxidized rapidly in the body.
5. Foods, being useful, are stored in the body.	5. Alcohol, not being useful, is not stored in the body.
6. Foods are the products of constructive activity, activity of protoplasm in the presence of abundant oxygen.	6. Alcohol is a product of decomposition of food in the presence of abundant oxygen.
7. Foods (except meats) are formed in nature for the nourishment of living organisms and are, therefore, inherently wholesome.	7. Alcohol is formed in nature only as an excretion. It is, therefore, in common with all excretions, inherently poisonous.
8. The regular ingestion of food is beneficial to the healthy body, but may be deleterious to the sick.	8. The regular ingestion of alcohol is deleterious to the healthy body, but may be beneficial to the sick (through its drug action).
9. The use of foods is followed by no reaction.	9. The use of alcohol, in common with narcotics in general, is followed by a reaction.
10. The use of food is followed by an increase in activity of the muscle cells and brain cells.	10. The use of alcohol is followed by a decrease in the activity of the muscle cells and brain cells.
11. The use of food is followed by an increase in the excretion of carbonic acid.	11. The use of alcohol is followed by a decrease in the excretion of carbonic acid.
12. The use of food may be followed by accumulation of fat, notwithstanding increased activity.	12. The use of alcohol is usually followed by an accumulation of fat through decreased activity.
13. The use of food is followed by a rise in body temperature.	13. The use of alcohol may be followed by a fall in body temperature.
14. The use of food strengthens and steadies the muscles.	14. The use of alcohol weakens and unsteadies the muscles.
15. The use of food makes the brain more active and accurate.	15. The use of alcohol makes the brain less active and accurate.

Alcohol Table.—Average percentage of alcohol contained in the following liquids:

Rum	60 to 75	Sauterne	11 to 18
Whisky	50 to 60	Burgundy	8 to 14
Brandy (British)	50 to 60	Moselle	8 to 12
Brandy (French)	50 to 55	Rhine Wines	7 to 16
Gin	48 to 60	Chablis	7 to 10
Port	15 to 18	Champagne	6 to 13
Marsala	15 to 21	Bitter Ale	6 to 9
Sherry	14 to 18	Cider	2 to 9
Madeira	14 to 17	Porter	4 to 7
Hungarian Wines	9 to 15	Beer	2 to 4
Claret	8 to 12	Ginger Beer	1 to 3

ALCOHOLISM.—Alcoholism is the term used to designate the physical and mental phenomena induced by the excessive use of alcohol.

Temulentia is a term signifying drunkenness; **mania-a-potu** is an acute mental derangement, occurring in those of strong neurotic tendencies; **delirium tremens** is an attack of delirium associated with tremors in persons with the numerous changes resulting from chronic alcoholism. Delirium tremens results in alcoholics suffering from some form of nephritis, preventing the elimination of some poison developed from the ingested alcohol. **Dipsomania, or oinomania,** is an alcoholic insanity in which an individual, at longer or shorter intervals, has paroxysms of alcoholic desires, between which he neither wishes nor craves alcohol.

Pathologic Anatomy. Acute Alcoholism.—The brain is the seat of an active hyperemia; the mucous membrane of the stomach and duodenum is markedly injected and covered with a ropy mucus slightly tinged with blood, and the gastric juice is altered in quality and quantity. The kidneys are also the seat of an active hyperemia.

Chronic Alcoholism.—In this condition of the economy there may be no organs or tissues that do not present morbid changes. The gastrointestinal mucous membrane presents the changes of chronic catarrhal inflammation; the liver, the first organ to receive the poison after the stomach, presents the changes of congestion, cirrhosis, or fatty degeneration; the kidneys show chronic congestion and often the changes incident to chronic interstitial nephritis. According to Hughes, the postmortem results found in 25 cases of delirium tremens dying in the Philadelphia Hospital were 14 with the changes of interstitial nephritis, 8 with chronic parenchymatous nephritis, and 3 with fatty kidney; all showed chronic gastric catarrh, and changes in the myocardium and in the aorta and arteries of the heart and brain. The muscular structure of the heart may undergo fatty degeneration and the vessels the senile changes of the aged. The brain structure presents the changes of sclerosis in various stages, and there may be chronic meningitis and pachymeningitis with hematoma. The nerves are altered, atrophied, and hardened, and the neuroglia, vessels, and ganglion cells of the spinal cord show similar changes.

Symptoms.—Acute alcoholism, resulting from the use of a large quantity of alcoholic fluid, occurs with symptoms of mild intoxication to drunkenness passing to acute delirium and acute coma. The condition begins with a period of exhilaration, passing to semidelirium and ending in acute coma, when the breathing is stertorous, the face bloated and congested, the lips are swollen and purplish, the pupils are contracted, the pulse is feeble and slow, the skin cold and clammy, the temperature depressed, and frequently the control of sphincters lost. An individual so affected is colloquially said to be "dead drunk."

The cases of ordinary drunkenness do not often pass beyond the stage of exhilaration ending in a mild coma or sleep.

Mania-a-potu, or acute alcoholic delirium, is the direct result of alcoholic excess in those engaged in a sudden debauch or who have drunk alcoholic beverages very "hard" for a comparatively short period. The individuals grow more and more

excitable, lose all desire for food, are unable to sleep, become the prey of horrible hallucinations —"the horrors"—finally terminating in mania that resembles delirium tremens in all save the tremor, which is absent.

Chronic Alcoholism.—The condition to which this term has been given constitutes a disease. It is the result of the continued use of alcoholic beverages until one or more of the morbid organic changes have occurred. These persons are markedly dyspeptic, with coated tongue, fetid breath, and early morning vomiting, straining, or retching, attended with much distress. There is a gradually developing muscular tremor, progressing to the ataxic gait, and insomnia. The face may become either pallid, flabby, and bloated, with an imbecile expression, or swollen, rough, and dusky, with swellings under the eyes, and yellow injected conjunctivæ. There is headache, vertigo, and attacks of hallucinations; the memory grows weaker, the judgment less accurate, the moral sense blunted, and the will-power weak and erratic. These and many other symptoms add to the distress of the individual, which he attempts to overcome by the use of more and more of the poison.

Delirium Tremens.—In the majority of instances delirium results from a prolonged debauch in an old drinker. It begins with an increased tremor, insomnia, irritable, excitable manner, followed by the characteristic hallucinations and illusions, during which snakes and all forms of repulsive reptiles are seen, causing the most intense horror and abject fear. There also occur illusions of smell and hearing. This marked excitement is followed by great depression, the skin is cold and clammy, the pulse feeble, the muscular system weak, the mind in a condition of coma-vigil, and a febrile condition, typhoid in character, develops. Uremic symptoms soon develop, the temperature suddenly bounding to 103° to 105° F., with albumin and casts in the urine.

The ordinary duration of an attack of delirium tremens is about 2 weeks in those recovering, although death may occur at any time from cardiac failure, uremia, or alcoholic pneumonia. Convalescence dates from the beginning of refreshing sleep, the patient awakening with a clear mind and desire for food. Should the delirium subside, the patient still continue to mutter and pick at the bed-clothing, the tongue become dry and cracked, and the regurgitation of dark brownish and bilious matter occur, the condition is critical, and an early fatal termination may be expected.

Dipsomania, or oinomania, is the inherited or acquired mental condition that craves the drinking of intoxicating liquors. This is a true mental disease. It manifests itself in periodic attacks of excessive indulgence in alcoholic drinking, or this symptom of this sad disease may be replaced by other irresistible desires of an impulsive kind, such as lead to the commission and repetition of various crimes, the gratification of other depraved appetites, robbery, or even homicide. Imbecility and dementia frequently result.

The paroxysms at first occur at long intervals, but gradually the intervals become shorter and shorter, until the individual entirely surrenders himself to alcoholic and other excesses.

Diagnosis.—Profound drunkenness or alcoholic coma may be and often is confounded with apoplectic and uremic coma. Von Wedekind suggests the following method for diagnosing drunkenness: "By simply pressing on the supraorbital notches with a steadily increasing force you may, with certainty of success, bring an unconscious alcoholic to his senses, and thus differentiate between alcoholic and other comas." In hospital practice one should always be on the lookout for fracture of the skull. It must be remembered that many such patients are given alcoholic drinks before reaching the physician. See Coma.

The symptoms of chronic alcoholism often bear a close resemblance to the following maladies: General paralysis, disseminated sclerosis, paralysis agitans, locomotor ataxia, cerebral and spinal softening, epilepsy, chronic dementia and nervous dyspepsia.

In individuals whose habits are unknown the question of diagnosis is attended with considerable difficulty. Anstie lays much stress upon the importance of the following 4 points, diagnostic of chronic alcoholism: Insomnia, morning vomiting, muscular tremor, and causeless mental restlessness.

Prognosis.—In acute alcoholism the prognosis is good if the patient is manageable.

In chronic alcoholism the organic changes, the direct result of the alcoholic habit, tend to shorten life by the production of fatty heart, Bright's disease, insanity, impotence, epilepsy, melancholia, and organic brain diseases. The danger in delirium tremens is heart failure or deepening coma. The association of chronic nephritis with delirium tremens, perhaps its cause, must always be taken into account in determining a prognosis. Acute lobar pneumonia is a very fatal complication of all forms of alcoholism.

Treatment.—In deciding upon a plan of medication in any of the varieties of alcoholism, the condition of the kidneys, heart, and vessels must be considered. And see Lambert Treatment for Narcotic Addiction.

Acute Alcoholism.—The treatment of a case of drunkenness requires no especial consideration, as the rapid elimination of the alcohol soon occurs if its ingestion ceases. Solution of ammonium acetate in large, frequently repeated doses assists the elimination of the poison. A full dose (half an ounce) of spirit of ammonia, in water, will often sober a "drunk."

In robust subjects the most rapid results are obtained by putting them to bed and administering a hypodermic of apomorphin hydrochlorid, 1/10 to 1/5 of a grain; after emesis the patient will usually go to sleep without further medication, and will awaken sober, but feeble. A combination of tincture of capsicum, 5 minims, tincture of nux vomica, 5 minims, compound tincture of cinchona, 1 dram, should be given every 3 or 4 hours, with koumiss, milk, beef-juice, or raw eggs *ad libitum*. The bowels should be relieved as speedily

as possible, and for this purpose use a mercurial, followed by a saline laxative. If the patient is too feeble for emesis, order solution of ammonium acetate, 4 drams, every 2 hours, and a wet pack; after this treatment, the acute effects of the alcohol speedily disappear. This is to be followed by a tonic course. For insomnia subsequent to acute alcoholism Brower usually prescribes a combination of sodium bromid, 15 grains, chloral hydrate, 15 grains, tincture of hyoscyamus, 15 minims, to be repeated in 1 hour, if necessary. Heat must be applied to the body if there is evidence of prostration and a cold and clammy skin.

For **mania-a-potu** the immediate and complete withholding of alcoholic beverages is essential to successful treatment. If the stomach will tolerate food—and it usually will—milk, diluted with lime-water, or Seltzer water, or hot beef-tea strongly seasoned with capsicum, should be frequently administered, together with such cerebral sedatives as potassium bromid, chloral, by the mouth or rectum, or the hypodermic use of morphin sulphate, 1/3 of a grain, with either hyoscin hydrobromid, 1/100 of a grain, or atropin sulphate, 1/100 of a grain. If the attack is associated with symptoms of cardiac depression, brisk friction, artificial warmth, stimulating enemas, and hypodermic injections of strychnin sulphate, 1/24 of a grain, repeated, or citrated caffein, 3 grains, repeated, or digitalis, are indicated. "If chloral is inadmissible by reason of weakness of the circulation, paraldehyd may be substituted, in doses of from 1/2 to 1 dram, repeated at intervals of from 1 to 2 hours until quietude is produced" (J. C. Wilson). Act on the bowels and kidneys in all cases.

For the **collapse** following a lethal dose of alcohol the stomach should be immediately emptied by emetics or the stomach-tube or pump, and the organ washed out with warm water or coffee, the patient placed in the recumbent posture and surrounded by artificial warmth, hot friction to the lower extremities, the use of artificial respiration or of faradism to the thorax, inhalations of ammonia, hypodermic injections of digitalis, strophanthus, or atropin. "The flagging heart may be stimulated by occasionally tapping the precordia with a hot spoon—Corrigan's hammer" (J. C. Wilson).

An attack of acute alcoholism or mania-a-potu may often be aborted with trional, 30 grains, repeated in 2 hours, or chloralamid, 30 to 40 grains, repeated.

Chronic Alcoholism.—The symptoms of chronic alcoholism are the direct result of the continuous action of a single toxic principle, and no success of even a temporary kind may be expected unless the poison be withdrawn. The rapidity with which this can be accomplished is a question for the skill, judgment, and experience of the physician to determine; the chief obstacle to its success will be moral rather than physical. Next to the disuse of alcohol is the question of diet. Much progress will be made as the appetite and digestion improve, and hence great attention should be given to it. The general health will also be benefited by fresh air, exercise, mental occupation, cold or tepid sponging, and an occasional hot bath at bedtime. For the combination of symptoms of spirit craving, morning vomiting, muscular tremor, mental restlessness, and insomnia, no drug is comparable with strychnin nitrate, either hypodermically twice daily or, what is preferable, by the stomach, to secure its local action on the mucous membrane. If insomnia is persistent in spite of the foregoing treatment, the temporary use may be made of such remedies as chloral, paraldehyd, or trional, 30 grains, repeated. In many cases it is desirable, for its mental effect, if for no other, to administer what the patient terms a substitute for his alcoholic beverages. The following is a good combination for that purpose:

℞. Tincture of nux vomica, ℥ ss
Tincture of capsicum, ℥ j
Fluidextract of lupulin, ℥ iij
Compound infusion of gentian, ℥ jss.

A dessertspoonful 3 or 4 times daily, well diluted.

For the anemia, loss of strength, and mental debility, benefit may follow the use of syrup of the hypophosphites with strychnin.

Delirium Tremens.—The patient should be isolated, have a skilful, sensible nurse, alcohol entirely withdrawn or the quantity greatly reduced, supplied with an easily digested nutritious diet, and remedies used to combat the excited nervous system. For the last purpose no one combination is comparable with hypodermic injections of morphin sulphate, 1/4 of a grain, with atropin sulphate, 1/120 of a grain, or hyoscin hydrobromid, 1/100 of a grain, repeated occasionally, as needed; or trional, chloralamid, or paraldehyd; chloral in the following combination also acts well if the stomach is not too irritable:

℞. Chloral, ℥ ss
Tincture of capsicum, ℥ ss
Peppermint water, ℥ vss.

A tablespoonful every 2 hours until sleep is produced; alternated with a cup of hot beef-tea, to which has been added a bolus of capsicum, 20 grains.

Care is necessary that a condition of coma is not produced by the remedies mentioned.

In patients with irritable stomachs a sedative mixture consisting of potassium bromid, 40 to 60 grains, and chloral hydrate, 20 grains, may be advantageously administered by rectum and repeated according to indications.

For depression and cardiac weakness, the internal use of any one of the following drugs is serviceable: Strychnin sulphate, citrated caffein, spirits of chloroform, ammonium carbonate, tincture of strophanthus, or digitalis.

The treatment of delirium tremens in the young differs from that in the old. In first attacks in young, strong subjects, withdrawal of forms of alcohol, light and easily assimilated food, moderate purgation, and 1/12 to 1/8 of a grain of

tartrated antimony are useful. If sleeplessness supervenes, 30 grains of potassium or sodium bromid, with 20 grains of chloral hydrate, may be given every 4 hours, in combination. Sulphonal, 30 grains, may be used. Sedatives must not be pushed. An experienced attendant should be present. Means of self-destruction should be removed. Restraints of a mechanic nature are not permissible. A padded room is of great service. In older cases a mild purge may be given, and at short periods, light and very nourishing food should be administered. Sedatives must be carefully watched. Laudanum, 30 to 40 minims, may be given at bedtime or to allay restlessness.

Dipsomania.—The management of these cases is similar to that previously mentioned for chronic alcoholism, although the strychnin treatment should be given the preference in doses of 1/30 to 1/15 of a grain hypodermically three times daily.

Strict attention must be given to the skin, bowels, and kidneys. If the heart is not depressed, the cautious use of hot-air bath or hypodermic injection of pilocarpin hydrochlorid, 1/3 of a grain, repeated at the onset of the mania, is advised.

ALEPPO BOIL.—A disease of the tropics characterized by crops of papules which ulcerate and remain open for months despite all treatment.

ALEURONAT.—A vegetable albumin used as a substitute for wheatbread in diabetes mellitus.

ALEXANDER'S OPERATION.—An operation devised for the cure of backward displacement of the uterus. It consists, as now performed, in laying open the inguinal canal, forcing the round ligament from its attachments and drawing it forward until the fundus of the uterus is felt to impinge against the anterior abdominal wall. The excess of ligament (2 or 3 inches) is now removed, and the remainder is stitched to the floor and pillars of the inguinal canal. The inguinal canal is obliterated, as in Bassini's operation for the radical cure of hernia, and the wound is closed. See Uterus (Retrodisplacements).

ALEXIA.—Word-blindness. A form of aphasia and a special type of psychic blindness, in which the patient is unable to recognize ordinary written or printed characters. **Musical alexia**, or musical blindness, is a pathologic loss of the ability to read music. See Aphasia.

ALIMENTATION.—See Dietetics, Infant Feeding, etc.

ALKALI.—The term includes the hydrated oxids of the alkali metals; these are electropositive, strong bases, uniting with acids to form salts, turn red litmus blue, and saponify fats. A **caustic alkali** (usually potash) is one so concentrated as to possess caustic properties. Potash and soda are called **fixed alkalies**, because they are permanently solid; soda is called a mineral, potash a vegetable, and ammonia a volatile, alkali. See Antacids.

ALKALIES, SWALLOWING.—Similar symptoms are produced by both potash and soda. Pearl-ash, or potassium carbonate, and soap-lees, or sodium carbonate, are the alkalies usually swallowed. An acrid caustic taste is experienced in swallowing, and there is burning heat in the throat, extending down the gullet. When vomiting does occur, the vomitus is mixed with dark, brown-colored blood and with flakes of mucous membrane. Local effects depend chiefly on the causticity of the fluid. Purging, with colicky pains in the abdomen, a cold and clammy tongue, and a feeble and quick pulse exist. After a time the tongue, lips, and throat swell and become soft and red. Saltpeter (potassium nitrate), potassium bisulphate, potassium bitartrate, potassium alum and sulphid, and even common salt (sodium chlorid), in large doses, have acted as poisons.

Treatment.—At once administer dilute acids, such as vinegar and water, lemon, orange, or lime juices, and such oils as form soaps with the alkalies. Opium should be freely given if there is much pain. The stomach-pump should not be used unless the case is seen early. The quantity required to destroy life is variable, the concentration rather than the quantity influencing this point. Three ounces of a strong solution of potassium carbonate have killed a boy in 3 hours. See Poisoning.

ALKALINITY.—The living body secretes materials that have an acid reaction (gastric juice, urine) and also materials that are alkaline (saliva, pancreatic juice, bile, etc.). In this way should one secretion become excessive, it becomes neutralized by the action of the one of opposite reaction, and thus the normal equilibrium is established. The medium of exchange throughout the body is the blood. This fluid normally has an alkaline reaction, and even maintains this reaction in nearly all pathologic conditions. Ralfe states that the alkalinity of the blood is maintained by the constant passage into it of the alkaline salts of the food and of alkaline carbonate derived from the oxidation of the lactic, oxalic, and uric acids furnished by the disintegration of the tissues. A sympathetic relationship exists between the acid secretions and the alkaline; thus, the saliva becomes more alkaline during gastric digestion, while the acidity of the urine is considerably lessened. It has been shown that a similar relationship exists between the elimination of carbonic acid by the lungs and the acidity of the urine, the latter falling as the former is increased, and vice versa. The alkalinity of the blood serves a good purpose in four ways: (1) It aids in maintaining the albumin in a liquid state; (2) it renders the serum more germicidal; (3) it increases the absorptive power of serum for gases; (4) it aids in oxidation. See Acidity.

ALKALOIDS.—All nitrogenous vegetable compounds of basic and alkaline character or their derivatives, from which bases may be isolated. They are the chief constituents of the active principles of poisons or the vegetable drugs, employed as medicines. Those alkaloids containing no oxygen are generally liquid and volatile; such are nicotin and coniin. The others are solid, crystallizable and nonvolatile. For the putrefactive alkaloids see Ptomains. Tannin is the best *antidote* for alkaloids in general, as it forms an insoluble tannate. Potassium permanganate is also serviceable; it should be administered in form of a solution 1 : 1000 to 1: 500.

ALLSPICE.— See Pimenta.

ALMOND (Amygdala).—There are two varieties, called *Amygdala amara,* or bitter almond, and *Amygdala dulcis,* or sweet almond. They are identical botanically, but differ in taste and in the presence of amygdalin. This is important, for hydrocyanic acid, a most violent poison, is produced by the reaction between amygdalin and emulsin in the presence of water. Amygdalin exists in the bitter, but not in the sweet, almond.

When the oil and the saccharin constituents of almonds have been removed, they may be made into good bread for diabetics, as they contain virtually no starch. The essential and the expressed oil of almonds have been recommended for the cough of phthisis, given in emulsion in a few drops. The emulsions of both the bitter and sweet almond are made in the same way, may be used for the same purposes in teaspoonful doses, and are especially serviceable in cough mixtures as a vehicle. In gonorrhea the emulsion used as a vehicle will help decrease the burning on urination. In excoriations, chapped hands, freckles, sunburn, etc., expressed oil of almonds is used locally in unguents and lotions.

An emollient and a soothing drink, useful in irritations of the stomach and intestines, and of the air-passages and pharynx, is the following:

℞. Sweet almonds, ℥ ss
Gum arabic, ℥ ss
White sugar, ℥ ij.
Rub up well by gradually adding—
Distilled water, ℥ viij.

Almond paste for the skin:

℞. Powdered bitter almonds, ℥ iv.
White of egg, ℥ j.
Beat well together to a smooth paste, gradually adding—
Spirit of wine, Rose-water, } each, ℥ ij.

℞. Sweet and bitter almonds, of each, ℥ ij
Spermaceti, ℥ ij
Oil of almonds, ℥ ss
Windsor soap, ℥ ss
Rose-water, ℥ j
Oil of rose, Oil of bergamot, } each, gtt. xij.

To either of the foregoing, powdered camphor, 2 drams, may be added. Oil of bitter almonds may be substituted for the oil of roses and the oil of bergamot.

Almond bread is a variety of bread made from almond flour, for use by diabetics. It is made as follows: Take of blanched sweet almonds 1/4 of a pound; beat them as fine as possible in a stone mortar; remove the sugar by putting in a linen bag and steeping for a quarter of an hour in boiling water acidulated with vinegar; mix this paste thoroughly with 3 ounces of butter and 2 eggs. Add the yolks of 3 eggs and a little salt, and stir well for some time. Whip the whites of 3 eggs and stir in. Put the dough thus obtained into greased molds and dry by a slow fire.

Oil of bitter almond is volatile, of aromatic odor, bitter, burning taste, slightly soluble in water, but freely so in alcohol and ether. Its dose is from 1/4 to 1 minim in a mixture. It contains from 2 to 4 percent of hydrocyanic acid which may be removed by distillation with caustic potash. **Bitter almond water** is a weak solution of the oil of bitter almond in distilled water. Its dose is indefinite; average, 1 dram. Oil of mirbane, or nitrobenzol, closely resembles oil of bitter almonds, and is used for flavoring. It contains no hydrocyanic acid, but is a dangerous poison when inhaled, even in small quantities.

Spirit of bitter almond, or essence of bitter almond, contains of the oil 1 part, dissolved in 80 parts of alcohol and water enough to make 100 volumes. Its dose is regulated according to the quantity of alcohol desired. Syrup of almond contains spirit of bitter almond 1 percent; dose, 1 dram.

Expressed oil of almond is made from bitter or sweet almond; dose, 1 ounce.

ALOES.—The inspissated juice of the leaves of *Aloe vera, A. Chinensis, A. Perryi,* etc. Its properties are due to a neutral principle, *aloin;* a tonic astringent, useful in amenorrhea, chronic constipation, and atonic dyspepsia. It is an emmenagog and anthelmintic. Dose, 1 to 6 grains.

Aloes is of a persistent bitter taste, and is slow in its action. Plethoric persons, pregnant women, patients with fever or with irritation or catarrh of the intestine, especially of the rectum, should not be given aloes. While beneficial in subacute or chronic constipation, aloes must not be used continually. In hemorrhoids from muscular relaxation, aloes is of great benefit. It is of value in amenorrhea from atony of the sexual system, constipation, or anemia. It is slowly purgative, affecting chiefly the large intestine, and is a powerful hepatic stimulant. In small doses it is stomachic and tonic. As an anthelmintic, it is given by the rectum. It is especially useful in dyspepsia, constipation, amenorrhea, hypochondriasis, hepatic congestion, flatulency, and mesenteric disease, ascarides, etc.

For constipation:

℞. Extract of aloes, Powdered rhubarb, Powdered ipecac } each, gr. xij.
Mix and divide into 12 pills. Take 1 or 2 as needed.

In amenorrhea:

℞. Pill of aloes and iron, ℥ j
Oil of savine, Oil of rue, } each, ♏ iij
Powdered capsicum, gr. viij.
Mix well and divide into 24 pills. Take 1 pill 3 times daily.

Preparations.—Dose, 1/2 to 2 grains. **A. Purificata,** *Purified Aloes*—prepared from aloes by melting and mixing with one-fifth its weight of alcohol, straining and evaporating; soluble in alcohol. Dose, 1 to 5 grains. From it are prepared the following preparations. **Extractum A.,** *Extract of Aloes*—prepared by mixing 1 part of

aloes with 10 parts of boiling water, standing 12 hours, decanting, straining, and evaporating. Dose, 1/2 to 5 grains. **Tinctura A.,** *Tincture of Aloes*—has of aloes 10, glycyrrhiza 20, diluted alcohol to 100 parts. Dose, 10 to 60 minims. **Tinctura A. et Myrrhæ,** *Tincture of Aloes and Myrrh*—aloes 10, myrrh 10, glycyrrhiza 10, alcohol and water to 100 parts. Dose, 10 to 60 minims. **Pilulæ A.,** *Pills of Aloes*—each has aloes and soap, 2 grains each. Dose, 2 pills. **Pilulæ A. et Ferri,** *Pills of Aloes and Iron*—each pill contains gr. j each of aloes, sulphate of iron and aromatic powder, with confection of rose. Dose, 2 pills. **Pilulæ A. et Mastiches,** *Pills of Aloes and Mastic* (*Lady Webster's Pill*)—each pill has of aloes, gr. ij; mastic, gr. ss; red rose, gr. ss. Dose, 2 pills. **Pilulæ A. et Myrrhæ,** *Pills of Aloes and Myrrh*—each pill contains of aloes, gr. ij; myrrh, gr. j; aromatic powder, gr. ss; mixed with syrup. Dose, 2 pills. **Pilulæ Laxativæ Compositæ,** *Compound Laxative Pills*—each pill contains of aloin, gr. 1/5; strychnin, gr. 1/128; belladonna extract, gr. 1/8; ipecac, gr. 1/16; with glycyrrhiza and syrup. Dose, 2 pills. **Aloes** is a constituent of pilulæ rhei compositæ and tinctura benzoini composita. Incompatible with *Aloes* are mercury nitrate, silver nitrate; with *aloin* are alkaline hydrates, bromin-water, ferric chlorid, lead acetate (basic), tannic acid.

ALOIN.—A neutral principle found in aloes. It forms fine needles, possesses a very bitter taste, and acts as a strong purgative. Dose, 1/2 to 2 grains. See ALOES.

For chronic constipation.

℞.	Aloin,	gr. iv
	Strychnin sulphate,	gr. 1/3
	Extract of belladonna leaves,	gr. iij

Make 20 pills. Take 1 at night.

ALOPECIA (Baldness; Calvities). **Definition.**—Alopecia is a physiologic or pathologic deficiency or loss of hair, either partial or complete.

Congenital Alopecia.—This commonly manifests itself either as a scanty growth, a development only in certain localities, or as a retarded appearance of the hair. In rare cases there may be complete absence of the hair, due to arrested development of the follicles. In such cases hereditary predisposition is usually present, and there is likely to be, in addition, delayed or defective dentition.

Senile Alopecia.—As its name indicates, this form of baldness is observed in the aged. With the atrophic skin changes that accompany senility there takes place a gradual thinning of the hair, beginning upon the vertex of the scalp, the frontal and the temporal regions, and slowly leading to a more or less complete baldness of the scalp.

Premature Alopecia.—This form of alopecia occurs chiefly in individuals between the ages of 20 and 35. It may be either idiopathic or symptomatic.

In the idiopathic variety the scalp presents no abnormal condition. At first only a few hairs fall from time to time, being replaced by a shorter and finer growth. Later these fall, and are followed by still finer hairs. In this manner the entire hair of the scalp may be lost. The affection occurs in both sexes, although much less frequently in women than in men. Heredity appears to be a strong predisposing factor.

The **symptomatic** form results from various local and general diseases. Rapid falling of the hair (*defluvium capillorum*) follows acute diseases, such as typhoid fever, smallpox, etc. Full regeneration of the hair follows the restoration to health.

Rapid and extensive loss of hair occurs with great frequency in the early stages of syphilis. The most prolific cause of premature alopecia is chronic dry seborrhea (**dandruff**) of the scalp. This affection, after a long duration, leads to atrophy of the hair follicles.

Other local diseases, such as lupus erythematosus, erysipelas, psoriasis, eczema, tinea tonsurans, tinea favosa, etc., may all produce more or less marked alopecia.

Prognosis.—In congenital and senile alopecia treatment is of little or no avail. In idiopathic premature alopecia the prognosis should be extremely guarded. In symptomatic alopecia, particularly when there is a removable cause and no hereditary predisposition, the prognosis may be considered more favorable.

Treatment.—Internal treatment is to be employed whenever the condition depends upon a systemic cause. Such tonics as iron, strychnin, phosphorus, arsenic, and cod-liver oil may be prescribed with advantage.

Local treatment is of great importance, particularly when dandruff is present. It consists in the proper cleansing of the scalp and the stimulation of the sebaceous glands to healthy action.

The tincture of green soap makes an admirable shampoo for the removal of epithelial and sebaceous débris. This may be advantageously followed by such a hair wash as:

℞.	Resorcin,	ʒ ij
	Salicylic acid,	gr. xxx to ʒj
	Castor oil,	ʒ ss to jss
	Alcohol, q. s. ad	ʒ vj
	Oil of bergamot,	ʒ j.

Rub into the scalp each night.

When the scalp is accessible, ointments may be used:

℞.	Precipitated sulphur,	gr. xxx to ʒj
	Petrolatum,	ʒ ss
	Oil of bergamot,	♏xxx.

The following is the composition of a popular French hair tonic:

℞.	Hydrochlorid of quinin,	ʒ j
	Tannic acid,	ʒ iij
	Alcohol (70 percent),	1 1/2 pints
	Tincture of cantharides,	ʒ ijss
	Pure glycerin,	ʒ ijss
	Eau de cologne,	ʒ x
	Vanillin,	gr. ij
	Powdered sandalwood.	ʒ j.

This preparation, after being well mixed and shaken, is allowed to stand for 4 days, and is then filtered. It is rubbed into the scalp daily for the purpose named.

The following also have been recommended for baldness:

℞. Aromatic spirit of ammonia, ℥ j
Glycerin, ℥ ss
Tincture of cantharides, ℥ j
Rose-water, ℥ vij.
Apply to scalp morning and evening.

℞. Tincture of cantharides, ℥ jss
Tincture of capsicum, gtt. xx
Glycerin, ℥ ss
Cologne water, ℥ j.
Use on the scalp at night.

℞. Fluidextract of jaborandi, Tincture of cantharides, Glycerin, each, ℥ ss
Vaselin, ℥ jss.
Apply locally with a sponge morning and evening.

ALOPECIA AREATA.—Alopecia areata is a disease of the hairy system characterized by the more or less sudden occurrence of round or oval, circumscribed, bald patches, in rare cases coalescing and producing total baldness.

Symptoms.—The disease is usually limited to the scalp, but may affect the beard, eyebrows, eyelashes, and, in rare instances, the entire cutaneous surface.

As a rule, one, two, or more patches are present upon the scalp. They are circumscribed and rounded, and vary in size from that of a coin to that of the palm of the hand. The skin is smooth, soft, of a dead-white color, and totally devoid of hair. Occasionally, the patches are pinkish, as a result of slight hyperemia. The follicular openings are contracted and less prominent than in the healthy scalp. The skin is thin, soft, and pliable to the touch. In the beginning the patches are level or slightly elevated, while later they are sometimes slightly depressed.

The course of the disease is extremely variable. In some cases the bald patches develop suddenly in the course of a few hours. In other cases the hair loss is gradual, extending over a period of a few days or weeks. The areas then spread by peripheral extension until they attain a certain size, when they remain stationary.

The duration of the disease varies greatly. Recovery seldom occurs in less than a few months, while many cases last several years. In young individuals the hair almost invariably returns sooner or later. In adults the baldness may persist and prove refractory to all treatment.

When regrowth occurs, the patch is first covered by fine, downy, whitish hairs, which are either shed or later converted into coarse and pigmented hairs.

As a rule, there are no subjective symptoms.

Etiology.—The disease is said to have its origin in a functional nerve disturbance, interfering with the innervation of the hair follicles. It has been known to follow psychic shocks (fright, etc.), injuries to the scalp, and section of nerves.

French writers insist upon the parasitic nature of alopecia areata, and cite epidemics of this disease in support of its contagious character.

It is probable that there are two varieties; the one neurotic and the other parasitic.

Pathology.—The affected hairs show an atrophy of the shaft and the bulb. The skin changes are at first mildly inflammatory, later atrophic.

Diagnosis.—Alopecia areata is most likely to be confounded with tinea tonsurans.

Alopecia Areata.	Tinea Tonsurans.
1. Rapid onset.	1. Slow, insidious onset.
2. Patches are: (*a*) Totally devoid of hair. (*b*) Pale or whitish in color. (*c*) Smooth and soft. (*d*) Follicles contracted.	2. Patches are: (*a*) Covered with broken off stumps. (*b*) More or less reddened. (*c*) Rough and scaly. (*d*) Follicles prominent; "gooseflesh" appearance.
3. Absence of fungus.	3. Tricophyton fungus present.
4. Common in adolescence and adult life.	4. Occurs almost exclusively in childhood.

Prognosis.—In children recovery almost invariably takes place. In young adults the prognosis is guardedly favorable, while in advanced age it is unfavorable. The duration of the disease is uncertain and relapses are not uncommon.

Treatment.—The internal treatment consists of the use of such tonics as iron, quinin, strychnin, cod-liver oil, phosphorus, and arsenic. Duhring considers arsenic to be "especially serviceable."

The local treatment has for its object the stimulation of the scalp and the consequent increased blood supply to the follicles. Among the many medicaments that have been advised are alcohol, cantharides, capsicum, the essential oils, turpentine, carbolic acid, ammonia, sulphur, iodin, mercury, beta-naphthol, etc.

The following lotion will be found of value:

℞. Tincture of cantharides, Tincture of capsicum, each, ℥ jss
Castor oil, ℥ ij
Cologne water, ℥ j.
Brush in vigorously once or twice a day.

Instead of lotions, ointments such as the following may be employed:

℞. Beta-naphthol, gr. xxx
Petrolatum, ℥ ss
Oil of bergamot, ♏ xxx.
Rub in thoroughly twice a day.

The faradic current applied with a wire-brush electrode is often useful. In obstinate cases blistering may be resorted to. See also Phototherapy.

ALPHOZONE.—Succinic dioxid. A germicide and antiseptic. It is said to be of value in local infections in which the substance can be brought in contact with the diseased surface. It is used in solutions of 1 : 1000 for general external use; as a nasal douche 1 : 3000 is preferred.

ALTERATIVES.—Certain remedies that alter the course of morbid conditions in some way not yet understood, perhaps by promoting metabolism. They certainly modify the nutritive processes, and thereby cure many diseases of chronic type. *Mercury* and *iodin* are the most prominent agents of this class, the former being endowed with the power of breaking up newly deposited fibrin and of disorganizing syphilitic deposits, while the latter acts energetically upon the lymphatic system and promotes absorption. *Arsenic* also is almost specific in many chronic skin affections, and has remarkable power over chronic pulmonary consolidations, probably producing fatty degeneration and softening of the effusion, so that it may be absorbed or expectorated.

The principal alteratives are: arsenic, antimony, gold, mezereum, sulphur, sulphids, mercury, colchicum, guaiacum, sanguinaria, xanthoxylum, calcium chlorid, iodin, iodids, stillingia, sarsaparilla, cod-liver oil, phosphorus.

Alteratives are indicated when excessively active cell-growth exists, and are contraindicated whenever there is a tendency to tissue break-down, or when that condition exists.

Cases of frontal headache, general malaise, and depression of spirits, with symptoms of biliousness, or the appearance of urates or oxalates in the urine, are improved by purgative doses of mercurials, taraxacum, nitric or nitrohydrochloric acids. In gout, colchicum and potassium salts are used. In nervous debility, as in neuralgia and chorea, phosphorus and arsenic are employed.

Arsenic is generally used in diseases of the skin of the dry variety; antimony finds marked usefulness in forms of inflammation of the bronchial mucous membranes. Mercury is alterative in small doses that do not purge, and it is also of use to break up newly deposited fibrinous masses, as in iritis and pericarditis. In the secondary stages of syphilis it counteracts the effects of the syphilitic virus upon the soft tissues. The iodids and iodin are useful in glandular swellings, and affect the lymphatic system. Alteratives stimulate the absorbent system, and in this way assist in the removal of fibrinous deposits and syphilitic growths. The iodids are most serviceable in the third stage of syphilis, although used in the secondary one.

ALTHÆA.—Marshmallow. The root of *A. officinalis*, a plant of the mallow family. It consists of about one-third of vegetable mucus and starch, together with 2 percent of the alkaloid *asparagin*. Its decoction is employed as a mucilaginous drink. *Asparagin* possesses sedative and diuretic properties, and is useful in ascites and gout. Dose, 2 to 3 grains in water.

ALUM.—Any one of a class of double sulphates formed by the union of one of the sulphates of certain nonalkaline metals with a sulphate of some alkaline metal. The standard (or common commercial) alum, the official **Alumen** (U. S. P.), is the aluminum-potassium sulphate, $Al.K.(SO_4)_2+12H_2O$. It is a powerful astringent and styptic in medicine, and is extensively used in the arts. It has a sweetish astringent taste, and an acid reaction; it is soluble in 9 parts of water, in 0.3 of boiling water, and is insoluble in alcohol. It is a good emetic, and is one of the best remedies in the treatment of lead colic. In ophthalmology alum is used in solution of from 1/2 of a grain to 10 grains to the ounce, dropped freely into the eye in cases of conjunctival disease. It is sometimes applied in solid stick, known as the **alum pencil**, which may be applied without everting the lid. Alum is employed by bakers to whiten their bread, but the effect upon the system is probably injurious. Ordinary **Ammonia alum** is the same as the foregoing, except that the potassium is replaced by ammonium. It was formerly official and is extensively used on account of its cheapness. What is known as *concentrated* or *patent* alum is the normal aluminum sulphate (*alumini sulphas*), which is not a true alum. **Alumen exsiccatum** is exsiccated or burnt alum. **A. Ammonioferric** (*Ferri et Ammonii sulphas*) (U. S. P.) is strongly styptic, and is useful in leukorrhea. Dose, 3 to 15 grains. There are other alums but they are of little interest to the physician. The dose of alum is about 7 1/2 grains. As an emetic for a child 1 dram may be used. *Incompatibles* are: Alkaline hydrates, borax, carbonates, galls, kino, lead acetate, lime-water, magnesia, magnesium carbonate, mercury salts, phosphates, tartaric acid, potassium chlorate. **A. Whey,** a preparation obtained by boiling 2 drams of alum in a pint of milk, and straining. It is used as an astringent and internal hemostatic in wineglassful doses.

In sweating of the soles of the feet:

℞.	Powdered burnt alum,	ʒ v
	Powdered salicylic acid,	ʒ ijss
	Powdered starch,	ʒ xv
	Talcum powder,	ʒ xx.

Use fresh daily.

In erythema, intertrigo, and eczema:

℞.	Alum,		gr. xx
	Zinc sulphate,		gr. x
	Glycerin,		ʒ j
	Rose-water,	q. s.	℥ iv.

In onychia:

℞.	Powdered burnt alum,	gr. iij
	Zinc sulphate,	gr. ij
	Lead subacetate,	gr. ij
	Water,	℥j.

ALUMINUM.—Al = 27. Quantivalence III. A silver-white metal distinguished by its low specific gravity, about 2.6. **A. Hydroxid,** $Al(OH)_3$, a tasteless white powder, feebly astringent; insoluble in water or alcohol, but soluble in strong alkaline or acid solutions. Dose 3 to 20 grains in powder or mixture. **A. and Potassium Sulphate,** $Al.K(SO_4)_2$, (see ALUM), a valuable astringent used

in catarrh, leukorrhea, gonorrhea. Dose, 5 to 10 grains. In teaspoonful doses, an emetic. **A. Sulphate**, $Al_2(SO_4)_3+16H_2O$, an antiseptic and astringent; used as a lotion in 5 percent solution.

ALUMNOL.—An antiseptic and astringent. Though precipitating gelatin and albumin, the precipitate is soluble in an excess of either, so that when it is used on purulent discharges they do not clog up cavities, and desirable penetration below the surface is accomplished. *Incompatible* with it are albumin, alkalies, gelatin, and silver nitrate. Alumnol does not irritate or cause pain, and is employed dry and in solution as a dressing for wounds and ulcers, acute inflammatory diseases of the skin, and acute and chronic inflammations of mucous membranes. In 1 to 3 percent solution it makes a good injection for gonorrhea, and a 4 percent solution is used to check the lacrimal discharge during an examination of the eye.

ALVEOLAR ABSCESS (Parulis).—This occurs from suppuration in connection with the fangs of a carious tooth. The chief features are throbbing pain, with protrusion of the tooth and swelling of the soft structures around the jaw. When not disturbed, it may discharge around the tooth, but more often it appears as gum-boil, having worked itself through the side of the jaw. It may burst into the nose, and, especially when the molars are involved, it has a tendency to break through the face. A chronic sinus is then likely to ensue, the orifice being surrounded by sprouting granulations. Consequences may be even worse; necrosis is not uncommon and pyemia has occurred.

Treatment.—Water, as hot as can be borne, should be used to wash the mouth. The gums should be lanced or leeched. Poultices are discountenanced. Extraction of the tooth when much diseased, or antiseptic repair of the opening is advised. The abscess sac may come away with the fang, and, if not, a free incision through the swollen portion of the gum, the edge of the knife being turned toward the bone, is to be made. If a sinus ensues, probing will usually show a sequestrum of bone or an old fang left, which must be removed.

ALYPIN.—A local anesthetic. It is represented to be less toxic than cocaine and of equal value but having no mydriatic or cycloplegic effects. Dose, 10 percent solution, externally; 1 to 4 percent solution, hypodermically.

AMAUROSIS AND AMBLYOPIA.—*Amaurosis* is a term that, from its vagueness, is happily becoming obsolete, signifying partial or total loss of vision. When partial, the term *amblyopia* is now used; when complete, Blindness (*q. v.*). The word is still sometimes used to express blindness when the cause is unknown or doubtful. Properly speaking, amblyopia means subnormal acuteness of vision, due neither to dioptric abnormalism nor to visible organic lesion.

Amblyopia ex anopsia is a term applied to partial or total blindness in an eye from disuse. It is of common occurrence in anisometropia and in strabismus. The individual with a squinting eye naturally has double vision; in order to obtain monocular vision he must either turn the axis of the squinting eye or learn to mentally suppress the image of that eye. If for anatomic reasons rotation is impossible, or if there is such difference of refraction that images of different distinctness and size are observed, the mental suppression of the image is the only alternative, and progressive amblyopia results.

Treatment is successful directly in proportion to the youth of the patient. It consists in restorative measures, such as correction of refractive error, tenotomy, and subsequent exercise of the weak eye.

Toxic amblyopia may be due to such conditions as provoke supersaturation of the blood with toxic ingredients: as, for instance, in disease of the kidney we may have, accompanying the resultant uremic poisoning, amblyopia, or even total blindness of both eyes, appearing sometimes suddenly and sometimes after a day or two of gradually failing vision. If the patient survives the attack of uremia, the blindness may completely disappear in a few days.

Diabetic amblyopia is distinguished by its association with the ordinary symptoms of diabetes.

Amblyopia from **malarial fever** and **quinin** has been reported, and in rare cases complete blindness has intervened. Quinin itself has produced it. See Optic Nerve, Atrophy.

AMAUROTIC FAMILY IDIOCY.—A rare, generally fatal family disease, occurring during the first year, lasting less than two years. It seems to be confined to the Hebrews. It is characterized by feeble mental development, progressive muscular weakness and failing vision terminating in idiocy, paralysis and blindness through optic atrophy. There is no available treatment; proper nourishment and hygienic surroundings are the best that can be suggested.

AMBLYOPIA.—See Amaurosis.

AMBRINE.—See Petrolatum.

AMBULANCE.—In Europe, the surgical staff and arrangements of an army in service. In the United States, a vehicle to transfer sick or wounded. An ambulance should accommodate 12 seated patients, 2 sitting with the driver and 10 inside on leather-padded seats. These seats should be made so as to fold up and be hooked to the sides when the floor of the ambulance is needed for patients on stretchers, 2 being accommodated. Running-gear should be strong but very elastic, and rubber tires are a serviceable and surgical improvement. A hanging foot-board is usually attached to the rear of the vehicle, and bunkers for drugs and dressings are placed under the driver's seat or beneath the wagon body. A two-wheeled cart is a recent innovation, and is designed to carry 4 persons sitting up or 2 patients lying down, and is drawn by a horse or mule. Railway cars may be converted into ambulances, care being taken to lessen jars and roughness in travel.

AMENORRHEA.—The absence of menstruation. Two varieties of amenorrhea have been described: one is termed **primary amenorrhea**, and is applied to those cases in which menstruation has never appeared; the other is termed **secondary amenorrhea**, and is applied to those cases in which

menstruation has ceased after having once been established.

Causes.—The causes of amenorrhea are various. It may be the result of imperfect development of the sexual organs or of some local uterine condition or general constitutional disease. Chronic diseases, such as phthisis, anemia, obesity, and chlorosis, are not infrequently associated with amenorrhea. It is frequently noted after the acute febrile diseases, as pneumonia and typhoid fever. Insanity and other nervous conditions may be causes. Change of climate is another frequent cause. It may be a symptom of pregnancy.

Symptoms.—The molimina of menstruation are often present, although there is no discharge of blood. There may be a feeling of fulness in the pelvis; there is frequently headache and flushing, and there may be nausea.

Treatment consists in the determination of the cause of the condition and its proper correction. If it is the result of some acute or chronic disease, no special treatment is demanded. If it is due to defective development of the genital organs, an effort may be made to stimulate them. Dilatation and curettage, followed by hot vaginal douches and pelvic massage, may prove beneficial. The general health must receive attention. Outdoor exercise, with plenty of fresh air and sunshine, must be prescribed. Iron and arsenic will frequently give good results. The diet should receive careful attention and the bowels should be well regulated. Oxalic acid given in 1/4-grain dose 3 times daily is probably the best emmenagog. See Emmenagogs.

℞. Extract of ergot,
Powdered aloes,
Dried sulphate of iron, } each, ʒ ss.
Oil of savin, ♏viij.
Make 30 pills. Dose, 1 pill 3 times a day.

AMETROPIA.—Ametropia exists when an imperfect image is formed upon the retina, due to defective refractive power of the media, or to abnormalities of the form of the eye. In *myopia* the anteroposterior diameter or the power of the refractive media is too great; *hypermetropia* (or *hyperopia*) is the exact reverse of the last; *astigmatism* is due to imperfect curvature of the cornea or of the retina, or to inequality of refracting power in different parts of the lens; *presbyopia* is due to inelasticity of the lens, producing insufficient accommodation; *aphakia*, or absence of the lens, produces both insufficient refracting power and loss of accommodation. See Hyperopia, Myopia, Astigmatism, Presbyopia, etc.

AMMONIUM.—A hypothetical compound radicle having the composition NH_4. It exists only in combination. It occurs most commonly in the form of *ammonia gas*, NH_3, which, dissolved in water, is the water of ammonia (NH_4OH) of commerce. The salts closely resemble those of the elements potassium and sodium. The chief commercial source of ammonium salts is the ammoniacal liquor from gas-works and bones. Many of the salts and aqueous solutions of the gas are official. In medicinal doses the salts of ammonium act as stimulating expectorants. In large doses they injure the structure of the red blood-corpuscles, and produce rapid emaciation by impairing digestion and increasing tissue waste when long continued.

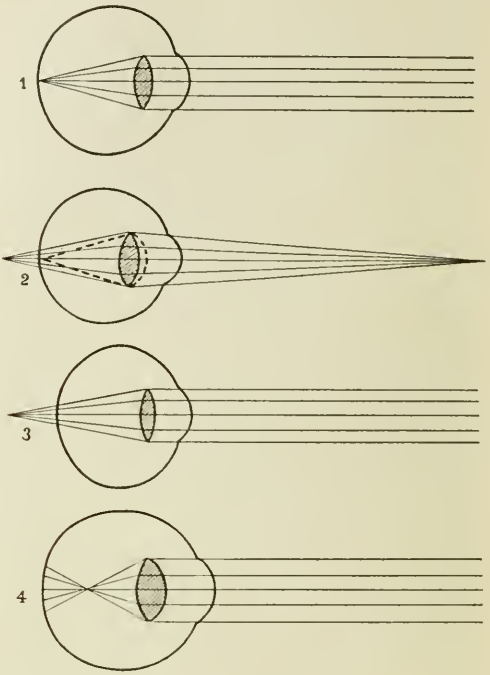


Diagram showing—1, normal (emmetropic) eye bringing parallel rays exactly to a focus on the retina; 2, normal eye adapted to a near point; without accommodation the rays would be focussed behind the retina, but by increasing the curvature of the anterior surface of the lens (shown by a dotted line) the rays are focussed on the retina (as indicated by the meeting of the two dotted lines); 3, *hypermetropic* eye; in this case the axis of the eye is shorter, and the lens flatter, than normal; parallel rays are focussed behind the retina; 4, *myopic* eye; in this case the axis of the eye is abnormally long, and the lens too convex; parallel rays are focussed in front of the retina.—(Kirkes' Physiology.)

Physiologic Action.—The gas ammonia is intensely alkaline and irritant to mucous membranes; when inhaled, it produces spasmodic cough and a sense of suffocation. Its prolonged inhalation will induce violent inflammation of the air-passages and edema of the glottis. It stimulates the nasal branch of the fifth nerve, exciting the vasomotor center by reflex action, and thus raising the arterial tension. Applied to the skin and allowed to evaporate, it has a slight rubefacient effect, but if evaporation is prevented, it penetrates the epidermis and has a powerfully vesicant action. Ammonia water swallowed undiluted may quickly cause death by suffocation, from the action of its vapor upon the air-passages; if not, it may excite gastroenteritis accompanied by coma, differing in the latter respect from potassium or sodium poisoning. After absorption, it stimulates both the respiration and the circulation by direct action

on their respective nerve centers. Ammonia exists normally in the circulation, where it keeps the fibrin in solution, and thus maintains the fluidity of the blood. It increases the glycogenic function of the liver, and is converted finally into urea. It is a powerful irritant to muscular tissue, causing tetanic contraction and subsequent rigor mortis when directly applied. Ammonium salts all stimulate and finally paralyze the spinal cord, motor nerves, and muscles.

Therapeutics.—Ammonium acetate is used in the spirit of Mindererus, a mild diuretic, inferior to sweet spirits of niter, and an antacid, in gastric indigestion. Dose, 1 to 2 fluidrams. A solution of the acetate is an active diaphoretic if the body is warm, and a diuretic if it is cool. A wineglassful will counteract many of the immediate effects of alcohol. **The solution of the acetate** is especially beneficial in the exanthemata, influenza, coryza, anomalous febrile conditions of children, acidity, and vomiting; also in acute alcoholism, and in erysipelas when there is feeble circulation, cyanosis and delirium. It is frequently combined with spirit of nitrous ether, as a diuretic and diaphoretic in febrile affections.

As a mild diaphoretic:

℞. Solution of ammonium acetate, ʒ iij
Camphor water, ʒ j
Syrup of orange, ♏ xx.
Make into a drink.

In bronchial catarrh:

℞. Solution of ammonium acetate, ʒ j
Wine of antimony, ʒ ij
Syrup of tolu, ʒ vj
Water, ʒ iv.
Make into a mixture and take a sixth part every 4 hours.

Ammonium benzoate is used chiefly as a diuretic and to acidify the urine, in which it is excreted as hippuric acid. It is serviceable in catarrh of the bladder and when the urine is loaded with phosphates, and is stimulant to the liver. Dose, 5 to 20 grains in water.

Ammonium bromid is a white granular powder, of salty taste, markedly pungent, soluble in water and the oral secretions. Large doses cause abdominal burning and gastroenteritis. It may be used in place of potassium bromid, but it is not so depressing, though more likely to disturb the stomach. The dose is from 10 to 30 grains. It is incompatible with spirit of nitrous ether.

In hysteria of females, epilepsy, nervous startings, and spasmodic contractions:

℞. Ammonium bromid, ʒ ij
Potassium bromid, ʒ iv
Aromatic spirit of ammonia, ʒ vj
Camphor water, enough to make ℥ vj.
Mix into solution and give a dessertspoonful to a tablespoonful every 4 hours.

In sick headache, except when from biliousness:

℞. Antipyrin, gr. xxv
Citrated caffein, gr. x
Ammonium bromid, gr. xxv.
Make into 5 powders, and take one as needed.

Ammonium carbonate is of much use in combination with the ammonium chlorid in bronchitis mixtures, acting as a stimulating expectorant. It is a rapid respiratory and cardiac stimulant. It also stimulates gastric secretion, is emetic, and may prevent iodism when administered conjointly with potassium iodid. The carbonate is used internally in the eruptive fevers, delirium tremens, continued fevers, pneumonia, etc., when much depression exists; as a stimulating expectorant in chronic bronchitis, in the bronchopneumonia of children, and in cardiac asthma. It is highly recommended in scarlet fever in doses of 3 to 5 grains every 1, 2, or 3 hours, all acid drinks or fruits being prohibited while it is being administered. With 10-minim doses of tincture of capsicum in an ounce of some bitter infusion it is exceedingly efficient, in 5- to 10-grain doses, for the sinking sensations and craving for stimulants experienced by subjects of alcoholism. It may be used as an emetic in bronchitis, when the tubes are choked with mucus and the circulation of the patient is weak; it may also be employed by inhalation, and administered internally, for similar purposes as ammonia water. Ammonium carbonate is best given in syrup of acacia.

In indigestion with acidity:

℞. Ammonium carbonate, ʒ ss
Sodium carbonate, ʒ j
Infusion of quassia, ℥ vj.
Mix into a solution and take a sixth part at a dose.

In certain obstinate skin-diseases:

℞. Ammonium carbonate, ʒ ijss
Syrup of sarsaparilla, ℥ viij.
A tablespoonful from 1 to 4 times a day.

In diabetes mellitus:

℞. Ammonium carbonate, ʒ ss
Rum, ʒ v
Simple syrup, ʒ v
Distilled water, ℥ iij.
Half to be taken night and morning.

Ammonium chlorid (formerly muriate) stimulates the mucous membranes and increases the secretion of mucus, but does not stimulate the respiration or cardiac action. It may be used as a spray and in fumes by heating: *e. g.*, in an iron spoon. In the treatment of gastric and intestinal catarrh in children, in subacute hepatitis, in chronic torpor of the liver, and even in cirrhosis and hepatic abscess, it has been useful. It is best given in licorice syrup or water to mask the taste. If given in pill form, it should be accompanied by some liquid diluent given at the same time to protect the stomach membranes.

The chlorid has high repute in catarrh of the stomach, with anorexia, bad taste in the mouth, flatulence, coated tongue, etc.—in short, the symptoms of so-called biliousness; also, in chronic congestion of the liver, jaundice from catarrh of the bile-ducts, nervous and sick headaches, myalgia, amenorrhea, muscular rheumatism, and neuralgia. In the last-named affection it should be given in 30-grain doses several times a day. It is also efficient in bronchial catarrh without fever, and in chronic bronchitis when the secretion is scanty and tough. It is remarkably efficient in sobering a victim of acute alcoholism; administered to one on the verge of delirium tremens, in doses of 1/2 of a dram in half a pint of water, swallowed at one draft, it is said to restore the patient's faculties so quickly as to astonish those who have never seen it so employed. Locally, in solution, it has been well employed in inflammatory swellings, as sprains, inflamed joints, orchitis, etc., as a lotion; also, to allay itching in prurigo, to remove ecchymoses and glandular enlargements.

For the "tight" cough of bronchitis:

℞.	Ammonium chlorid,	gr. v
	Extract of licorice,	gr. ij
	Cubebs, powdered,	gr. ij
	Codein,	gr. j.

Make 20 pills.

One every 2 hours until relieved.

In pleurisy, pneumonia, etc.:

℞.	Ammonium chlorid,	ʒ ij
	Extract of licorice,	ʒ iij
	Antimony and potassium tartrate,	gr. ij
	Distilled water,	℥ viij.

Make into a mixture, of which from a teaspoonful to a tablespoonful is to be given each second hour. Omit the antimony when a sufficient effect has been produced on the disease.

In albuminuria:

℞.	Ammonium chlorid,	gr. x
	Tincture of iron chlorid,	♏ xv
	Water,	ʒ j.

To be taken twice a day.

Ammonium iodid may be used as a substitute for the potassium iodid salt, and is quite alterative. For enlarged tonsils it may be used as a local application. Given with glycerin to make a solution of 30 grains' strength, it may also be applied once daily with a swab or camel's-hair brush for the same difficulty, particularly if struma is an underlying cause. If exposed to the air, decomposition will result in this solution.

Ammonium liniment has 35 parts of ammonia water, 57 of cotton-seed oil, 5 of alcohol, and 3 of oleic acid.

Ammonium spirit is a 10 percent solution of the gas in alcohol. Dose, from 10 minims to 1 dram, diluted.

Aromatic spirit of ammonia contains ammonium carbonate, water of ammonia, oil of lavender, lemon, and nutmeg, alcohol, and water. It is used in ammoniated tinctures of guaiac and valerian. Dose, 15 to 60 minims.

Ammonium valerate corresponds in action to its titular base. Dose, 7 1/2 grains.

Ammonium Salicylate.—Dose, 4 grains.

Ammonia water is an aqueous solution of ammonia, containing 10 percent by weight of the gas. It is colorless, of pungent odor, acrid taste, and strong alkaline reaction. Stronger ammonia water contains 28 percent by weight of the gas. Dose, from 5 minims to 1/2 of a dram. **Ammonia in strong solution** may be used as a rubefacient and vesicant, and its vapor, by cautious inhalation, in syncope and the results of shock. Locally, it is a good application to bites of the less venomous reptiles and to insect stings.

Incompatible with *Ammonia* preparations are acids, acid salts; with the *Aromatic Spirit* are acids, acid salts, lime-water, aqueous fluids; with the *Acetate* are alkaline carbonates, potassium and sodium hydroxids; with the *Benzoate* are acids, liquor potassæ, ferric salts; with the *Carbonate* are acid salts, alkaloids, alum, salts of copper, iron, lead and silver, magnesia, magnesium sulphate, mercurous and mercuric chlorids, potassium bitartrate and bisulphate, tartar emetic, zinc sulphate; with the *Chlorid* are alkalies and their carbonates, alkaline earths, lead and silver salts.

Poisoning.—When ammonia is inhaled in excess, give vapors of hydrochloric acid by inhalation to form the chlorid. If ammonia is swallowed, give vegetable acids and demulcents to protect the mucous membranes. Cardiac sedatives, as aconite, veratrum, digitalis, etc., are indicated as physiologic antagonists.

AMNESIA.—Defect of memory. Loss of memory for words. See APHASIA.

AMNII, LIQUOR.—An alkaline fluid of low specific gravity, containing water, albumin, creatin, certain salts, urea, and epithelium, and varying in amount from 1 pint to 1 quart at term. Its **origin** is unsettled; it is partly of maternal origin, the result of transudation through the placenta; partly from the amniotic cells; and later in pregnancy it is somewhat increased in amount by fetal excretions, mainly urine. Its **function** is largely protective. It distends the uterus, thus affording room for free movement, growth, and development; it affords an equable temperature for the fetus and receives its secretions; it protects the mother from injury due to exaggerated fetal movements, and at birth performs a most valuable part in the dilatation of the cervix.

Color.—Normally, the liquor amnii is light amber in color and somewhat opaque. It may be dark, from the presence of meconium or disintegrated blood.

Putrefaction.—This is a rare condition, and is usually associated with death and decomposition of the fetus. Occasionally, the child will be born alive, even though the liquor amnii be intensely putrid in character. Sometimes gas is produced in this process of putrefaction, which accumulates in the uterus, giving rise to the condition known as **physometra.**

Hydramnios (Dropsy of the Amnion).—An excessive amount of liquor amnii. This is said to exist when 2 quarts or more of fluid are present. Hydramnios is not an infrequent condition, occurring once in two or three hundred pregnancies. Two varieties will be described—the **acute** and the **chronic.**

The acute variety, in which the excessive secretion takes place in a few hours or days, is rare. Its **cause** is usually amniotitis or some form of traumatism, and it presents **symptoms** common to sudden distention of the abdomen—pain, some fever, rapid and irregular pulse, and great difficulty in respiration.

Treatment should consist in the immediate evacuation of the fluid by puncture of the membranes, through the external os. This will be followed by abortion, which should be treated in the usual manner.

The chronic variety is that usually met with. It begins at the third or fourth month of gestation and steadily increases, causing, as a rule, little or no difficulty.

The causes of this condition have been ascribed to both fetus and mother. The fetal causes are: (1) Obstruction to the fetal circulation, causing excessive transudation of serum; (2) excessive secretion of urine; (3) excessive excretion from fetal skin, as occurs in nevus and in elephantiasis congenita cystica. The maternal causes are: (1) General anasarca; (2) exaggerated hydremia; (3) multiparity.

The diagnosis of this condition is attended by no unusual difficulty, the history of pregnancy, the abnormal distention of the abdomen, and the great movability of the fetus being the important factors. Extreme cases may be mistaken for ascites, ovarian cyst, or multiple pregnancy.

No **treatment** is required, as a rule, except rest and the application of an abdominal binder. Should marked pressure symptoms appear, particularly if circulatory or respiratory in character, the membranes should be ruptured and the uterus evacuated.

Postpartum hemorrhage is not an uncommon complication of these cases, and therefore every precaution should be taken for its prevention.

Oligohydramnios.—A deficiency in the amount of liquor amnii. This is a rare condition, occurring once in three or four thousand pregnancies. It is disadvantageous, because the uterus is not distended, and therefore the child is likely to be injured or deformed. Labor may be unusually prolonged and difficult (**dry labor**).

AMNION.—The innermost of the fetal membranes; it is continuous with the fetal epidermis at the umbilicus, forming a sheath for the umbilical cord and a sac or bag in which the fetus is inclosed. It contains 1 pint to a quart of liquor amnii.

Development.—The inner layer is derived from the epiblast, the outer from the mesoblast. The cavity formed by the inner folds is called the **true amnion,** and contains the liquor amnii; that formed by the outer folds is called the **false amnion,** and contains the allantois, the umbilical vesicle, and occasionally a fluid resembling the liquor amnii.

Function.—To secrete and contain the liquor amnii. The amnion and chorion, containing the liquor amnii, and projecting through the os uteri early in labor, are popularly known as the bag of waters.

Inflammation (Amniotitis).—This is usually attended with exudation, either serous or plastic. Plastic exudation occurring in the first few months of gestation may give rise to bands of adhesion—**fetoamniotic bands**—that may cause premature separation of the placenta, fetal deformities, or even amputation of fetal extremities.

Abnormal Tenuity.—This sometimes gives rise to rupture, with the formation of parchment-like rolls of amnion inside the chorion.

Rupture.—If both amnion and chorion should rupture, abortion will usually follow. If rupture occurs at a point remote from the internal os, more or less constant dribbling of the liquor amnii may continue for weeks or months before delivery (**amniorrhea, amniotic hydrorrhea**).

AMŒBA COLI.—See DYSENTERY (Amebic).

AMPUTATION.—Amputation consists in cutting off a limb or its subdivisions in the continuity of the bone structure or at the articulation. The latter is often called disarticulation. The term amputation is misapplied not infrequently to removal of the mamma, penis, cervix uteri, etc.

Classification.—Amputation is classified, according to the time of its performance, into **immediate, primary,** and **secondary.** Immediate amputation is practised during the shock, and, therefore, within a few hours after the receipt of the injury; primary, after recovery from shock and before the occurrence of inflammation, usually within 24 hours after the receipt of the injury; secondary, at any time after the expiration of the limits of the latter period. Immediate and primary amputations are more fatal than secondary. The great benefits arising from antiseptic practice in severe injury have lessened the number of deaths from immediate and primary amputations, and at the same time increased the favorable outcome of the secondary.

The chief aims of amputation are the saving of the life of the patient and the securing of a serviceable extremity. Consequently, amputation should not be performed, if practicable, until shock is over, and then only with the scrupulous use of antiseptic and bloodless methods. When an extremity requires removal, surgical ability and mechanic ingenuity combined may secure greater benefits than can be derived from either alone; therefore, the attainment of the surgeon and the skill of the mechanic should both be utilized.

Indications.—It is impossible to give more than a general idea of the indications for amputation. Injuries of the upper extremity are much less liable to be followed by gangrene than those of the lower limb, on account of the freedom of collateral circulation. Before deciding upon amputation, we must consider whether both arterial and venous circulations are cut off, whether the tissues are devitalized, whether it is possible to prevent suppuration and septic infection, whether the limb can be made useful again, and whether the age and

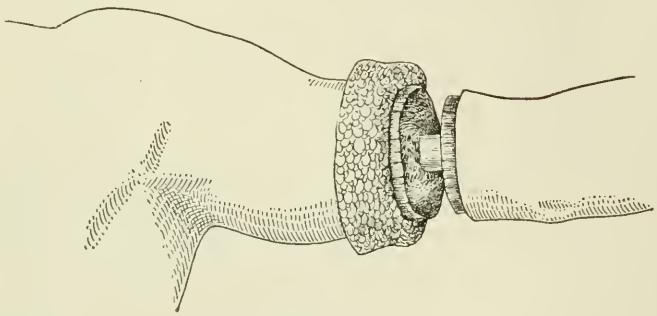
physical condition admit of saving the limb. The conditions for which amputation is usually performed are compound fractures and dislocations, extensive lacerated and contused wounds, gangrene, malignant tumors, and, occasionally, incurable and distressing deformities.

The instruments, etc., required for amputations are a tourniquet, rubber bandages, knives of several sizes, both single and double edged, saws, retractors, cutting bone forceps, strong forceps to hold bone fragments, tenacula, hemostatic forceps, dissecting forceps, scissors, needles, sutures, ligatures, needle-holder, drains, splints, and dressings. For the major joint amputations large steel pins are needed, around which to make compression. Abundance of hot water should be at hand to check oozing.

The chief points in planning an amputation are: (1) To sacrifice as little as possible; (2) to provide an ample covering of skin; (3) to arrange the flaps so that their weight shall keep them in position; (4) to make sure there is free exit for any fluid that may accumulate; (5) to keep the scar away from the line of pressure; (6) to provide a satisfactory stump.

The various methods can be reduced to three: (*a*) The circular; (*b*) the old flap operation, in which all the tissues down to the bone are included; and (*c*) the modified flap operation, in which the covering is formed of skin alone, all the other structures being divided on a level with the end of the bone.

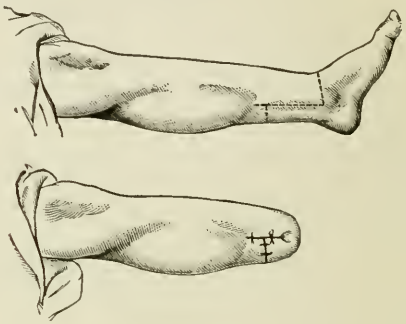
The Circular Operation.—The limb is divided by a succession of circular sweeps; the first through the skin; the second (after the skin has been retracted) through the superficial muscles; the third through the deep muscles and the periosteum; and the fourth, when all the tissues are drawn back, through the bone. It is practically limited to the arm, and cannot be used over conic parts, as the skin cannot retract, or where the bone would lie in the center of the stump, for in that case it would abut upon the cicatrix. If the limb is injured on the one side only, it may be very wasteful; and in cases of disease in which the tissues are hard and brawny, or the skin tied down by adhesions, it is impracticable. When this operation is indicated, the covering of skin is good, without much muscle, drainage is satisfactory, and the scar very small.



Circular Amputation.

The Old Flap Operation.—This may be performed either by transfixion, cutting from within outward, or by dissection, separating the soft tissues from the bones in an upward direction; the flaps may be anteroposterior, lateral, and equal in length, or one may be much longer than the other. With the exception of one special modification (Teale's amputation), the old operation is seldom performed on any part but the extremities; the flaps are heavy and thick, containing a large amount of muscle; the vessels may easily be slit, or wounded higher up than they are divided; the surface of the wound is very large, and the nerves are contained in the flaps.

In Teale's amputation (which is reserved almost entirely for the lower third of the lower limb) the anterior flap, which contains all the tissues dissected up from the bones, is square and equal in length and breadth to half the circumference of the limb at the spot at which the bones are to be divided. The posterior flap is of the same breadth, but only one-fourth of the length. The bones are divided at the line from which the flaps spring, and the long flap is folded around the end, and united behind it to the posterior one, the cut surfaces facing each other. The flaps are measured out and marked down first, and the two lateral incisions made before the transverse ones. The drainage is admirable, and the stump left very soon becomes serviceable, if care is taken to keep the larger vessels and nerves in the shorter flap.



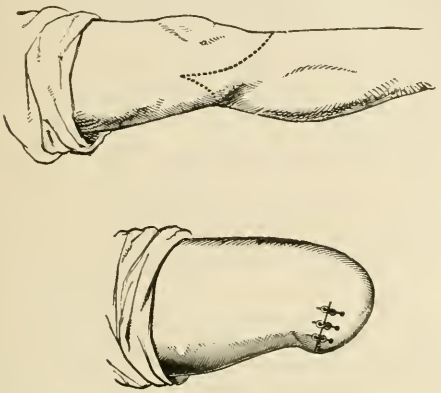
Teale's Amputation.

The Modified Flap Operation.—In this, one flap (or sometimes both) is formed from the skin and subcutaneous tissue only; the rest of the structures are divided by a circular sweep at the same level as the bone. It is a method capable of far wider application than any other, and may be modified in a number of different ways.

In Carden's operation, for example (which, though first devised for the knee, may be employed in amputating many other parts), a rounded or semioval flap is reflected from the front of the limb, and all the structures divided down to the bone, this being sawed through slightly above the plane of the muscles. This leaves an almost flat

stump, covered with integument; the edges of the wound are dependent, and the cicatrix lies well out of the way. In other cases (amputation of the forearm, for instance) both flaps may be formed in this way, of equal length or not, according to the amount of tissue available; or lateral flaps may be cut, as in the leg, or a kind of hood dissected up, as in Stephen Smith's method.

The position of the surgeon in performing an amputation is always such that he can raise the flap with his left hand, without crossing with the



Carden's Amputation, with Short Posterior Flap.

right; usually, therefore, he stands on the right-hand side of the limb. The number of assistants required depends naturally upon the part to be removed; one holds the limb, and afterward supports the stump in a convenient position; another assists the surgeon in retracting the flaps, sponging, and tying vessels; and a third may be required to control the main artery. When it is possible, the patient should be carefully prepared; the bowels opened; the urine examined, the pulse, respiration, and temperature noted; and the limb thoroughly cleansed, and, if necessary, shaved. The last meal should be a light one, and should precede the operation by at least 3 hours. The anesthetic, of course, requires a special assistant.

During the operation the bed should be thoroughly warmed, and hot bottles, pillows, etc., arranged so that the patient may be placed in a comfortable position at once, with the stump slightly raised and secured against any accidental movement or spasmodic contraction of the muscles. Unless the patient is thoroughly covered up, the loss of heat during an operation (especially under ether) adds seriously to the shock.

The stump is the product of amputation, and should be an agent of comfort and usefulness to the patient. **Stumps may be classified,** practically, as good and bad, the latter being subdivided into conic, irritable, etc. The technic of amputation aims to secure a sound, unirritable stump, with good circulation and ample leverage. The first three of these qualities depend mainly on the length, form, vascular supply, and sensibility of the flaps; the last depends on the length of the bone. The skin of a healed stump should be freely movable, except at the site of the scar; therefore, the flaps should be long enough to more than provide both for structural and reparative shrinkage. Short and adherent flaps of pressure-bearing stumps are exceedingly prone to attacks of annoying and crippling affections. Integument normally exposed to pressure, and, therefore, automatically constructed to receive it, as that of the palm of the hand and of the sole of the foot, makes the best flaps.

The proper length of flaps should be carefully considered. When two are made, each should equal not less than one-fourth of the circumference of the limb at the point where the bone is to be divided, and any decrease in the length of one flap should be attended by a proportionate increase in the length of the other. The greater the retractile tendencies of a flap, the longer it should be made. Flaps into which portions of long muscles enter, and those formed in part or wholly of skin from certain aspects of the extremities, contract the most markedly. The length of the flaps controls to a notable degree the site of the cicatrix. In the construction of flaps it should not be forgotten that the contractility of integument and subcutaneous tissue is lessened by inflammatory infiltration, overdistention, old age, and by natural and acquired thickness, and that the divided borders of stiffened and thickened tissues are difficult of approximation.

The cicatrix should be so located, when practicable, as not to be subjected to undue pressure or friction; therefore, in pressure-bearing stumps, the best situation is at the side; in others, at the end. However, if the flaps are ample to provide for a freely movable integumentary covering at the end, the location of the scar there is a matter of but little importance.

The arteries should be cut transversely, tied securely in sound tissue, and at a suitable distance from the origin of collateral branches.

The ends of tendons should be divided on a line with the borders of the flaps; for if too long, they interfere with union, and if cut too short, their open-mouthed sheaths may harbor deleterious products. For this latter reason the sheaths ought to be closed at once with stitches, which, if desirable, may include the divided ends of the tendons.

The nerves should be severed so high that the ends will not become involved in the process of repair; in single long flaps they may be removed entirely.

The periosteum should not be bruised or lacerated, but be cut through neatly at the point of bone section.

The bone should be sawed carefully and transversely, and not be denuded of periosteum at any part, otherwise necrosis and delayed union may follow.

Oozing should be arrested by the application to the surface of hot sterilized water, or by other means.

Unite the flaps without tension, with interrupted sutures, and so as to provide for drainage; adjust antiseptic dressings carefully and uniformly to

the stump and so confine them in place with bandages as to support the flaps and obliterate dead spaces. Drainage agents may be required for a brief time. Proper support of the stump in an elevated position is commended.

A good stump should be symmetric and insensitive, and should have a good circulation, good leverage, and a narrow, movable cicatrix uninfluenced by the skin traction incident to weight-bearing. However, serviceable stumps need not possess all of the attributes.

A bad stump is the antithesis of the preceding, and the logical sequel of thin, short, or ill-nourished flaps. A cold or edematous or hypersensitive stump, due to improper care, bad habits, defective local or general circulation, constitutional dyscrasia, or defective surgical technic, is soon likely to be the seat of ulceration, sloughing, eczema, cuticular hypertrophies, and even periosteal and bony inflammation.

A so-called **painful stump** is usually dependent on the irritation caused by abnormal bony growths, by a bulbous enlargement of the end of a nerve, by the involvement of the nerve extremities in a normal or abnormal fibrous formation.

The Conic Stump.—The end of this stump is the end of the bone, covered or not, as the case may be, with thin, adherent skin, or skin with destructive changes involving, perhaps, even the bone itself. Flaps scanty from the first—from sloughing, from unusual contraction, from low bone division, or from excessive epiphyseal growth—characterize the conic stump. The last of these causes is manifestly, though infrequently, effective in young subjects only, especially after amputations near the knee or through the humerus, when the remaining epiphyses of the respective bones are left unimpaired. These cases not infrequently require repeated amputation to remove the infirmity.

The Best Method of Amputation.—No single method of amputation is applicable to all cases. Each case demanding amputation must be estimated upon its own individual merits. Structural changes of the soft parts, causing induration ulceration, or devitalization, which limit or abrogate the necessary technic of one or more methods of practice, require that another conforming with the demands shall be selected. The method best suited to an individual instance is one that can be quickly and easily done without needless sacrifice of healthy tissue, and that provides good drainage, suitable and well-nourished flaps, and a narrow, properly located cicatrix. Transverse section of the vessels and a minimum area of muscular exposure are significant desiderata in amputation.

The circular method meets the foregoing conditions more fully than any other. However, the flap methods are especially applicable to instances of unequal availability of the soft parts, and also to any portion of an extremity. The availability of a method of amputation is based chiefly on the safety and utility of the measure. Therefore, the seat of the proposed operation is a matter of vital and practical importance: vital, because the nearer to the trunk the amputation is made, the greater the rate of mortality; practical, because the shorter the bone is cut, the less will be the leverage of the stump. It is often difficult, indeed, for these reasons, to determine the proper site for amputation. The exchange of suitable leverage for the sound tissues needed for primary union lessens permanently the functional use of a stump. On the other hand, the preservation of the leverage at the expense of the health of a stump may be bad practice. Bone leverage when sacrificed cannot be regained; but a painful ulcerated stump may be cured by care and simple operative measures, and, at the worst, by reamputation, which will entail no greater sacrifice of bone than if originally performed. If the amputation is done for disease instead of for injury, then, indeed, the need of primary cure is of much greater significance; therefore, the comparative importance of leverage is correspondingly lessened.

The mortality of amputation, while controlled significantly by the influence of age, sex, causation, site of amputation, etc., is influenced to a marked degree in each of the foregoing instances by the technic employed. Amputations of a comparatively similar nature performed in the preantiseptic period, which gave them a mortality rate of about 30 percent, now give less than 5. Operations performed on those from 20 to 40 years of age are twice, and from 40 upward thrice, as fatal as at 20 years and under. Amputation for disease is from 10 to 15 percent less fatal than for injury, and in the latter secondary are nearly twice as fatal as primary amputations. Amputations at the upper extremity are less fatal than corresponding ones at the lower, and in either instance the mortality increases as the trunk is approached. For example, the mortality in amputation of the arm is 9 times greater than in amputation of the finger; and that in amputation of the thigh is 10 times greater than in amputation of the toes.

Special Amputations.—The phalanges of the digits of the hand and foot are better amputated by making long palmar and plantar flaps cut from without than by transfixion, as by the latter method the tendons and the vessels may be split and the flaps themselves be unsymmetrically formed, particularly at the bases, where, especially in amputation at the joints, they are made too thin and narrow, thus inperiling their nutrition and unfitting them for properly covering the ends of the bones. The open mouths of the tendinous sheaths should be closed at once with a stitch, to prevent them from harboring infecting agents, which may cause extended and serious inflammation of their structures. If the stitch includes the divided end of the tendon, better fixation of the latter to the end of the stump will be secured.

Amputation of the second, third, and fourth fingers and toes at their bases is best done by making the racket flap; and amputation of the first and fifth by a short internal and a long external flap, so fashioned as to place the injured integument in the position of greatest functional requirement. In amputation of the digits of the hand and foot, especially of the thumb and great toe, any needless sacrifice of bone must be avoided, in order that their functions may be preserved as

much as possible. The amputation of a finger with the head of its metacarpal bone lessens the power of the grasp, but adds, for a time at least, to the symmetry of the part. The first, second, and fifth metacarpal bones are more useful for prehensile purposes than for cosmetic reasons; and, therefore, their integrity should be respected accordingly. The first and second metatarsal bones are of the greatest importance functionally, and consequently should not be needlessly shortened. In amputation at the carpus and tarsus, as in operations of the phalanges, long palmar and plantar flaps, made by cutting from without, are the best, and for similar reasons. Lisfranc's amputation at the foot is serviceable, indeed, but its modifications, except those of Baudens and Stokes, are of doubtful utility in traumatic cases. Amputations through the tarsus (Chopart's Forbes', etc.) so lessen the leverage and destroy the power of the flexors that a reasonable doubt as to their utility is frequently properly entertained. Moreover, the present usefulness of prosthetic agents when fitted to a suitable stump (Syme) now affords excellent and comfortable service with a fair degree of symmetry.

Subastragaloid amputations and their modifications are ingenious and serviceable as independent means of support, but they are difficult and tedious of performance, invested with a relatively high rate of mortality, and are comparatively ill suited to artificial means of locomotion. However, those who cannot avail themselves of the benefits of mechanic remedies may find practical relief in a healthy stump constructively unsuited to mechanic aid. Amputation at the ankle-joint, with (Pirogoff) or without (Syme) osteoplastic method, is to be commended, more especially the latter. Syme's amputation is a beneficent conception, for when properly practised, it is easily performed, heals promptly and without complications, has a comparatively low rate of mortality and a high grade of usefulness, both with and without mechanic aid. Pirogoff's amputation is ingenious, and often relatively serviceable, especially when not supplemented directly by mechanic aid. In the former operation the flap may slough if its vitality is impaired, by old age, diseased or injured vessels, harsh treatment, and too free dissection. In the latter the bone fragment may necrose, slough, or fail to unite, and its relation with the leg may become distorted by muscular action or pressure. The various modifications of this amputation promise but comparatively little, indeed, in the direction of final efficiency, and rarely lessen the number or degree of the complications of the original method of practice.

Amputation at the ankle and wrist-joints by circular or lateral flaps is highly objectionable at the former site and opposed by some at the latter. The natural bulbous end of the extremity and the feeble circulation of these flaps at the ankle interfere with the proper adjustment to the stump of an artificial appliance. The best point of amputation at the lower third of the leg is at the beginning of the upward expansion of the limb—about 3 or 4 inches from the lower ends of the bones. Amputation at the wrist-joint gives a bulbous stump also, which is, however, better suited to the application of an artificial appliance than when at the ankle-joint. Besides, in the former the insertions of the long supinator and the broad pronator muscles remain unimpaired, with an obvious advantage to functional activity. However, the higher rate of mortality in disarticulation, the feeble circulation of the flaps, and the exposed portion of the stump to the effects of cold and moisture, are important reasons for amputation above the styloid processes.

Amputation at the lower one-third of the arm or of the leg may be done by the circular, elliptic, or lateral flap methods, with a satisfactory outcome. The circular is more frequently employed than any of the others, and in the leg the cutaneous flap is often supplemented with a periosteal lining raised from the subcutaneous surface of the tibia, while still adherent to the overlying tissues. The flaps are then so apposed as to cause the periosteal surface to come in contact with the divided end of the tibia.

Amputation at the upper one-third of the arm or of the leg is better accomplished by musculocutaneous than by cutaneous flaps. When double, the flaps are located antero-posteriorly or laterally; when single, preferably at the outer aspect of the leg and the anterior of the arm. The racket flap, with the handle at the posterior surface and extending well upward for drainage purposes, will provide a serviceable stump when practised at any part of the leg.

Amputation at the knee-joint is best done by the method devised by Dr. Stephen Smith. The flap is substantially of the racket variety, with the handle located posteriorly. The operator must adhere closely to the prescribed manner of action, or the flap will be found inadequate to properly cover the end of the femur, requiring, perhaps, the removal in turn of the patella, and even of the condyles. The reversal of this method—bringing the handle of the racket in front—in amputation for senile gangrene is practised by Dr. Smith, with the view of forming flaps endowed with the greatest vascular supply.

Amputations at the knee-joint and the elbow-joint by the circular and long anterior flap methods are practised. In the former anteroposterior coaptation should be made, for obvious reasons. In the latter method the flap at the elbow is formed by transfixion, is musculocutaneous and vigorous; at the knee, however, the opposite characteristics obtain, especially in elderly and debilitated subjects. The anterior elliptic method of amputation is practised at both of these joints, more especially at the elbow, and here with notable satisfaction. In amputation at the knee-joint and the lower end of the femur, fluid accumulations in the synovial space beneath the quadriceps tendon, which communicates with the joint cavity, must be prevented by drainage or by pressure, to obviate the possible inflammation, perforation, and extravasation incidental to their presence.

Amputation through the condyles of the femur is less satisfactory than disarticulation at the knee-

joint. The stump of the latter is more serviceable and better suited for weight-bearing than the former. However, when the decision rests between amputation and excision of the knee, the flaps of Carden, Gritti, and Stokes will aid in deciding, and are well suited for the purposes of execution. The osteoplastic elements of the last two and of similar methods embody ingenious and commendable theoretic suggestions that, unhappily, are frequently marred by the failures that follow their adoption. The methods of amputation of the thigh and of the humerus would not differ from each other in any essential degree but for the important muscular and flexion peculiarities of the stump of the former, because the relations of the hard and soft parts are similar in all practical respects. Oval, cutaneous, and musculocutaneous flaps, made at diverse aspects of the limbs, and in the latter method by transfixion or cutting from without, are employed, and especially the latter, at the hip. The simple circular incision (Celsus) and the circular and the unequal integumentary flap methods, with single complete transverse division of the muscles, and that with repeated incomplete transverse divisions alternating with retraction, forming thereby a truncated, cone-shaped cavity, with the end of the bone at the apex, are each admirably suited to amputation of the arm, and to the thigh as well, when proper allowances to meet its important peculiarities are made. The periosteal flap may be readily employed with equal facility in either of the circular methods; and, too, may be utilized with propriety in other varieties of amputation at these situations.

Amputation at the hip and the shoulder-joint—more decidedly the former—are procedures of grave significance. The magnitude of these amputations, the danger from hemorrhage, the extensive surface exposed to infection, and their proximity to the trunk, invest them with great importance. The first and the fourth of these evils are inflexible. The second and third—formerly dreaded the most—have yielded in great part to the beneficent control of advanced surgical technic. The second of these is now best met by the elastic compression methods devised by Trendelenburg and Wyeth, and by the digital pressure plan proposed by McBurney. The third is lessened much, at the hip, by the ingenious incisions of Furneaux Jordan and Dieffenbach; at the shoulder by those of Spence; and the evils of infection are supplanted by the good results of antiseptic practice.

Further descriptions of the special amputations are given under the special headings, Arm, Hip-joint, Shoulder, etc.

AMUSIA.—Pathologic loss or subnormal ability to produce or comprehend music or musical sounds; an abnormality as regards music analogous to aphasia as regards the faculty of speech. In **motor amusia** the music is understood, but there is loss of the power of singing or of otherwise reproducing music. In **paramusia** there is faulty and imperfect reproduction of music. In **sensory amusia** there is musical deafness, or the loss of the power of comprehension of musical sounds. See Aphasia.

AMYGDALA.—See Almond.

AMYGDALITIS.—See Tonsillitis.

AMYL NITRITE.—A liquid containing about 80 percent of *amyl nitrite*, $C_5H_{11}NO_2$, together with variable quantities of undetermined compounds. It occurs as a clear, yellowish liquid, of ethereal and fruity odor, aromatic taste, and neutral or slightly acid reaction, extremely volatile, insoluble in water, but freely soluble in alcohol, ether, chloroform, and benzin. It is produced by the action of nitric or nitrous acid upon amylic alcohol, and when impure, may have nitric or hydrocyanic acid in it. Dose, internally, 1/4 to 1 minim dissolved in alcohol; by inhalation, from 2 to 5 minims; but larger doses are probably safe.

The effect of an ordinary inhalation of amyl nitrite on man is very transitory, excepting the headache, which may last several hours. Of all the nitrites, this is the most prompt but least enduring in action, and is best administered by inhalation. It causes sugar to appear in the urine, and increases the quantity of urine voided. Mixed with blood it forms methemoglobin, which is not so readily deoxidized as hemoglobin, and under its influence the blood in the body becomes of a dark chocolate color, both in the arteries and in the veins.

Therapeutics.—The inhalation of amyl nitrite is a useful palliative in angina pectoris, epilepsy, tetanus, and many of the respiratory neuroses, as spasmodic asthma, whooping-cough, laryngismus stridulus, etc. It is indicated in the pale-faced form of migraine; in the cold stage of intermittent and pernicious remittent fevers, to prevent internal congestion; also in convulsions, including the puerperal form. In chloroform anesthesia when death has threatened it has been effectively used, and also in poisoning by strychnin, to relieve the convulsions. See Nitrites.

Incompatibles are alcohol, antipyrin, and potassium hydroxid.

AMYLOID DEGENERATION.—See Albuminoid Disease.

AMYOTROPHIC LATERAL SCLEROSIS (Charcot's Disease).—A degeneration of the pyramidal tracts of the spinal cord and atrophy of the motor cells in the anterior cornua and medulla oblongata. It is a disease of middle age. The cause is unknown.

Symptoms.—There is muscular wasting, with loss of power, spastic contractions, diminished electrical excitability and exaggerated reflexes. When the medulla is involved, bulbar symptoms appear. Sensation is normal and the sphincters are rarely affected.

Diagnosis.—It is distinguished from pure **progressive spinal muscular atrophy** by the exaggerated reflexes and muscular rigidity, and from pure **lateral sclerosis** by the muscular atrophy.

Prognosis is unfavorable.

Treatment is of no avail. Rest in bed, hot bathing, massage and electricity may be employed.

ANALGEN.—A white, tasteless, crystalline powder, almost insoluble in water, soluble with difficulty in cold alcohol, but more readily in hot alcohol and dilute acids. It melts at 406.4° F.

It is employed as an analgesic, antineuralgic, and antipyretic, in doses of from 7 to 15 grains. Unof.

ANALGESIC.—See ANODYNE.

ANAM ULCER.—A form of phagedena such as is common in hot countries. It begins with an inflammation starting from a small abrasion of the skin, generally on the foot and leg, with sloughing of the inflamed skin, producing a sharp-cut ulcer that spreads slowly, preceded by an area of inflammation. Its course is remarkably slow, and its resistance to treatment obstinate. Syphilis and anemia are predisposing factors.

ANAPHRODISIACS.—Agents that allay the sexual desire and lower the sexual function. They lessen the excitability of the nerves of the genital organs by depressing the genital centers in the brain and cord, and by lessening the local circulation.

The principal anaphrodisiacs are bromids, potassium iodid, camphor (at last), opium (at last), lupulin, cocain, tobacco, digitalis, conium, belladonna, stramonium, gelsemium, nauseants, purgation, venesection, ice (locally), cold baths, vegetable diet.

A few drops of a 4 percent solution of cocain upon the glans penis will destroy all the erection-power for a quarter to half an hour.

Anaphrodisiacs are used to lessen the sexual passions in nymphomania, satyriasis, and allied conditions. Local lesions, such as irritation of the external genitals, prurigo of the external organs, excoriations of the os uteri, balanitis, the presence of worms in the vagina or in the rectum, should be suspected and, if found, appropriate treatment given.

In nervous or overexcitable sexual conditions:

℞.	Potassium bromid,	gr. xxv
	Tincture of hyoscyamus,	ʒ ss
	Spirit of chloroform,	♏ x
	Water, enough to make,	ʒ jss.

To be taken in two drinks.

ANAPHYLAXIS.—The condition resulting from serum treatment. An individual who has been treated by serum is from that moment sensibilized as regards that serum with the consequence that later injections even a year afterward may cause complications much more alarming than the original. (See SERUM THERAPY AND VACCINE THERAPY.)

ANASARCA.—An accumulation of serum in the areolar tissues of the body. If associated with effusion of fluid into serous cavities, it is called *general dropsy*. If the affection is local, it is called *edema*. This local form is generally the result of some mechanic obstruction to the flow of blood in the part. See EDEMA, HEART-DISEASE, NEPHRITIS.

ANATOMIC AGE. Its Value in the Grading of Early Life.—Up to the present time the age of an individual has been computed by years. Chronologic age will probably always hold good in all civilized communities from a legal point of view. When, however, the question of age is brought to bear upon our school systems whether in classifying and grading children as to their studies, or in pitting them against one another in athletic sports, it becomes a very serious question as to whether chronologic age is a wise division during the formative period of early life. Again, when the important questions of labor and choice of a vocation are brought before us, and we have to determine at what age a child shall be allowed to work, and what the degree of work should be according to the chronologic age, the decision becomes momentous; and we can at once see that a chronologic division for this purpose is not only insufficient but clearly pernicious. Weight and height have long been known to be very inadequate factors for determining chronologic age and this has lately been especially and conclusively shown by Crampton.

It behooves us then to look at the question of age in early life, first, from a legal point of view, manifestly chronologic; secondly, as regards athletics, manifestly anatomic; thirdly, educational as regards school grades, manifestly physiologic and anatomic; and fourthly, as regards child labor and vocation, manifestly a combination of chronologic, physiologic, and anatomic conditions. Legal chronologic age does not enter into this discussion. Anatomic age must be carefully studied before school grades, child labor, and vocation can be dealt with intelligently. From a medical point of view the physiologic and anatomic conditions can for the present be considered as one since the normal physiologic development of the various functions probably corresponds to and keeps pace with the normal anatomic development.

The great importance of an exact knowledge of anatomic development as expressed by the bones and joints to avoid overstrain at a time of life when this avoidance is of prime necessity, should be impressed forcibly upon the public in general, and especially upon those who have charge of the athletic grading of boys and girls, whether in football, basketball, or general gymnastics. Having determined what the anatomic growth is at different stages of development during the growing period, we can then apply this knowledge to the broad questions of education, labor and vocation.

If an anatomic classification can be made it will make no difference in its practical application whether the individual child is healthy or unhealthy, normal or abnormal, is of one race or another, or of one physical parentage or another, except so far as boys and girls, as will be explained later, can be separated normally in their anatomic development. That is, with such an anatomic classification, we can practically work out our problems of early life irrespective of whether the individuals are boys or girls and whether the girls menstruate early or late. This anatomic classification is also clearly valuable for the purpose of adapting children from birth through adolescence to their proper healthy surroundings and to a life suited to their individual strength and capacity.

An extended study of the joints by means of the Roentgen ray has shown that it is the development of the ossific centers of the tarsal and carpal bones and of the epiphyses, which in the most practical way represents step by step the various degrees of development from birth to the comple-

tion of growth. It seems also to be true that a practical knowledge of the normal anatomic changes of these parts, which take place in early life, may lead to the solution of many important problems connected with the safeguarding of the developmental period of infancy, childhood and adolescence.

In the process of development from birth to adolescence the normal changes which take place

This hand represents a stage of development denoted by the presence of all the carpal bones with the exception of the pisiform. The lower epiphysis of the radius is present but not that of the ulna.—(*Rotch.*)

in the bones of the wrist and hand correspond so closely to those of the other joints that in the great majority of individuals the wrist and hand may be accepted as a fairly correct index to the general development. It is true that in their progressive development the ossific centers of the elbow, shoulder, knee and ankle present somewhat finer shades of growth in the sense of more rapid changes, but for clearness of definition and for readiness of topographic interpretation they do not compare with the wrist and hand.

It is quite evident that some more reliable means for determining physical development, resisting power, and fitness for especial work or vocation is needed beyond what we have had in the past. Rotch's work has shown that the carpal bones and the epiphyses of the hand and wrist provide us with such means. There are, however, certain facts connected with the appearance and growth of the carpal bones and epiphyses which must first be understood and appreciated before the practical lesson which they teach can be made use of. (1) The ossific centers of the carpal bones beginning with the os magnum and unciform and ending with the pisiform appear in regular order in the process of development and thus mark off distinct periods. (2) The ossific centers of the

This hand represents a stage of development denoted by the presence of all the carpal bones and the lower epiphyses of the radius and ulna.—(*Rotch.*)

epiphyses, in like manner, appear in regular succession, increase in size, form lines of ossification and finally unite. These two sets of ossific centers mark clearly the entire development of the individual from birth through infancy, childhood, and adolescence to the completed development of the adult. (3) The early periods of development, perhaps two-thirds of them, are marked by the *appearance* of the ossific centers and the later third by the progressive massing of the carpal bones and the gradual *union* of the epiphyses of the entire wrist and hand. (4) For practical purposes the *appearance* of the epiphyses of the metacarpal bones and of the phalanges is not especially adapted to or indeed necessary for forming part of an index for the first two-thirds of development, but it is the ossification and *union* of these epiphyses and those

ANATOMIC AGE

of the radius and ulna which is of great importance in marking the latter third of development up to its completion. (5) A rule which almost invariably holds good is that those epiphyses which appear first are the last to unite. A notable instance of this is the lower epiphysis of the radius which appearing very early in childhood is the last to unite and in its distinct gradations of ossification presents a most valuable index of development up to the completion of epiphyseal growth. The gradual narrowing and shortening of the line of ossification until it disappears are very significant of the passing of adolescence into adult life. Another instance of this rule is that the epiphyses of the terminal phalanges of the hand, appearing later than those of the metacarpal bones and the

This hand represents a stage of development denoted by the greater massing of the carpal bones and the ossification of the terminal phalanges.—(*Rotch.*)

first and second phalanges, unite first. (6) It has been found that the external appearance of the hand, whether large or small, broad or long, does not indicate the development of the bones, and that the Roentgen picture alone can show the degree of development. (7) The work of Pryor and Rotch proves conclusively that girls in their development begin to show ossific centers earlier than do boys. It has long been known that at puberty girls develop more rapidly than boys do, for instance in weight, and that the girl develops in her sexual functions much sooner than the boy, the former becoming a woman some years before the latter becomes a man. From the very beginning of life, however, the female shows an earlier epiphyseal development than does the male and she completes her epiphyseal development and becomes in that sense an adult perhaps one or two years earlier than the boy.

Without reference, therefore, to chronologic age we can grade young human beings from birth to adult life by taking a Roentgen picture of the wrist and hand. The epiphyseal development shown by this picture, though only a factor in the general development, is one of the greatest importance. We must not, however, be misled by thinking that the development of the epiphyses always indicates the actual general physical strength of an individual. The muscles may be weak and not up

This hand represents a stage of development denoted by the ossification of the epiphyses of the metacarpal bones and of the first and second phalanges.—(*Rotch.*)

to the standard. On the other hand, the carpal bones and the epiphyses of the radius and ulna indicate what the development really is, and has been; and the muscular strength and endurance should be worked up to the degree of development shown by this anatomic index. In like manner, where there is an overbright brain and a corresponding lack of epiphyseal development the child should be taken from study and improved physically until its anatomic index equals its brain capacity. The bones of the hand and wrist, therefore, unfold to us an underlying evidence of development which can be used practically for grading early life, and this **"anatomic index"** can only be disclosed during life by means of the Roentgen ray.

Having determined the especial anatomic development, we can then determine what grade in

school, what kind of physical work, or what vocation is adapted to the individual's particular epiphyseal qualification.

In order to simplify the grading, Rotch has prepared a table, which, under the headings of letters, represents the different grades of development in sequence. These letters, however, are merely illustrative of a certain method and probably eventually will be changed when in the future it can be decided by still further observation

This hand represents a stage of development denoted by the ossification of the lower epiphysis of the radius.—(*Rotch.*)

whether a number of developmental periods, for instance, should be grouped together under one letter for practical purposes. It should be noticed also, as is seen in Table II, that older boys and younger girls can be grouped under one heading but a separate anatomic index of this kind for boys and girls is also being prepared.

Looking at the question from a purely developmental point of view, we can take the distinct differences in the progressive development and form from them a provisional anatomic index. Thus at birth the wrist and hand show no ossific centers of the carpal bones or of the epiphyses. As development progresses the carpal bones and the lower epiphyses of the radius and ulna appear in uniform succession so that each of these appearances can be designated by a letter and starting with "A" for the appearance of the os magnum and unciform bones we arrive at the letter "L" denoting the appearance of the pisiform bone, and "M" denoting the greater massing of all the carpal bones and the ossification of the epiphyses of the terminal phalanges. From this time on we can make use of the ossification and union of the remaining epiphyses for later grades of the anatomic index. Thus the letter "N" could be used to denote the ossification of the epiphyses of the

This hand represents a stage of development denoted by the almost complete union of the lower epiphysis of the radius.—(*Rotch.*)

metacarpal bones and of the first and second phalanges, and then the later and terminal stages leading up to completed development, shown by the different stages of ossification and final union of the lower epiphysis of the radius can, in like manner, be designated by "O", "P", "Q" and so forth.

Table I shows the order in which the ossific centers of the carpal bones and the lower epiphyses of the radius and ulna appear.

Table I

A. Os magnum, unciform.
B. Os magnum, unciform, lower epiphysis of radius.
C. Os magnum, unciform, radius, cuneiform.
D. Os magnum, unciform, radius, cuneiform, semilunar.
E. Os magnum, unciform, radius, cuneiform, semilunar, trapezium or scaphoid.

F. Os magnum, unciform, radius, cuneiform, semilunar, trapezium, scaphoid.

G. Os magnum, unciform, radius, cuneiform, semilunar, trapezium, scaphoid, trapezoid.

H. Os magnum, unciform, radius, cuneiform, semilunar, trapezium, scaphoid, trapezoid, lower epiphysis of the ulna.

I. Same as group **H** as to number of bones, but more advanced in development.

J. Same as group **I**, but more advanced in development.

K. Same as group **J**, but the pisiform bone appears just under the cuneiform and all the carpal bones and epiphyses are much more massed and further advanced in development.

L. Same as group **K**, but much more advanced in development; pisiform appears plainly at lower end of cuneiform.

M. Very much more advanced in development than **L**, and the pisiform bone almost as large as the cuneiform. All the bones of the wrist are much more developed than in any previous group.

Table II

Pryor's comparison of the wrist according to sex, showing how the girl presents at an earlier chronologic age the different stages of development.

	Sex.	Age Years.	
A	Female..	1/2	Magnum, unciform.
	Male...	1	
B	Female..	1 1/2	Magnum, unciform, radius (lower epiphysis).
	Male...	2	
C	Female..	2 1/2	Magnum, unciform, radius, cuneiform.
	Male...	3 1/4	
D	Female..	3 1/2	Magnum, unciform, radius, cuneiform, semilunar.
	Male...	4 1/4	
E	Female..	4 1/4	Magnum, unciform, radius, cuneiform, semilunar, and *one* of the following: *Scaphoid, trapezoid, trapezium.*
	Male...	5 1/4	
F	Female..	4 3/4	Magnum, unciform, radius, cuneiform, semilunar, and *two* of the following: *Scaphoid, trapezoid, trapezium.*
	Male...	5 3/4	
G	Female..	5 1/4	Magnum, unciform, radius, cuneiform, semilunar, scaphoid, trapezoid, trapezium.
	Male...	6 3/4	
H	Female..	6. 1/4	Magnum, unciform, radius, cuneiform, semilunar, scaphoid, trapezoid, trapezium, ulna (lower epiphysis).
	Male...	7 1/4	
I	Female..	7 1/2	Same as **H**, but more advanced.
	Male...	9	
J	Female..	8 1/2	Same as **I**, but more advanced.
	Male...	10	
K	Female..	10 1/4	Magnum, unciform, radius, cuneiform, semilunar, scaphoid, trapezoid, trapezium, ulna, pisiform.
	Male...	12 3/4	

The pictures are presented in order to more clearly illustrate the meaning of an anatomic index. The letters are simply empirical, and need not necessarily represent these especial degrees of development.

ANATOMIC NOMENCLATURE.—The expression **BNA** is a shorthand title for a list of some 4500 anatomical terms (*nomina anatomica*) accepted at Basle in 1895 by the Anatomical Society as the most suitable designations for the various parts of the human anatomy which are visible to the naked eye. The terms are all in correct Latin and have been selected by a group of the most distinguished anatomists in the world, working six years at their task, as the shortest and simplest available names for the different structures; the majority of the terms were already in use in the various text-books, but some of them were selected from anatomic monographs not considered in the text-books, and a few of them are brand-new, introduced into the list, where an examination of the literature and of anatomic preparations showed that none of the terms hitherto coined was satisfactory.

One name only is given to each structure, and the mass of synonyms which encumbered the text-books can thus be swept away. If one of the larger text-books of gross anatomy be examined, as many as 10,000 terms will be found employed, the half of which are synonyms, and if the anatomic terms used in the various standard text-books be collected into one list, the total number amounts to more than 30,000. It is no small achievement to have reduced the necessary number of terms in gross anatomy, as it is known today, to less than 5000—an achievement for which both students and teachers of the subject must be thankful. Even more important is the exclusion from the list of all obscure or ambiguous terms, each name employed having a definite and easily ascertainable meaning. The construction of the list has led, too, to the establishment of certain general principles regarding the formation and use of anatomic terms, and these principles promise to be of great service in simplifying terminology and keeping it uniform as anatomic science continues to develop.

As the six years' work of the Commission proceeded *certain principles of terminology* crystallized out and simplified the further revision. It was found, however, that while these principles were of value as general rules, none of them could be employed absolutely without exception. The more important decisions arrived at were the following:

(1) Each part shall have only one name.

(2) Each term shall be in Latin and be philologically correct.

(3) Each term shall be as short and simple as possible.

(4) The terms shall be merely memory signs and need lay no claim to description or to speculative interpretation.

(5) Related terms shall, as far as possible, be similar—*e. g.*, femur, arteria femoralis, vena femoralis, nervus femoralis.

(6) Adjectives, in general, shall be arranged as opposites—*e. g.*, dexter and sinister, major and minor, anterior and posterior, superficialis and profundus. The Commission was occasionally forced to deviate from these rules, but only when compromise appeared to be unavoidable was there any departure. In regard to the retention of personal names, the Commission compromised by giving each part an objective name and putting widely used personal names in brackets, thus leaving to time the final decision.

It is in books, and more particularly in atlases, that it is especially desirable that the BNA be used in its Latin form; and indications are already pointing to its general acceptance by American and British writers.

ANEMIA.—A reduction of the total volume of the blood, or of one or more of its constituents, cellular or chemical. Anemia as a temporary condition is observed after hemorrhage—acute anemia—and in a large number of different pathologic conditions; it occurs in the infectious fevers, in all reduced states due to whatever cause, and as a result of certain poisons, both chemical and metabolic. The term is also used to denote certain distinct diseases of the blood and blood-making organs, the so-called primary or idiopathic anemias—chlorosis, pernicious anemia, leukemia, splenic anemia, and Hodgkin's disease.

Anemia may be general or local. *Ischemia* is a form of local anemia and is the result of mechanic interference with the circulation of the affected part from vasomotor spasm, thrombosis, embolism, or the action of styptics.

Oligocythemia and *polycythemia* are used to denote respectively a reduction and an abnormal increase in the number of red blood cells. Increase of the leukocytes is spoken of as *leukocytosis* or *hyperleukocytosis*, while the opposite condition is known as *leukopenia*. *Oligochromemia* means a reduction in the percentage of hemoglobin.

Diminution of the total volume of blood in the body, *oligemia*, must of course occur after a large hemorrhage, but the condition cannot be recognized clinically, or at least distinguished from anemia in the sense of a reduction in the cellular elements or the hemoglobin, or both, hence the word is practically used in that sense only by the clinician.

Estimation of Total Blood Volume.—Haldane and Smith have devised a method based on the power of the erythrocytes to absorb carbon monoxid. Four minutes after a measured quantity of carbon monoxid has been inhaled, the blood is examined for the degree of saturation, and the total quantity calculated in the following manner: The quantity of carbon monoxid necessary to saturate the entire mass of the blood is first determined, this being the same as the quantity of oxygen required for saturation. The blood specimen is then compared with a specimen of ox blood having a known capacity for oxygen. Example: "A patient having absorbed 100 c.c. of CO, it is found that his blood is saturated 20 percent with this gas. The total capacity for CO, and therefore for oxygen, is 500 c.c. The patient's blood is further found to have the same color as an ox's blood, of which the capacity for oxygen is shown to be 20 volumes percent. The volume of the patient's blood therefore is $\frac{500}{20} \times 100 = 2{,}500$ c.c."

General Symptoms of Anemia.—Depending on the severity of the anemia some or all of the following symptoms are observed and are an indication for a blood examination with instruments of precision: Weakness, languor, loss of appetite, pallor of the skin and mucous membranes, headache, vertigo, palpitation of the heart, and dyspnea. Emaciation may or may not be present and is sometimes conspicuously absent; edema is always seen in severe forms; a soft, systolic, so-called hemic murmur is heard over the heart, the vessels in the neck pulsate visibly, and capillary pulsation may be present. The diagnosis cannot be made with certainty by clinical signs and symptoms, as these may be present (*e. g.*, pale face and lips, etc.) with a normal blood count; while, on the other hand, individuals in apparently normal health sometimes show a considerable degree of anemia.

The anemias are classified as (1) primary, essential, or idiopathic: chlorosis, pernicious anemia, leukemia, splenic anemia, and Hodgkin's disease; and (2) the secondary, or symptomatic.

ANEMIA, LYMPHATIC (Hodgkin's Disease).—See LYMPHADENOMA.

ANEMIA, PERNICIOUS.—A grave form of anemia characterized by great reduction in the number of erythrocytes, a relatively lesser diminution of the hemoglobin, leukopenia, and the presence in the blood of microcytes, macrocytes, poikilocytes, normoblasts and megaloblasts.

Etiology.—The cause is not known. It may follow prolonged exposure and fatigue, shock, mental strain, malaria, syphilis, alcoholism. Among predisposing factors believed to be responsible may be mentioned: pregnancy and lactation, and prolonged gastrointestinal disease leading to atrophy of the gastric tubules. Certain intestinal parasites, especially *ankylostomum duodenale* and *bothriocephalus latus*, are associated with a form of anemia which cannot be distinguished from the pernicious type, but which should properly be regarded as a secondary form. The disease is more common in Germany and Switzerland than in other localities, and relatively rare in America, although reports indicate an increasing prevalence in certain districts in the states of the Middle West. Males are more frequently attacked than females; Osler had 17 males and 10 females in a series of 27 cases. It is a disease of middle life and rarely develops before the age of 20. The most commonly accepted view assumes as the cause hemolysis due to absorption of poisons from the intestinal tract, produced either by bacterial action or perverted metabolism.

Pathology.—The internal organs often show a degree of fatty degeneration. The stomach may show atrophy of the gastric tubules. The liver is usually enlarged and fatty. The liver cells may be colored with iron (hemosiderin) pigment, and there is often pigmentation of the sympathetic ganglia. The spleen is often unaffected. The tubules of the kidneys are often pigmented with the iron stain. Hyperplasia of the red marrow of bone has been found by H. C. Wood.

Symptoms.—In addition to the general symptoms of anemia, which have been enumerated, the patients present a peculiar lemon-yellow waxy pallor of the skin and blanched mucous membranes; gastrointestinal disturbances, anorexia, nausea, vomiting and diarrhea are prominent features; palpitation and dyspnea are severe; a hemic murmur may be heard; hemorrhages occur into the skin and mucous membranes, and from the nose, stomach and intestines. Retinal hemorrhage is an occasional accident, and disorders of vision are common. Nervous symptoms may arise, such

as numbness or paresthesia or even paralysis. There is no emaciation, and many patients present, on the contrary, a well nourished appearance which is in striking contrast to the extreme pallor and general exhaustion which is progressive. The urine is dark, of low specific gravity, and contains an increased quantity of uric acid. The urinary findings, however, are not constant. Fever of irregular type is present; the evening temperature may attain 102° or even 103° F., and is followed by a morning remission.

Blood Changes.—If a puncture is made, the drop of blood appears pale and watery, and slips off the part as though containing an oily substance, and coagulates slowly. If placed under the microscope, one may notice the loss of characteristic rouleaux formation seen in normal blood.

A high color index is characteristic of pernicious anemia. The reduction of red blood cells may be very great; the number is usually below 2,000,000 and may not attain 1,000,000. The hemoglobin percentage is relatively in excess, and the leukocytes are diminished, usually below 5,000 to the cubic millimeter of blood. Osler found an average erythrocyte count of 1,500,000 with 30 percent of hemoglobin. Da Costa and Cabot in larger series of cases obtained 1,361,000 and 1,200,000 respectively, with approximately the same hemoglobin percentage.

In the stained preparations all varieties of abnormal erythrocytes may be found: macrocytes, microcytes and poikilocytes, nucleated cells (normoblasts and megaloblasts). An excess of the megaloblasts over the normoblasts is by most authorities regarded as pathognomic of pernicious anemia. Polychromatophilia, or irregularity in the staining of different parts of the cell, and basophilic degeneration occur. The leukocytes are diminished as a whole, while the lymphocytes usually show a relative increase; myelocytes are often found. See BLOOD (Examination).

Diagnosis.—Marked oligocythemia with a relatively high percentage of hemoglobin is not sufficient for a positive diagnosis, as these conditions may be present in any form of severe anemia. It is essential that megaloblasts and normoblasts be found in the peripheral blood in order to make a positive diagnosis.

Prognosis.—Unless the disease is due to some removable cause such as intestinal parasites, the prognosis is invariably fatal. Temporary remissions are not infrequent and are quite characteristic of the disease. The duration varies from a few months to several years.

Treatment.—The patient should be constantly in the open air, day and night, and should therefore, if possible, be removed to a mild and equable climate. Sea air and, in the early stages, sea bathing are beneficial; great altitudes must be avoided. Besides being supplied with plenty of fresh air and sunlight, the patient must be properly fed. Strict regularity must be enforced, and as much light, nourishing food provided as the digestive tract can assimilate. Milk and raw eggs are the most suitable articles of diet. Bone-marrow, either fresh or in the form of the glycerinated extract, is recommended, but has not proved of much value. The bowels should receive careful attention. Direct transfusion has been tried repeatedly during the past few years, but the results have been disappointing, although temporary improvement has been noted in some cases. Hypodermoclysis, an easier measure, answers the same purpose. Medicinal treatment consists in the exhibition of intestinal antiseptics, salol, betanaphthol, or strontium salicylate, which is a favorite in this disease. Iron is of little value; the most satisfactory drug is arsenic, regarded for a long time as almost a specific. It may be given either in the form of arsenic trioxid, in the dose of 1/60 to 1/40 grain, or as Fowler's solution in gradually ascending doses, with care not to exceed the physiologic limit of the drug.

The following formulas are recommended:

℞. Arsenic trioxid, gr. ss
Calcium glycerophosphate, ʒ j.
Divide into 20 capsules. One after each meal.

Strychnin, in doses of 1/30 of a grain, may be combined with the foregoing ingredients. Vallet's mass, in doses of 4 or 5 grains, may be beneficial, as:

℞. Arsenic trioxid, gr. ss
Strychnin sulphate, gr. 2/3
Mass of ferrous carbonate, ʒ ij.
Divide into 20 pills or capsules. One after each meal.

We may combine quinin, as:

℞. Arsenic trioxid, gr. j
Strychnin sulphate, gr. j
Quinin sulphate, ʒ jss
Mass of ferrous carbonate, ʒ ij.
Divide into 40 pills or capsules. One after each meal.

Cacodylate of sodium has been recommended as less irritating than other preparations of arsenic, being suitable also for hypodermic use. The dose is 1/2 of a grain, three times a day. Atoxyl is still another preparation of arsenic given in doses of 1/3 to 1/2 of a grain hypodermically every other day. Late in the disease, inhalations of oxygen have been recommended.

To eliminate the possibility of general infection the use of antistreptococcus serum has been suggested. See CHLOROSIS, LEUKEMIA, LYMPHADENOMA.

Aplastic Anemia.—An intractable, pernicious and rapidly fatal form of anemia occurring in young adults, characterized by hemorrhages into the mucous membranes and "aplastic" bone-marrow. It is distinguished from pernicious anemia by the low color-index, absence, or scarcity, of nucleated red cells and of poikilocytosis. Polychromatophilia is not marked. Though the leukocytes are normal in number, the lymphocytes are enormously increased while the polynuclear neutrophiles are reduced.

ANEMIA, PSEUDOLEUKEMIC, OF INFANCY.—See Pseudoleukemic Anemia of Infancy.

ANEMIA, SECONDARY (Symptomatic).—This type of anemia accompanies practically all chronic organic diseases; the acute infectious fevers; parasitic infections, which include malaria and syphilis, and particularly uncinariasis and bothriocephalus latus infection (see under pernicious anemia); toxemias and poisoning with certain metallic poisons. The following classification is practical for the clinician:

(1) Anemia from hemorrhage from any cause—acute anemia. This includes, besides traumatic and surgical hemorrhage, postpartum hemorrhage, hemorrhoids, purpura, hemophilia, menorrhagia and metrorrhagia, ruptured aneurysms. Parasites in the intestines, kidney, etc., may cause hemorrhage.

(2) Anemia from long-continued drain on the albuminous materials of the blood (Osler). This group includes a large number of organic and constitutional disorders: rheumatism, Bright's disease, tuberculosis, prolonged suppuration, the acute infectious fevers, as acute malaria, scurvy, rickets, chronic gastrointestinal disease, carcinoma and sarcoma.

(3) Toxic anemias. The metallic poisons that especially produce anemia are lead (basophilic degeneration of erythrocytes), mercury, arsenic, phosphorus, and the potassium salts, especially the chlorate. Another important group is formed by the anilin derivatives; the oxyhemoglobin in the blood is converted into methemoglobin. Anemia is caused by the toxins generated by specific organisms, such as that of tuberculosis, of syphilis, or of chronic malaria. Anemia also results from the absorption of metabolic poisons from the alimentary tract, *i. e.*, autointoxication, and, according to some authorities, pernicious anemia should on that account be classed under this head. Here also may be included for convenience the parasitic anemias.

(4) Anemia from malnutrition and inanition.

Symptoms.—The general symptoms described under *anemia* are present in variable degrees depending on the intensity of the blood changes. It should be emphasized, however, that a marked degree of anemia may be present without the classic subjective and objective signs, and that the final decision must be made by the blood picture.

Blood.—It is customary to distinguish two types of secondary or symptomatic anemia according to the relation existing between the number of red cells and the percentage of hemoglobin, known as the color-index. See Blood (Examination). Sometimes the erythrocyte count is high, say between 4,000,000 and 4,500,000, with a disproportionate reduction of the hemoglobin 60 to 70 percent, or even a greater discrepancy. This is spoken of as a *chloranemia*, or chloranemic type of anemia; the blood picture resembles that of chlorosis. Again, the color-index may be high, that is, the percentage of hemoglobin less reduced in proportion than the number of red cells, simulating the condition found in pernicious anemia; hence the term *anemia of the pernicious type*. The reduction in the different constituents of the blood varies within wide limits and, as has been stated, there is no constant correspondence between clinical symptoms and the blood findings. In the graver forms of secondary anemia changes in size and shape of the erythrocytes as well as in their staining properties—microcytosis, macrocytosis, poikilocytosis (in one word, anisocytosis), polychromatosis and basophilic degeneration—are not at all uncommon. Basophilic degeneration is observed especially in the anemia accompanying chronic lead poisoning, without, however, being pathognomonic of that condition. The occasional presence of nucleated red cells, both normoblasts and megaloblasts may render the diagnosis from pernicious anemia practically impossible by the blood count alone. Special features of the various etiologic forms of secondary anemia are discussed under the respective diseases.

A moderate degree of leukocytosis is generally present, the increase affecting the polymorphonuclear neutrophiles. Like the production of nucleated red cells (normoblasts) this is a regenerative phenomenon and tends to subside as the blood regains its normal constitution. A low leukocyte count, especially if the lymphocytes are relatively increased, is an unfavorable sign, occurring in grave forms of secondary anemia. See Blood (Examination).

Diagnosis.—The blood should be carefully examined, and a thorough search made for any exciting cause. Often a minute history of the case will unravel the obscure nature. A patient has been observed in a profound anemic state, and after excluding most of the causes, it was found that he had been a sufferer from internal hemorrhoids for years, upon which fact he had placed little importance. An operation gave complete relief.

Prognosis.—According to the definition of symptomatic anemia the prognosis of the anemia itself is always favorable, the final outcome depending entirely on the nature of the etiologic disease.

Treatment depends upon the cause. Aside from improving the general hygienic conditions, nutritious food and iron are indicated in full doses.

ANEMIA, SPLENIC.—See Splenic Anemia.

ANESTHESIA.—A condition of insensibility or loss of sensation due to pathologic conditions of the nerve-centers, of the conducting paths of the nerves, or of the peripheral terminations of the same, or to artificial impairment by means of anesthetics. Nitrous oxid, ether, and chloroform are the three agents chiefly used to produce general anesthesia. Artificial anesthesia may be effected in one of three ways: First, by benumbing the part by means of cold; second, by intercepting its nervous communications; third, by arresting the activity of the nerve-centers concerned in sensation.

Indications.—Besides its common use (to abolish pain during surgical operations, renal colic, etc.), anesthesia may be employed to produce muscular relaxation in hernia, dislocations, and fractures,

and to aid in examining tumors, joint-diseases, and malingerers, and to prevent the suffering of labor, chiefly in the second stage.

Anesthesia in labor has certain advantages: viz., first, it greatly modifies the intensity of the patient's suffering; second, it relaxes the soft structures, and thus facilitates the expulsion of the fetus. The disadvantages are: First, it diminishes the intensity of the uterine contractions to an appreciable extent; second, it is followed by nausea, vomiting, and headache if not administered in moderate amounts; and third, it predisposes to postpartum hemorrhage.

Contraindications for anesthesia are fatty degeneration or dilatation of the heart, renal and pulmonary disease, enlarged tonsils, cerebral tumor, and chronic alcoholism—particularly the first and last named.

Anesthesia is dangerous in cases of intestinal obstruction, with distention of the abdomen and a weak and failing pulse. After-sickness is much less common after ether than after chloroform, and this is of great importance in abdominal operations. The disadvantage of ether is that it is irritant to the respiratory mucous membranes, especially pronounced when inflammation thereof exists. It depends upon the administration whether ether produces extreme venous engorgement and leads to much oozing from the field of operation. The after-oozing is greater with chloroform than with ether. Anesthesia in empyema is extremely perilous.

Forms of Death from Anesthetics.—1. From sudden paralysis of the cardiac ganglia, early in the inhalation, by reflex action proceeding from some peripheral injury before complete anesthesia is produced. Thus, in the extraction of teeth, a small quantity of chloroform having been administered, the heart is enfeebled, and the action of the cerebral hemispheres suspended, but not those of the basal or medullary ganglia. If at this stage the fifth nerve is irritated by the intimate relation of its nucleus with that of the pneumogastric, reflex inhibition may be transmitted over the latter, arresting the cardiac ganglia. The stage of incomplete anesthesia is always a dangerous one in which to perform any operation around the distribution of the fifth nerve.

2. In the stage of rigidity, from tetanic fixation of the respiratory muscles, the blood backing up on the venous side and arresting the heart's action, respiration ceasing before the cardiac action is stopped.

3. In the stage of complete relaxation, by paralysis of respiration, or by paralysis of the tongue, causing obstructed respiration.

4. In the same stage, by paralysis of the motor ganglia of the heart.

5. From depression of the functions by chloroform narcosis and from shock, and may occur in the anesthetic state or afterwards.

ANESTHESIN.—The ethyl ester of paramidobenzoic acid; it occurs as a white powder, soluble in ether, alcohol, fatty and ethereal oils; insoluble in water. It is used as an anesthetic for minor injuries, painful skin affections and those of mucous membranes, carcinomatous ulcers, etc., as a dusting powder, also in throat and nose practice. Its anesthesia lasts longer than that of cocain, and it is much less toxic. The hydrochlorid is used internally in gastric hyperesthesia and ulcer, in doses of 5 to 7 grains. Doses of 30 grains have not proved toxic.

ANESTHETICS, GENERAL. Table of General Anesthetics.—The following are some of the substances, or agents, that have been used for general anesthesia: **Amylene**, C_5H_{10} a mobile liquid, thin, colorless, translucent; action rapid, producing partial anesthesia. It is used in Germany under the name of *Pental;* it is best administered by means of Junker's inhaler, which modifies its unpleasant odor; it should not be brought near a flame. **Carbon Tetrachlorid,** not so irritating to the organs of respiration, but far more dangerous than chloroform. **Chloroform,** by inhalation. Largely employed in general surgery. It seems to have a selective action upon the nervous system, and also exercises a direct influence upon the muscular tissues of the heart. It paralyzes the vasomotor system, and death results from cardiac paralysis. Chloroform should always be administered freely mixed with air. The *method of definite mixtures*, however, as recommended by Clover and by Bert, while admirable in theory, is not entirely practical. The *Lister method*, also known as the *Scotch* or *open method*, of administering chloroform, consists in pouring a small amount of the anesthetic upon a common towel arranged in a square of six folds, and holding this as near to the face as can be borne without inconvenience. Various inhalers have been devised for the administration of chloroform, the best of which are: *Clover's*, which consists of a large bag capable of containing a given volume of air, into which the vapor of a given quantity of chloroform is allowed to enter, the mixture being so arranged that the tension of chloroform vapor in the air is maintained below 4.5 percent; *Junker's* as modified by *Dudley Buxton*, which consists in the inhalation of air containing the chloroform vapor, the latter being taken up by pumping the air through a bottle containing half an ounce of the anesthetic; *Krohne and Sesemann* have modified the foregoing by doing away with the intermittent, jerky delivery of the vapor, and by adding to the face-piece an expiration valve guarded by a stiff feather, which rising in expiration and falling in inspiration, registers the force and strength of respiration (*feather respiration register*); *Sansom's* apparatus is a modification of *Snow's*, substituting a gutta-percha covering for the cold-water jacket of Snow; *Snow's inhaler* consists of a metallic cylindric vessel, containing two coils of blotting-paper, permitting free circulation of air, and surrounded by another cylinder containing water, the latter being for the purpose of equalizing the temperature. *Syncope* resulting from chloroform administration should be treated by lowering the head, artificial respiration, inhalation of nitrite of amyl, electric stimulation, and possibly acupuncture of the heart. **Electricity.** See ELECTRICITY, Anesthesia. **Ethene Chlorid,** formerly called *ethy*

lene chlorid, Dutch liquid, chloric ether, closely resembles chloroform, but is less of a cardiac depressant. It is considered safer than chloroform. Death results from paralysis of the respiratory centers. **Ethyl Chlorid** is a very rapid anesthetic, producing a narcosis which lasts from one to three minutes. It may be sprayed upon gauze or given through an inhaler. It can be used only for short operations. A few surgeons have used it to induce anesthesia before administering ether, but for this purpose it is undoubtedly less safe than nitrous oxid. It causes death by paralyzing the respiratory centers. **Ether,** by inhalation, is probably the safest known agent for the production of prolonged narcosis. Its action is directed largely to the nervous system, which becomes profoundly affected. It frequently causes spasmodic action and suspension of respiratory action. Death results from paralysis of respiration. It may be administered alone or in combination with nitrous oxid gas, in which case the patient is more rapidly narcotized. A variety of inhalers has been devised for its administration, as follows: *Allis's* is probably the best form of open inhaler. It consists of a metal frame so arranged that a flannel bandage can be stretched across and the whole surrounded with a leather case, which acts as a face-piece. *Clover's portable ether inhaler* consists of a dome-shaped receptacle pierced by a central shaft connecting with a rubber bag, into which the patient breathes. Moving with the face-piece is a metal indicator to register the amount of ether admitted. A water-chamber surrounds the ether vessel to regulate the temperature. *The cone* is much used in America. A towel is folded into the shape of a cone, a sponge is placed at the apex, and the ether poured upon this. *Hewitt's apparatus* may be used for giving gas and ether. In his inhaler the inspiratory and expiratory valves are placed in a little chamber near the face-piece; a free draft of air is permitted. *Ormsby's inhaler* consists of a leather face-piece, crowned with a cone-shaped wire cage covered with leather and joined to a soft leather bag, covered by a loose net to prevent excessive expansion. The wire cage contains a sponge on which the ether is poured. *Rendle* adds to a cone containing a flannel cap a mask for the face. *Rectal etherization* may be resorted to in operations about the face and throat. The ether vapor is introduced into the bowel, the process taking longer for complete anesthetization than by the usual method. **Ethidene Chlorid** is similar in its action to chloroform. Patients take a longer time to recover consciousness than when chloroform is used, but they experience fewer after-effects, and recover rapidly. Anesthetization occurs in from 3 to 5 minutes. **Hydrobromic Ether** (*bromid of ethyl*) produces unconsciousness and anesthesia in 1 minute, and complete muscular relaxation in 2 or 3 minutes. The heart's action is somewhat weakened. Return to consciousness after withdrawal of the ether is very prompt. Its use may be followed by vomiting. According to some observers, death results from cardiac failure, while others believe it kills by direct action upon the respiratory center. It is best administered by an Allis inhaler, and is of most service in minor surgery for short operations. **Hypnotism** (*q. v.*). **Nitrous Oxid,** by inhalation, is much used by dentists for extraction of teeth. It may be employed in minor surgical operations. There are but few after-effects, those most often observed being headache and malaise. Given in conjunction with oxygen under pressure its administration may be prolonged indefinitely in major surgical operations. *Clover's gas and ether inhaler* is intended for the administration of a mixture of these anesthetics; it is so arranged that gas can be given alone, or in combination with the ether. *Buxton's apparatus* is used for the administration of gas only, and possesses a special contrivance to filter the air. *Fontaine's chamber* is an apparatus devised to keep the patient under an atmospheric pressure equal to 26 inches mercury, so that the vapor inhaled would be 50 percent gas and 50 percent air, and asphyxia thus be prevented. The employment of *supplemental bags* has been advocated by Braine. The patient breathes into these bags, the gas supply being turned off and the expiratory valve closed. This method produces a more prolonged period of unconsciousness. Various accessory instruments, etc., are required in administering gas, such as gags, mouth-openers and mouth-props, spoons, etc. **Nitrous Oxid** is the safest of all anesthetics and the most agreeable to take. It requires the shortest time for induction. There is no stage of excitement. The patient comes out of the anesthetic at once and there are practically no after-effects upon any part of the body. The administration of nitrous oxid can be longer extended with impunity than that of any other anesthetic.

Danger-signals are (1) cyanosis, deep and continued; (2) slowing and depression of the pulse; (3) vomiting. Cyanosis calls at once for turning off the gas and turning on fully the oxygen.

In order to obtain satisfactory relaxation in the robust or in alcoholics, ether is given as a preliminary measure—by cone or open method—for 2 to 5 minutes, then nitrous oxid and oxygen alone are used. A preliminary routine dose of morphin (1/4 grain) and atropin (1/150 grain) is beneficial. Crile gives besides morphin, 1/150 grain of scopolamin or less two hours before operation in order to prevent appreciations of the operative trauma.

Nitrous oxid and ether can be used when ether is contraindicated, as in kidney disease. It has been used with satisfaction in advanced pulmonary disease. In the desperate cases in which operation under ether or chloroform is hazardous, nitrous oxid and oxygen anesthesia is a boon. It is dangerous chiefly in heart lesions. It is not suitable for the general practitioner because it requires special training to acquire the technic, but among expert anesthetists it is gaining fame rapidly and is being used in some clinics as the routine anesthetic.

Gatch has established the fact that rebreathing of the nitrous oxid and oxygen in periods of 2 minutes is innocuous and beneficial to respiration and circulation and materially reduces the cost of the anesthesia. Just enough oxygen should be given to keep the patient pink and prevent or overcome cyanosis.

Anesthetic Mixtures.—**A. C. E. Mixture:** alcohol, sp. gr. 0.838, 1 part; chloroform, sp. gr. 1.497, 2 parts; ether, sp. gr. 0.735, 3 parts. **Billroth's:** chloroform, 3 parts; alcohol and ether, each, 1 part. It is best administered by the open method. **Linhart's:** alcohol 1, chloroform 4. It is administered similarly to chloroform. **Martindale's:** a volumetric mixture, the ingredients of which evaporate almost uniformly; it consists of absolute alcohol, sp. gr. 0.795, 1 volume; chloroform, sp. gr. 1.498, 2 volumes, pure ether, sp. gr. 0.720, 3 volumes. **Medico-Chirurgical Society of London:** ether 3, chloroform 2, alcohol 1. **Methylene,** or **Bichlorid of Methylene,** a mixture of methylic alcohol 30 percent, and chloroform 70 percent. The so-called *"liquid of Regnauld"* consisted of 80 percent chloroform, 20 percent methylic alcohol. Methylene is not often used, several deaths from cardiac paralysis having followed its employment. **Nussbaum's:** ether 3, chloroform 1, alcohol 1. **Richardson's:** alcohol 2, chloroform 2, ether 3. **Sanford's**—the so-called *"chloramyl"*—is a mixture of chloroform and amyl nitrite in the proportion of 2 drams of the nitrite to the pound of chloroform. It is a dangerous mixture, both drugs depressing the heart. **M. S. Mixture:** ether 56 3/4, chloroform 43 1/4 by volume; it is said to be a true molecular solution, containing neither of its ingredients free. **Schleich's:** chloroform, petroleum ether, sulphuric ether, in varying proportions. **Scopolaminmorphin:** 1/64 of a grain of scopolamin (hyoscin), and 1/5 of a grain of morphin, are divided into three doses, which are injected hypodermically 2 1/2, 1 1/2, and 1/2 hour before the operation. The patient falls into a sound sleep which lasts for about 5 or 6 hours after the last injection. Inhalations of chloroform or ether may be necessary. Several deaths have been reported, and the method is not recommended. **Vienna General Hospital:** ether 9, chloroform 30, alcohol 9. **Vienna Mixture:** ether 3, chloroform 1. **Von Mering's:** chloroform, 1 volume; dimethylacetal, 2 volumes. It is said to produce no failure of respiration or heart, and no lowering of the blood-pressure. **Wachsmuth's:** one-fifth part of oil of turpentine is added to the chloroform. It is said to prevent any danger of heart failure.

Various methods have been suggested by means of which the influence of the anesthetic may be prolonged, or its dangers and sequels largely averted. The following are the most important: **Dastre-Morat's** consists in the injection of 1 or 1.5 c.c. of the following mixture: Morphin hydrochlorid, 10 centigrams; atropin sulphate, 5 milligrams; aq. destill., 10 grams. The atropin is said to lessen the after-sickness and abrogate salivation and bronchial secretion. **Forné's:** the preliminary administration of chloral before using chloroform, 2 to 5 grams an hour before. **Kappeler's:** a combination of chloral hydrate and ether, 40 grains of the former. The duration of anesthesia is prolonged and the recovery retarded, but the after-effects are more marked. **Nussbaum's:** injection of 1/6 to 1/2 of a grain of morphin previous to the administration of chloroform. Less of the anesthetic is needed, while the stupor is prolonged; vomiting is increased. **Obalinski's:** hypodermic injection of cocain, 2 to 5 centigrams of a 3 percent solution during chloroform anesthetization. **Trélat's:** administration of 2 to 4 1/2 grams of chloral hydrate, and 10 to 20 grams of syrup of morphin in 60 grams of water, repeating the dose in 15 minutes, and following by chloroform anesthesia.

Comparative Safety of Anesthetics.—A comparison of these agents in respect to their safety has been made by Dr. Richardson, who considers methylic ether to be the safest of all, and the others as follows:

Safe: Ethyl bromid, ethyl chlorid, ether, ethene (olefiant gas), ethene chlorid, methyl bromid, methyl chlorid, methyl ether, methene chlorid, methane (marsh gas), nitrous oxid.

Of doubtful value: Amylene, amyl chlorid, butyl chlorid, benzene (benzol), carbon disulphid, carbon dioxid, carbon tetrachlorid, methyl alcohol, methylal, spirit of turpentine.

Dangerous: Amyl hydrid, butyl hydrid, carbon monoxid, ethyl hydrid, chloroform, and ethene dichlorid are considered useful, but require care.

Mortality.—It has been estimated that with *nitrous oxid,* there is one death in 300,000 cases; with *ether,* one death in 15,000; with *ethyl chlorid,* one death in 12,000; and with *chloroform,* one death in 3,000.

Nitrous Oxid and Oxygen Anesthesia Compared with Ether.—Crile's recent investigations in cytolysis show that there is decidedly more destruction of chromatin after ether than after nitrous oxid. Again, there is no lowering of the phagocytic power after nitrous oxid, as after ether. Nitrous oxid does not reduce hemoglobin or cause any permanent blood change. There is no acetone or indicanuria as a result. Postanesthetic complications are absent, particularly shock; and nausea occurs in only 17 percent of cases as compared with 42 percent in ether.

Ether Compared with Chloroform.—When swallowed, ether is less irritant than chloroform to the mucous membranes, but its vapor is more so to the air-passages. It is more of a general stimulant, and less depressant to the heart and circulation. It does not clot the blood. Its vapor is very inflammable, less pleasant to inhale, slower in action, has a longer stage of excitement and a less profound narcosis, and causes a greater degree of vomiting. It is less dangerous than chloroform, death from the inhalation of ether occurring slowly and usually by paralysis of respiration—from chloroform, it is almost always sudden, and is generally believed to occur by paralysis of the heart. Ether has undoubtedly been the direct cause of a number of deaths, besides several which occurred some hours after termination of its anesthesia.

Attempts have repeatedly been made to estimate the comparative safety of the various anesthetics used for the production of general anesthesia. In 1879 the "Glasgow Committee" of the British Medical Association concluded in favor of ether, declaring that chloroform lowered the blood tension and depressed the action of the heart. In 1889 the Hyderabad Commission

arrived at the conclusion that chloroform produced an arrest of respiration before there was a stoppage of the heart. It is thought, however, that the climate—that of India—may have had some effect in producing this result, since in temperate climates the heart usually fails before there is a depression of respiration.

Ether should be administered in cases in which chloroform acts unsatisfactorily and in which dangerous symptoms repeatedly manifest themselves; in acute hemorrhage, as the vasomotor tone is stimulated while it is depressed by chloroform; in shock, when an anesthetic is necessary, ether is to be preferred. In general pulmonary emphysema it is far safer than chloroform. Children take ether remarkably well. The usual objection to it is its liability to irritate the respiratory mucous membrane. It is not more irritating, if properly administered, than chloroform. Old age is said to contraindicate ether, because of a pre-existing chronic bronchitis in many cases. Properly administered, it will not increase bronchitis. It is particularly indicated in old age, since it is a cardiac and vasomotor stimulant. In fatty heart, endocarditis, syncope, if an anesthetic must be used, ether, being less dangerous than chloroform, should have the preference. At night ether is preferable to chloroform being less irritating to those about the patient than chloroform. Its liability to catch fire can be obviated with a little care.

Chloroform is preferable to ether when, for any reason, the latter does not act well. The change to chloroform will be found desirable and satisfactory. Conditions of the urine, indicating nephritis, acute or chronic, as well as acute pulmonary affections, demand chloroform rather than supersaturation with ether by open inhalers. In alcoholics it is frequently desirable to begin the narcosis with chloroform and continue with ether after the patient is anesthetized. This may also be desirable in the excessively nervous and hysteric; the fumes of chloroform being, as a rule, more pleasant to inhale than ether. In obstetrics, when it is usually not necessary to carry the narcosis beyond the second degree, chloroform should be used, but in acute hemorrhage, as in placenta prævia, it should not be employed, ether being preferable. In operations about the face necessitating the use of the cautery, ether being very inflammable, chloroform should be chosen. It is true that if ether is administered with closed inhalers, care being taken that the ether-bottle is closed, this objection to ether may be overcome, as may also its use by night. In arterial disease when for any reason increased arterial tension is undesirable, chloroform will usually be found preferable to ether, as ether is a direct cardiac and vasomotor stimulant and increases liability to rupture.

Preparations for general anesthesia should include the removal of articles from the mouth, such as artificial teeth, candy or tobacco, etc.; looseness of the clothing about the neck and abdomen; the recumbent position, the head not being raised high. Articles needed in case of emergency are a mouth-gag, a pair of tongue-forceps, a hypodermic needle in working order, solutions of strychnin, atropin, brandy, and digitalis. An electric battery is a desirable article to have at convenient distance.

The loss of heat during anesthesia may be greatly prevented by carefully covering the patient with blankets and surrounding him with hot-water bottles. In prolonged operations the patient should be especially cared for in this manner.

Preparation of the Patient.—From 1 to 4 days preceding narcosis the patient should receive an active cathartic, as the mild mercurous chlorid or compound cathartic pill, in either case followed by a mild saline. He should be encouraged to drink as much water as possible, best accomplished by ordering a glassful at regular intervals during the day. If suffering from prolonged illness, and if hemorrhage or shock is expected, he should receive once daily an infusion of normal saline solution, preferably introduced into the colon through the canalized Wales' bougie. The quantity should consist of about two quarts, and should be given about the middle of the day in the recumbent position, in which the patient should remain until it is retained.

Strict oral hygiene should be insisted upon. The teeth should be put into good condition by a dentist, and the patient should use waxed floss silk regularly after food, and rinse the mouth with a mild antiseptic solution, such as peroxid of hydrogen, one teaspoonful to a wineglass of water, half strength Dobell's solution or a saturated solution of boric acid.

Preliminary preparation in emergency cases must, of course, be adapted to the exigencies of each case. If food has recently been taken, gastric lavage should always be employed, washing until all food-particles have been removed. Patients who are not directly under the observation of the surgeon should be instructed not to take any food for at least 5 hours preceding narcosis, and this food should be of a variety easily digestible. It may be said that failure to observe these principles has frequently caused loss of life.

Thorough examination of the patient should never be omitted. The condition of the heart, arteries, lungs, and the urine need especial attention. The last is particularly important when open inhalers are used and little effort is made to reduce the quantity of the anesthetic to a minimum. That nephritis can be produced or aggravated by the injudicious administration of ether by open inhalers and supersaturation there is no doubt. The same is true as well of pneumonia following etherization.

Hypodermic injections of from 1/8 to 1/4 of a grain of morphin have been given until a short time before anesthesia to steady the heart, prevent vomiting, and aid in bringing about anesthesia, but they are apt to mask the symptoms of dangerous narcosis and hence lead to fatal results. Milk and other foods that digest slowly are not suitable previous to anesthesia. Hot broth or beef-tea 3 or 4 hours before administration of the anesthetic

is the best plan. A nutritive enema may be given weak patients one-half hour before operation.

Enema for preanesthetic administration:

℞.	Yolk of egg,	j
	Beef-tea,	℥ j
	Milk,	℥ j
	Brandy,	℥ j
	Pepsin,	gr. x.

The brandy to be added after the food elements have been peptonized.

Preparation of the Table.—In private houses when a trained nurse is not in attendance, the anesthetist should see that the table is properly prepared for the comfort and safety of the patient. To this end fold a quilt or blanket lengthwise, twice, so that it will be 4 thicknesses; place this on the table; cover it with several thicknesses of newspaper, and over this throw a sheet. The blanket will be longer than the table and the extra length may be folded under at the head for a pillow; this will make the patient's head lie more comfortably than it would on a perfectly level table, and an ordinary pillow is usually too high. If an emaciated patient lies on a hard table during a protracted operation, decubitus may ensue. These pressure ulcerations are very difficult to cure and add to the gravity of the case. If there is a carpet on the floor of the room in which the operation is to take place, old newspapers may be spread on the carpet to protect it from damage. Such a precaution will be appreciated by the family, though they would not think of it unless mentioned.

In curetting and other vaginal operations where much water is used, the clothing sometimes gets saturated. If there is no appliance at hand, such as a rubber pad, to prevent this, it may be avoided in a large measure by placing some blocks of wood under the legs at the head of the table.

Administration of Ether.—If using an inhaler, about 1 or 1 1/2 ounces should be poured upon the gauze, the patient being encouraged to breathe deeply. This is exactly the reverse of chloroform administration. The cone should never be suddenly applied to the patient's face. As the upper air-passages become accustomed to the vapor, the cone should be gradually brought to cover the nose and mouth, excluding as much air as possible. Complete narcosis is generally effected in non-alcoholic patients in about 5 minutes. If ether is administered in this way, the unpleasant symptoms will rarely occur. The same attention to respiration, pulse, pupil, and the color of skin should be given as with chloroform. It should be well understood that ether should not be continuously administered. After the patient is anesthetized, the cone should be removed frequently, permitting him to breathe fresh air; when reapplying the cone a very small quantity of the anesthetic will suffice for further narcosis. It is frequently said that one cannot, with any accuracy, gage the amount of ether necessary for any particular narcosis. In reference to this it may be stated that a narcosis lasting 2 hours can, with a closed inhaler in nonalcoholic cases, be maintained with from 3 to 4 ounces.

Probably the best way to administer ether is by the drop method which consists in giving it drop by drop upon a piece of gauze or an Esmarch inhaler. See Intratracheal Insufflation of Ether.

Ether has been known to take fire 15 feet from a gas-jet; hence great care must be exercised in administering it at night. The container should be of tin, not of glass, and it should be securely corked in the intervals of use. The vapor is nearly twice as heavy as air, and if undisturbed, it will settle to the floor and flow along it for a considerable distance before diffusing into the air. Hence a fire low down, as in a stove, is more dangerous than a gas-jet high up.

Administration of Chloroform.—Vaselin should be applied to that portion of the patient's face immediately covered by the mask. It should be well understood, no matter what style of administration is used, that chloroform vapor should never exceed 4 percent of the air inhaled (Snow). This is best assured by giving the agent gradually, drop by drop, on several layers of gauze, through which air readily moves. Under no circumstance should the mask ever be saturated with chloroform. That so many deaths occur from chloroform is explainable largely by overdosage by this improper method. By dropping the chloroform just as the patient inspires, the quantity required will be greatly reduced. As soon as anesthesia is complete, the mask should be removed, permitting the patient to breathe the air. A little practice will teach one when to reapply the mask. The time to establish a complete chloroform narcosis in adults should never be less than 5 minutes. To anesthetize in less time than this would necessitate concentration of the vapor, with its attendant dangers. During the whole narcosis strict attention should be given to variations in the respiration, pulse, skin, pupil, eyelids, lips, etc. When chloroform is used in a closed room, where there is a light, the vapor is decomposed, chlorin is set free, and some compounds formed which are very irritating to the respiratory tract. A towel saturated with ammonia and hung up, or a little ammonia scattered about, will lessen this difficulty.

Syme administered chloroform in 5000 cases without a single death therefrom. He ascribed this excellent record to his adherence to the following rule: "Never mind the pulse, never mind the heart, leave the pupil to itself, but keep your eyes on the breathing, and if it becomes embarrassed to a grave extent, pull the tongue well out with an artery forceps." The Edinburgh rule is practically this: "Watch the respiration, the heart will take care of itself;" but Professor Stewart suggests that a second one should be inculcated: namely, "Watch both the breathing and the pulse; and if the heart threatens to fail for want of blood, fill it by raising the legs and compressing the abdomen."

Complete anesthesia is indicated by deep, rhythmic respiration, absence of corneal or conjunctival reflex, muscular relaxation, an insensibility of pain. It should be remembered that some patients will be completely anesthetized and the corneal reflex still

persist. It is rarely necessary to push the anesthetic to the production of stertor in order to abolish this reflex. Relaxation of the eyelids during narcosis will usually obviate touching the conjunctiva. If this becomes necessary, gently pulling open the upper eyelid and touching its inner margin with the tip of the finger will answer. In children the corneal reflex is quickly abolished. Here substitution of the palmar reflex suffices, or close attention to the respiration will always indicate complete anesthesia.

Administration of nitrous oxid gas requires a mouth-piece or face-piece which should fit accurately and tightly all the contour of its application. The aim should be to exchange all the air in the air-passages for the gas. Breathing should be slow and deep, about 15 times a minute, and never jerking. Expirations should be complete. The breathing should become stertorous or interrupted, the pulse very feeble, or convulsive twitchings should occur before the face-piece is removed. Lividity of the skin, insensibility of the eyelids, or the state of the pupil, will not show whether the influence of the anesthetic is complete or not. Air may be admitted every fourth or fifth respiration, since the continuance of the gas without air will bring on convulsive movements. Anesthesia by this agent, therefore, is not adapted to operations lasting as long as 5 minutes and requiring steadiness.

Signs of Importance during Anesthesia. Breathing.—While every sign that will give any indication of the patient's condition is important, the character of the breathing is most important of all. The ear, rather than the eye, should be depended on for the assurance that the patient is breathing properly, for the chest may continue to rise and fall regularly and no air enter the lungs. The ear will instantly detect this condition, as the sound of air entering the trachea and the bronchial tubes is unmistakable. Snoring is an assuring sound, but the stertor produced by a partial closure of the glottis is ominous, and the moment it is heard the jaw must be brought more forcibly forward; if it does not cease then, the anesthetic must be discontinued until the condition is corrected. It sometimes happens that the patient will take a long inspiration, like a sigh, due to some manipulation of the surgeon; when this occurs, the inhaler must be removed until the breathing is again natural. It is not necessary nor is it advisable that the anesthetist should concentrate his attention on the breathing or, in fact, on any point; his ear should be so well trained that it will instantly detect the slightest change in the character of the respiration, even while his attention may be directed elsewhere. It not infrequently happens, when the patient is just sinking into unconsciousness, that he will hold his breath; if the pulse is good, this is not alarming, and the inhaler need not be removed; however, if there is any doubt as to the condition, the anesthetic had better be stopped until breathing is normal.

The Pulse.—The anesthetist should keep one finger constantly on the facial or temporal artery; without directing much attention to the pulse, he will thus be warned if any marked change takes place. At the beginning of anesthesia the pulse will often be very rapid, due to the excitement of the patient, but as soon as unconsciousness is complete, it usually becomes much slower.

The Pupils.—The appearance of the pupils furnishes valuable indications of the condition of the patient. On beginning the anesthetic they dilate, then contract until normal or a little smaller, and usually remain contracted during the maintenance of safe anesthesia. If they are dilated and respond to light, it indicates that the anesthesia is not profound; if dilated and do not respond to light, it indicates that the anesthetic has been pushed to a dangerous extent and it must be instantly stopped; the variations of the pupils in different individuals is so great that too much must not be risked on their appearance. Occasionally, the pupils will be as small as pinheads. It is well in such cases to inquire whether the patient may not have been given a dose of morphin a short time before. Again, the pupils will be very much dilated throughout the anesthesia, and this, too, is a disquieting condition. In fact, any variation from the conditions usually witnessed is to be looked on with suspicion and the vigilance of the anesthetist redoubled.

Color of the Face and Lips.—The color of the lips and face should be noticed before beginning the anesthesia, for any marked change in their appearance indicates impending trouble. If the face becomes blue, it shows that the patient is not getting enough air and the inhaler must be removed at once. The color of the face is a valuable indicator in women, but is less useful in men. A patient with bright-red lips or rosy cheeks is not in any immediate danger from the anesthetic.

Treatment of Complications.—As spasm of the muscular system and collection of mucus in the throat of the patient are likely to occur in the early stages of anesthesia, accompanied by irregular, jerky, and abortive respiratory efforts and marked cyanosis, much unnecessary anxiety may be avoided if the surgeon always assures himself that there is nothing loose in the mouth of the patient before administering the anesthetic.

If particles of undigested food should be the cause of obstruction, the forceps or finger will usually dislodge them. If it does not, complete inversion of the patient and slapping the back vigorously will usually suffice. Efforts at vomiting indicate incomplete anesthesia. Gently pushing the anesthesia will abolish this reflex. If vomiting occurs, the patient should be turned completely on the side with head slightly lower than the body. Before continuing the anesthetic the patient's mouth should be thoroughly cleansed. Blood entering the larynx will interfere with respiration. If not prevented, it will cause death by asphyxia. If this occurs during the operation, the patient should be placed in the Trendelenburg position.

It should be a rule during anesthesia to watch both the respiration and the circulation. The color of the face is a valuable guide. Cyanosis, indicating feeble respiration or obstruction of the

respiratory tract, and pallor should lead at once to an investigation of the condition of the circulation. Efforts at vomiting are to be overcome by pushing the anesthesia. If vomiting occurs, the head is to be turned to either side, so that the ejecta may not be inspired. Stertorous breathing indicates profound anesthesia, and it is desirable to keep within this limit. Paralysis of the diaphragm also indicates that the anesthetic has been pushed too far. During normal inspiration the diaphragm descends, pushing down the intestines and distending the abdomen. When anesthesia has been carried too far, the action is reversed, the diaphragm is paralyzed and hangs helpless. With each inspiration it is drawn up into the thorax, and the abdomen retracts. When this occurs, the ether is to be withdrawn until the normal action is restored. This most valuable observation was first pointed out by Hare and Martin. Wide dilatation of the pupil demands immediate withdrawal of the ether.

Should the respiration show evidences of failing, the anesthetic is to be instantly removed, the tongue is to be brought well forward, and the throat is to be cleared of mucus or other obstruction; the head is then to be extended and the fingers hooked behind the angle of the lower jaw, which is to be brought well forward. This raises the epiglottis. This method is an improvement on that proposed by Howard, which consists in bringing the patient's head over the end of the operating table until it swings free, when it is carried backward and downward, until the utmost possible extension of the head and back is obtained. If voluntary respiration does not begin at once, some external stimulus is to be used. One always at hand is that pointed out by Hare, of baring the abdomen of the patient and dashing a quantity of ether upon it. Artificial respiration, preferably by Sylvester's method, about 18 respirations a minute, should be practised. Rhythmic traction of the tongue, Laborde's method, 18 times a minute, will stimulate respiration. Applications of cloths wrung out of very hot water over the region of the heart will stimulate it to increased action. The König-Mass method of rapid compression of the chest, the thumb of one hand being applied over the heart, will stimulate both respiration and the cardiac beat. Direct insufflation of air into the chest by bellows (Fell) or by means of a soft-rubber catheter introduced into the trachea, may sometimes be valuable. The anesthetist takes several deep inspirations, then exhales into the catheter to his entire extent. Introduction of a normal saline solution into a vein, the temperature being 105° F., or if into the rectum, the temperature being 115° F., is of supreme value. Hot coffee introduced into the colon is excellent. Atropin, 1/60 of a grain, and strychnin, 1/50 of a grain subcutaneously, being sure to have dosage large enough, are indicated. Amyl nitrite should never be used—it increases vasomotor depression. Alcoholic stimulants are contraindicated, as they tend to deepen narcosis.

Remote Sequels of Anesthesia.—These are nausea, vomiting, bronchitis, pneumonia, nephritis, and paralysis. Nausea, vomiting, and bronchitis are more frequently the results of improper preparation of the patient and of faulty methods of administration than of the anesthetic itself. If nausea and vomiting persist, 1/2 ounce of hot water or some cold substance, at varying intervals, with or without the addition of 10 drops of lemon-juice, will often abate it. The factors in the production of pneumonia following ether are a predisposition on the part of the patient; supersaturation and inhalation of cold ether by open inhalers; septic inhalers; sudden chilling of the patient. Pneumonia is an exceedingly infrequent sequel of anesthesia. Bronchitis is occasionally seen. Proper administration of the anesthetic and the reduction to the smallest quantity possible to produce perfect anesthesia will reduce the complication of nephritis to a minimum. Paralysis may be central or peripheral in its causation. The latter is most frequent, and is caused, usually, by pressure upon a supplying nerve or by pressure of a crutch or apparatus for maintaining the position of the patient. Central paralysis may be caused by rupture of a vessel in the brain. An improper method of administering the anesthetic is here the cause, as it is in so many other complications during or following narcosis.

Acid intoxication or acetonuria sometimes develops, particularly after chloroform narcosis. It is said to be due to acute fatty degeneration of the liver, as the result of which diacetic acid and acetone are formed. The symptoms consist of vomiting, restlessness, delirium and coma, jaundice, and the odor of acetone on the breath. Sodium bicarbonate should be given internally and normal salt solution should be administered by hypodermoclysis.

ANESTHETICS, LOCAL.—Local anesthesia is indicated in operations in which the field of operation is not extensive, and in which the best procedure cannot be determined upon beforehand. It is of doubtful service for children or for excitable and intractable individuals.

The following is a list of local anesthetics: Alcohol, acetanilid, carbolic acid, carbon bisulphid, carbonic acid snow, chloroform, cocain, compression, creosote, electricity, ether spray, ethyl chlorid, eucain, formanilid, freezing, guaiacol, ice, infiltration-anesthesias, magnesium sulphate, novocain, quinin and urea hydrochlorid, rhigolene spray, salt, Schleich's fluid, stovain, tropocain, essential oils, such as cassia, cinnamon, cloves, sassafras, etc.; but very few of them are of any practical interest to the surgeon.

Methods of Administration. 1. *Subcutaneous Injection.*—When a solution is used hypodermically, it is of the utmost importance that it be properly introduced and placed. The hypodermic syringe should be held almost parallel with the skin, and the point of the syringe introduced into, but not through, the skin. The injections should be into the malpighian layer of the derma, where a network of sensory organs comes into contact with it. Injections into the areolar subcutaneous layer tissue are likely to be followed by rapid absorption and toxic symptoms. Injections into

the malpighian layer will produce rapid, certain, and safe anesthesia. When the first injection is made, a small white wheal will result, somewhat like a mosquito-bite. Successive wheals are made, sufficient to cover the area to be anesthetized.

2. *Local application* of the anesthetic to the mucous membrane, cornea, membrana tympani.

3. *Freezing*, generally by means of ethyl chlorid spray.

4. *Infiltration*, (*q. v.*).

5. *Catalytic.*—A weak constant current medicated with cocain solution, or, better, cocain and adrenalin may be used to anesthetize a small area of skin. See ELECTRICITY, Anesthesia.

6. *Cataphoric Cocainization.* See CATAPHORESIS.

7. *Intraspinal.* See INTRASPINAL ANESTHESIA.

ANEURYSM.—A tumor consisting of a dilated artery or communicating with an artery. In the early stages there is an expansile pulsation of the tumor generally associated with a systolic murmur or bruit. In the later stages the laminated coagulum increases, so that pulsation may be absent, and pressure of the growing aneurysm upon the adjacent organs may give rise to secondary disturbances, as pain, dyspnea, dysphagia, paralysis, or spasm.

Causes.—The chief **predisposing causes** are: (1) *Atheroma*, whereby the coats of the artery are softened and unable to resist an increased expansile pressure of the blood; and (2) *embolism*, which may lead to inflammatory changes and consequent weakening of the arterial walls immediately above the embolus. Thus the conditions which induce atheroma and embolism may also be considered as predisposing causes of aneurysm. Of these, however, syphilis, the abuse of alcohol, continued vascular strain, and ulcerative endocarditis may be especially mentioned. Syphilis is by far the most common cause of aneurysm in women.

The **exciting causes** are such as produce the rupture or yielding of the diseased coats, either by direct mechanic violence, or by increased blood-pressure in the vessel owing to violent and sudden action of the heart and obstruction by muscular contraction of the capillary flow. Hence, blows or strains, mental emotion, and violent and sudden exertion of all kinds may be mentioned as exciting causes.

Process of Formation.—An aneurysm may be formed in several ways: (1) By the simple dilatation of a diseased portion of an artery, due to the yielding of the softened coats to the expansile force of the blood-current. (2) By the giving way of the internal and middle coats at the diseased spot, and the yielding of the external coat to the force of the blood. This is the most frequent way in which an aneurysm is formed—the elastic fibers of the internal coat as the result of the atheroma soften and break down, the middle coat gives way, and the external coat, unable to resist the blood-pressure, is bulged out, forming the sac of the aneurysm. (3) By the giving way of all the coats at the diseased spot and escape of the blood into the tissues, which become condensed around it to form a sac. (4) By the giving way of the external and middle coats, and the protrusion of the internal coat through them (very rare). (5) By the giving way of the internal and part of the middle coats, and extravasation of the blood between the layers of the middle coat.

Structure of an Aneurysm.—An aneurysm consists of a sac and its contents. The *sac* may consist: (1) Of all the coats of the artery (A and B); (2) of the external coat only (C); (3) of condensed tissues external to the artery (F); (4) of the internal coat only (very rare) (D); (5) of the separated layers of the middle coat, between which the blood has been forced, with the external and internal

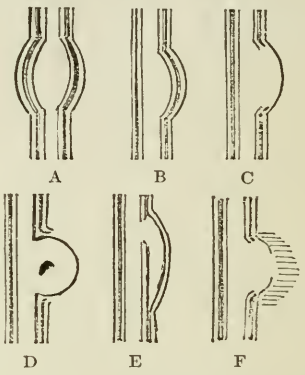


DIAGRAM ILLUSTRATING THE STRUCTURE OF AN ANEURYSM.

coats on either side—dissecting aneurysm—(E). The practical point, however, to be borne in mind is that it is only while the aneurysm is small, and then by dissection alone, that these distinctions can be made.

Classification.—Spontaneous aneurysms may be divided into the fusiform, the sacculated, and the dissecting.

1. **A fusiform aneurysm** is a dilatation of the whole circumference of a portion of an artery. The sac consists of all three coats, and is continuous with the lumen of the artery at each end.

2. **A sacculated aneurysm** is one in which dilatation occurs in part of the circumference of the artery only (B, C, and D). It may consist of all three coats, but more often the internal and middle coats give way, and it is formed of only the external coat, or, after it has existed some time, chiefly of the condensed cellular tissue around. According as all three coats were or were not present, the aneurysm was formerly spoken of as *true* or *false*. As these aneurysms increase in size the sac becomes composed almost entirely of the tissues around. While they are still enclosed by one of the coats of the artery, they are sometimes called *circumscribed*, and after all the coats have given way, *consecutive* or *diffused* (F).

3. **A dissecting aneurysm** is one in which the internal coat of the artery and part of the middle coat have given way and the blood has been forced between the two layers of the middle coat for a variable distance parallel to the course of the artery (E).

Spontaneous recovery may take place: (1) By the gradual deposit of fibrin from the blood in a laminated manner on the walls of the sac, so that

the aneurysm is completely consolidated, and subsequently by condensation and shrinking becomes converted into a small nodular mass of fibrous tissue. (2) By the filling of the sac with ordinary coagulum, the passive clot, as it is called, in contradistinction to the deposit of laminated fibrin (the active clot). (3) By the inflammation and sloughing of the sac and the plugging of the artery above and below with clot, and the subsequent changes described under the spontaneous arrest of hemorrhage.

A fatal termination may be brought about by: (1) Rupture of the sac; (2) inflammation and sloughing of the sac attended by hemorrhage; (3) pressure upon important parts; (4) gangrene due to the obstruction to the circulation in consequence of the large size of the aneurysm, or to the plugging of a large vessel by a portion of detached clot; (5) general constitutional disturbance. Rupture when it occurs into a serous cavity is generally by a rent or fissure; into a mucous canal, by a small, round, ulcerated opening; on to a cutaneous surface, by sloughing of the skin covering the sac. In the first case the rupture is generally rapidly fatal from excessive hemorrhage; in the last two, as a rule, only after repeated hemorrhages, the slough having at first a tendency to cause the coagulation of the blood and block the opening.

Pressure Effects.—The pressure of the sac of an aneurysm may cause: (1) Inflammation and condensation of the parts around, which thus become blended with the sac; (2) diminution or obliteration of the lumen of a large vein; and hence (3) edema and dilatation of the superficial veins; (4) irritation or interruption of the conducting power of nerves, giving rise to pain, spasm, or paralysis; (5) erosion of the bones and cartilages; (6) obstruction of the esophagus, trachea, or thoracic duct.

Effects on the Circulation.—Hypertrophy of the left ventricle of the heart; obstruction of vessels and enlargement of the anastomotic channels; syncope and gangrene.

Symptoms.—The attention is usually first drawn to the disease by pain, swelling, and a feeling of muscular weakness, or by stiffness in a joint. On examination, a tumor is discovered in the course of the main artery. It pulsates, and the pulsation is *expansile*—that is, on placing the hand upon the aneurysm it is felt at each systole of the heart to enlarge in every direction, or if the hands are placed on either side of the tumor, they are seen to be slightly separated at each pulsation. If the artery on the cardiac side of the tumor can be compressed, the pulsation of the tumor is felt to cease, and the tumor itself to become perceptibly smaller and less tense. On cessation of the pressure, however, it quickly fills again in two or three forcible pulsations, and resumes its former characters. On raising the limb, the pulsation is less forcible; on lowering the limb, more forcible, the tumor at the same time becoming more tense. The pulse below the tumor is smaller on the affected than on the sound side, and a sphygmographic tracing, if taken, shows the pulse to be delayed on the diseased side and diminished in force, the tracing being less abrupt in its rise and more rounded. On listening with the stethoscope, a bruit is heard in most cases. In consequence of pressure on the vein corresponding to the artery, there is often edema of the part below, and sometimes varicosity of the superficial veins.

In **internal aneurysms** no tumor may be felt; the signs are then often obscure, and the diagnosis will depend upon the effects the aneurysm produces by pressing upon important parts.

The signs of an aneurysm undergoing spontaneous cure are usually obvious. The tumor decreases in size, and the pulsation in it gradually decreases and finally ceases. At times a rapid cure may ensue; the pulsation then ceases suddenly and the tumor is felt to be hard, the patient often complaining of great pain at the moment of consolidation.

The signs of a leaking aneurysm—*i. e.*, an aneurysm in which blood is beginning to be slowly effused into the tissues—are as follows: The pulsation is less distinct, the outline of the tumor less circumscribed, the growth progressive, and the pressure signs more urgent.

The Signs of Sudden Rupture of an Aneurysm.—(1) If the rupture is into a serous cavity, the signs are those of internal hemorrhage, rapidly followed by death. (2) If into a mucous canal, there will be sudden hemoptysis in the case of the trachea or bronchus, hematemesis in the case of the esophagus or stomach, melena, if the patient lives long enough, in the case of the intestines. (3) If the blood is effused into the tissues, there will be pain, faintness, loss of pulsation and bruit, rapid increase in the size of the swelling, edema, coldness, and cessation of the pulse in the parts below, followed by increasing syncope from the loss of blood, or, if death does not soon occur, by gangrene. (4) Rupture externally is very rare; the signs are evident.

Diagnosis.—An aneurysm may have to be differentiated from simple dilatation of an artery, an abscess or a tumor over an artery, a pulsatile tumor of bone, and enlargement of the thyroid gland. In a simple dilatation there is an absence of bruit. In an abscess or tumor over an artery the pulsation is not expansile, there is no bruit, and the swelling is not emptied or made less tense on compressing the artery above. A tumor may often be lifted from the vessel. In the case of an abscess, there will probably be a history or signs of previous inflammation. In a tumor raising an artery over it the pulsation is only felt in the course of the artery, and there is no expansile pulsation in the swelling. In pulsatile tumor of bone the pulsation is not equally expansile; and although pulsation ceases on compressing the artery above, the swelling does not become smaller, like an aneurysm, or refill on removal of the pressure in two or three beats of the heart. Portions of expanded bone may also be felt in parts of the tumor, and there may be glandular enlargement and other signs of malignancy. A carotid aneurysm may be distinguished from an enlarged thyroid gland by the gland moving with the larynx in deglutition.

Treatment.—In no disease, perhaps, has an

accurate knowledge of its pathology done more to insure success in treatment than in aneurysm.

Medical Treatment.—Both internal and external aneurysms have been cured by medical treatment alone. Indeed, in some forms of internal aneurysm it is the only means at our command. In external aneurysms, however, local treatment in addition is nearly always expedient or necessary. Absolute rest, both bodily and mental, should be enjoined; the patient must lie in bed, and not move for any purpose whatever, not even to feed himself. The diet should be limited in quantity, unstimulating but nutritious in quality, and the fluid portion restricted as much as possible. The following diet scale is advised by Tufnell: Bread and butter, 4 ounces; meat, 3 ounces; potatoes, 3 ounces; fluid, 8 ounces in the 24 hours. Small repeated bleedings, when there is excessive action of the heart, or the patient is plethoric, may occasionally be useful. Medicines seem to have little efficacy, but iodid of potassium in large doses, acetate of lead, aconite, and digitalis have been recommended, either for promoting the coagulation of the blood or retarding the heart's action. When there is a history of syphilis, iodid of potassium should certainly be given.

Surgical Treatment.—In all suitable cases of external aneurysm, pressure, where it can be applied between the aneurysm and the heart, should first be tried, aided under certain circumstances by the method of flexion. These measures failing, or appearing unsuitable, the artery should be tied, if practicable, on the proximal side, and preferably at some distance from the sac, where the artery is more likely to be healthy. When pressure or ligature cannot be used on the proximal side, as, for instance, in aneurysms at the root of the neck, it becomes a question whether distal pressure or ligature, scratching the wall with needles (*Macewen's method*), manipulation, galvanopuncture, coagulating injections, or the introduction of wire or horsehair should be tried, or whether recourse should be had to medical means alone. In some varieties of traumatic aneurysm when the artery is presumably healthy, and in certain forms of aneurysm, as gluteal, when a ligature of the artery at a distance from the sac is attended with great risk, it may even be expedient to resort to the old method of opening the sac, turning out the clot, and securing both ends of the bleeding vessel by ligature. Each of these methods requires discussion. Before resorting to surgical methods, however, the circulation through the aneurysm should have been previously quieted as much as possible by rest, recumbency, restriction of the diet, and regulation of the secretions. Where the aneurysm is on an artery of the lower extremity, any embarrassment of the venous circulation and consequent edema that may be present should be lessened or removed by elevating and lightly bandaging the limb.

Compression.—It is applied upon some part of the affected artery between the aneurysm and the heart, and in such a way as to retard the circulation and so cause deposits of laminated fibrin. Carte's circular tourniquet is used for the purpose; also Gibbon's modification of Charrière's compressor, or Hoey's clamp. In some cases a five-pound bag of shot or an ordinary four-pound weight may be placed over the artery, with a pad intervening, or "*digital compression*" may be used; kept up by relays of assistants, the patient, if necessary, being kept under the influence of chloroform or morphin.

The advantages of compression are that it can be discontinued at once, if need be; secondary hemorrhage, the frequent accident of the ligature, is obviated; and even if it fails, the knife may still be resorted to. Compression is contraindicated when the integuments are inflamed or the limbs much swollen, from venous obstruction, and also in cases which are very rapidly increasing. The pressure should not be severe enough to cause great pain, and if there is room, it should be applied at two or three points in the course of the artery, and not carried to the point of completely closing the vessel. If very restless, the patient may be gently chloroformed, or kept quiet by morphin for 2 or 3 hours at a time.

Ligature.—When compression is inapplicable or unavailing, the artery must be secured between the aneurysm and the heart by:

1. *The Hunterian Method.*—The point of election must be neither too near the aneurysm, so as to tie a portion of the vessel that is diseased, nor too far from it, lest the circulation through it be kept up too freely by means of collateral branches. The direction and extent of the incision obviously depend on the situation of the artery to be operated on. A healthy portion of the artery is selected; great care is taken in exposing the vessel to disturb the sheath as little as possible; two ligatures are used; they are drawn sufficiently tight to gently approximate the inner tunic; the stay knot is tied and the end cut short.

2. *Anel's operation* consists of applying a ligature to the affected artery close above the aneurysm. The objections to this method are that the operation is performed on a part of the vessel that is already diseased, and that the proximity of the wound to the aneurysm is liable to excite inflammation in and around the sac.

3. *Brasdor's distal ligature* is applied to the diseased artery beyond the aneurysm, on the distal side. It is resorted to in aneurysm of the carotid, innominate, or subclavian artery, when the ligature cannot be employed between the aneurysm and the heart.

4. *Wardrop's operation* consists in tying one or more twigs branching off beyond the aneurysm. It is a modification of Brasdor's operation.

In separating the artery from its accompanying veins, the greatest care must be taken not to inflict injury upon the vessels.

The double ligature above and below the sac, either (1) by the old method of first laying the sac open and then securing the bleeding ends of the artery, or (2) by the method of Antyllus, of first securing the artery and then laying the sac open, is only employed in exceptional cases. Thus the *old method* is sometimes resorted to in traumatic aneurysm of the axillary artery in preference to

tying the subclavian, and also in gluteal aneurysm, where the Hunterian method of tying the common or internal iliac is attended with so much risk. The great danger is the possibility of the patient dying of hemorrhage under the operation. During the operation, therefore, in the case of the axillary artery, pressure should be made on the subclavian, an incision through the skin and fascia above the clavicle being made to insure its better control. In the case of the gluteal, Davy's lever or the abdominal tourniquet should be used. The true *method of Antyllus* may, in rare instances, be required, as in some forms of aneurysm at the bend of the elbow.

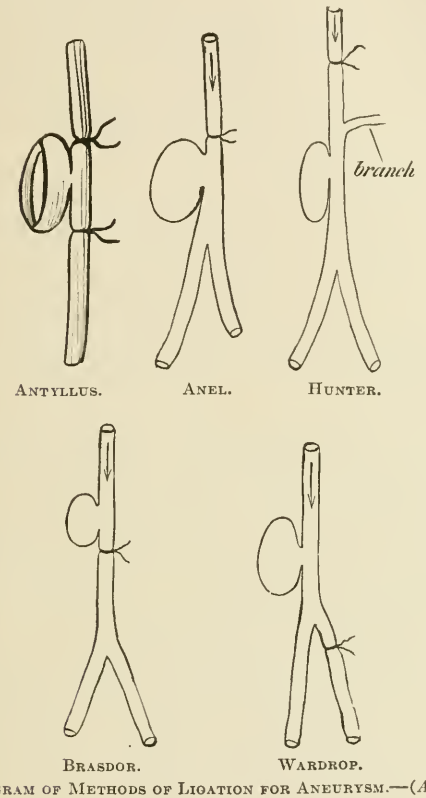

Diagram of Methods of Ligation for Aneurysm.—(*After Moullin.*)

Manipulation.—A spontaneous cure is sometimes brought about by the impaction of a portion of clot either in the mouth of the sac or in the artery below. Manipulation of the sac aims at breaking up and displacing any clot that may have formed, in the hope that a portion may become impacted in this way, and so lead to consolidation. Sir William Fergusson, who first introduced this method, used it with success, and others have done so likewise. It is far from being unattended with danger, however, since a portion of the clot may be carried away by the blood-stream and become lodged in a vessel leading to an important organ, as the brain. It should, therefore, only be tried when other means are impracticable or appear attended with even greater risk.

Irritation of the Interior of the Sac by Needles (*Macewen's Method*).—This method aims at so irritating the walls of the aneurysm as to induce slight inflammation and the formation of white thrombus. The skin having been made aseptic, long needles are passed into the sac and the walls systematically scratched all around the aneurysm. It is applicable to aneurysms where pressure or proximal ligature cannot be employed. Consolidation occurs very slowly.

Galvanopuncture, electrolysis, injections of perchlorid of iron, tannin, and the like, and the **introduction of foreign bodies, as horsehair or iron wire,** which have all for their object the coagulation of the blood in the sac, are highly dangerous procedures, and have not hitherto been attended with much success, although some favorable cases have been reported.

Extirpation.—Favorable as are the results from the Antyllus operation, they do not equal those obtained from the total extirpation of the sac, an operation to which attention has recently been directed by Scriba, Delbet, Trelat, and Kubler. Practised by Philagrius of Macedon in the fourth century, it was forgotten until the end of the seventeenth, when it was resorted to with success in a brachial aneurysm by Purmann. It is generally designated as the operation of Purmann. A method might certainly be called ideal which in 40 cases was followed by but one death, and after which gangrene and secondary hemorrhage were not at all observed. The one death resulted from acute anemia several hours after an operation made by Socin for aneurysm of the scalp. In 24 of the cases large arterial trunks like the axillary, brachial, femoral, and popliteal were involved. Ransohoff was able to find 4 more cases of popliteal aneurysm similarly treated, thus making 28 extirpations of major aneurysms of the extremities without a death.

Of the 46 cases, including those of Kubler, the 4 just referred to, and the cases previously reported, 31 were traumatic and 15 spontaneous. Twelve were arteriovenous, the remainder arterial. The presence of a sac in recent traumatic aneurysms has been questioned. Nevertheless, Trendelenburg found one in an injured femoral artery as early as the sixth day. While in such cases of recent traumatic aneurysm the mere incision and double ligation may answer, it certainly seems better surgery to insure that retraction of the arterial stumps into the sheath above and below that is so essential to safe occlusion of their lumens. This applies particularly to the distal end from which secondary hemorrhage, if it occurs at all, is more likely to ensue.

The disadvantages of total extirpation are the difficulty of its execution and the danger of wounding important parts to which the sac has formed adhesions. The first of these is not greater than that which attends the removal of tumors of the same size with adhesions. Under the artificial ischemia obtained by the rubber tourniquet, a careful dissection of the sac-wall is made through an ample incision. The smaller vessels are ligated as encountered, before they are divided. The

afferent and efferent vessels are sought, ligated, and divided above and below the sac. To accomplish this it may be necessary to divide the sac in its long axis. It is in the dissection of the deeper portion of the sac that the attending vein may be injured. The danger from this accident has certainly been overrated. From the table of Kubler it appears that the femoral vein was injured in 3 cases, the popliteal in 5, the axillary in 1, and the brachial in 3. In all but one of these the vein was ligated or resected, but gangrene did not ensue. The supposed disadvantage of ligating an unhealthy part of the vessel has already been seen to be largely assumption. Fifteen of the cases were spontaneous aneurysms.

Aneurysmorrhaphy.—This procedure, which was introduced by Matas in 1889, has gained constantly in favor since 1902, when he first described it in print. It consists in incising the sac and obliterating, by means of chromicized catgut sutures, all the arterial orifices opening into it. According to this method, "no attempt is made to reconstruct the parent artery." In treating sacculated aneurysms, however, in which there is only a single opening between the sac and the artery the opening is closed without encroaching upon the lumen of the artery, after which the incision into the sac is sutured and the sac folded upon itself by rows of sutures passed through its walls. This procedure is known as *endo-aneurysmorrhaphy with partial arteriorrhaphy.* Another procedure applicable to fusiform aneurysms having two arterial orifices situated close together on the floor of the sac is called *endo-aneurysmorrhaphy with complete arteriorrhaphy.* A new channel is made out of the walls of the sac by holding them over a rubber tube or catheter and sewing them together in such a manner as to restore the continuity of the artery lost in the sac, the tube being taken out just before the last sutures are tied. Matas states that preservation of the lumen of the parent artery is "only indicated positively in the sacciform aneurysms with a single opening where the parent artery exists as a formed vessel and in which the closure of the fistulous opening can be accomplished with the greatest ease." There is no doubt that this operation constitutes a decided advance in the surgery of aneurysm. Many surgeons are now employing it in cases in which they would have formerly practised extirpation, and are of the opinion that it is equally satisfactory and much safer.

In 1908 Matas collected 85 cases of aneurysm of various arteries operated upon by the methods above described. Out of this number there were 78 recoveries, 4 cases of gangrene, 2 cases of secondary hemorrhage, and 4 relapses. The relapses all occurred in cases in which reconstructive methods had been employed.

For **special aneurysms** see AORTA, etc.

ANGINA.—See LARYNGITIS, LUDWIG'S ANGINA, PHARYNGITIS, VINCENT'S ANGINA.

ANGINA PECTORIS (Stenocardia). Description.—The symptom-complex to which the term angina pectoris is given is seen in persons the subject of arteriocardiac disease, and those in whom no evidence of the presence of this disease can be found. The former is termed *true*, or *angina pectoris vera;* the latter, *false*, or *pseudoangina, angina pectoris notha* of Forbes.

Pain in the region of the heart, and an extreme sensation of anguish or of immediate dissolution are the subjective symptoms, and fixation of the body, pallor, with an expression of anguish or terror, cold extremities, a profuse sweat, slowness of the pulse, and enfeeblement, perhaps irregularity of the heart's action, are the congeries of objective symptoms that make up the complexus known as an attack. In some instances at the time of the attack the patients faint (*syncope anginosa*), or fainting attacks may occur in a patient with myocarditis and alternate irregularly with attacks of angina. In others, an attack of vertigo is followed by deep coma (apoplectoid) with or without convulsions, with slowness of the pulse, the **Adams-Stokes syndrome** (*q. v.*). Such attacks may precede or, as in the foregoing class, alternate with true angina.

Again, attacks may be characterized by the anguish and all the objective symptoms of angina, but without pain—*angina sine dolore.* The painless angina is more likely to occur if the heart is dilated. A patient may have had frequent attacks of painful angina. As the bodily strength fails, the heart dilates and mitral incompetency arises. Such leakage at the orifice relieves intracardiac pressure and seems to prevent the occurrence of pain.

It is to be remembered that in both forms of angina, true and false, the same symptoms obtain. In the latter form cardiovascular changes are not necessarily present. In true angina, myocarditis and arterial sclerosis are present and, perhaps, causal. Patients who have some advanced arterial disease may have attacks of pseudoangina. Both forms will be considered in the various subsections in order to emphasize their difference.

Etiology.—We have been speaking of attacks of angina, but a consideration of the attacks cannot be separated, in estimating the diagnosis, prognosis, and treatment, from the condition of the patient. Angina, true or false, is not a disease, but a symptom. It is an incident in the course of disease. True angina pectoris is an incident in the course of arteriocapillary fibrosis with myocarditis. Its etiology is bound up with that of arteriosclerosis. Not all subjects of vascular change are liable to attacks of angina, however. Added to the organic basis, two things appear to obtain—a fairly strong heart-muscle, a mobile vasomotor nervous system that responds to exciting causes by spasm of peripheral vessels, increased arterial tension, and, as a sequence, increased intraventricular pressure. For this reason he whose walk is on lower planes, whose sympathies are dulled, whose fires burn low, and in whom, with general nutritive failure, the cardiac muscle is weakened, is not subject to angina, although the victim of the most extreme vascular atheroma.

True angina pectoris occurs in subjects who have passed the meridian. They belong to the upper walks of life, and have been high livers and

perhaps drinkers, and have engaged in an occupation requiring mental strain and anxiety, perhaps emotional also. Professional men, bankers, and brokers are the most common subjects. Hence it is most common in *men.* Those who have had gout or syphilis are victims of arteriosclerosis, and in this wise can be traced a causal relation to angina.

All those infectious diseases that cause valvulitis and endarteritis are considered antecedent conditions in the subjects of angina pectoris. Finally, the liability to attacks of angina appears to occur in members of the same family or in successive generations.

False angina pectoris, on the other hand, is more likely to occur in *women,* early in life or about the menopause, and to be associated with poor nutrition in consequence of long and continued indigestion or the habit of taking small amounts of food. In a neuropathic type of constitution there is found, therefore, alternating with the attacks of pseudoangina or occurring in another decade of the patient's life, various neurotic phenomena. Such attacks are prone to take place in a neurasthenic subject. The reflex forms of pseudoangina have for their origin some disturbance of the functions of the various organs. The gastrointestinal form, for instance, is often seen after attacks of indigestion. The same form of angina is seen in toxic conditions, particularly in a toxemia associated with the excessive use of tea, coffee, or tobacco. With the anginal pain, palpitation, irregularity, and rapid heart-action are observed. The toxic forms of pseudoangina are usually associated with spasm of the peripheral vessels. When tobacco is the cause, the disturbance of the special senses, vertigo, the loss of reflexes, paresthesia, and cerebral confusion due to nicotin poisoning are present. In such subjects palpitation, irregularity, intermittency tachycardia or bradycardia, and attacks of syncope also occur. To arrive at a distinction between the two forms of angina it is necessary to bear in mind the wide divergence of etiologic factors in each instance.

Symptoms.—The antecedent symptoms and physical signs of cardiovascular disease need not be described. The patient with such disease, after 50, with any of the foregoing causes operative, may for some time have slight attacks of cardiac pain, each increasing in severity and gradually having added to it, one at a time, the symptoms of true angina pectoris. These pains will be observed to take place after exertion, after excitement, or after undue mental and physical effort combined, as detailed by a patient whenever he wrote an important business letter. He could dictate the letter without cardiac pain, but the combined act of composition and execution gave rise to anginal attacks. Sooner or later—perhaps after the end of a year, during which the patient may have had some forms of cardiac asthma or marked arrhythmia—attacks in their severest form take place. In other subjects the attacks of angina are preceded by the symptoms of failure in compensation, which, with careful rest and perhaps the use of digitalis, is gradually overcome. Dropsy may have been present to a considerable degree, and the phenomena of dilatation marked. With gradual restoration to health the heart-muscle regains its tone, the peripheral vessels continue mobile and contract, readily giving high arterial tension. After having run the gauntlet of dilatation, the severe attacks of angina begin. In a third group of cases the first attack may be the lethal attack, or the first may be very severe, followed by mild attacks until cardiac dilatation, with its subsequent train of symptoms, arises. Again, after a period of attacks at long intervals, they may without cause become more frequent and perhaps be the cause of death.

The pain is located in the region of the precordia. It is sometimes very severe in the epigastric region, and it is difficult to disabuse the patient's mind of the belief that the attack is one of indigestion. In other instances the pain is marked in the arms and not very pronounced in the thorax. In a large proportion of cases the pain radiates from the heart around to the axillary region, or extends upward to the shoulder and down the left arm. With the extreme pain there is paresthesia. The fingers and hands are particularly the seat of numbness and tingling. In one case the patient, a physician, in addition to precordial pain, complained of extreme pain in the jaws following the course of the vessels. He believed the pain was due to the fact that these vessels were overdistended and could not go beyond a certain limit because of confinement in the bony space. With the onset of severe pain and the great sensation of anguish, vomiting may occur. This symptom continues until the stomach is emptied of food, or it may disappear spontaneously. Immobility of the body is an important symptom. The position assumed depends upon the whereabouts of the patient at the time, or his habits. Some patients experience attacks whenever they exert themselves in walking, securing relief by resting on the nearest door-step or bench in the public square. Others support themselves at the nearest lamp-post or tree-box, or by the side of a house. The recumbent posture is assumed by some. Rarely does relief seem to occur while the patient is moving about, although the case of Mr. Charles Sumner was a notable exception. Coldness of the hands and feet, pallor, and a countenance of anguish are nearly always observed. Sometimes patients are very much perturbed, and at other times—notwithstanding their very great peril—they are cool and collected. Respiration is sometimes held in abeyance by the patient during the passing of the pain, or repeated full inspirations are taken, followed as the paroxysm reaches its height by a prolonged, often sighing expiration. In a larger number of instances the pulse-rate is slow. It is often irregular and intermittent. In angina sine dolore, with the hurried respirations, the pulse usually increases in frequency, and as the disease advances, becomes irregular and feeble. Usually the attack is not followed by any marked or critical discharge of urine, although sometimes a severe attack may be followed by involuntary discharge of urine and

feces. The temperature remains normal, or may be subnormal. The mind is usually clear; there is no delirium.

In pseudoangina pectoris the patient is usually the subject of neurasthenia, or the possessor of one or more of the hysteric stigmata. Certainly a neuropathic history may be elicited, or a history of some primary irritation elsewhere, or of some form of toxemia. The pain very closely resembles, and indeed cannot usually be distinguished from, the pain of the true form. The pulse, however, is more likely to be rapid. The respirations are increased, but are of a type of respiratory neurosis not associated with congestion or other signs of cardiac failure. Moreover, we find in such cases the various train of symptoms or phenomena that attend toxic conditions.

It is this form of angina pectoris in which vasomotor symptoms are most prominent, and to which the term angina vasomotoria was given by Nothnagel.

Prognosis.—True angina is a very grave affection. If the first attack is not lethal, no one can predict when another may take place. Recurrent attacks in a patient with high arterial tension and a hypertrophied heart are most serious. If the patient has also aortic regurgitation—the most common form of valvulitis in angina—the likelihood of sudden death is very great. Prognosis must depend entirely upon the extent of the cardiovascular disease; upon the character and severity of the attacks, and the frequency of their occurrence. The onset of dilatation and the occurrence, on account thereof, of mitral incompetency, as pointed out by Musser, is a favorable process, and lessens the liability to attacks.

Diagnosis.—True angina must be distinguished from pseudoangina and from cardiac pain due to pericarditis as well as that due apparently to neuralgia. Age, the occupation, the habits, and the hereditary predisposition count strongly for or against true angina. The presence of organic disease and the character of the attacks are most important diagnostic features of true angina. Patients with this form live but a short time, whereas pseudoangina never causes death, and death takes place from other causes much later in life.

Angina must be distinguished from pain in the breast caused by inframammary neuralgia, from pleurisy and neuritis, and also from that common cause of pain in the region of the precordia, gastric distention from flatulency, and flatulent distention of the colon. A consideration of the diagnosis of the various causes is not necessary in this connection.

Pseudoangina pectoris is distinguished from true angina pectoris chiefly on account of the etiologic differences. The phenomena of the attacks are much the same, save that fixation is not marked, and there is not the same anguish that we see in true angina.

Treatment of the Attack.—The physician is first called upon to treat an attack of angina pectoris. Often there is not enough time to weigh the data upon which a distinction between true and false angina is made. If cardiac pain occurs in a male subject past 50, it is fair to presume it is an attack of true angina, and proceed at once to administer complete relief.

Morphin.—The first step is to give at once a hypodermic injection of 1/4 of a grain of morphin sulphate, preferably with atropin. The possible presence of nephritis is not a contraindication. The dose may be repeated in half an hour. The heart's action should by this time have been ascertained. If it is attended by frequent incomplete systoles, alternating with full ones, it is well to give nitroglycerin hypodermically also, or to begin at once its administration by the mouth. Notwithstanding relief to pain may be secured, the patient should be kept under the influence of morphin for at least 24 hours by administering the drug every 4 or 6 hours. If the attack is one of angina sine dolore, there is much more reason why the morphin should be continued, for in the cardiac dilatation that attends this condition the drug exerts an undoubted tonic influence. Moreover, the dose of morphin to relieve pain must be large, for, as Yeo points out, anginal patients bear the drug very well. Sometimes we hesitate to give morphin because of its secondary effects or the idiosyncrasy of the patient. In the instance of angina, neither need be weighed.

Amyl Nitrite.—If the patient has had a previous attack, he is usually supplied with sealed glass bulbs containing this drug. Its immediate use is essential. Sometimes it fails to give relief. Four or 5 minims may be inhaled from a handkerchief every 10 minutes. To some, the cerebral effect is almost as distressing as the heart-pain. Patients at times decline to use it.

Erythrol tetranitrate is said to be especially useful in preventing anginal pain. Its action is slower and more lasting than that of amyl nitrite or nitroglycerin, beginning in 15 minutes and persisting for three or four hours. The dose is from 1/2 to 1 grain by the mouth in chocolate-coated tablets.

Chloroform.—The inhalation of 10 to 20 drops of chloroform generally gives sufficiently prompt relief. It is not attended by unpleasant symptoms, and is free from danger if used cautiously. The patient may be supplied with small bottles containing the proper dosage (1 to 2 teaspoonfuls), which he may inhale through a sponge. As soon as he is under the influence of the drug, the bottle will fall from the hand.

While these measures are used, other less positive means may be employed to prevent a recurrence or combat the effects of the present attack. As flatulence is possibly the most common exciting cause, it must be relieved. The remedies employed for its relief have the advantage of counteracting the shock, or, if the heart is weak, of stimulating that organ. Aromatic spirits of ammonia, Hoffmann's anodyne, small doses of whisky or brandy in hot water, or crême de menthe cordial may be given every 15 minutes or half hour. Counterirritation with mustard plasters relieves pain and flatulence, and should be applied over the precordia and epigastrium.

The treatment of an attack of pseudoangina

pectoris varies with the nature of the primary ailment. If the pain is extreme, morphin may be used in any form save that which is apparently of gouty origin. The hysteric form should be given Hoffmann's anodyne, valerian, the bromids, or asafetida. In the toxic forms sedative remedies, as morphin and bromid, and the cardiac stimulants, as Hoffmann's anodyne, aromatic spirit of ammonia, minute doses of digitalis and strychnin are indicated. In those forms which are reflex from gastrointestinal disorder, drugs that control fermentation and acidity are to be given at once. Preparations of sodium and ammonia, spirit of chloroform, carbolic acid, creosote, charcoal, and other remedies that allay flatulence are of service. In this class of cases small doses of calomel, as gastric sedative and antiseptic, are of the greatest service.

In all forms of pseudoangina. external applications may be used, as in true angina, and probably greater relief will result. Nitrite of amyl and nitroglycerin may be used, as in true angina, but unless the heart is weak or is the seat of mural change, the remedies are not by any means effectual.

The gouty form of pseudoangina should be treated by the immediate administration of a blue pill with euonymin or podophyllin, and frequently repeated doses of colchicum.

Treatment of the Subject of Angina.—The management of an attack of angina has just been considered. After relief has been secured from the attack, it is necessary to prevent future attacks or to modify them by treatment of the patient. Just as true angina is associated with more or less diversified constitutions and pseudoangina with marked individual conditions, so the management and the treatment differ entirely. It has been well said, with regard to the former, that every aspect of the patient's life must be inquired into and regulated. Treatment, therefore, is largely hygienic and dietetic, and includes a consideration of exercise, diet, occupation, and habits of the individual. In general it may be said that the patient should take a moderate amount of out-door exercise, the extent being controlled by the degree of mural change in the heart and the amount of dilatation that has taken place. In a few cases the resistance exercises in the Swedish movement cure are of very great benefit. In others, in addition, the Nauheim baths are valuable aids. In another class of cases carefully graduated exercise with hill-climbing, in accordance with the methods of some of our German confrères, equalizes the circulation and lessens the tendency to high arterial tension. Tonic baths are to be employed, excluding those that induce shock, particularly if the patient is the subject of aortic regurgitation. Cold sponge-baths or cold douches applied over the neck and spine while the feet are submerged in hot water are usually sufficient. The diet must be variously modified, depending upon the form of indigestion present. Foods that are liable to cause flatulency are to be interdicted. Generally, the patient is aware of the class of food that disagrees with him, although often it may be said it is not the class of food so much as the manner of its preparation that causes indigestion and flatulence. Fried and greasy articles of food, the so-called made dishes, rich sauces, and nuts and cheese should usually be forbidden. In many, liquids at meals cause flatulence, so that it is necessary to discontinue the use of fluids, or limit them to a small amount at meals. Patients should be instructed to take fluids between meals, and abundantly. If the patient is gouty or rheumatic, alkaline or alkaline-sulphur waters, not containing salts of sodium, should be taken freely. Under no circumstances, however, should the waters be aerated. For the same reason the amount of food should be limited so that the stomach is not overloaded, and if the patient is a large eater, the food should be taken more frequently: as, for instance, 4 times in the waking hours.

The patient should be instructed not to expose himself to cold and not to have the extremities chilled. He should not walk against winds, and unless cardiac nutrition is good, should be judicious in climbing stairs or hills. It is quite necessary that exertion should not be made after the taking of a full meal. Patients should sleep in a well-ventilated room, and yet be well provided with covers so that they are not chilled during the night.

The drugs that are of use in true angina vary with the state of arterial tension and the condition of the heart-walls. If there is high arterial tension, it is well to give nitroglycerin. One drop of a 1 percent solution, or a pill of 1/100 of a grain, should be taken every 4 hours. The dose should be increased until a physiologic effect is experienced. It may then be continued at this dose, but at the end of a week or ten days should again be increased. The effect of the drug wears off remarkably soon, so that it may be necessary after a time to give as much as 15 drops of a 1 percent solution 3 or 4 times daily. In aortic disease with high arterial tension iodid of potassium is often of very great advantage. It should be given in doses of 10 grains 3 or 4 times daily. The nitrites are also valuable remedies, as the nitrite of sodium in doses of from 2 to 5 grains 3 times a day. If the patient is gouty, it is quite necessary to manage the case on lines that are employed in this condition. The action of the bowels and the kidneys, and also the skin, must be carefully attended to, and from time to time colchicum and iodid of potassium given. In cases of weak heart in which there seems to be fatty change, arsenic in small doses is recommended by Balfour. In such cases strychnin may be employed. If there is marked anemia, preparations of iron may be used, and it must be borne in mind, as pointed out by Weir Mitchell, that large doses of the tincture of chlorid of iron reduce high arterial tension. Thirty to 40 minims may be given 3 or 4 times daily. Great care should be taken to see that the bowels are kept open, and that salines, particularly salts of magnesium, are administered from time to time, and if the patient is gouty, such remedies as apparently influence hepatic functions, as preparations of mercury or podophyllin, must be given every 2 or 3 weeks.

As flatulency so frequently precedes an attack, or at least gastric disorder with flatulence, all patients with angina pectoris should see to it that they are supplied with remedies that allay this condition. It must be remembered that flatulence often occurs 3 or 4 hours after meals, or about the time the food is passing from the stomach into the duodenum. It is well to give a drug about this time to anticipate the excessive distention. A prescription containing carbolic acid, spirit of chloroform, aromatic spirit of ammonia, bicarbonate of soda-mint water, if given in proper proportions 3 or 4 hours after a meal, is generally very satisfactory. Three grains of sulphocarbolate of sodium may produce a happy effect. A pill of creosote and charcoal is also of great advantage. Frequently flatulence occurs before meals or immediately after meals, when its degree can be controlled by the use of powder or cachet containing bismuth, bicarbonate of sodium, aromatic powder with or without rhubarb, depending upon the degree of constipation. Of course, small amounts of whisky in a hot grog are of advantage in elderly persons who are wakeful on account of flatulence. Hoffmann's anodyne, spirit of camphor, soda-mint, and small doses of bichlorid of mercury are remedies that may be employed.

The Treatment of False Angina Pectoris.—Here, again, the management selected for the individual case must be that which materially controls the causal condition. To outline that treatment would be to discourse upon the treatment of neurasthenia or of hysteria, of the various intoxications, as of gout, rheumatism, tobacco, tea, and coffee. It would be necessary to direct how to manage all cases of indigestion or other reflex causes of anginal pain. These various methods of management need not be entered into. In general it may be said that in all forms hydrotherapeutic measures are probably of the greatest service. These measures must be modified according to the individual conditions. Change of air and scene is sometimes necessary.

The drugs to be prescribed are most frequently the sedatives, as preparations of valerian and of the bromids. The famous compound pill of sumbul and the pill of the three valerianates is often satisfactory, although any attempt at curing the condition by drugs alone is dangerous, as the actual causal condition is too often overlooked, or we are temporarily led into a sense of false security.

ANGIOKERATOMA.—Lymphangiectasis; telangiectatic warts; a very rare disease of the extremities, characterized by warty-looking growths that develop on dilated vessels in persons with chilblain, etc. Dark spots the size of pins' points or pins' heads, evidently vascular, develop as an attack of chilblain is subsiding. The disease is peculiar to childhood, and especially occurs in females.

ANGIOLEUCITIS (Lymphangitis). — See Lymphatics (Diseases).

ANGIOMA.—A tumor formed of blood-vessels; called also erectile or vascular tumor. See Tumors, Nevus.

ANGIONEUROSIS.—A vasomotor ataxia due to deranged vasomotor system. It may manifest itself as a (1) hyperemia-dilatation of the cutaneous vessels due to angio-paralysis, or (2) as anemia-contraction of the peripheral vessels due to angio-spasm, or (3) as a combination of both. Closely allied to these functional disorders are migraine, urticaria, and circumscribed edema, exophthalmic goiter, Raynaud's disease. Factors in their etiology are heredity (a family history of disordered metabolism, gouty or rheumatic diathesis or nervous disorders), toxemia, emotions, fatigue, and, as Cohen suggests they may result from disturbed thyroid secretion. Besides the cutaneous angioneuroses there are many visceral forms giving rise to symptoms characteristic of the region affected, as, for instance, edema of larynx or lungs, asthma, hay fever, gastro-intestinal symptoms even sometimes simulating hepatic colic or appendicitis, cardiac, cerebral, or genito-urinary symptoms.

These "pseudo-conditions" may be independent of or associated with organic change or if long continued may lead to lesions. Treatment consists in regulations of the general health and is otherwise symptomatic. The organic extracts may be of use.

ANGIONEUROTIC EDEMA (Giant Urticaria).—A vasomotor neurosis characterized by sudden, transient, localized, edematous swelling. Heredity, nervous temperament, digestive disturbances, exposure to cold are probably factors in its etiology. It may appear on any part but especially on the face, hands, feet, genitalia. The treatment is symptomatic, tonics being indicated to increase nervous and muscular tone. See Angioneurosis.

ANHIDROSIS.—Deficiency of perspiration. See Sweat-glands.

ANHIDROTICS.—Agents that check perspiration, the opposites of the diaphoretics, which promote this secretion. They usually act either—1. By depressing the action of the sweat-glands. 2. By depressing the excitability of the sweat-centers. 3. By reducing the circulation in the skin.

The most important are the following, the figures indicating their mode of action as above arranged.

Belladonna,[1] atropin,[1] hyoscyamus,[1] stramonium,[1] muscarin,[2] agaricus albus,[2] salvia (sage), acids, locally,[3] pilocarpus, pilocarpin, nux vomica, strychnin, ergot,[3] sulphuric acid, chloralformamid, quinin (?), picrotoxin, Dover's powder, opium[2] (small doses), zinc salts,[3] local cold.[3]

Strychnin, camphoric acid, atropin, Dover's powder, pilocarpin, picrotoxin and zinc salts, all respiratory stimulants, are very efficient against the sweating of phthisis, though most of them are classed as diaphoretics. This is explained by the theory that the accumulation of carbonic acid in the blood by depressed respiration caused by severe coughing, stimulates the sweat-centers, an action which is opposed by agents stimulating the respiratory center.

ANIMAL EXTRACTS.—See Organotherapy, Thyroid Treatment, etc.

ANISE (Anisum).—The fruit of *Pimpinella*

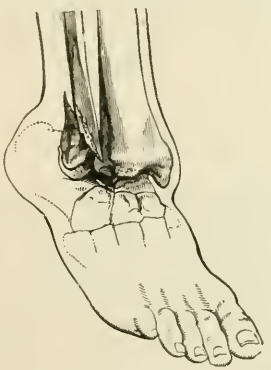
Anisum. Its properties are due to a volatile oil. It is slightly stimulant to the heart-action and to the digestive organs. It is useful chiefly to liquefy bronchial secretions, and is therefore a favorite ingredient in cough-mixtures. Dose, 5 to 10 grains. **A., Aqua,** oil of anise 1 part, water 500 parts. Dose, indefinite (average, 4 drams). **A., Oleum,** an ingredient in tinct. opii camph. Dose, 1 to 5 minims. **A. Spt.,** a 10 percent solution of the oil in alcohol. Dose, 1/2 to 2 drams.

ANKLE, DISEASE.—Tubercular disease of the ankle-joint is very common in children, beginning in the synovial membrane, the tibial epiphysis, or in the tarsus. Early diagnosis is difficult, the symptoms being obscure and ill defined.

The swelling is most characteristic when seen from behind, and it takes the form of a soft, puffy fulness lifting up the extensor tendons in front and occupying the hollows on each side of the tendo Achillis. Flexion and extension are more limited than in the opposite foot. Recovery may be expected if treatment is commenced at once and a fair range of movement obtained. Antitubercular remedies, guaiacol or iodoform ointment, and rest through means of splints or plaster are to be employed. Injections of iodoform emulsion may be useful, the needle entering below the outer malleolus. Opening, draining, injecting iodoform emulsion after washing out with normal salt solution and fixation of the joint in plaster are to be practised when caseation has ensued. When joint-disorganization occurs, excision may be performed. Osteoplastic resection is sometimes advised (Vladimiroff-Mikulicz operation). See JOINTS (Diseases).

ANKLE, DISLOCATIONS.—As a result of excessive dorsal or plantar flexion, the foot may be dislocated backward and forward respectively.

Lateral dislocation is not possible without malleolar fracture, which is spoken of under its appropriate head. See ANKLE (Fracture). The position of the foot is entirely characteristic: in one instance there is the lengthening of the heel, the astragalus projecting behind, and the shortening of the front foot, the tibia and fibula projecting in front; in the other, the front foot is lengthened and the heel shortened for contrary reasons. Reduction is effected by strong flexion in the direction that produced the displacement combined with direct pressure on the tibia backward or forward.



DISLOCATION OF FOOT BACKWARD.—(*From Moullin.*)

The astragalus may be dislocated from the tibia and fibula above and from the os calcis and scaphoid below and in front, and in an inward, outward, forward, or backward direction. The forward dislocation is the most common, and occurs from a wrench of the extended foot. The astragalus may be felt projecting under the skin and threatening to protrude through it at the instep. In the backward form it is a prominence beneath the tendo Achillis. The lateral varieties are generally compound.

The treatment should consist in pushing back the displaced bone into its socket by making pressure in the proper directions, the calf-muscles being relaxed by position, the foot then extended, and, if necessary, the tendo Achillis or other tendon or ligament felt tense divided. Anesthesia is generally required. If reduction is then found impossible, it must be left alone or excised. In compound dislocation it should, as a rule, be excised.

The subastragaloid dislocation is one in which the bones of the foot are displaced from the astragalus, which retains its natural connections with the tibia and fibula. The varieties are similar to those in the foregoing, the backward and inward variety being the most common. The foot is inverted, the sole turns inward, and the external malleolus is prominent in this variety.

The foot should be drawn forward, the leg forced backward, the tendo Achillis and tibialis anticus being divided; if necessary, anesthesia is used. The reduced foot should be placed on a splint and an ice-bag employed. If sloughing occurs, Pirogoff's or Syme's amputation may be necessary.

Dislocation of the other tarsal bones—the os calcis, the scaphoid, the cuboid, and the cuneiform bones—is extremely rare, and demands nothing more than mention.

Compound dislocation of the ankle-joint is a most serious injury, and may require immediate amputation if the patient is in poor health. The condition of the kidneys is of importance, as is age, the risk increasing with advancing years. The joint may be restored if the soft parts or the bones have not been bruised, although the joint has been exposed, but only through most perfect drainage. Acute suppurative arthritis is the condition to be guarded against.

ANKLE, EXCISION.—This operation is seldom practised. Syme's amputation involves less risk and may be relied upon. Excision may be performed either by two lateral incisions or an anterior transverse one, the latter being the more simple. See EXCISION.

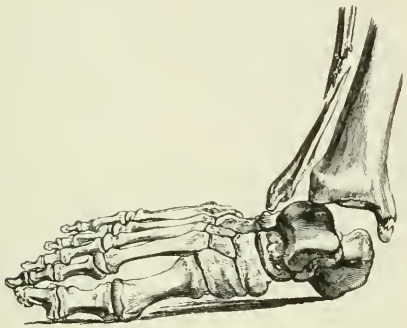
ANKLE, FRACTURE.—Typical malleolar fracture, or fracture of the ankle, or Pott's fracture, consists in fracture of the fibula slightly above the malleolus and displacement of the foot outward, with rupture of the internal lateral (deltoid) ligament, or fracture of the tip of the internal malleolus, which is commoner.

This injury results from hypereversion of the foot; the foot being caught and fixed, for instance, the body falls laterally to the side of the fixed foot.

This brings the strain on the deltoid ligament. This either gives way or the tip of the internal malleolus is torn away. The force continuing to act on the foot as a whole crowds the astragalus against the external malleolus, and produces fracture of the fibula by flexion.

If the foot is taken in the hand, the leg above the malleolar region being fixed, an abnormal lateral displacement may be produced, together with abduction of the foot to an unusual degree.

The fractured edge of the tibia stands out very prominently, the skin over it being tense; sometimes this breaks, producing a compound fracture, in which event an actual outward dislocation of the



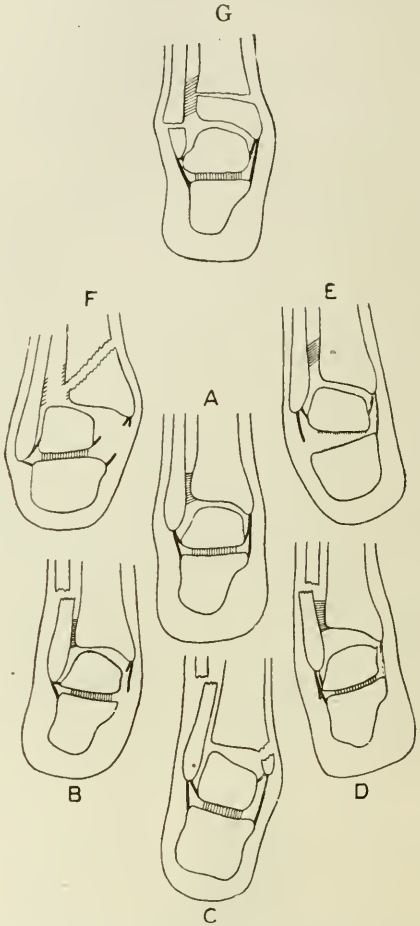
Pott's Fracture.—(*From Moullin.*)

foot occurs. The lower end of the tibia may project through the rent in the skin and resist efforts at reposition until the interposed skin is divided and retracted.

This injury is a very serious one, even if uncomplicated by being compounded. Besides being an articular fracture, this joint must bear the weight of the entire body. Without its inner support, the deltoid ligament, the foot falls into a valgus position and is incapable of performing its function even tolerably well.

Treatment.—An anesthetic should always be given to accomplish reduction, as it is of the utmost importance that perfect replacement be effected. The foot is sometimes displaced backward as well as outward, and this must be carefully considered in effecting reduction. A dressing should now be applied that will hold the foot in a slight varus position and at the same time permit ready and daily inspection. The old straight splint of Dupuytren serves this purpose well. The splint is applied to the inner aspect of the leg, projecting beyond the sole of the foot. A pad is placed beneath the splint over the lower end of the tibia, just above the malleolus; another pad is placed over the external malleolus below the point of fracture of the fibula. The application of a bandage now manifestly draws the foot toward the splint, and offers a certain means of combating the outward displacement and the valgus position. Attention must be paid to the dropping of the toes in plantar flexion, which favors a backward displacement of the foot. If such tendency exists after the internal splint is applied, it may be necessary to supplement it by a posterior splint with a right-angled foot-piece to control this dropping of the toes. The leg is now semiflexed upon the thigh and laid upon its outer surface on a pillow.

This dressing has the virtue of being easily removable, while plaster of Paris is not. During the first two weeks the dressing should be removed every 3 or 4 days, with a view of insuring the



Diagrams Illustrating Injuries about the Ankle-joint. (*After Treves*). A. Normal. B. Pott's fracture, with rupture of the internal lateral ligament. C. Pott's fracture, with fracture of the internal malleolus. D. Fracture of the fibula and displacement of the foot inward. E Subastragaloid dislocation. F. Dupuytren's fracture, *i. e.*, rupture of the interosseous membrane, oblique fracture of the tibia, rupture of the internal lateral ligament. G. Separation of the lower epiphysis of the tibia and of the fibula.—(*From Spencer and Gask.*)

continuance of good position, and for the purpose of massage and instituting gentle passive movements. After the second week, when good position is assured, a plaster-of-Paris dressing may be applied, extending from the knee to the tips of the toes. When this is applied, care must be taken to place the foot at a right angle to the leg, as after consolidation. After consolidation of this fracture, a persisting inability to flex the foot

dorsally to a right angle is the source of great inconvenience and disability.

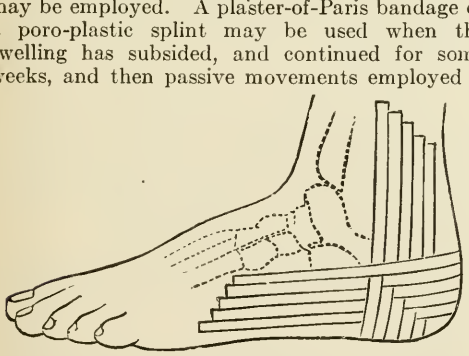
After 5 weeks, ordinarily, the splint may be removed. The foot should be protected, however, for several months by slightly raising the inner side of the shoe and perhaps providing an orthopedic appliance (club-foot shoe, support for flat foot) to prevent relapse into the valgus position.

In compound fracture this same straight splint may be applied to the outer side of the leg, the arrangement of the pads insuring the maintenance of the proper position. In this way the inner aspect of the ankle is left accessible for inspection and dressings; or a plaster-of-Paris splint may be applied, with suitable windows cut out.

Separation of the epiphyses at the lower end of both leg-bones is a rare injury, occurring only in children, and sometimes after forcible redressment of club-foot. Treatment is on general principles.

ANKLE, RESECTION.—The Mikulicz operation is osteoplastic resection of the ankle-joint, when the anterior part of the foot is perfectly sound. The heel, with the astragalus, os calcis, and soft parts over them, is removed, the articular surfaces of the tibia and fibula above and of the cuboid and scaphoid below are sawed off, and the front of the foot is brought vertically under the leg, so that the toes assume the position of extreme equinus. Langenbeck and König perform resection through bilateral longitudinal incisions, while an external transverse arched incision is employed in the Reverdin-Kocher method.

ANKLE, SPRAINS.—When there is much swelling, sprains of the ankle may be with difficulty differentiated from fractures, and if there is doubt, they should be treated as fractures. Absolute rest, cold and evaporating lotions, and a wet bandage may be employed. A plaster-of-Paris bandage or a poro-plastic splint may be used when the swelling has subsided, and continued for some weeks, and then passive movements employed if



(From *Spencer and Gask.*)

any stiffness is left. Recently, massage has been employed very successfully in conjunction with an elastic bandage or a rubber roller.

Immersion of the part in water as hot as can be borne for a half hour twice daily and then applying a firm bandage is most satisfactory in many cases.

A treatment that, according to Gibney, "involves no loss of time, requires no crutches, and is not attended with any impairment of functions," is as follows: A number of strips of rubber adhesive plaster, about 9 to 12 inches in length and of appropriate width, are prepared. Beginning at the outer border of the foot, near the little toe, the first strip partially encircles the joint and ends behind the foot. The second strip is begun on the inner side of the foot and is applied on the opposite side, nearly meeting the first strip behind. Other strips are applied in like manner, each one overlapping the last and crossing its fellow of the opposite side in front, so that the ankle is snugly and smoothly encased, care being taken not to completely encircle the joint with any one strip. After having bound the foot firmly, it is well to add one broad strip running around the foot from the internal side of the leg down the internal side of the foot, across the plantar surface, and up the outside of the leg, "as much as possible to take the place of the middle fasciculus of the external lateral ligament, which is so often the one most injured." It is a good plan to place a pad of absorbent cotton over the external malleolus and in the fossa below, to prevent undue pressure and chafing. Anyone of the injured ligaments may receive a similar reinforcement from an extra strip. Then apply a roller smoothly over the entire surface, allowing it to remain until the plaster takes firm hold. The hot-air treatment has proved valuable. See SPRAINS, JOINTS (Injuries).

ANKLE-JERK.—See REFLEXES.

ANKYLOBLEPHARON.—See EYELIDS.

ANKYLOSIS.—This signifies, literally, a crooking of the joint. In a general sense it is reserved for fixation of the joint, with which there is often associated an angular deformity. The diseased process may be in the joint proper, in the periarticular tissues, the overlying muscles and tendons, or even in the integument. Every joint-fixation has thus often been included in the term ankylosis. A division has likewise been made into the fibrous, or false, and the bony, or true, ankylosis. A better division is that by which the term *contracture* is used to designate joint-fixation by abnormalities of the soft parts, and *ankylosis* from fibrous or bony union of the articular surfaces proper.

Contracture.—Acute inflammation of the joints and tubercular processes are, as we have seen, very often early associated with muscular contraction, which, from the inception, immobilizes the joint absolutely, except to examination under anesthesia. After the subsidence of the primary disease, the contraction may continue and simulate the locking of the joint. The periarticular swelling and the thickening of the capsule attending rheumatism will often leave a joint in a similar apparently ankylotic state. The cicatricial contraction that follows severe burns may likewise produce an apparent ankylosis.

True ankylosis has been properly divided into the fibrous and the osseous, although in long-standing cases a combination of both forms will usually be found, and only in very chronic cases does it ever come to a complete bony union of the articular ends, with total obliteration of the joint-cavity. The diseases that are most productive of the true ankylosis are: acute suppurative arthritis,

tubercular disease, and chronic rheumatism. In the last-named, ankylosis of many joints is often seen. Gonorrheal arthritis, the nonsuppurative complications of puerperal septicemia, and the acute infectious diseases are less often followed by bony ankylosis.

The diagnosis of the conditions that fix a joint is ordinarily easily made; but that of fixation from extraarticular causes must always be differentiated from that of true ankylosis. The clinical history of the case and the condition of joint-movement under anesthesia would make the recognition simple. The differentiation between the fibrous and the bony ankylosis, is, as a rule, also easily established. A bony ankylosis will absolutely prevent joint-motion, whereas in the fibrous varieties the patient alone, or with a little assistance, can always elicit a certain degree of motion. The knee forms an exception to this rule; notwithstanding an osseous ankylosis, some degree of motion can be elicited.

Cases of osseous ankylosis of the patella to the anterior surface of the femoral condyle with slight joint-motion have been observed. The operation revealed the joint interior free except where the patella had formed attachments.

The use of the X-rays has elucidated the diagnosis of these joint conditions and a skiagraph should be had in every instance in which remedial measures are contemplated.

Treatment.—The treatment of joint-fixation necessarily varies with the conditions that produce it. If the result of cicatrices, fascial or muscular contractures, attention must be directed to them rather than to the joint itself. The first must be remedied by plastic operation. Contractures of muscle and fascia may often be overcome under an anesthetic. Constant traction or pressure by means of a properly applied brace will frequently succeed when failure has attended forcible correction under an anesthetic. If this fails, resort must be had to a division of the tendons and fascia, either by subcutaneous operation or, preferably, by open division.

In cases of ankylosis that are known to be fibrous, operative measures are called for only after a milder treatment by baths, massage, and active and passive joint-movements have been tried without effect. Mechanic appliances to stimulate motion may also be tried. Very frequently, indeed, by the combined use of massage and weight-extension, the deformity that so often accompanies ankylosis may be overcome. In the failure of these methods, recourse may be had to forcible breaking up of the fibrous adhesions that fix the joint, always under an anesthetic (*brisement forcé*).

The fewer the number of adhesions broken up at a sitting, the less is the reaction; therefore, anesthesia may be resorted to at intervals of a week or 10 days, and thus gradually the deformity be overcome and an opportunity given for the little that is gained each time to be maintained. By this method there is avoided the danger of lacerating a large vessel or nerve running in close proximity or adherent to the joint-capsule. In breaking up adhesions, force should first be applied to increase the deformity. The angle of flexion of the knee and elbow should, by the first movement, be even more reduced. Upon this flexion should follow the first attempt at extension. Unfortunately, with the most careful and frequently repeated attempts to overcome a fibrous ankylosis, failure to restore, even approximately, normal joint-function is the rule. The fibrous bands that have been broken up reunite and the ankylosis is speedily reestablished. If, therefore, the ankylosed part is placed in the most favorable position possible, it is all the patient may hope for.

The treatment of bony ankylosis must ordinarily be limited to the correction of the deformity. If the position of the limb is a correct one, osseous ankylosis is not to be interfered with. In the overcoming of deformity, the operation may be done through the joint or in close proximity to it. In ankylosis of the hip, in which there is often extensive new bone-formation, it is better to divide the bone below the trochanter (Gant's operation). When the neck of the bone has not been destroyed by disease, its subcutaneous division with a saw, after the method of Adams, may be resorted to. In ankylosis of the knee, recourse must usually be had to the excision of a wedge, with base anterior, before the deformity can be corrected. Bony ankylosis at the elbow is best treated by excision, which will leave a very serviceable, although an abnormally movable, joint. Murphy advocates the attempt to restore function to these joints by the implantation of a generous flap of fat and connective tissue between the bone surfaces, and reports good results. Baer uses chromicized pig's bladder carefully adjusted between the bone ends for the same purpose and has secured from 15 to 90 degrees of motion in various cases. See HIP-JOINT, KNEE-JOINT, etc.

ANKYLOSTOMA.—A genus of nematoid worms, one species of which, *A. duodenale*, is found in the human intestine. This is now referred to the genus *Dochmius*.

A peculiar anemia, called **ankylostomiasis**, is produced by the parasite sucking the blood from the walls of the duodenum. It is especially prevalent among brickmakers and other workmen in Europe. It is called also dochmiasis, brickmakers' anemia, tunnel anemia, miners' cachexia, Egyptian chlorosis, tropical chlorosis, etc.

The ankylostoma is a cylindric worm generally found in the small intestine, the female being from 10 to 18, the male from 8 to 12, millimeters in length.

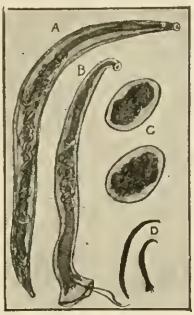
The embryo develops outside the body, but if taken into the alimentary canal through the medium of the food, lodges in the small intestine, where it undergoes development. The eggs are smooth, oval in shape, and usually contain several daughter-cells. Frequently, the eggs only are seen in the dejections, and therefore a microscopic examination is of first importance.

Symptoms and Clinical Course.—Grave forms of anemia are frequently met with when this parasite infests the alimentary canal, the lymphocytes being markedly increased.

When the parasite is suspected as the cause, the

stools should be allowed to stand for 24 or 48 hours, when the embryo will be fully developed, and may readily be identified by means of the microscope.

Treatment.—No solid food should be given for at least 24 hours before giving an anthelmintic. Of the remedies advocated, probably the oleoresin of male fern is best. It may be given in doses of from 1/2 to 1 dram, and repeated in 3 hours, after which a full dose (1 fluidounce) of castor oil should be administered. See HOOKWORM DISEASE.



UNCINARIA DUODENALIS, OR ANKYLOSTOMA DUODENALE.—(A) female, (B) male, (C) eggs, (D) male and female of natural size.—(*Greene.*)

ANODYNES AND ANALGESICS.—Anodynes are medicines that give relief from pain. They are nearly all hypnotic or narcotic.

The chief anodyne is opium or its alkaloid morphin. Others are canabis inndica, belladonna, hyoscyamus, stramonium, conium, veratrum, lupulus, gelsemium, potassium bromid, chloral hydrate, chloroform, ether, and camphor.

Hoffmann's anodyne is a preparation of ether known as the compound spirit of ether. See ETHER.

Chloral relieves pain only by inducing sleep, and only in dangerous doses does it produce anesthesia.

Butyl-chloral exerts a special anesthetic effect on the fifth nerve, and also induces sleep. Gelsemium also especially affects the fifth nerve; hence both these drugs are of particular value in the treatment of facial neuralgias. Belladonna chiefly affects the peripheral ends of the sensory nerves, and is applied with benefit in plasters, ointments, or liniments directly to the local spot or area of pain. Aconite, veratrin, cocain, and opium are also used as local applications for the relief of pain.

Anodynes may be administered by enema or suppository, by hypodermic injection, by endermic application, and by inhalation, as well as by the mouth. Certain measures are used locally as analgesics or anodynes, such as the application of cold, electricity, various forms of counterirritation, dry or moist heat, acupuncture, and the abstraction of blood.

An anodyne liniment:

℞.	Tincture of aconite,	ʒ ij
	Tincture of opium,	ʒ iv
	Tincture of arnica,	ʒ j
	Chloroform,	ʒ ij
	Soap liniment, enough to make,	ʒ iv

Apply as a liniment.

Analgesics are remedies that relieve pain either by direct depression of the centers of preception and sensation in the cerebrum, or by impairing the conductivity of the sensory nerve-fibers. Opium is the most efficient of all analgesics, because it arrests the afferent impressions at every step of their progress—at their formation, along the courses of their conduction, and at the points where they impinge on the sensorium.

Antipyrin, acetanilid, phenacetin, phenocoll, and exalgin are powerful analgesics, and relieve pain without disturbing the brain. They are especially useful in neuralgic pains, in headaches, and in pain due to affections of the spinal cord: *e.g.*, in the agonizing pains of locomotor ataxia.

An analgesic pill:

℞.	Phenacetin,	gr. xx
	Salol,	gr. xx
	Cinchonin salicylate,	gr. x.

Make 10 pills.

One every 2 hours, until relieved.

See DENTAL ANODYNES.

ANOREXIA.—Want of appetite, abhorrence of or aversion to food, is symptomatic of certain mental affections. It is met with in gastric disorders, and in chronic diseases. It is present in all fevers, in many chronic exhausting diseases and under the stress of violent emotion (grief, worry, anxiety), may be purely hysterical or neurasthenic and may take the form of mere loss of the hunger sense, actual revulsion, a sense of repletion, actual perversion, or nausea upon taking as light amount of food. Chlorosis, chronic alcoholism, hysteria, nervous and emotional overstrain, influenza and septic processes, including advanced tuberculosis. It often results from the dietetic fads and fancies of the physician or patient (or friends?), and from monotonous and narrow dietaries. Loss of appetite may be more apparent than real. Inquiry often shows that digestion is proceeding properly, but a habit of eating without allowing a proper interval between meals exists, or that the food is of too nutritious a nature, or an undue amount of alcoholic stimulants prevents hunger.

For loss of appetite:

℞.	Gentian, Quassia, Cinnamon, each,	ʒ ij.

Put into a pint of boiling water and, when cold, strain; take a wineglassful thrice daily as an appetizer.

℞.	Strychnin sulphate,	gr. j
	Arsenic trioxid,	gr. ij
	Quinin sulphate,	gr. xl
	Iron sulphate,	gr. xl
	Extract of taraxacum,	ʒ ss.

Mix and make 40 pills.

SIG.—One pill after each meal.

Anorexia nervosa, or hysterica, is a symptomatic or nervous manifestation of hysteria in which there is an entire absence of hunger and a distaste for food, eventually leading to starvation. Food

is often promptly vomited as soon as taken, though water may be retained. It occurs chiefly in neurotic girls between 12 and 16 years of age, and occasionally in children. It should be distinguished from cancer of the stomach, gastric ulcer, and diabetes. It rarely proves fatal. The treatment consists of isolation, hypnotic suggestion, hydrotherapy, electrization of abdomen, gavage, and lavage of the stomach. Forced alimentation and complete and continued isolation, with massage, are beneficial. Drugs have not been found of use.

ANOSMIA.—Partial or complete loss of the sense of smell—unilateral or bilateral—associated with impairment or loss of the sense of taste. Local nasal disease affecting the mucous membranes, injury or disease of the fifth nerves, disease involving the inner and lower parts of one or both anterior lobes of the brain, or the under surface of the temporosphenoid lobes may cause it. It may be associated with hemianesthesia of hysteric or organic origin. Taste is lost when anosmia is complete, except for sour, sweet, salt, and bitter substances.

ANTACIDS OR ALKALIES.—Remedies that neutralize acids, check alkaline secretions, and stimulate acid secretions, when in contact with the ducts of the organs producing them. Thus, a dilute alkali given before meals will stimulate the production of the acid gastric juice, and if applied to the mouth of the pancreatic duct, will check the secretion of the alkaline pancreatic juice. The principal articles that belong to this group are the following, which would always be administered in dilute solution:

The following are direct antacids, lessening the acidity in the stomach, many of them also acting as remote antacids, lessening the acidity of the urine:

Liquor potassii hydroxidi, liquor sodii hydroxidi; carbonates and bicarbonates of potassium, sodium, lithium, magnesium, and ammonium; magnesia; lime-water; chalk; aromatic spirit of ammonia.

Ammonium and its carbonates after absorption are eliminated as urea, and do not lessen the acidity of the urine.

The following are remote antacids, do not lessen acidity in the stomach, but lessen that of the urine, being oxidized in the blood and excreted as carbonates:

Potassium acetate; potassium citrate; potassium tartrate; sodium phosphate; sodium acetate; sodium citrate; lithium citrate.

Antacids are given to correct excessive acidity in the stomach that may be due to secretion of too abundant or too strongly acid a juice, as in acute dyspepsia, or to the decomposition of food from impaired digestion. Sodium salts are preferable to those of potassium, and lime salts should be used if diarrhea exists. Alkalies are best given after meals. See ACIDITY.

ANTAGONISM.—The fact that the physiologic action of certain substances may be affected, even neutralized, by the presence in the body at the same time of other substances having an opposite character. This balance is presumed to take place in the blood or in the tissues. An antidote so affects the chemic or physical character of a poison as to make it destitute of injurious action on living animal tissues. Poisons directly antagonize one another. The term antagonism is commonly used to express a physiologic action. Antagonism implies a balance of functional disturbance, and not an alteration of structure. There is no instance wherein the antagonism of two drugs is absolutely complete along the whole line of action. Morphin and atropin are nearly so. Digitalis and saponin and atropin and muscarin are very closely antagonistic.

Two mutually antagonistic principles may exist in the same plant, as the alkaloids pilocarpin and jaborin in pilocarpus.

The following table, modified from Brunton, gives the antagonistic poisons, as well as their mutual antagonistic and lethal doses in each case in which they have been determined. The doses are expressed in grains or fractions of a grain to a pound weight of the animal:

Antagonists.		Antagonistic Dose.		Lethal Dose.	
I.	II.	I.	II.	I.	II.
Aconitin and Atropin		1/750	1 3/5	1/900	7
Aconitin and Digitalin		1/600	2/5	1/900	1
Aconitin and Strychnin		1/750	1/125	1/900	1/288

ANTEFLEXION.—See UTERUS (Anteflexion).

ANTEMORTEM STATEMENT.—See DYING DECLARATIONS.

ANTERIOR POLIOMYELITIS, ACUTE.—See PARALYSIS, INFANTILE.

ANTHELMINTICS.—Agents that destroy (vermicides) or cause the expulsion (vermifuges) of intestinal worms. The chief vermifuges are castor oil, jalap, and scammony. They dislodge and expel the worms by the increased peristaltic action that they occasion.

The chief vermicides are as follows:

For Thread-worms: Alum, sulphate of iron,

lime-water, quassia, eucalyptol, sodium chlorid, tannin, vegetable astringents, and naphthalin. These substances are all used locally by enema.

For Round-worms: Santonica, santonin, spigelia, chenopodium, senna, calomel, and naphthalin.

For Tape-worms: Aspidium, kamala, kousso, granatum, pelletierin, pepo, turpentine, chloroform, and naphthalin.

Adjuncts, such agents as prevent the excessive secretion of intestinal mucus, thus affording a nidus for the worms, are bitter tonics, preparations of iron, ammonium, and sodium chlorid. Thymol is specific against the **Hook-worm** (*q. v.*).

Vermicides are generally given after fasting for 8 or 10 hours, in order that, the intestines being empty, the drugs may act more readily on the worms. Some 3 or 4 hours after a purgative is given to expel the dead or stupefied worms. Thread-worms chiefly infest the rectum, and are more effectually killed by enemas, such as strong infusions of quassia chips, salt and water, vinegar and water, solution of the sulphate or chlorid of iron, oil of turpentine, castor oil, a decoction of aloes, or an infusion of senna.

An anthelmintic against the round-worm for children above 4 years of age is:

℞. Powdered spigelia, gr. x
Calomel, gr. iv.

Mix into a powder. To be taken for two mornings in succession and on the afternoon of the second day followed by a purge.

Another anthelmintic against round-worms is:

℞. Spigelia root, ℥ ss
Senna leaves, gr. xl
Orange bark,
Bruised santonica seeds,
Bruised fennel seeds, } each, ℥ j
Boiling water, ℥ xij.

Macerate in a closed vessel for 2 hours and strain. Give a wineglassful every morning.

The fluidextract of spigelia, 1 dram to a child of 2 years, 2 drams to an adult, is serviceable, as are also divided doses of the fluidextract of spigelia and senna in from 2- to 3-dram doses. Santonin, 1/4 to 1/2 of a grain, in the form of troches, or santonin and calomel troches are serviceable.

Oil of chenopodium may be given on sugar in from 5 to 20 drops.

Against the tape-worm, pelletierin, in 1- to 2-grain doses in capsule, is the most efficient remedy. Tanret's pelletierin, dispensed in phials containing about 5 drams is a satisfactory preparation. Pumpkin seeds made into a paste with sugar are sometimes used. The oleoresin of aspidium, or filix mas, in 1/2- to 1-dram dose, may be used for an adult, to be followed by a calomel purge and a saline.

Ogilvie urges the administration of larger doses of the fluidextract of male fern for children than are usually given. He believes that the small doses of 15 minims are inadequate, and also more likely to produce toxic symptoms. For several days before the treatment he directs that the child be given less food than usual, and then a simple milk diet for one day, on the evening of which a purgative draft of jalap and magnesium sulphate is given, to be repeated the next morning at 7 o'clock. At 8 o'clock one-half of the following mixture should be taken, and the remainder at 9 o'clock:

℞. Fluidextract of male fern, ♋ ss
Mucilage of acacia, ♋ iij
Almond mixture, q. s. ♋ ij.

Two hours later a dose of castor oil and jalap should be given, even if the entire worm has been expelled, as it is necessary to remove the vermifuge from the intestines. See Worms.

ANTHEMIS.—See Chamomile.

ANTHRACOSIS.—A chronic interstitial pneumonia with pigmentation of the lung, in coal-miners. See Pneumonokoniosis.

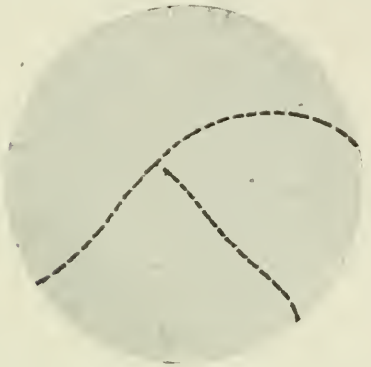
ANTHRASOL.—An antiseptic and parasiticide. Like ordinary tar, it allays irritation of the skin, but is claimed not to obstruct the follicles nor to favor the development of acne. It is used locally in the form of a 5 to 10 percent petrolatum ointment in eczema; 10 percent ointment with glycerite of starch and 10 percent of wool fat (adeps lanæ) in pruritus; 20 to 30 percent ointment or paste, in lichen; in combination with sulphur and soft soap, in parasitic skin affections.

ANTHRAX (Charbon, Malignant Pustule, Wool Sorter's Disease).—The other synonyms are splenic fever, splenic apoplexy, gangrene of the spleen, carbuncle fever. It is a specific affection communicated by animals suffering from splenic fever. Graminivorous animals are liable to splenic fever,

Bacillus Anthracis in Blood of Rabbit.—(*Coplin.*)

and those who tend these animals or handle their hides and flesh after death are generally affected. The infection enters man through the lungs or digestive tract or skin (probably only when there is an abrasion). It is a peculiarity of the disease that there is an entire absence of pus-formation until the slough is being thrown off. After a slight itching, a vesicle forms, then an indurated red area

appears around it, which may become of the diameter of an inch or more. This area is usually elevated about 1/8 of an inch above the healthy skin, while a central depression of about 1/20 of an inch is seen. The lymphatic glands enlarge. There is a remarkable absence of pain. Constitutional symptoms set in from 8 to 10 days after the



Anthrax Bacilli with Square or Slightly Concave Ends sometimes seen; Fuchsin Stain. (× 1000.)—(*Williams.*)

papule appears. The vesicles may dry up and form a black slough, which is separated and cast off as any other inflammatory process.

It is the presence of the **bacillus of anthrax** that gives this disease its essential character. The anthrax bacillus, the largest of the pathogenic bacilli, is rod-shaped, having a rectangular form caused by the rounding off of the corners. It is

Anthrax Bacilli, Showing Spores. (×1000.)—(*Williams.*)

not motile and does not have flagella, but contains spores. The bacillus and especially its spores are remarkably resistant. The bacilli grow upon artificial culture media, such as gelatin, and have a tendency to arrange themselves in the shape of threads. These bacilli stain with ordinary saturated alcoholic or aqueous solutions of anilin dyes and by Gram's method. See Bacteriology, Pathologic Technic.

Symptoms.—The disease may be external or internal, in the former assuming the type of "*malignant pustule*" or "*malignant anthrax edema.*" The latter form is usually pulmonary, more rarely intestinal.

Malignant pustule begins a few days to a week after exposure, with itching and smarting pain at the site of inoculation, on the arm, hand, or face. A papule appears which becomes a vesicle. This discharges its serum and a number of smaller vesicles are disclosed at the margin of the enlarged papule. Induration and edema are intense. Adjacent lymphatic necrosis may be extensive, lymph glands become involved. Symptoms of general infection appear—fever, rapid pulse, thirst, dyspnea, enlarged liver and spleen. Death usually supervenes in several days.

Malignant anthrax edema begins in the eyelids and travels to the head, arms, hands. The local symptoms are secondary to the constitutional disturbance. The skin is red and edematous. There may be vesicles but no papules. The edema may become extensively gangrenous. Recovery is exceedingly rare.

Wool-sorter's disease is acquired by inhaling the bacilli into the lungs. The onset is sudden with chill, fever, high temperature, pain, dyspnea, bronchitis, and cough, together with the physical signs of lung involvement. There is often no external lesion. It is rapidly fatal, the patient often dying in 24 hours in collapse. Other cases are more protracted, and there may be vomiting, diarrhea, delirium, and unconsciousness, while the brain may be the chief seat of involvement, the capillaries being filled with bacilli. *Rag-picker's* disease is another pulmonary variety involving the pleura accompanied by constitutional disturbance.

Intestinal anthrax or *mycosis intestinalis* is due to the ingestion of meat or milk of infected animals. At the onset there may be a chill followed by moderate fever, nausea, vomiting, diarrhea, general pains and prostration; dyspnea, petechiæ and pustules may be observed; the spleen is enlarged. Hemorrhage may occur from the mucous membrane in contradistinction to the external form. Marked cerebral symptoms may be observed. Convulsions may occur before death.

Diagnosis of the external form is generally easy. In most cases the characteristic eschar is recognized. A boil or carbuncle may be mistaken for it, especially when on the face. A poisoned wound, a soft chancre, erysipelas, or cellulitis may cause confusion, but the history is to be inquired into and a microscopic examination of the serum will prove the diagnosis. Cultures may be made and a mouse or guinea-pig inoculated.

Prophylaxis is of signal importance. It consists in cremation of all animals dead from the disease, disinfection of hides, wool, rags etc., by superheated steam, isolation of infected pastures, and the disinfection of infected buildings.

Treatment.—In the external form it is of the utmost importance that the whole of the indurated area be destroyed or removed. Deep crucial in-

cisions should be made, followed by potassium hydroxid or strong phenol and the wound dressed with phenol (1:20) or powdered with mercury bichlorid. Local or perhaps general anesthesia is indicated. Subcutaneous injections into the adjacent parts of solution of phenol (1/2 to 3 percent) or tincture of iodin (3 to 5 percent) or mercury bichlorid, or iodin and potassium iodid are valuable in controlling the infection.

Constitutional symptoms should be treated by rest in bed, a plentiful supply of animal food, beef-tea, milk and eggs, including quinin in large doses, strychnin, and alcoholic stimulants. Sodium sulphite in 10-grain doses has been recommended. Collargol intravenously is said to effect a cure. Morphin may be given for the insomnia and diarrhea.

Internal anthrax demands the same general treatment but is usually intractable. At the onset free purgation is advisable, and the bowels should be kept open. Senega and other expectorants are useful when the lungs are affected, and inhalations of air charged with carbolic acid or some other antiseptic agent may be used.

In Massachusetts an outbreak of *anthrax among tannery workers* occurred in 1916. Among the 25 cases so studied it was found that every one of the persons infected had been handling dried "China" hides. In this country the great majority of cases of anthrax infection are due to imported hides and as a result of contact in the early stages of the tanning process. Therefore, this *infection can be controlled* first, by the exclusion of infected material from this country; secondly, by the disinfection of the material after it arrives in this country, and, thirdly, by the safeguarding of the workers who handle the material (Potter).

Serum Therapy.—Sclavo's anti-anthrax serum has been used with success. It should be employed whenever it can be obtained. The dose is about one ounce injected subcutaneously. It has been suggested that injections of the bacillus pyocyaneus be given, because it is known that this organism when injected into animals with the bacillus of anthrax materially modifies the virulence of the latter.

ANTIBODIES.—See SERUM THERAPY AND VACCINE THERAPY.

ANTIDIPHTHERITIC SERUM. See DIPHTHERIA ANTITOXIN; SERUM THERAPY.

ANTIDIPLOCOCCUS SERUM.—See SERUM THERAPY.

ANTIDOTES.—Agents that so affect a poison, physically or chemically or both, as to remove it from the body or alter its character by forming with it an insoluble or inert compound before its absorption, with the object of *preventing* its toxic action upon the organism. **Antidotes.** See ANTAGONISM. Antidotes act against vegetable and mineral poisons in the alimentary canal or respiratory tract, but are not available against poisons administered hypodermically. There are (1) *chemic or true antidotes*, which unite chemically with the poison, converting a soluble and absorbable substance into a compound which is more or less insoluble and nonabsorbable, or harmless though soluble, and (2) *mechanic or antidotal measures*, which include such medicinal or mechanical processes as tend to remove a poison from the body, either before or after the use of an antidote; and include emesis, the use of the stomach-pump, purgation, etc. Among the latter are emetics, cathartics, washes, injections, ligatures, poultices, the use of the stomach-pump, of tourniquets, etc. The chemic antidotes include albumin, alkalies, potassium permanganate, milk, charcoal, soap, starch, oils, tannin, turpentine, acids, alkalies, carbonates, hydrates, sulphates, sodium chlorid, iodin, and iron preparations, etc. See POISONING.

ANTIEMETICS.—Agents which diminish nausea and vomiting; some of them act by means of a local sedative influence upon the end-organs of the gastric nerves, others by reducing the irritability of the vomiting center in the medulla. The most important are *Local Gastric Sedatives:* alcohol, alum, arsenic, belladonna, bismuth, carbonic acid, cerium oxalate, chloroform, phenol, potassium nitrate, creosote, ether, ice, opium, hydrocyanic acid, silver nitrate, small doses of calomel and ipecac, hot water, cocain, *General Sedatives:* opium, morphin, codein, hydrocyanic acid, bromids, chloral, nitroglycerin, alcohol, amyl nitrite, food.

Ice, swallowed in small pieces, is probably the most efficient of the local sedatives. *Phenol* and *Cocain* are also effective antiemetics, given in small doses by the mouth at short intervals. *Astringents* are very useful where there is congestion of the gastric mucous membrane, as in the vomiting of alcoholism and phthisis, when *Silver Nitrate* and *Alum* are especially to be recommended. *Opium* and its principal alkaloid, *Morphin*, will produce nausea and vomiting in many persons, even when given in very small doses. See EMETICS; VOMITING.

ANTIFEBRIN.—See ACETANILID.

ANTIFORMIN.—A strongly alkaline solution of sodium hypochlorite. A germicide said to be more than three times as active as phenol, recommended for the disinfection of urine, stools, sputa, hands and instruments. It is said to be of value in certain skin diseases. It dissolves bacteria and protozoa but does not affect acid-fast bacteria, as tubercle and lepra bacilli, therefore its use facilitates the demonstration of tubercle bacilli. It is used externally in 2 to 10 percent solutions; as a disinfectant in 5 percent solution; as a spray in 4 : 1000 solution; for demonstration of tubercle bacilli in 15 percent solutions.

ANTIGALACTAGOGS.—Agents and measures which diminish or arrest the secretion of milk. Belladonna or its alkaloid atropin is the most efficient, acting whether applied locally or administered internally. Antipyrin has similar power, so also has camphor applied locally and potassium iodid, colchicum with magnesium sulphate, tobacco, sage, quinin, tannin, etc. Compression of the breasts, by bandaging or strapping with adhesive plaster, has positive antigalactic action.

ANTIGENS.—See SERUM THERAPY AND VACCINE THERAPY.

ANTIGONOCOCCUS SERUM.—This serum is obtained from the blood of healthy rams that have been inoculated with gradually increasing quantities of the most virulent strain of gonococci obtainable. It is not offered as a substitute for well established germicides in the treatment of acute gonorrhea, but as being of probable service in the sequelæ and complications of gonococcic infection—as orchitis, epididymitis, teno-synovitis, and in particular gonorrheal arthritis. See Gonococcus Infection.

ANTILITHICS AND LITHONTRIPTICS.—Agents which are supposed to promote the solution of concretions in the excretory passages (lithontriptics) or to prevent their formation (antilithics.) These terms are generally restricted to remedies affecting the urinary calculi, but those directed against the biliary form are included here for the sake of consistent classification. The chief agents against *Biliary Calculi* are: ether and turpentine (Durande's solvent), sodium bicarbonate, sodium salicylate, sodium phosphate, castile soap, alkaline waters, especially vichy; against *Uric Acid Calculi* are: distilled water, potassium salts, lithium salts, magnesium citroborate, piperazin, lysidin, lycetol; against *Calcium Oxalate Calculi* are: dilute nitrohydrochloric acid, carbonated water, lactic acid (for digestion); against *Phosphatic Calculi* are: ammonium benzoate, benzoic acid, dilute nitric acid.

There is probably little or no solvent value to the agents recommended for biliary calculi. In the case of uric acid calculi the administration of *Potassium* or *Lithium Salts* is based on their power of combining with the acid in the calculus.

ANTIMENINGITIC SERUM. See Cerebrospinal Meningitis.

ANTIMENINGOCOCCIC SERUM. See Cerebrospinal Meningitis.

ANTIMONY.—Sb = 120; quantivalence, I, III, V. A nonmetal having a metallic luster.

Action.—Irritant, emetic, diaphoretic, expectorant, powerfully depressant to heart and nervous system. In large doses by the mouth, or if injected into the circulation, its effects are practically identical with those of arsenic, but vomiting is always a prominent symptom. This is due to its effect as a gastric irritant, and the intestine may possibly remain unaffected, as antimony is absorbed more slowly than arsenic and the larger portion of the poison may be gotten rid of by the violent emesis excited. The sweat, the saliva and the mucous secretion of the respiratory tract are increased. The prolonged use of the drug is liable to cause fatty degeneration of many organs. It is excreted into the stomach and intestine, in the urine, and also probably in the bile and milk.

Uses.—The use of tartar emetic is now almost entirely confined to diseases of the respiratory passages. When a free secretion of mucus has once been established, it should, as a rule, be discontinued. Also, on account of its depressant properties, it is not a suitable preparation for infants or very young children. When an emetic is required in acute inflammations of the respiratory tract, ipecacuanha is usually preferable. As a diaphoretic it has been largely supplanted by pilocarpin.

In **poisoning**, tannic acid, or any substance containing it, is the antidote. Opium, alcohol, ether, and other antispasmodics are physiologic antagonists. Demulcent drinks should be freely given. Alkalies and lead salts decompose tartar emetic.

Preparations.—Metallic antimony is not official, and is not used in medicine. It is represented, however, by the following official salt and preparations, viz.:

Antimonii et Potassii Tartras, *Antimony and Potassium Tartrate* (*Tartar Emetic*), $2KSbOC_4H_4O_6.H_2O$—small white crystals or a granular powder of sweet, disagreeable metallic taste, soluble in 17 of water at 59° F., and in 3 of boiling water, insoluble in alcohol. It is decomposed by alkalies, and by lead salts. Dose, 1/16 to 1/4 of a grain (average expectorant dose, 1/10 of a grain; emetic, 1/2 of a grain) but after tolerance is established as high as 2 grains may be given. It is an ingredient of the two following, viz.: **Vinum Antimonii,** *Wine of Antimony*—has of tartar emetic 4, boiling distilled water 65, alcohol 175, white wine to 1000. Contains about 2 grains of tartar emetic to the ounce, and is an ingredient of Mistura Glycyrrhizæ Composita. Dose, 5 to 20 minims. **Syrupus Scillæ Compositus,** *Compound Syrup of Squill, Cox's Hive Mixture, Hive Syrup* (see under Squill)—contains about 1 grain of tartar emetic to the ounce, with Squill, Senega, etc. Dose, 30 minims; should be administered cautiously to children.

Incompatible with *Tartar Emetic* are: Acacia, acids (mineral), albumin, alcohol, alkalies, ammonia, ammonium carbonate, antipyrin, bicarbonates, carbonates, calcium chlorid, gelatin, lead salts, lime-water, mercuric chlorid, metallic salts, sulphids, tannic acid, and astringent vegetable preparations.

In whooping cough:

℞. Antimony and potassium tartrate,	gr. ss
Tincture of opium,	♏ xx
Distilled water,	ʒ j.

A teaspoonful every, or every alternate, night.

An expectorant:

℞. Antimony and potassium tartrate,	gr. j
Powdered ipecac,	gr. x
Powdered opium,	gr. ij
Powdered licorice,	ʒ j.

Mix well and divide into 10 powders.

Or—

℞. Wine of antimony,	ʒ ij
Solution of ammonium acetate,	℥ j
Syrup of tolu,	ʒ vj
Water,	℥ iv.

Mix well and give a sixth part every 4 hours.

ANTINARCOTIC LEGISLATION.—For many years the use (and abuse) of narcotic drugs was untramelled by legal enactments. Within the last few years we have suffered from an overdose of legislation on the subject, so that now one hardly knows what his duty is in the matter. The different States have, of course, their own laws, and many cities have also their own enactments; and these laws and enactments are many and various. There should be one Federal law governing the whole subject. (See HARRISON LAW.) The multiplicity of laws (and the endless variety of interpretations of the same), and the restrictions and "red tape" which are imposed upon honest and reputable physicians and druggists, have proved burdensome in the extreme. It is hoped that *some good* has also been accomplished.

The very useful summary of the main features of the various State laws, on the following pages, was published in the *Medical World*, November, 1916.

ANTIPERIODICS.—Remedies that affect certain periodic febrile diseases, preventing paroxysms or lessening the severity thereof. They are so called because they tend to break up the periodicity of the attacks which are characteristic of the disease, and they probably arrest the development in the blood of successive crops of pathogenic organisms. The principal ones are the cinchona bark and its alkaloids (especially quinine), bebeeru bark and its alkaloid berberine, salicin, salicylic acid and the salicylates, arsenic, opium and its alkaloid narcotin, eucalyptol, iodin, and Warburg's tincture.

ANTIPHLOGISTICS.—Measures and medicines that are regarded as having some specific action in reducing, or in preventing the progress of, inflammatory processes. Opium and mercury are especially effective in inflammations of serous membranes, aconite and antimony in inflammations of the respiratory tract and organs, and veratrum viride in puerperal metritis.

The chief antiphlogistics are the following: Aconite, veratrum viride, tartar emetic, mercury, opium, gelsemium, digitalis, ergot, ipecac, potassium nitrate, rest (recumbent position), venesection, local depletion, purgation, counterirritation, cold. Antiphlogistics are nearly all contraindicated in the presence of tissues whose vitality is impaired through former diseased conditions. See INFLAMMATIONS.

ANTIPLAGUE SERUM.—See PLAGUE.

ANTIPNEUMOCOCCUS SERUM.—This serum has been used with success in some cases although in other cases disappointment is reported in spite of its alleviating many of the symptoms. The dose is 20 c.c. hypodermically every 4 to 6 hours while the temperature is above 103° F. See PNEUMONIA; PNEUMOCOCCUS INFECTIONS.

ANTIPYRETICS.—Agents or measures that reduce the body-temperature when abnormally high. This may be done by two principal methods as follows:

By lessening the production of heat, by	1. Diminishing tissue-change; 2. Reducing the circulation.
or	
By promoting the loss of heat, by . . .	3. Dilating the cutaneous vessels and producing increased radiation. 4. Producing perspiration and its evaporation. 5. Abstracting heat from the body.

The following list (Potter) contains nearly all the antipyretics, the number following each referring to its proper method of action, as previously enumerated:

Quinine.[1]	Trimethylamin.[2]	Alcohol.[1,3]
Quinidin.[1]	Salol.[1]	Digitalis.[2]
Cinchonin.[1]	Acetanilid.[1,4]	Aconite.[2]
Cinchonidin.[1]	Antipyrin.[1,4]	Camphor.[1]
Berberin.[1]	Acetpheneti-	Antimonials.[2,4]
Benzoic acid.[1]	din.[1,4]	Veratrin.[2]
Carbolic acid.[1,3]	Chinolin.[1]	Colchicum.[2]
Picric acid.[1]	Resorcinol.[1]	Leeching.[2]
Salicin.[1]	Kairin.[1,4]	Cupping.[2]
Salicylic acid.[1]	Kairolin.[1,4]	Blistering.[2]
Sodium salicy-	Hydroquinon.[1]	Poulticing.[2]
late.[1,4]	Thallin.[1,4]	Nitrous ether.[3,4]
Quinin salicy-	Pyrocatechin.[1]	Dover's powder.[4]
late.[1]	Phenoresorcin.[1]	Cold bath.[5]
Methyl salicy-	Eucalyptol.[1]	Cold drinks.[5]
late.[1]	Thymol.[1]	Ice to surface.[5]
(Oil of gaul-	Other essential	Cold sponging.[5]
theria).	oils.[1]	Wet-packing.[5]

Purgation and venesection produce antipyretic results, but their mode of action is doubtful (Brunton). The body-temperature is raised by belladonna (or atropin) and by cocain, but not to so great a degree as to constitute fever or enable them to be classed as pyretics. Tuberculin, various albumoses, and certain animal poisons, as that of shell-fish, will also produce a rise of temperature.

ANTIPYRIN.—$C_{11}H_{12}N_2O$. Phenyl-dimethyl-pyrazolon. Phenazonum. A crystalline substance obtained from phenyl hydrazin. It forms salts analogous to those of ammonium, and occurs as colorless and inodorous scaly crystals, with a bitter taste, freely soluble in water, alcohol, and chloroform, less so in ether. With ferric chlorid it gives a deep red color, a green one with nitrous acid, and a yellow color, deepening to crimson on warming with nitric acid. It is not irritant to the stomach or tissues and may be administered hypodermically. Antipyrin has little flavor, is not unpleasant, and is therefore readily given to children; in this respect it is far superior to quinin. Dose, about 4 grains; best given in aqueous solution with one-half its quantity of sodium bicarbonate.

Incompatibles.—Antipyrin may be decomposed when brought into contact with nitrous compounds, a new and poisonous substance being supposed to be formed, of uncertain composition, but resembling the anilin greens. The mixture of this drug with spirit of nitrous ether is, therefore, highly

DIGEST OF STATE ANTINARCOTIC LAWS

State.	Prescription Required.	Dispensing Permitted.	Exemptions to Law.	Record Required.	May Treat Addicts	Refilling Prescription Prohibited.	Possession by Laity Prohibited.	
Alabama	Yes		Yes					
Alaska	Opium only.							Sale to addicts prohibited. Cause of revocation of license of druggist.
Arizona	Yes		Yes	Yes	Yes		Yes	After three weeks administration of narcotics consultation required and report names, etc., to health officer of town.
Arkansas	Yes							
California	Yes		Yes	Yes	Yes		Yes	Report habitues treated within twenty-four hours to Board of Pharmacy. Addicts may be committed.
Colorado	Yes	Yes	Yes	Yes exc. "personally attend."			Yes	Sale to addicts prohibited. Revocation of license if convicted of illegal dispensing.
Connecticut	Yes	Yes	Yes	Yes exc. "personally attend."	Yes	Yes		Revocation of license of addicts.
Delaware	Yes		Yes					Narcotic sold must be labeled. Forbidden to sell except to sick.
Dist. of Columbia	Yes		Yes					
Florida	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Health officer may prescribe for addicts. All physicians send to City Board of Health within three days of each narcotic prescription. Report to Board of Health or county judge if patient will not persist in treatment. Incurables may have prescription narcotic after investigation by Board of Health or judge. Revocation of license.
Georgia	Yes		Yes					
Hawaii	Yes							Treatment of addicts provided for.
Idaho	Yes	Yes	Yes					Practitioners convicted of violating law made ineligible to continue practice.
Illinois	Yes	Yes	Yes	Yes exc. "personally attend."		Yes		
Indiana	Yes	"Administering" instead of dispensing in law.	Yes					
Iowa	Yes							Law refers to cocain, cotton root, ergot, tansy, savin.
Kansas	Yes							Morphin, cocain and chloral.
Kentucky	Yes		Yes					
Louisiana	Cocain only.							
Maine	Yes	Yes	Yes	Yes within 48 hours.	Must not prescribe to addicts.		Yes	
Maryland	Yes		Yes				Yes	
Massachusetts	Yes	Yes	Yes	Yes	Yes	Yes	Yes	
Michigan	Yes	Yes	Yes					
Minnesota	Yes	Yes	Yes	Yes			Yes	
Mississippi	Cocain only.						Yes cocain	
Missouri	Yes		Yes		Only "for immediate preservation of life."			Opium smoking houses forbidden.

ANTINARCOTIC LEGISLATION

Montana	Yes		Yes		Yes			
Nevada	Yes	Only by pharmacist.	Yes		Yes			Copies of all orders for narcotics must be mailed to Board of Pharmacy within twenty-four hours.
Nebraska	Yes				Yes Record kept and copy filed with county attorney within five days.	Yes		
New Hampshire	Cocain						Yes	
New Jersey	Yes	Yes						Sale prohibited.
New Mexico	Yes	Yes	Yes					
New York	Yes Copy given to purchaser; verification needed if amounts over four grains morphin, etc. Prescription for hypodermic syringe.	Yes	Yes				Yes	Restricts amount in drug stores. Druggist prohibited from filling prescriptions of dentists and veterinarians for own use. Copy of prescription to be given to patient by druggist. No copy of physician's prescription to be given except the amount be less than 1 gr. to f ℥ or 2 gr. to 1 ℥ ointment, in which case a certificate is given showing the amount. Revocation of license. Limit of quantity allowed on hand.
North Carolina	Yes							
North Dakota	Yes				No		Yes	
Ohio	Yes		Yes				Yes	
Oklahoma	Yes		Yes					Teach narcotic effects in public schools.
Oregon	Yes		Yes				Yes	Pharmacy law: Unlawful for any person to manufacture, sell or dispense any drugs . . . unless such person be a registered pharmacist.
Pennsylvania	Cocain only.						Yes	
Philippines							Yes	Prescription for patient who does not need narcotics; cause for revocation.
Rhode Island	Yes		Yes				Yes	
South Carolina	Cocain only.						Yes	
South Dakota	Yes	Yes	Yes	Physicians must keep duplicate of narcotic ℞.			Yes	Quantity of cocain, etc., limited. Cocain can only be dispensed in liquid form. 5 percent limit.
Tennessee	Yes	Yes	Yes	Duplicate prescription of narcotic dispensed.			Yes	Quantity of cocain, etc., restricted. Cocain can only be dispensed in liquid form. 5 percent strength.
Texas	Yes		Yes					
Utah	Yes	Yes	Yes	Yes	Yes Report in 24 hrs. to State Board of Pharmacy.		Yes	
Vermont	Yes	Yes	Yes	Yes				
Virginia	Yes Yes for hypo. syr.	"Admin." perm.	Yes		Yes, Sanit. May prescribe ad lib. but copy of ℞ must be sent to Board of Health in 24 hours.			Limit of amount prescribed: 16 gr. opium, 8 gr. morphin, 8 gr. heroin, 8 gr. cocain, 8 alpha eucain, 8 gr. beta eucain, 1 oz. laudanum in 48 hours.
Washington	Yes		Yes					
West Virginia	Yes		Yes				Yes	
Wisconsin	Yes							Quantity limited.
Wyoming	Yes	Yes			Yes			Any administration or prescription of narcotic in excess of quantity in law shall report within five days to State Board of Health.

ANTINARCOTIC LEGISLATION

dangerous if this supposed reaction is at all likely to occur.

Incompatibles are: Alum, ammonia-water, amyl nitrite, benzoates, beta-naphtol, bromin, butyl-chloral hydrate, calomel, chloral hydrate, copper sulphate, chromic acid, cinchona alkaloids, euphorin, ferric chlorid, ferric salts in solution, ferrous sulphate, hydrocyanic acid, iodin, iodids, lead subacetate, mercuric chlorid, nitrites, orthoform, phenol, potassium permanganate, pyrocatechin, pyrogallol, resorcin, sodium bicarbonate, sodium salicylate, spirit of nitrous ether, tartar emetic, tannic acid, thymol, urethane; also tinctures of catechu, cinchona, hamamelis, iodine, and rhubarb; and infusions of catechu, cinchona, rose-leaves, and uva ursi. Antipyrin and euphorin liquefy when rubbed together.

Physiologic Action.—Antipyrin is a powerful antipyretic, a local anesthetic, and a general analgesic, and also possesses diaphoretic, mydriatic antiseptic, disinfectant, hemostatic, and slight hypnotic powers. After the ingestion of a full medicinal dose (20 grains), there is a stimulant stage of short duration, in which the heart's action is increased, and a subjective sense of heat is experienced, with flushing of the face. This is soon followed by profuse sweating, coldness of the surface, slowed pulse, considerable depression, and, if fever is present, a lowered temperature.

Therapeutics.—Antipyrin performs three important functions: (1) It lowers temperature; (2) it allays pain; (3) it checks convulsions and manifestations of motor excitation. It is more used to allay pain than for any other purpose. It is valuable in nervous headache, migraine, neuralgia, dysmenorrhea, locomotor ataxia crises, seasickness, neuralgia, sciatica, and lumbago, hypodermically. It is next in importance to the bromids in idiopathic epilepsy, is particularly of value in whooping-cough, and is useful in chorea and bronchial asthma. Antipyrin is used locally as a sedative, moderate analgesic, and hemostatic. It is a valuable adjunct in the treatment of nasal catarrh. It has been used with calomel on corneal opacities. Large doses are followed by marked cyanosis, dyspnea, and collapse, and various skin lesions may follow its continued administration. These symptoms usually pass off upon the application of external heat and the free use of stimulants.

In epilepsy:

℞. Ammonium bromid, ʒ j
Antipyrin, ʒ j
Solution of potassium arsenite, ʒ j
Peppermint water, enough to make, ʒ vj.

Mix into a solution and give a teaspoonful in water night and morning.

ANTIPYRIN SALICYLATE.—See Salipyrin.

ANTISEPTIC AND ASEPTIC SURGERY.—A thorough exposition of this subject is contained in the article on Abdominal Section.

ANTISEPTICS AND DISINFECTANTS.—Antiseptics are agents which arrest the development of the microorganisms which produce decomposition. In stronger solutions than those required for their antiseptic action, most of the antiseptics are germicidal and are therefore disinfectants; but all disinfectants are antiseptics. The chief antiseptics are named in the following list, the figures giving the minimum strength of their effective solutions, though these figures cannot be applied to all bacteria and their spores indiscriminately:

Mercuric chlorid, 1:50,000
Mercuric iodid, 1:40,000
Formaldehyd, 1:25,000
Silver nitrate, 1:12,500
Aluminum acetate, 1:6000
Creolin, 1:5000
Chlorin, 1:4000
Creosote, 1:3000
Naphthol, 1:3000
Copper sulphate, 1:2000
Pyoktanin, 1:2000
Bromin, 1:1666
Thymol, 1:1500
Salicylic acid, 1:1500
Eucalyptol, 1:1000
Hydrogen dioxid, 1:1000
Calcium hypochlorite, 1:1000
Trikresol, 1:1000
Benzoic acid, 1:900
Sulphuric acid, 1:800
Quinine sulphate, 1:80
Zinc chlorid, 1:500
Phenol, 1:333
Alcohol (absolute), 1:333
Potassium permanganate, 1:300
Acetic acid, 1:250
Alum, 1:222
Ferrous sulphate, 1:200
Coffee (freshly roasted) 1:200
Arsenic trioxide, 1:166
Boric acid, 1:143
Hydrated chloral, 1:107
Resorcinol, 1:100
Antipyrin, 1:25
Calcium chlorid, 1:25
Zinc sulphate, 1:20
Sodium borate, 1:14
Potassium bromid, 1:10
Potassium iodid, 1:10
Ammonium chlorid, 1:9
Sodium chlorid, 1:6
Glycerin, 1:4

The best antiseptics for surgical use are those which act sufficiently on microorganisms without injuring or irritating the tissues. The *Mercuric Salts* are very poisonous. *Chlorin*, *Bromin*, and *Iodin* are too irritant. *Benzoyl-acetyl peroxide*, though actively germicidal, has no antiseptic power on account of its proneness to break up in the presence of organic substances (Novy). *Salol* is of little value but the products of its decomposition in the intestines are active germicides, and it is one of the best intestinal antiseptics (Wood). *Benzoic Acid* and *Naphthol* are good intestinal antiseptics, but complete asepsis in this situation is impossible.

Disinfectants are agents which destroy the specific germs of infectious diseases. Many antiseptics do not possess germicidal power, and therefore are not disinfectants; but all disinfectants are antiseptics. Disinfectants act in several ways, some as oxidizants, others by combining with albumin, others by chemical combination forming substitution-compounds, others by arresting molecular changes, and still others by altering the reaction of the media containing the germs. The principal disinfectants are named in the following list, the figures following each giving the strength of its aqueous or aerial solution necessary for rapid and certain action:

Fire, the most efficient.	Chloretone, 1:100
Heat, moist, at 212° F.	Calcium hypochlorite, 1:100
Heat, dry, at 302° F.	Eucalyptol, 1:100
Benzoyl-acetyl peroxid, 1:1000	Creolin, 1:100
Mercuric chlorid, 1:1000	Lysol, 1:100
Iodin, 1:500	Trikresol, 1:50
Bromin, 1:500	Phenol, 1:33
Benzoic acid, 1:250	Sulphurous acid, 1:25
Salicylic acid, 1:200	Liq. Sodæ chlorinatæ, 1:20
Formaldehyd, 1:100	Ferrous sulphate, 1:20
Hydrogen dioxid, 1:100	Acetic acid, 1:134
Potassium permanganate, 1:100	Lime, fresh, 1:4
Chlorin, 1:100	Zinc chlorid, 1:2

Many good disinfectants are not available by reason of cost or some side action, as hydrogen dioxid, bromin, iodin, potassium permanganate. *Formaldehyd* is the best surface disinfectant, but has slight penetrating power. It has the advantage of being nontoxic and not retarded in action by albuminoid matter. *Sulphurous Acid* is of very doubtful value, even when present to the extent of 10 percent in moist air (Koch). *Chlorin* is used rather as a deodorant than a disinfectant, its germicidal power being uncertain (Munson). *Burnett's Fluid* is a 50 percent solution of zinc chlorid, and equivalent to the official Liquor Zinci Chloridi. *Labarraque's Solution* is the same as the official Liquor Sodæ Chlorinatæ. Both these preparations depend for their efficacy upon the amount of free chlorin which they give out. *Condy's Fluid* is a 2 percent aqueous solution of potassium permanganate; and though a good antiseptic and deodorant, it is practically useless as a disinfectant, being constantly expended in oxidizing the organic matter of the infective substance, and would be required in enormous and impracticable quantities (Davies).

The popular idea of disinfecting *the air* of a room by burning sulphur, etc., is an absurdity, because foul air is easily removed by simple ventilation. In disinfecting a room in which there has been a case of contagious or infectious disease, the true aim is to kill the germs contained in the dust on ledges, in the crevices between the boards, or adhering to the walls, and a dry gas is powerless for this purpose, which is best accomplished by using a *Corrosive Sublimate Solution* of the strength of 1:1000; or by *Lime* washing, provided that the lime be freshly burnt, and caustic; or by spraying with *Formalin*, or by dropping the latter on hot plates or sheets of hot metal (Potter). See Disinfection.

ANTISIALAGOGS.—Remedies or medicines that are effective against salivation. Atropin is the principal agent of this class, acting by paralyzing the terminations of the nerves of secretion. Physostigma counteracts this paralysis, but acts as an antisialic by lessening the blood supply to the glands. Opium diminishes the reflex excitability of the reflex center and also diminishes the secretion. Others acting locally are: Borax, potassium chlorate, soda, lime, lithia, magnesia, insipid or nauseous articles of food or medicine.

ANTISPASMODICS.—Agents that prevent or allay spasm of voluntary or involuntary muscles in any portion of the organism. Some of the agents belonging to this class act by stimulation of the higher nervous centers, the coordinating power, and the circulation, as alcohol and ether in small doses, camphor, musk, valerian, etc.; others by depressant influence on the motor centers, as the bromids, and still others by paralysis of the end organs of the vasomotor nerves, as amyl nitrite. A few depress all the vital functions, as aconite, tobacco, lobelia, hellebore, and prussic acid; and many stimulate the bowels to expel gaseous accumulations; namely: asafetida, cajuput, valerian, musk, aromatic oils, etc.

The principal antispasmodics are: Alcohol, ether, paraldehyd, chloroform, amyl nitrite, nitrites, bromids, potassium iodid, potassium nitrate, arsenic, valerian, conium, aconite, lobelia, tobacco, hellebore, opium, belladonna, stramonium, hyoscyamus, hydrocyanic acid, physostigma, curare, ammoniac, castor, musk, galbanum, sumbul, ipecacuanha, senega, silver salts, zinc salts, copper salts, asafetida.

Potassium bromid is the most powerful antispasmodic in such convulsive diseases as epilepsy, laryngismus stridulus, and infantile convulsions; valerian, asafetida, and the bromids, in hysteria; arsenic, copper, conium, and zinc, in chorea; lobelia and stramonium, in spasmodic asthma, nitrite of amyl in spasm of the blood-vessels.

The indications for the administration of antispasmodics are chorea, whooping-cough, epilepsy, asthma, delirium tremens, hiccough, hysteria, nervous excitability, and neurasthenia.

ANTISTAPHYLOCOCCUS SERUM.—See Staphylococcus Infection.

ANTISTREPTOCOCCUS SERUM.—A serum originally obtained by Marmorek from injecting the streptococcus and products into the horse. It has been used to combat all conditions caused by the streptococcus, although the reports of success are variable. See Streptococcus Infections.

ANTISYPHILITIC.—A remedy directed against, or used for the relief of, syphilis. Usually an Alterative (*q. v.*). See also Syphilis.

ANTITETANIC SERUM.—See Tetanus.

ANTITHYROID PREPARATIONS.—The blood or milk of animals whose thyroid glands have been removed has proved effective in the treatment of exophthalmic goiter of the mild type, and of obscure nervous disorders which are apparently dependent upon thyroid hypersecretion. *Antithyroidin.* Dose, 8 to 15 minims by mouth three times a day, gradually increasing as necessary. *Thyreoidectin.* Dose, 5 to 10 grains in capsule form three times a day. See Thyroid Treatment.

ANTITOXIN.—See Diphtheria Antitoxin, Serum Therapy and Vaccine Therapy.

ANTITYPHOID SERUM.—See Typhoid Fever.

ANTIVENIN.—A term given to the blood-serum of animals rendered immune against snake-poison, on account of its antidotal properties. Calmette's is the recognized serum for serpent bites and has been used successfully in many cases. It is of

decided value in all forms, but especially against cobra venom. It has been employed in cases of leprosy with excellent results. The dose is 20 to 40 c.c. repeated frequently in conjunction with other measures, *e. g.*, ligature above the wound which should be laid open, well sucked and surrounded by injections of an aqueous solution of calcium chlorid. See Bites and Stings, Serpent Venom.

ANTIZYMOTICS.—Agents preventing the process of fermentation; antiferments. They are usually subdivided into Antiseptics and Disinfectants (*q. v.*). See Fermentation.

ANTRUM.—See Jaws, Nose.

ANURIA.—See Urine (Retention, Suppression.)

ANUS, FISSURE.—A small, painful crack or ulcer, usually situated just within the anus, and seldom involving more than the skin or mucous membrane.

Causes.—Almost always constipation; sometimes neglect of local cleanliness or other source of irritation. The passage of unusually hard feces is often the immediate exciting cause. When the ulcer is once thoroughly established, healing is prevented by the action of the sphincter and the irritation of its surface during defecation.

Symptoms.—The chief of these is pain, the result of spasm of the sphincter. It is often very severe, and occurs during and after defecation. It may last for a few minutes or longer, even for several hours, and then cease until the next stool. The pain may not only be felt in the anus, but may be reflected down the thighs or to other parts, as the uterus, vagina, or testicles. The stools are often slightly streaked with blood, sometimes with pus. On examination, the sphincters are found spasmodically contracted. On gently everting the margins of the anus, the end of the ulcer will be discovered usually at the posterior part, a small, external pile or edematous fold of skin that is generally present then serving as guide to it. The insertion of the finger is attended with great pain.

Treatment.—In mild cases the use of laxatives and the application of astringent lotions or sedative ointments before and after defecation may be sufficient.

Allingham recommends the following ointment:

℞.	Calomel,	gr. iv
	Powdered opium,	gr. ij
	Extract of belladonna,	gr. ij
	Ointment of elder flowers,	ʒ j.

Tuttle insufflates a small quantity of anesthesin upon the surface of the ulcer and after a few minutes applies a few drops of pure ichthyol on a pledget of cotton. These applications are made every second day. The results are said to be excellent except in cases in which the sphincter is hypertrophied, hard, and spasmodically contracted, or the ulcer deep and indurated, and especially when the fibers of the sphincter are exposed. For the relief of spasm as well as of the pain sometimes produced by the ichthyol, an ointment composed of equal parts of the official ointments of stramonium, belladonna, and hyoscyamus is very efficacious.

If these fail, the sphincter may be forcibly dilated, or the ulcer measures divided together with half or more of the external sphincter by drawing a straight bistoury longitudinally through the base of the ulcer. The bowels should then be kept confined for 4 or 5 days, and the stools afterward kept soft for a fortnight or longer; or the sphincter may be divided subcutaneously by passing a tenotomy knife beneath it through the mucous membrane and cutting outward toward the skin. Ball treats these cases by cutting off a small pile at the end of the fissure. This simple operation, and that of the subcutaneous division of the sphincter, may be done without pain by painting the mucous membrane with cocain or spraying it with chlorid of ethyl, and does not necessitate the patient's lying in bed for more than 2 or 3 days.

Irritable sphincter of the anus, when independent of fissure or ulcer, is a serious source of trouble in defecation, since the power of the bowel is insufficient to overcome the impediment caused by the contracted muscle. It is generally found in hysteric females. It is relieved by mild laxatives, the local application of cocain, or an opiate ointment, and the occasional passage of a bougie coated with a sedative ointment.

ANUS, FISTULA.—By fistula, in the general sense of the term, is meant a sinus in the vicinity of the anus, left by an abscess that has healed up to a certain point, and then either remained stationary or grown worse. It may be complete, with one opening in the bowel and the other on the skin; or incomplete, the internal or the external opening only being present. The former of these is known as a blind internal fistula, the latter as a blind external one. In point of importance, fistulas may be divided into anal and rectal. The former merely occur near the margin of the anus, and are either entirely subcutaneous or are merely covered in by some of the fibers of the external sphincter; the latter are larger and deeper, running from the ischiorectal fossa, between the sphincters, or even above the internal one, and are often complicated by sinuses under the skin or in the submucous tissue.

The causes of fistulas are essentially those of the abscesses that give rise to them: injury to the mucous membrane, from fish-bones or other foreign bodies; tuberculous deposits; stricture; extravasation in the loose fatty tissue of the ischiorectal fossa; inflamed hemorrhoids; cutaneous boils, etc. The cause of their persistence is to be found in the mobility of the part, the spasmodic contraction of the sphincter and the levator ani, and, if there is an internal opening, the constant entrance of irritating substances from the bowel. Blind internal fistulas are the most rare, complete ones by far the most common, although it is sometimes a little difficult to find the internal opening. Probably, most are incomplete at first, but the second opening is soon formed; the abscess, as it enlarges, works its way simultaneously toward the bowel and the skin, and unless it is opened early, the mucous membrane is separated from the subjacent tissue to such a degree that it gives way by ulceration even after the pressure of the pus is relieved.

A fistula may be either a straight passage from the skin to the bowel, or it may be complicated by sinuses running from it in every direction. The most common of these is in the submucous tissue; the internal orifice is nearly always on a level with the internal sphincter, seldom more than an inch or an inch and a half from the anus; but sinuses may run up from this under the mucous membrane for several inches. More rarely, instead of taking this direction it passes round the bowel, causing what is known as a *horseshoe fistula*, and opening sometimes on one side, at others on both. In other cases, especially when there is a stricture of the rectum, these offshoots extend under the skin of the buttock, and open several inches away.

The walls of a recent fistula are covered with granulations, and secrete a thin, purulent fluid; after repeated attacks of inflammation they become thick and dense, the lining smooth and glistening, like the surface of a chronic ulcer on the leg. The external orifice may be the size of a pinhole or lie in the center of a little button-like mass of granulations; or, in tuberculous patients and after the rupture of a chronic abscess, there may be a large, irregular opening with undermined edges, like a scrofulous ulcer on the neck. The internal orifice presents very much the same character; at times it feels like a distinct papilla resting on the base that is firmer than the surrounding parts; on the other hand, especially in the case of blind internal fistula, it may be a large, irregular ulcer.

Symptoms.—So long as there is free exit for the discharge, fistulas merely give rise to inconvenience and discomfort. The skin around the anus is constantly moist, the surface becomes tender and eczematous, and little cutaneous boils are likely to form. In the worst cases there may be an escape of feces and flatus through the orifice, but there is never the agonizing pain of fissure. Now and then the orifice becomes obstructed; the discharge collects; the skin becomes hot and red and tender; the action of the bowels is attended with pain, and a small abscess forms. When this breaks or is opened, the symptoms subside again, but at each recurrence there is either an increase in the density of the tissues around or the formation of an outlying sinus.

Diagnosis.—There is rarely any difficulty in this; the patient is usually aware of the cause of his suffering; and the presence of a small orifice by the side of the anus, from which a drop or two of thin semipurulent fluid can be squeezed, is conclusive. It is necessary to ascertain the kind of fistula; whether it has an internal opening, and where it is; whether there are many sinuses in connection with it, and where they run; and, particularly, whether there is any cause for its persistence other than the action of the sphincter and the mobility of the part. There may be, for example, a stricture of the rectum, high up, and a complete fistula with its internal orifice in the usual situation near the anus; or, what is even more perplexing, there may be a complete fistula and necrosis of the sacrum or coccyx at the same time; the diseased bone has caused the formation of an ischiorectal abscess, and this has led to the development of a fistula. Of course, in any of these cases an operation upon the fistula alone is worse than useless.

The patient should lie upon a couch, on the affected side, with the knees drawn up. In most cases the orifice of the sinus is visible at once, but sometimes it is very small, concealed behind folds, or may be closed for the time being. If it cannot be seen, the induration can nearly always be felt, even when the fistula is a blind internal one, and very often slight pressure causes a drop of pus to exude. Sometimes the whole track of the sinus can be made out with the finger.

When there is an opening, a probe may be gently passed into it before anything further is done, in the hope that it may succeed in reaching the internal orifice without exciting the action of the sphincter. Usually, the sinus runs almost under the skin toward the bowel. If this does not succeed, the finger must be introduced and the mucous surface carefully explored just inside. Generally there is no difficulty in feeling the opening; if, however, it cannot be found, a speculum may be used, or some milk or other colored fluid is injected into the orifice; nearly always some of it finds its way into the bowel. It is a common mistake to pass the finger in too far at first and overlook the opening.

Blind internal fistulas differ from the others. They usually communicate with the bowel by an aperture of some size; and from the fact that fecal matter is constantly entering and setting up inflammation, they are very often attended with a good deal of pain. There is no discharge externally, but the patient is usually aware of a swelling by the anus emptying itself every now and then into the bowel with temporary relief. Digital examination nearly always reveals a hard and painful mass in the ischiorectal fossa, and often an irregular ulcer of considerable size in the bowel. Occasionally, the sac can be emptied by pressure; but to make the diagnosis certain, a probe bent like a hook must be passed down into the sinus through the anus. Fistulas of this kind are usually caused by a foreign body perforating the mucous surface of the bowel, or by the softening of some tuberculous deposit in the wall.

Treatment.—As a rule, fistulas can only be cured by operation. In exceptional cases in which there is no internal opening and in which the patient will submit to prolonged treatment, the sphincter may be stretched, the sinus stimulated with strong carbolic acid or tincture of iodin, and the external orifice kept widely open in the hope that it will close; but it nearly always ends in failure, after a long waste of time. The only method that is reliable is division of all the structures between the fistula and the anus, so as to lay it open from one end to the other and give it complete rest.

An aperient is given the night before, and an enema the morning of the operation. The patient is placed under an anesthetic, and laid on the affected side, close to the edge of the table, with the knees well drawn up and held by an assistant, who also raises the upper gluteal fold. The sphincter is gently dilated, and a director passed from the external orifice along the sinus into the bowel. Care must be taken to bring it out at the internal

opening and not make a fresh one, except in the case of a blind external fistula. Then the point of the director is brought out through the anus, so that the structures to be divided are stretched over it like a bridge, and a clean incision made through them with a sharp-pointed bistoury.

If this cannot be done, the finger is introduced into the bowel, a blunt-pointed bistoury passed along the director until its end can be felt coming through the orifice, and then, after withdrawing the director, the finger and the bistoury are brought out together so as to divide with one sweep all the structures that lie between them.

After this, exploration must be made for outlying sinuses. A submucous one may be laid open with a pair of blunt-pointed scissors; or if, from its position, there is any risk of serious hemorrhage, an elastic ligature may be passed through it by means of a suitable probe and tied as tightly as possible. Those under the skin are treated in the same way; or if they are of great length, a drainage-tube may be passed along them and brought out through an incision at the other end. If one is overlooked, an abscess is almost sure to form before the wound is healed, and render a second operation necessary In case of old fistulas lined with a smooth layer of false mucous membrane, the walls must be scraped thoroughly with a sharp spoon, so as to insure removal of all the indurated mass. Polypoid outgrowths and hemorrhoids are dealt with at the same time, and loose and undermined flaps of skin are cut away, though discretion is necessary.

Any bleeding point is tied or twisted at once, the wound packed with iodoform gauze, and a firm pad placed over the anus and secured in position with a T-bandage. The following day all external dressings are removed, and the deeper layer allowed to separate in a bath. The wound is cleansed night and morning and after each defecation, pain being prevented by cocain, and a single fold of lint laid between the edges. The application should be varied from time to time, according to the state of the granulations. The bowel should not act for 4 or 5 days after the operation, and the stools should be kept soft until the wound is perfectly sound. The recumbent posture is essential until healing is completed, although it is not necessary for the patient to be kept in bed for more than a week or ten days.

Moullin has succeeded in obtaining union by first intention by thoroughly refreshing the base of the sinus after the sphincter had been divided, and bringing the surfaces together in accurate contact with deep wire sutures. It is necessary, however, to move them at the first sign of suppuration, or secondary sinuses may form. Buried catgut sutures would probably answer better; but this can only be tried when the fistula is recent and simple in character, and when the patient is young and healthy.

In cases in which there are deep sinuses, when there is much reason to fear hemorrhage, or when the patient is exceedingly nervous, an elastic ligature may be used to divide the tissues gradually. It should be a solid cord, passed through from the bowel into the sinus, drawn as tightly as possible, and secured by means of a leaden clamp. Generally, it cuts through in from six days to a fortnight, and without pain; but sometimes it is followed by serious inflammation, and if there are any secondary sinuses present—and it often happens that this cannot be determined until the fistula is laid open—it is almost sure to fail. The length of time the wound takes in healing is approximately the same as follows other methods of division.

Incontinence of feces is always present for two or three weeks after the operation, and inability to control flatus for some time longer; but if the sphincter is divided at right angles and in only one place, there is seldom any permanent loss of power. According to Allingham, it is fairly safe if ever so narrow a ring of the upper part of the band of the internal sphincter is left. An exception, however, must be made in the case of anterior fistulas in women; the sphincter vaginæ and the sphincter ani decussate in the perineum, and the free incision through the front part of the anus is not unlikely to be followed by incontinence. In these cases it is well to apply the actual cautery freely to the old cicatrices, and to the external and internal sphincters as well, in several places, so as to narrow the orifice of the anus by the subsequent contraction; it is said that the muscular fibers, which are always very much degenerated, soon regain a considerable degree of their former power. Phthisical patients are exceedingly liable to fistula, but except in cases of extreme exhaustion, operation is advisable.

ANUS, IMPERFORATE.—See RECTUM (Abnormalities).

ANUS, PRETERNATURAL.—A term used for cases in which the aperture of the bowel communicates directly with the surface of the body, the escape of feces being direct and not through a fistula. Three varieties exist: (1) Congenital; (2) accidental; and (3) acquired. The first variety is limited to cases in which Meckel's diverticulum opens at the umbilicus. It may persist for years after birth. The opening is small, and generally closes spontaneously with the umbilical cicatrix. The second variety results from a wound, perforating ulcer, or gangrene, usually following strangulated hernia, and is the usual form of artificial anus. The third variety is the result of surgical operations upon the intestines, purposive or accidental.

Treatment of an artificial anus requires protection of the skin surrounding the opening, by painting with collodion, or by constant oiling with simple ointment or vaselin. Wearing a receptacle and protecting or guiding the escaping feces into this by means of a thin india-rubber tissue may be tried. As a rule, the patient will construct some sort of pad to receive escaping feces. Scrupulous cleanliness is imperative. The general health is to be maintained, and opium administered to check inordinate movements of the intestines. Constipation is to be prevented when the opening is into the colon, and the stools kept soft. Pressure by means of a truss or disc fixed over the fistula may bring about a spontaneous cure in mild cases. The difficulty is from the spurs or buttresses of

the opening, which refuse to heal. An india-rubber tube inserted into the two ends of the bowel has allowed the elastic pressure to overcome this and maintains the passage of the intestine free. Caustic measures to overcome this éperon are usually of little avail. Of the radical measures for the cure of an artificial anus, Denonvilliers' operation, Dupuytren's operation, and resection of the intestines have been employed. The last is an improvement upon the uncertain and tedious and ever-dangerous operation of Dupuytren, and its risks are more capable of being estimated, and, hence, guarded against.

Gangolphe counsels the employment of peritoneal incision and enterorrhaphy in cases of preternatural anus. There are, he points out, two methods of dealing with this condition: In one the surgeon works from without inward in the immediate neighborhood of the opening and, after gradual dissection, exposes the two extremities of the divided intestine, and draws these outward; in the other, the peritoneal cavity is opened by an incision made through the abdominal wall at some distance from the false anus. The latter method possesses many advantages. It is rapid, and the surgeon, without dread of wounding any important organ, cuts directly into the abdominal cavity. It is certain, as the finger introduced into the abdomen can explore the structures in the immediate neighborhood of the false anus, and guides the scissors or other cutting instruments by which the perforated portion of the intestine is set free. It permits free exposure and complete isolation of the structures submitted to operation. The risks of infection are diminished, and the manipulations of the surgeon facilitated by the free exposure of the perforated or divided portion of intestine. It is applicable to every case of false anus, and is likely to prove successful when the former method has failed. Gangolphe gives a description of his operative method, which, with variations in detail to meet special circumstances, he has practised with complete success in three instances. The first stage consists in making an oval incision about the false anus extending through sound skin and other layers of the abdominal wall as far as the peritoneum. This membrane is now incised at the upper wall so as to permit the introduction of the finger into the peritoneal cavity for the purpose of exploration. The extent of the adhesions of the intestine to the abdominal wall having been determined, the oval portion of abdominal wall formed by the first incision is set quite free, and the divided portion of the intestinal canal is freely exposed. The subsequent stage of the operation will depend on the size of the false anus and the extent of the intestinal adhesions. If the opening is small and involves only a portion of the circumference of the gut, it may be closed by lateral suture after excision of surrounding callous tissue. If there is much loss of intestinal structure and a spur has formed at the seat of the false anus, the author would set free both ends of the intestine, and then bring them together either by circular suture, Murphy's button, or Laplace's forceps. The last two methods are indicated in any case in which the patient cannot tolerate a long operation, and when the surgeon is inexperienced in the application of intestinal sutures, or is operating under unfavorable conditions. In cases of extensive adhesions it would be necessary, after apposition by suture or button at the ends of the intestine, to separate the loops of intestine from one another and from the abdominal wall by very careful dissection, and after closure of the external wound to drain the seat of operation. See Intestines (Surgery).

ANUS, PROLAPSE.—See Rectum (Prolapse).

ANUS, PRURITUS.—Itching about the anus, though often dependent upon local conditions, may occur without apparent cause. Such cases have been attributed to gout or disordered digestion. Eczema, hemorrhoids, and condylomata are fruitful sources of pruritus. Drinking milk in large quantities daily has been a cause.

Symptoms.—The itching is often intolerable, and is made worse when the patient is warm, as when in bed. If local causative conditions are present, they will be readily detected.

Treatment is directed to the removal of the cause, such as thread-worms, fissures, ulcers, pediculi pubis, hemorrhoids, etc. If the condition is an expression of a well-marked neurosis, arsenic, quinin, phosphorus, tonics, salicylates, antipyrin, or acetanilid should be given. The general health must be improved and the bowels closely looked after, and local treatment to allay the irritability of the peripheral nerves given. Cocain gives short relief and morphin suppositories with or without belladonna, often aggravate, although they may temporarily relieve, the itching. A small plug of wool or a simple wad of cotton inserted into the rectum may prove effectual.

An ointment consists of:

℞.	Carbolic acid or creosote,	ʒ j
	Camphor,	ʒ j
	Lard or vaselin,	ʒ ij.

When ointments do not give relief, benefit may be obtained by dusting freely the parts in the neighborhood of the anus with carbonate of bismuth. Lotions are seldom successful. This lotion may be tried, viz.:

℞.	Boroglycerid,	ʒ j
	Peppermint water,	ʒ xx.
Mix well.		
℞.	Chloral hydrate,	ʒ ij
	Rose-water,	ʒ x.

Friction and scratching must be avoided. Given at bedtime, a small enema of from 3 to 5 ounces of cold water will often act well. The constant current may give marked relief.

Cotton-wool may be used after defecation in the place of paper.

Before retiring, the patient may apply very hot water to the parts, dry them, and apply frequently a mixture containing—

℞.	Chloral,	ʒ j
	Gum camphor,	ʒ ss
	Glycerin, Water, } each,	ʒ j.
Mix well.		

The "scarf skin" must be made to peel off by the use of iodin, pure carbolic acid, corrosive sublimate (gr. iv to ℥j of cosmolin), calomel (℥ij to ℥j of cosmolin), etc.

AORTA, ANEURYSM.

Varieties.—(1) Thoracic; (2) abdominal.

The arch of the aorta is divided by Gray into 3 parts: the ascending, the transverse, and the descending. The ascending portion is 2 inches in length, arising from the left ventricle, on a level with the lower border of the left third costal cartilage, behind the left edge of the sternum. It ascends obliquely upward to the right to the upper border of the right second costosternal articulation. The transverse portion commences at the upper border of the right second sternal articulation, and arching to the left and forward, passes in front of the trachea and esophagus to the left of the third dorsal vertebra. The descending portion extends downward to the left side of the fourth dorsal vertebra.

The thoracic aorta extends from the left lower border of the fourth dorsal vertebra, and ends in front of the body of the twelfth dorsal vertebra, at the aortic opening in the diaphragm.

The abdominal aorta begins at the aortic opening in the diaphragm, descends a little to the left side of the vertebral column, and terminates over the body of the fourth lumbar vertebra, where it divides into the two common iliac arteries.

Etiology.—This disease usually occurs in the male sex, after 40 years of age. Any disease that will cause degeneration of the arterial system is likely to bring it on. Gout, syphilis, alcoholism, and rheumatism often give rise to an aneurysm; occasionally, it results from sudden violent exertion.

Aneurysms may be (1) true, (2) false, and (3) arteriovenous.

The **true** aneurysm is one in which the sac is composed of only one coat of the blood-vessel.

The **false** aneurysm—or dissecting aneurysm—is one that dissects its way between the coats of the blood-vessels.

The **arteriovenous** aneurysm is one in which a localized dilatation of an artery (aneurysm) communicates with a vein.

According to **shape**, they may be divided into (1) fusiform, (2) vascular, and (3) cylindric forms.

The dilated blood-vessel is usually the result of arteriosclerosis, with a subsequent rapid degeneration causing a weakening of the wall of the blood-vessel, giving rise to the varieties previously mentioned.

Thoracic Aneurysm

Definition.—A localized dilatation of the thoracic aorta, the arch being the most frequent seat.

Etiology and Pathology.—Same as for aneurysms in general.

Symptoms and Course.—The mode of onset may be sudden, and generally without warning. Should the aneurysm be of sufficient size to press upon the adjacent bronchi, there will be a short, high-pitched, or "metallic" cough, often in itself diagnostic. Dysphagia and dyspnea may be common symptoms. Occasionally, there is a deep-seated pain over the affected area.

Physical Signs.—At times there is a bulging in the precordial region and visible pulsation on inspection, with a distinct thrill on palpation; localized dulness will be found on percussion, and a "bruit" on auscultation. Generally, there is a diminished volume and irregular rhythm of one radial pulse.

The **Pressure Symptoms** of aneurysm are thus given by Greene:

Esophagus: dysphagia. *Trachea:* brazen cough (gander cough), dyspnea, stridor, bronchorrhea and hemoptysis (if not from sac itself). *Root of the lung, and the pleura: symptoms suggesting phthisis*, pulmonary collapse, pleurisy, etc. *Pericardium:* pericarditis. *Chest wall:* localized, dull pain. *Nerve trunks:* neuralgic pains, paroxysmal and intermittent. *Pulmonary artery:* systolic pulmonary murmur, dilated right heart. *Sympathetic fibers:* dilated or contracted pupil, unilateral sweating or pallor. *Cardiac plexus:* anginal attacks. *Superior vena cava:* edema of upper extremity, cyanosis. *Thoracic duct:* marasmus. *Vagus:* dyspepsia, nausea, vomiting, dyspnea, hiccough. *Phrenic:* unilateral diaphragm paralysis. *Recurrent laryngeal:* hoarseness, aphonia, spasm or paralysis of left cord, *paroxysmal dyspnea. It must not be forgotten that any or all of these symptoms may be caused by mediastinal growths other than aneurysms.*

Diagnosis.—May be confounded with a **solid tumor**, but in this case there would be no expansile pulsation on inspection, no thrill on palpation, nor bruit on auscultation.

Empyema.—There would be no history of the symptoms of this disease. Physical signs are entirely different. See EMPYEMA.

Prognosis.—Always grave, and death may supervene at any time. The average duration is from 1 to 3 years.

Abdominal Aneurysm

Definition.—A localized dilatation of the abdominal aorta. Generally, the disease is in the neighborhood of the celiac axis.

Etiology.—The same as thoracic aneurysm.

Pathology.—The same as thoracic aneurysm.

Symptoms and Course.—There is often localized pain disseminated along the course of the nerves in this region. Vomiting is common; occasionally, the rhythm of the femoral pulse is disturbed and there is a delayed cardiac wave on one side.

The physical signs, as those of thoracic aneurysm, are generally well marked.

Diagnosis.—**Aortic pulsation** in hysteric women is at times mistaken for aneurysm, but the regular rhythm of the femoral pulse, the absence of the deep boring pain, and the absence of tumor will exclude aortic pulsation.

Lumbar or psoas abscess may cause a fluctuating tumor, but there is an absence of the thrill on palpation, and bruit on auscultation. In abscess there is usually more pain, higher fever, a history of sweats and chills, and a septic condition is marked. Lumbar abscess is situated lower down than the tumor of abdominal aneurysm.

Prognosis.—Very good.

Treatment of Aortic Aneurysm.—The method that has met most favor is that now known as Tufnell's treatment, though Valsalva originally suggested a restricted diet and practised frequent venesections. Bellingham advised starvation without bleeding. Tufnell's treatment consists in absolute mental and physical rest in the recumbent position, together with a moderate, dry diet. The object of this is to diminish the blood-pressure and volume of blood, to increase the proportion of fibrin in the latter, and to promote its coagulation. The method is as follows:

For breakfast, 2 ounces of bread and butter and 2 ounces of milk; for dinner, 2 or 3 ounces of meat and 3 or 4 ounces of milk or claret; for supper, 2 ounces of bread and 2 ounces of milk. Thus it is hoped to diminish the blood volume and reduce the pressure within the sac, to render the blood more fibrinous, and favor coagulation. The addition of iodid of potassium is Balfour's modification. The proper maximum dose is 15 to 20 grains (1 to 1.3 grams) 3 times a day. An additional effect of the iodid of potassium is the relief it affords to pain. It is supposed also to act by increasing secretions, thus thickening the blood. Dr. Balfour also claims that it lowers the blood-pressure.

Other methods of securing coagulation and contraction of the clot are acupuncture, suggested by Velpeau, and consisting in placing an iron wire or a needle into the aneurysm, with the hope that the blood will coagulate on it, filling the aneurysm with horsehair or fine wire for the same purpose. The wire is introduced through a hypodermic needle. Galvanopuncture, suggested by Loretta, furnishes perhaps the most satisfactory results. Two needles are introduced into the sac, and a mild current of electricity passed through them. In this way a combined electrolytic and mechanic effect is obtained. Stewart has successfully employed the combined electrolytic and mechanical method, using silver wire which is introduced into the sac through an insulated hollow needle. The anode is attached to the wire and the negative pole, by means of a flat electrode, is applied to the sacral region. The introduction of astringent substances, as solution of acetate of lead or persulphate of iron, into the aneurysm may be mentioned only to be discouraged, for the danger of producing embolism far exceeds the chance of benefit. Ligation of the carotid, subclavian, or both has also been done for aneurysm of the aorta, with satisfactory results. It is, however, a formidable operation.

No other internal treatment for aneurysm other than that suggested by iodid of potassium has ever been of any use. As a part of the medicinal treatment of thoracic aneurysm it should be added that, when there is violent action of the heart, cardiac sedatives are sometimes indicated to allay this, in addition, of course, to the enjoined rest. Among these sedatives we include aconite and veratrum viride in extreme cases, also cold to the seat of the swelling and to the cardiac region. If arterial tension is high, nitroglycerin or one of the other nitrites, such as sodium nitrite, erythrol tetranitrate and the like, is of advantage. If there is a syphilitic history, iodid of potassium is at once indicated, beginning with 10 grains 3 times a day after meals, and gradually increasing to 30 or 40 grains 3 times daily.

If pressure symptoms are great and the patient is plethoric, resort may be had to venesection. A half-pint of blood may be removed from the circulation once or twice a week. Often an ice-bag over the seat of the aneurysm relieves the pain. As a rule, stimulants are contraindicated. The bowels should be kept open with Rochelle or Epsom salts, 1/2 ounce before breakfast. The reduced iron, 3 to 4 grains in pill form, may be given after meals. See ANEURYSM.

AORTA, INJURIES.—Injuries of the aorta, as a rule, are very rapidly fatal. Punctures of the aorta inside the pericardium, through the second intercostal space, and wounds of the coronary artery, cause profuse hemorrhage as well as direct interference with cardiac movements. It is not uncommon to find foreign bodies, such as fish-bones, driven through the esophagus into the aorta.

APERIENTS.—See CATHARTICS.

APHAKIA.—Absence of the crystalline lens. This malformation is sometimes congenital, but exists, of course, in persons upon whom discission or extraction has been performed. It is diagnosed by the deep anterior chamber, the trembling iris, high degree of hyperopia, and the loss of accommodation. There is also absence of the small inverted image of a candle held close to the eye. The treatment consists in prescribing correcting bifocal glasses for reading and distance. See CATARACT.

APHASIA.—Partial or complete loss of the power of expression or of comprehension of the conventional signs of language, from no lesion of the peripheral organs or nerves, but from lesions of the cortical centers concerned. Aphasia may be either motor or sensory.

Motor or Ataxic Aphasia.—A loss of speech, owing to inability to execute the various movements of the mouth necessary to speech. The muscles are not paralyzed, but are not coordinated, owing to disease of the cortical center. It is usually associated with *agraphia*, "aphasia of the hand," inability to write, and right-sided hemiplegia. *Motor agraphia* must be distinguished from sensory. The latter is sometimes amnesic—that is, the patient cannot write the word because he cannot call it to mind; at others it is a part of word-blindness. Motor agraphia is quite independent of ability to read aloud—that is, of effort memories necessary to speech, the difficulty being connected with the movements of the hand. In the former case he may still be able to write on dictation, in the latter not. Agraphia also varies greatly in degree. The patient may write one or two letters, or he may be totally unable to write voluntarily or from dictation. The seat of the lesion of motor agraphia is still unsettled.

Some aphasics can write, but are unable to articulate words or sentences. This variety is variously named **aphemia, alalia,** or **anarthria,** according as the impairment of speech is more or less marked. Charcot supposes the center for articulate language divided into four subcenters:

a visual center for words, an auditory center for words, a motor center of articulate language, and a motor center of written language. Lesions of one or more of these centers produce the characteristic forms of aphasia, all of which have clinical exemplifications.

Sensory Aphasia (Amnesia).—Loss of memory for words, which may exist alone or in association with the motor aphasia. Amnesia appears clinically in three distinct forms: (1) Simple loss of memory of words. (2) *Word-deafness*, or inability to understand spoken words (there is usually some paraphasia connected with this form). (3) *Word-blindness*, or inability to understand written or printed words. Recently, Hinshelwood has laid great stress upon the existence of word-blindness without letter-blindness, and vice versa.

Paraphasia is a form of aphasia in which there is inability to connect ideas with the proper words to express the ideas. **Agrammatism** is a phenomenon of aphasia consisting in the inability to form words grammatically, or the suppression of certain words of a phrase. **Ataxaphasia** is inability to arrange words synthetically into sentences. **Bradyphasia** is abnormal slowness of speech, from pathologic cause. **Tumultus sermonis,** a stuttering manner of reading, from pathologic cause. **Conduction aphasia** is not due to any central lesion, but to defect in some commissural connection between centers. **Gibberish aphasia,** aphasia in which the patient can utter many words, but uses them in such a way as to express no meaning.

The following table (taken from Tyson) shows the situation of the lesions causing aphasia:

		Seat of Lesion.
Apraxia, inability to recognize the nature and purpose of an object.		
Mind-blindness (Loss of visual memories.)		Supra marginal and angular gyri, or the white matter beneath, in the left hemisphere in the right-handed and right hemisphere in the left-handed.
Mind-deafness, including amusia, or auditory amnesia.		Upper temporal gyrus of left hemisphere in the right-handed.
Mind atactilia		Gyrus fornicatus, hippocampal gyrus, precuneus and post-parietal (Mills).
Mind anosmia		Uncinate gyrus (Ferrier), and hippocampal gyrus.
Mind ageusia		Temporal gyrus (Ferrier).
Aphasia, inability to comprehend words correctly and to use them properly.		
Sensory aphasia, inability to recognize word-pictures, loss of memory of word-pictures.	*Word*-blindness, in which memory of the appearance of a word is lost.	Angular and inferior parietal gyri.
	Word-deafness, in which memory of the sound of a word is lost.	Posterior part of 1st and 2d temporal gyri (Seppilli and Starr).
	Amnesia inability to recall a word.	Disturbance of association tract.
Motor aphasia, inability to utter words, though knowing well what to say.	Including *alexia,* or inability to read aloud.	Posterior part of 3d left frontal (Broca's) convolution.
Paraphasia, a confounding of words in speaking in which the wrong word is used instead of the right one.		Island of Reil and any disturbance of the association tracts.
Amimia. Loss of power of expression by signs.		Third left frontal convolution, receiving or concept centers.
Paramimia. Misuse of signs to express thought.		Disturbance of association tracts.
Agraphia, inability to write.		
Sensory agraphia, inability to write because of want of idea as to what a word (*a*) is or (*b*) looks like.	(*a*) Amnesic agraphia.	Association tract.
	(*b*) A part of word-blindness.	Angular and inferior parietal gyri.
Motor agraphia, inability to write because of want of motor power of writing.	A part of motor paralysis.	Not settled, but possibly middle of the ascending frontal convolution or ascending parietal.

Derangements of Speech of Irritative Origin.—In addition to those due to direct lesion of the speech-centers, there are also derangements of speech due to irritation. Such are the different kinds of stuttering, the labiochoreic and gutturotetanic stuttering and choreic speech. The first two probably reside in the cortical speech-centers, but the choreic spasms do not necessarily, for the muscles concerned in their production are unnerved from other centers as well.

The study of derangements of speech is by no means easy, but it may be facilitated by pursuing a systematic method like the following, which is that of Starr slightly modified:

A. To determine whether apraxia is present.	1. Test the power of recognizing the nature, uses, and relations of objects.
B. To test integrity of the auditory speech-area and association tracts between other sensory areas and the temporal convolutions.	1. The power to recall the spoken name of objects seen, heard, or handled. 2. The power to understand speech and musical tunes. 3. The power to recall to mind objects named.
C. To test the condition of the visual word-memories in the angular gyrus and of the connections between this area and the surrounding sensory and motor areas.	1. The power to understand printed or written words. 2. The power to read aloud and understand what is read. 3. The power to recall objects whose names are seen. 4. The power to write spontaneously and to write the names of objects seen, heard, etc. 5. The power to copy and write at dictation. 6. The power to read understandingly what has been written.
D. To test the integrity of Broca's center and its association tracts.	1. The power to speak voluntarily; and if it is lost, the character of its defects. 2. The power of repeating words one after another.

When aphasia is associated, as is so often the case, with paralysis of the right arm, the writing-test may be made with the left hand, when the patient will often produce the so-called aphasic mirror-writing, which can only be read by the

use of a mirror; or, if he cannot write with the left hand, as also happens, he may be asked to form words by letters cut out of printed pages.

The prognosis varies much, according to the nature of the lesion, to age, to ability, and to means of reeducation.

The treatment is that of the hemiplegia that accompanies it, and, in addition, teaching new words and the sound of letters. Prolonged rest alone secures relief. When associated with right-sided paralysis, long courses of alteratives may benefit, and if syphilis is present, potassium or sodium iodid and mercury should be given. Any disorder, concomitant or causative, must be attended to. See Brain, Speech Defects.

APHONIA.—Complete loss of musical tone, which occurs when the vocal bands cannot meet, or meet more or less imperfectly. It may be due to paralysis or paresis of the adductor muscles, alterations in the bands themselves, deficiency in the strength of the expiratory current, and abrogation of or perversion of the will, occurring in the morbid mental conditions of hysteria or other nervous disease. The intimate relations of the voice to the functions of the brain would lead us to expect that it would be influenced by the emotions. Thus a person may be hoarse with rage, speechless with terror, etc., and the origin of these cases of nervous aphonia is frequently some sudden emotion, causing loss of control of the voice.

When the aphonia is due to affections such as ulcerations or coating with false membrane, local treatment of the various conditions will restore the voice. The general treatment will depend on the constitutional state. See Laryngitis, Larynx.

APHRODISIACS.—Drugs that increase the sexual desire and power. They act by reflex or by direct action upon either the cerebral or the spinal genital center. The chief agents are nux vomica and its alkaloid, strychnin, phosphorus, nitroglycerin and cannabis indica. Others are cantharis, gold, cimicifuga, serpentaria, sanguinaria, opium (at first), camphor (at first), ergot, iron, alcohol, bitter tonics, flagellation, and meat diet. Strychnin acts by increasing general nutrition and exalting the reflex excitability of the genital centers. Hemp probably only causes a mild delirium, which may or may not take a sexual direction. Cantharis directly irritates the mucous lining of the urethra, and is dangerous in aphrodisiac doses. Alcohol in small doses excites the genital center in the brain; so do opium and camphor at first, the latter being decidedly anaphrodisiac after a time. The power of damiana is doubtful. Urtication and flagellation of the nates produce priapism by irritation of the genital center in the cord through the sensory nerve of the part. Ergot is considered useful by contracting the dorsal vein of the penis, preventing its emptying too rapidly.

℞. Tincture of cantharides, } each ♏ xl
Tincture of nux vomica, }
Mix well, and give 10 to 20 drops 3 or 4 times daily.

℞. Extract of nux vomica, gr. xx
Extract of glycyrrhiza, ʒ ijss
Mix and divide into 80 pills. Take 2 to 4 three times a day.

APHTHÆ.—Small white ulcers, spots, or vesicles of the mouth, occurring chiefly in children under 3 years of age, and generally associated with some febrile affection. It must not be confounded with thrush, in which disease the spots are smaller and are due to the presence of the parasitic fungus characteristic of that disease. See Stomatitis (Aphthous).

APINOL.—Obtained by destructive distillation of pine wood. It is said to be an antiseptic, local anesthetic and expectorant; to be useful when applied externally to wounds, burns, ulcers, and denuded surfaces for the relief of pain and promotion of healing. It is also claimed to be of service when given internally in catarrhal inflammation of the digestive tract and, when used by inhalation, to assist in freeing the respiratory passages from accumulated mucus. Dose, internally from 5 to 15 minims with cane sugar as a menstruum.

APIOL.—An oily liquid, of green color, acid reaction and pungent taste, soluble in alcohol, ether, chloroform, and in glacial acetic acid; extracted from the parsley. Apiol is probably a mixture of several substances, and as found in commerce is often an impure oleoresin. Dose, 3 to 10 minims in capsule two or three times a day; as an emmenagogue, 15 minims in one daily dose.

In small doses (3 to 5 minims) apiol is carminative, diuretic, diaphoretic, expectorant, and stimulant to the circulation. In full doses (15 minims) it is decidedly emmenagogue and feebly antiperiodic, but produces headache, tinnitus aurium, intoxication, and giddiness, its action generally resembling that of quinin. Large doses (30 to 60 minims) are decidedly narcotic.

Apiol has had some reputation in intermittents and in malarial neuralgias, but is most frequently employed in amenorrhea and dysmenorrhea, being of especial advantage in the amenorrhea of anemia, also when the menstrual discharge is fetid. It is becoming fashionable as a supposed abortifacient, but is useless for this purpose, and if freely used may produce decided narcotism, especially if the preparation employed should happen to be an active one. Cases of poisoning by apiol are seldom seen, as the French preparation in capsules sold in this country are generally inert for either good or evil, though an important source of revenue to the druggists.

APNEA.—Formerly used as synonymous with asphyxia, meaning breathlessness; difficult respiration; partial or complete suspension of breathing. It is employed now only in the physiologic sense, to denote the condition in which the blood is too highly oxygenized. The presence of an overabundance of oxygen prevents stimulation of the medullary respiratory center, and respiration is arrested in consequence. See Asphyxia.

APOMORPHIN.—An artificial alkaloid prepared from morphin or codein, usually in the form

of the hydrochlorid. It occurs in minute crystals, is odorless, of bitter taste, and soluble in about 45 parts of water and same quantity of alcohol, almost insoluble in ether or chloroform, and decomposed by boiling water or boiling alcohol. Solutions should be fresh when used, as they alter rapidly by keeping, and should have a few drops of hydrochloric acid added to them to prevent decomposition. The emetic dose is 1/15 to 1/8 grain hypodermically. It is given by the mouth in doses of 1/10 to 1/6 grain. In children, 1/60 to 1/30 grain should not be exceeded.

It is a systemic emetic acting directly upon the vomiting center, and is the quickest, most certain, and least irritating of all emetics. It is useful whenever an emetic is needed; in subacute and chronic catarrh of the stomach and air-passages to get rid of mucus by emetics, and in acute bronchitis it may quiet irritation and stimulate the secretion. In narcotic poisoning from alcohol or opium it is an invaluable emetic, although if very old and damp, it may add to the narcotic effect.

APOPLEXY.—A term applied to a sudden and prolonged loss of consciousness and motor power not due to heart-failure. It is generally due to cerebral hemorrhage, embolism, or thrombosis. See Brain (Hemorrhage, Thrombosis and Embolism).

APOTHECARIES' WEIGHT.—A system of weights and measures used in compounding medicines. The Troy pound of 5760 grains is the standard. It is subdivided into 12 ounces. The ounce is subdivided into 8 drams, the dram into 3 scruples, and the scruple into 20 grains. For fluid measure the quart of 32 fluidounces is subdivided into pints, the pint into 16 fluidounces, the ounce into 8 fluidrams, and the fluidram into 60 minims. The following abbreviations and symbols are used:

♏, *minim.*	℥, *uncia*, an ounce (480 grains).
gt., *gutta*, a drop. (gtt. = drops.)	lb. *libra*, a pound.
℈, *scrupulus* a scruple, (20 grains).	O, *octarius*, a pint.
ʒ, *drachma* a dram (60 grains).	C, *congius*, a gallon.
	gr., *granum*, a grain.
	ss, *semissis*, one-half.

See Weights and Measures.

APPENDICITIS.—Appendicitis is an inflammatory disease of the vermiform appendix, which may vary in degree from a single congestion of this organ to a complete destruction in part or whole of any or all of its tissues.

Description.—The vermiform appendix is a small intestinal tube which may vary in the normal condition from 3 to 12 cm. in length and from 3 to 6 mm. in diameter. Usually, the nearer the size of the appendix conforms to the normal, which is approximately 6 cm. long and 4 mm. in diameter, the less likely it is to become inflamed. Still, there are many appendices which have apparently remained normal throughout the life of the patient, which have varied greatly from this size in both directions. The lumen in the normal structure is uniform in diameter, open at one end where its lining is continuous with the lining of the cecum. At this point there is usually a little fold of mucous membrane which closes this lumen more or less perfectly against entrance of fecal material from the cavity of the cecum; but frequently the lower end of the cecum is funnel-shaped and the beginning of the appendix is continuous with this, so that the conditions seem especially favorable for the forcing of fecal material into the appendix from the cecum.

Location.—This organ is attached to the lower end of the cecum, in the right lower quadrant of the abdominal cavity into which it projects in various directions, being held only by its cecal attachment and by its mesenteriolum. The other end of the appendix is closed. Its walls are composed of a lining of mucous membrane filled with lymphoid tissue, a second layer of circular muscle fiber, a third layer of longitudinal muscle fiber and a covering of peritoneum; and on one side it is attached by a delicate fold of the peritoneum, known as the mesenteriolum, which contains the blood-vessels and nerves supplying this organ. Between the mucous membrane and the layer of circular muscle there is a loose layer of connective tissue.

Nerve supply is from the superior mesenteric plexus of the sympathetic nerve.

Blood Supply.—The chief arterial supply comes from the posterior ileocecal artery. In the female, a small branch from the ovarian occasionally reaches the appendix through the ligament of Clado, which seems to be of some importance in connecting chronic appendiceal infection with dysmenorrhea.

The vermiform appendix is **located** in a part of the abdominal cavity whose spontaneous isolation from other portions of the peritoneal cavity is greatly facilitated by the existing anatomic conditions. This is of the utmost importance for the patient, from the standpoint of safety. These conditions which must constantly be borne in mind in planning the treatment of patients suffering from appendicitis, are clearly shown in the accompanying illustration.

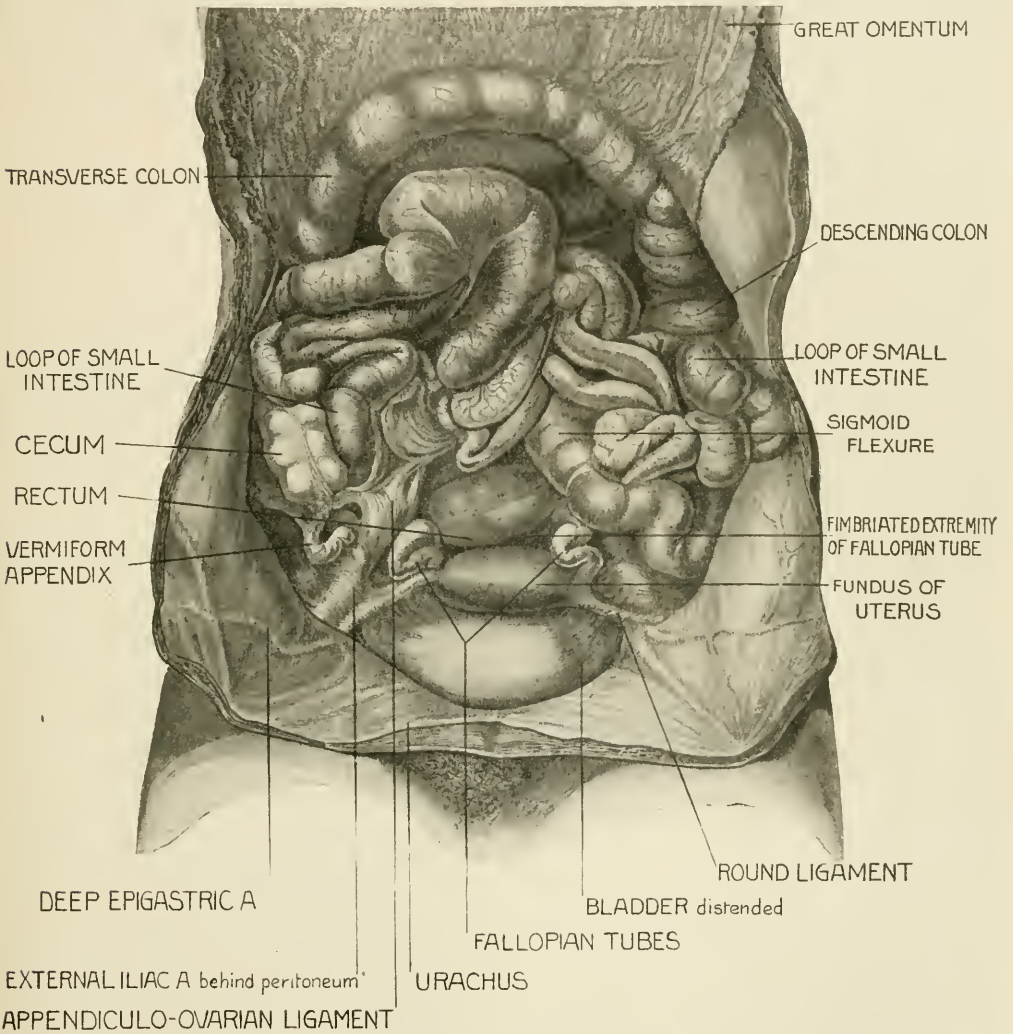
The appendix has for its boundary: *above*, the cecum; on the *outer side*, the lateral abdominal wall; *posteriorly*, the posterior wall composed of the iliacus muscle covered with peritoneum; *below*, is the pelvic cavity, which has been accustomed to dispose of septic material through ages; to the *inner side*, it may be protected by the sigmoid flexure of the colon, or the small intestines may be banked against it on this side. Aside from this, the omentum is long enough to completely surround the vermiform appendix in case of an inflammation, thus practically separating this organ from the remaining portion of the abdominal cavity. This is of the greatest importance, because infectious material from the infected appendix can in this way be prevented anatomically from reaching other portions of the peritoneal cavity, thus reducing the great danger of its destroying the life of the patient by producing a diffuse septic peritonitis.

Functions of the Appendix.—Undoubtedly the vermiform appendix served to store food in many of the lower animals and it seems reasonable to

accept the theory that in man and some other mammals the structure is a rudimentary remnant of an organ which served the same purpose during some portion of the evolution of these species. None of the theories which have been advanced giving the vermiform appendix in its present development definite physiologic functions seem at all satisfactory, and it seems plain that the structure is always useless, and generally more or less harmful, although Macewen has made a very attractive argument to the contrary, which should give rise to further investigation.

Etiology of Appendicitis.—As predisposing causes are some anatomic peculiarities: (1) Abnormally long appendices; (2) appendices with a narrowing at the cecal end; (3) those with a very narrow mesenteriolum or those in which this structure is entirely absent. It has often been observed that several members of the same family contain abnormally long appendices and that consequently five or six members of the same family come for operations for the relief of appendicitis. This has been attributed to the fact that all of these persons were exposed to the same errors in diet and hygiene and were subject to the same infections. The same fact as to diet and hygiene would apply to a somewhat slighter extent to persons belonging to the same nationality.

Age.—Patients between 12 and 30 years of age are most commonly affected; but the disease may occur in patients less than one year and over 80 years of age, and a very large number of patients between 1 and 12 years of age have been observed, in whom a diagnosis of acute gastritis or gastro-enteritis had been made, while they were actually suffering from appendicitis. It consequently seems likely that during this age many cases are overlooked, and that when all of the patients suffering from intraabdominal inflammatory disease are subjected to a careful physical examination the



proportion of young patients diagnosed as suffering from appendicitis will be greatly increased.

Diet.—Carelessness in diet undoubtedly causes much irritation of all portions of the alimentary canal and the resulting congestion and infection must be an important factor in the causation of appendicitis. In a large series of severe cases of acute appendicitis which were carried over the acute attack, Ochsner has never observed a recurrence when the patient subsisted entirely upon liquid diet, care being taken to prevent constipation (which in itself seems to be an important predisposing cause).

Sex.—This has but little importance as a predisposing cause. In hospitals in which all cases of surgery (including gynecologic cases) are operated on by the general surgeon there are as many females as males treated for appendicitis.

In some communities more cases of appendicitis occur during certain months or seasons of the year. It is possible that the occurrence of infectious diseases like influenza, tonsillitis and dysentery may increase the relative number of cases of appendicitis when these conditions are prevalent. It is also possible that during the months when more indigestible foods are consumed there may be an actual increase in appendicitis, but it will require much careful observation to establish these facts. Typhoid fever seems to predispose to appendicitis. That the two conditions may occur at the same time has been frequently observed in all communities where the water supply is infected with sewage. All of the infectious diseases are supposed to predispose to appendicitis.

Exciting Causes.—(1) *Eating* too much or too rapidly, or articles of food that cannot be readily digested (especially when the patient is physically exhausted) is the most frequent exciting cause. This seems to be especially true in cases of recurrent appendicitis, many cases being entirely free from recurrence so long as a strictly liquid diet is adhered to, and but mild recurrences being observed so long as they confine their diet to liquids, when tired.

(2) *Traumatism* can be applied directly to the appendix but very seldom. On the other hand, traumatism can cause a recurrence even in cases in which it is not applied directly over the region of the appendix.

(3) *Foreign Bodies.*—In cases in which the lumen of the appendix is normal in size, fecal matter in small quantities may undoubtedly be forced into it. Larger objects like gallstones, seeds of fruits, intestinal worms, shot derived from game, pins, portions of bone and many other objects and even teeth have become lodged in the appendix. The bacteria which find entrance into the appendix most commonly are the colon bacilli, the various saprophytic bacteria, bacilli of typhoid fever, dysentery, tuberculosis; the ray fungus has been found in the appendix, and in one instance at least, the ameba of dysentery, and all of the microorganisms of suppuration. (See Colon Bacillus Infection.)

Pathology.—Appendicitis is due to an infection of the tissues of the appendix, most commonly by the colon bacillus, the streptococcus, the staphylococcus or the pneumococcus. The colon bacillus is probably always present in this infection, its virulence being greatly increased, according to Turck, by the presence of obstruction. The infection is increased by interference with the blood supply of the appendix, by means of adhesions, angulations, distention of this organ and its mesenteriolum. The infection may be acute or chronic and may vary in degree from a mere congestion to a complete destruction of the tissues; it may involve only the mucous lining or this together with the muscular layers and peritoneum.

Varieties.—Acute appendicitis occurs in the following forms, according to Deaver:

(1) Catarrhal.
(2) Interstitial.
(3) Ulcerative.
    (a) Nonperforative.
    (b) Perforative.
(4) Gangrenous.

Chronic Appendicitis:
(1) Catarrhal.
(2) Interstitial.
(3) Obliterating.

This classification seems so reasonable and comprehensive that it can be generally accepted.

In acute appendicitis, Stanton has shown from the study of a great number of specimens that there is a very definite progress of the disease for each successive day of the attack, so far as the microscopic picture is concerned, although the gross lesions may differ greatly.

By making a gross as well as a microscopic examination of this series of 485 cases of acute appendicitis and determining the length of time which had elapsed from the time at which the attack commenced to the time at which the appendix was removed it was possible to determine the degree of invasion of the tissues which are fully described in the report of this research and which led to the following conclusions. "The character of the histologic changes is essentially similar in all of the appendices in this series which were removed during the first few days of the disease and consists of a severe, diffuse inflammation, accompanied by focal areas of hemorrhage and necrosis. These focal areas of necrosis may increase in extent during the first few days and give rise to microscopic areas of gangrene or they may remain of microscopic size and be quickly repaired. The various anatomic varieties, such as the gangrenous, perforative and ulcerative forms, are determined by the extent and distribution of these necroses. Evidences of repair are seen as early as the third day, and in the nongangrenous cases the histologic picture of an acute process has changed to that of a distinctly reparative process by the fifth day. In those cases in which the necrosis is so extensive as to give macroscopic evidences of gangrene, the histologic picture of an acute process persists for a longer period, but even in these cases (unless there is a later acute process engrafted on the earlier lesion) the evidences of repair are by the sixth or seventh day the predominating feature of the lesion. Evidences of a

recurrent acute process are by no means uncommon, and were present in from 10 to 15 percent of the cases after the first week.

"During the second week of the attack the repair proceeds rapidly, fibroblasts, new-formed blood-vessels and lymphocytes making up the chief features of the histologic picture. The rapidity with which the repair of the appendix itself is accompanied depends chiefly on the extent of the primary destruction and on the presence or absence of a periappendiceal exudate. By the end of the second week, in the majority of cases, the repair is so far advanced that the new-formed connective tissue may constitute the only evidence of a previous inflammation, although in cases with extensive periappendiceal exudates evidences of active organization of the exudate itself are still to be seen.

"Except for the completion of the repair in those cases accompanied by more extensive periappendiceal lesions, the histologic changes occurring after the second week are seen chiefly in the more fibrous nature of the new-formed connective tissue which persists so as to be readily recognizable in the majority of cases. Of the patients operated on one month or more following an acute attack, 78 percent were cases of chronic interstitial or chronic obliterative appendicitis very often accompanied by adhesions. Six percent of the appendices were apparently normal, while in 16 percent the demonstrable pathologic changes were confined to the mucosa.

"A notable feature seen in the histologic examination of these cases is the fact that in no instance was the pathologic change confined to the mucosa in the appendices examined during the first 10 days of the attack.

"In this series of cases, purulent fluid outside of the appendix was present in 51 percent of the patients operated on from the third to the tenth day of the attack. After the tenth day the relative number of cases accompanied by abscesses decreases steadily, with a corresponding rise in the number of cases presenting adhesions without the presence of pus, which would seem to indicate that resolution by absorption had played an important rôle in the repair of the lesion. This is doubtful, however, and is probably in large measure due to the fact that the involvement of the peritoneal cavity was less extensive in those cases in which operation was delayed. In a number of cases, however, the adhesions were so massive as to leave little doubt of the previous presence of an extensive periappendiceal exudate.

"After the third day the exudates on the peritoneal surface contain highly vascular granulation tissue, and it is probable that the high operative death rate between the third and tenth days in part may be accounted for by absorption from the denuded granulating surfaces as well as by the extent of the peritonitis and the bad general condition of the patients."

Although there is a marked uniformity in the microscopic findings in acute appendicitis on the successive days there is a marked difference in the effect upon the patient because this depends less upon the condition of the appendix itself than it does upon the extent to which the surrounding peritoneum has been affected. An absolutely gangrenous appendix may in one case give rise to but slight symptoms throughout the course of the disease, while in another case it may cause the death of the patient at any time after the first day after the beginning of the acute attack. On the other hand, a very slight perforation or a circumscribed gangrene may destroy the life of the patient in one case, while in another it may give rise to but slight symptoms. As a general rule it may be laid down that for the first 7 days from the beginning of the attack the danger increases with the time passed.

For many years these facts kept the physician in doubt as regards the prognosis and served as a basis for illogical treatment, because it seemed that so long as there was no certainty as towhat would happen, no matter how late it came under treatment, it must be imperative to remove the cause at the earliest possible moment.

Following the introduction of this plan Mynter pointed out the fact that practically all patients recovered who were operated on within the first 24 hours after the beginning of the attack of acute appendicitis without regard to the extent or character of the pathologic condition found in the appendix. Of those operated on within the first 48 hours after the beginning of the attack the death rate was very low. On the third day the death rate increased enormously and this increase continued until the seventh day when it gradually decreased. Many other surgeons made similar observations. Richardson classified the cases between the second and tenth day as too late for an early and too early for a late operation.

As a result of these various observations, it became clear that an early diagnosis must be made, in order to reduce the mortality by removing the appendix if possible on the first, but surely before the end of the second day of a severe acute attack. In order to make this possible it was necessary first, to educate the public to call the physician early; second, to educate the physician invariably to obtain an accurate history and always to make a careful physical examination; and third, never to give opium or morphin in any form in any case of acute intraabdominal pain during the first two days of the attack, and never at any time, except after making a diagnosis in a definite class of cases to be described in detail later.

After making a diagnosis of acute appendicitis in cases which come for examination before the infection has extended beyond the tissues of the appendix, all authorities in this country agree that if a competent surgeon is available the appendix should be removed at once, because this will result in the immediate and permanent recovery of the patient. It prevents the occurrence of complications like peritonitis and subsequent adhesions, which impair the health of the patient by obstructing the normal passage of intestinal contents and which may give rise to acute intestinal obstruction later on. It also prevents metastatic infection of other parts of the body and of

recurrent attacks which are likely to result in invalidism.

For many years there has been an enormous mortality in cases operated on when the diagnosis was made after the infection had already invaded the surrounding tissues. In the meantime many observations have shown that so long as the infection remains circumscribed in the vicinity of the appendix the patient still makes a safe recovery from the acute attack. It was also found that in many cases of beginning diffuse peritonitis in which the infection had apparently progressed to a marked extent beyond the vicinity of the appendix it still could become circumscribed and the patient could still make a safe recovery.

Putting all of these facts (as well as the microscopic findings) together, it is plain that the physician must try to obtain one or the other of two conditions in every case of acute appendicitis, namely, the removal of all the infectious material in cases in which the infection has not reached beyond the tissues of the appendix, or the infection must be induced to become circumscribed in the region of the appendix, thus eliminating it from the other parts of the peritoneal cavity.

In order to make the first condition possible it is, of course, necessary to make an early diagnosis and this can only be accomplished when a careful physical examination is made in every case of intraabdominal pain or of acute digestive disturbance; this examination must invariably be made when the physician is first called, and always before opium, in any form, is given.

Many times these symptoms seem so slight that it does not appear worth while to trouble the patient to remove his clothing; a careful physical examination should, however, be looked upon as the absolute duty of the family physician. Then, if a competent surgeon is at hand, the appendix should invariably be removed at once, and under no condition should a patient suffering from appendicitis be permitted to take food or cathartics of any form by mouth. Not even milk or broth, and in more severe cases not even water, should be given.

Fortunately, the public is now sufficiently educated, so that a physician is called in early; whereas formerly, the error of giving food and cathartics by mouth was often committed by friends before a physician was called.

Diagnosis.—It must be insisted that in making a diagnosis of acute appendicitis it is important to obtain a correct history of the case, and in every instance to make a careful physical examination of every patient who complains of digestive disturbances or of abdominal pain, whatever the character of the disturbance or the pain may be. Errors in early diagnosis of acute appendicitis are more commonly made because of a lack of care in determining the previous history of the case and from a lack of making a physical examination than from any other cause. As the prognosis and course of acute appendicitis both depend so largely upon a very early diagnosis, it is most important that these points be not overlooked.

In most instances the patient gives a history of previous gastric disturbances, such as nausea or vomiting, a dislike of certain articles of food, discomfort after eating a full meal when tired, gaseous disturbance after eating, in fact all of the symptoms which are usually supposed to characterize gastritis or gastric catarrh. These symptoms are usually described as being more severe after eating a large meal or after eating especially indigestible food and more especially when these indiscretions have been indulged in at a time when the patient was exhausted either physically or mentally. In children a capricious appetite is often an additional symptom. In these cases there is often a history of a number of acute attacks which are supposed to have been entirely confined to the stomach and have been looked upon as instances of acute gastritis. Until recently, acute attacks of appendicitis in children have almost invariably been first diagnosed as acute gastritis and attributed to some special indiscretion in diet; and because of this diagnosis, the patient has usually not been subjected to a careful physical examination of the abdomen, but has been given a cathartic by the physician or parent to remove the irritating food from the stomach and the intestines, often with most harmful or even fatal results. Fortunately for the child, it usually refuses food under these conditions, the favorable effect of which refusal will be considered later. In children in many instances there are marked evidences of malnutrition, which together with the symptoms which have just been described should cause the diagnostician to be suspicious of appendicitis. Frequently these children are retarded in their growth as compared with other children of their own age, or with other children in the same family.

It is important to guard against forcing the infectious material from the appendix into the surrounding tissues by making severe pressure upon the abdomen during the examination. Violent examinations are often followed by rapid increase in unfavorable symptoms.

At this point it may be well to direct the attention to the importance of experience in recognizing the symptom-complex of appendicitis. A young physician who has had an opportunity of seeing many of these cases during his service as resident in a hospital will often make a correct diagnosis when an older physician with much greater wisdom, learning and general experience, will fail.

Symptoms and Physical Signs.—Bearing in mind the importance to be placed upon the history of gastric disturbances, such as nausea or vomiting, or discomfort after eating, or erratic appetite, still a negative diagnosis must never be reached without a physical examination having been made.

The cardinal symptoms are:

1. *Pain* usually beginning in the vicinity of the umbilicus which later becomes located near a point halfway between the umbilicus and the right anterior superior spine of the ilium—McBurney's point.

2. *Rigidity* of the right rectus abdominis muscle, especially marked over McBurney's point, except

when morphine has been given before the physical examination is undertaken.

3. *Pain* upon pressure over McBurney's point.
4. *Nausea* or *vomiting.*
5. *Obstruction* to the passage of gas and feces.
6. Apparent or real *swelling* in the vicinity of McBurney's point.

Aside from this the patient may have had a chill. He may have a temperature above or below normal; and the pulse may be normal or rapid. In acute cases an examination of the blood shows an increase in the relative number of leukocytes, which may be very slight or it may exceed ten times the normal number. Aside from confirming the diagnosis of the presence of an infection, the blood examination has no significance.

Increase of relative number of leukocytes indicates an increase in severity of infection or increase in invasion with resistance. A low leukocytosis may mean slight infection or it may mean severe infection with slight resistance. In either case, the general condition of the patient will indicate to the experienced diagnostician what the local conditions are as regards the severity of the attack.

It is, however, a safe rule, that when a competent surgeon is present, one should never advise against an operation in acute appendicitis because the attack is mild in character. On the other hand, in the absence of a competent surgeon the presence of a mild attack is a most excellent reason for advising against an immediate operation, because if neither food nor cathartics are given by mouth until the attack has subsided one can prognosticate with absolute certainty that a mild case can be carried on to a condition in which the patient can be safely transported to a hospital where a competent surgeon can be found. After the patient has recovered from the acute attack, a recurrence can be prevented for an indefinite period if the patient be given only liquid or semiliquid food, such as soups, broth, gruel, milk, buttermilk, mush, prunes, cooked fruits and vegetables forced through a colander, soft-boiled eggs, meat juices, and fruit juices. It is also important to prevent constipation.

Regarding the second condition to be obtained, viz.: the limitation of the infection to a circumscribed area, it seems important to bear in mind the elements which serve to cause a diffusion of the infection.

The anatomic conditions have been shown to be favorable to keeping the infection in the region of the cecum unless it is carried to other parts of the peritoneal cavity by the motion of the small intestines. In order to prevent this motion an attempt must be made to inhibit peristalsis. This was accomplished many years ago by the so-called opium treatment, but it can be accomplished in a much more satisfactory manner by removing the stomach contents by gastric lavage and then prohibiting food and cathartics of all kinds by mouth. It must be remembered, however, that even the smallest quantities of liquid food or the mildest form of cathartics may cause dangerous peristalsis. Even water should not be given by mouth for fear of causing intestinal motion. Water can be supplied according to a method introduced by Murphy by means of proctoclysis through a soft-rubber catheter inserted into the rectum for a distance not to exceed 3 inches, care being taken to arrange the apparatus so that the normal salt solution will be instilled into the rectum drop by drop, in order not to cause any irritation.

It is well to continue this for a period of two hours during which time from 500 to 2000 c.c. of the solution may be absorbed. Whenever any irritation or incontinence occurs the proctoclysis should be interrupted. In case the patient suffers pain, from 10 to 30 drops of deodorized tincture of opium should be dissolved in 100 c.c. of normal salt solution and this should be given by rectum in the same manner. This may be repeated every 2 to 6 hours if the pain recurs, but the quantity should be reduced as the severity of the pain decreases. In order to support the patient's strength, it is well to add 1 ounce of one of the concentrated, predigested liquid foods in the market to the normal salt solution once every 3 to 4 hours.

This method of supplying food and water by rectum should be continued until the patient has been normal for 4 days, when it is safe to begin giving beef-tea or broth by mouth at regular intervals of 3 hours. After a few days a little gruel may be given. Milk should not be given until the patient has been apparently well for at least 10 days.

In order to prevent the occurrence of parotitis as well as to increase the patient's comfort, it is well to encourage the use of chewing gum, which will favor the flow of saliva and will not only prevent the formation of parotitis, but will cause this condition to subside if it has already begun.

From what has been said it is plain that if patients regularly consulted physicians at the very beginning of their attacks of appendicitis and if they then always received a careful physical examination an early diagnosis could almost invariably be made and in the presence of a competent surgeon the appendix could regularly be removed with safety to the patient.

Unfortunately these conditions do not always obtain; and frequently the condition of the patient has been made much worse by giving food or cathartics by mouth, or an incompetent physician has been called at first who has prescribed without having made a careful physical examination. In this manner many of these patients come under the care of the physician or surgeon at a time when the infectious material has already passed beyond the circumscribed space in the vicinity of the cecum. If these cases which come under treatment too late for an early operation and too early for a late operation are all operated on at once as soon as a diagnosis is made, the mortality is necessarily extremely high, because the operation cannot remove all of the infectious material, but the necessary manipulations will tend to distribute this to other portions of the cavity. It is in this class of cases that the treatment which has just been described is most useful, because it will serve to change a dangerous and acute condition into a relatively harmless chronic condition. In the

meantime circumscribed abscess may form which should be opened and drained, and later the appendix should be removed after all of the acute inflammatory conditions have subsided. It is well to wait long enough before undertaking this operation to insure the absorption of all of the infectious material, in order not to bring on a dangerous septic condition.

In the meantime it is well to place the patient entirely on liquid diet, because by doing this the operation may safely be postponed for an indefinite period, while if solid food is given a recurrence may occur at any time.

In chronic appendicitis there is more or less absorption of septic material from the appendix, as well as absorption of decomposing substances from the alimentary canal because of obstruction to the passage of intestinal contents due to the presence of adhesions. In all of these cases it is well to remove the appendix, to loosen the adhesions causing obstruction and to cover the raw surfaces with peritoneum. It is well to look for a short kink in the ileum within 5 or 10 cm. from its entrance into the cecum, because this location which has been pointed out by Lane is especially likely to give rise to angulation. We have observed this condition, known as Lane's kink, sufficiently often to make it worthy of especial attention.

Technic of Operation for the Removal of the Vermiform Appendix. Preliminary Treatment.—In operation for acute appendicitis no preliminary treatment is indicated because all time spent before the operation is begun is so much time wasted.

If the patient has suffered from nausea or vomiting, the pharynx should be sprayed with a 2 percent solution of cocain and gastric lavage should be performed through a large stomach tube. In these cases it is well to give a hypodermic injection of 1/4 grain of morphin and 1/100 grain of atropin at once as soon as the operation has been determined upon, then to spray the pharynx with a 2 percent solution of cocain and to make gastric lavage just before the anesthetic is begun. In this manner the lavage can be performed without discomfort to the patient and the amount of anesthetic necessary will be greatly reduced.

The patient should then be anesthetized with ether, the abdomen should be very carefully, but very gently washed with green soap with a gauze pad, then it should be shaved, then washed again with green soap and warm water, then with a solution of 1 part of bichlorid of mercury in 2,000 of hot sterile water, then with 95 percent alcohol, then it may be dried and the operation may be begun. The abdomen may be painted with compound tincture of iodin full strength before operation.

Incision.—If the disease is confined to the appendix, McBurney's incision is to be preferred. This consists in an incision parallel with Poupart's ligament and half way between this structure and the umbilicus, the middle of this incision being in the line drawn from the anterior superior spine of the ilium to the umbilicus. The incision may be made from 3 to 15 cm. in length, according to the space required for removing the appendix in the case under consideration. At one time much stress was laid upon the importance of a very short incision, but this is now generally looked upon as foolish pedantry. The incision is carried through the fascia of the external oblique muscle, splitting but not cutting its fibers, exposing the internal oblique muscle which extends at right angles to the former. The fibers of the internal oblique are then separated, exposing the aponeurosis of the transversalis muscle. This is then cut together with the peritoneum, and the anterior surface of the cecum is exposed. Following the longitudinal band of this intestine downward leads to the beginning of the appendix. If this is free from adhesions a clamp is applied to the base of the appendix and a second one to the mesenteriolum. The latter is cut and ligated. A purse-string suture of fine silk or linen is then applied around the base of the appendix, the suture passing down to the mucous membrane of the cecum, but not through it. It is well to pass a suture around the point where the mesenteriolum enters the cecum in order to compress any artery which enters at this point. The appendix is then cut away even with the outer surface of the forceps and the compressed stump is inverted into the lumen of the cecum while the purse-string suture is being tied. In rare instances when the appendix is very vascular, it is well to tie a fine catgut ligature about the compressed base of the appendix before inverting it and tying the purse-string suture. A few Lembert sutures are passed over this in order to reinforce the purse-string suture. If there are any raw surfaces they are carefully covered by suturing peritoneum over them. Then the cecum is dropped into the peritoneal cavity, the omentum is brought down over the cecum and the wound is closed by successively suturing the various layers with continuous catgut sutures. If the appendix is very adherent, it is better to grasp its cecal end by two strong hemostatic clamps placed closely together. The appendix is then cut off between these forceps and the adhesions are then caught successively by hemostatic forceps and cut between these and the appendix until the distal end of the latter is reached. Then the operation is completed as described above.

Occasionally an abscess is encountered outside of the appendix in a case in which it seemed possible to remove all of the infectious material with the appendix. In these cases it is wise to pack away the intestines with gauze pads moistened with normal salt solution in order to prevent the pus from touching any of the surrounding peritoneum. Then sponge away the pus carefully to prevent soiling the surrounding peritoneum, and institute some form of drainage for a few days after the operation until the infected area has been eliminated from the surrounding peritoneal cavity by adhesions.

The drainage may consist of a strip of gauze, or a glass tube covered with gauze, or a cigarette drain, or a rubber tube split longitudinally. Ochsner prefers a glass tube covered with gauze; but the form matters but little so long as provision is made for the escape of pus. It is of course

important not to injure the parietal or intestinal peritoneum by unnecessary manipulations during the operation.

In case the operator is not fairly certain that the infection is still confined to the appendix it is usually better to make the incision in a longitudinal direction over the middle of the lower half of the right rectus abdominis muscle. The incision passes through the skin, superficial fascia, and fat, and through the aponeurosis covering the anterior surface of the rectus muscle. The fibers of the latter are then separated longitudinally, then the posterior sheath of the transversalis fascia and the peritoneum are cut. The appendix is found and removed as described above.

In case drainage seems indicated in this operation it should be carried through a button-hole to the right of the incision, care being taken to separate and not to cut the muscle fibers. This can be done easily by making an oblique incision 2 cm. long, parallel with Poupart's ligament, passing through the fascia of the external oblique abdominal muscle, splitting, but not cutting its fibers, and then passing a pair of blunt-pointed forceps through the abdominal wall and separating the heads which will separate, but not injure the muscle. The drain can usually be removed after two or three days.

This is also the proper incision in cases in which gallstones are suspected, because by elongating the incision upward it is possible to remove the gallstones without making a second incision. In cases in which there is a complication with disease of the ovaries or the Fallopian tubes or the uterus, it is best to make a median incision between the umbilicus and the os pubis.

After-treatment must, in the main, be negative. The patient should be fed by nourishing enemata, and water should be supplied by continuous proctoclysis which may be repeated whenever thirst reappears. In case of severe shock subcutaneous injection of from 500 to 1000 c.c. of normal salt solution should be administered.

In suppurative cases the Fowler position is indicated.

In cases of nausea or vomiting or gaseous distention of the abdomen, the pharynx should be cocainized and gastric lavage should be practised. This should be repeated whenever these conditions recur.

In case of pain, from 10 to 30 drops of deodorized tincture of opium dissolved in 100 c.c. of normal salt solution should be given by rectum as often as necessary to keep the patient comfortable. So long as no nourishment is given by mouth, opium given in this manner is perfectly harmless. It is well for the patient to chew gum in order to prevent parotitis.

Conclusions.—Ochsner thus sums up the treatment of appendicitis:

Regarding the treatment of recurrent appendicitis, all authorities on the subject are agreed upon the plan of removing the appendix by a competent surgeon, during a time when it is not acutely inflamed. To this should be added the fact that many a surgeon is competent and safe to perform the operation at this time who could not safely do the work during an acute attack. It should also be borne in mind that so long as such a patient is confined absolutely to liquid diet and avoids constipation he will remain free from recurrence; even for an indefinite period of time. He can consequently postpone this operation to a convenient time and he can safely travel any distance to secure competent surgical skill.

For the treatment of acute appendicitis Ochsner formulates equally satisfactory rules:

(1) A careful physical examination should always be made in patients suffering from gastric disturbances, nausea, vomiting, gaseous distention or pain in any portion of the abdomen, so that an early diagnosis can be made. In acute cases violent manipulations are dangerous and not necessary during examination. They may cause a diffusion of septic material.

(2) The mortality in appendicitis results from the extension of infection from the appendix to the peritoneum, or from metastatic infection from the same source.

(3) This extension may be prevented by removing the appendix while the infectious material is still confined to that organ.

(4) The distribution or extension of the infection is accomplished by the peristaltic action of the small intestines.

(5) It is also accomplished by operation after the infectious material has extended beyond the appendix and before it has become circumscribed.

(6) Patients suffering from acute appendicitis should be operated on as soon as the diagnosis is made, provided they come under treatment while the infectious material is still confined to the appendix, and if a competent surgeon is available.

(7) Aside from insuring a low mortality this will prevent all serious complications.

(8) In all cases of acute appendicitis, and in all cases of peritonitis without regard to the treatment contemplated, the administration of food and cathartics by mouth should be absolutely prohibited and large enemata should never be given.

(9) In case of nausea or vomiting, or gaseous distention of the abdomen, gastric lavage should be employed.

(10) Opium in any form should never be given before a diagnosis has been made, and never in the presence of any form of peritonitis, unless gastric lavage has been done; and the introduction of every form of nourishment and cathartics by mouth is absolutely prohibited. This applies to even the simplest forms of liquids, like beef tea or broth, and also to the use of champagne and other stimulants.

(11) This applies equally to postoperative treatment.

(12) In cases coming under treatment after the infection has extended beyond the tissues of the appendix, especially in the presence of beginning diffuse peritonitis, conclusions (8) and (9) should always be employed until the patient's condition makes operative interference safe.

(13) In case no operation is performed, neither nourishment nor cathartics should be given by

mouth until the patient has been free from pain and otherwise normal for at least four days.

(14) During the beginning of this treatment not even water should be given by mouth, the thirst being quenched by rinsing the mouth with cold water and by the use of small enemata. Later small sips of very hot water frequently repeated may be allowed, and still later small sips of cold water. There is danger of giving water too freely, and there is great danger in the use of large enemata.

(15) All of these cases are greatly benefited by installation of normal salt solution by the drop method, by rectum, as introduced by Murphy, or by some other safe nonirritating method; this is one of the most valuable means of inhibiting peritonitis. It is well to give normal salt solution continuously for one to two hours, and then to interrupt this treatment for two hours.

(16) In rare cases where this method cannot be employed, normal salt solution should be given subcutaneously in quantities of 500 to 1000 c.c. sufficiently often to overcome thirst and keep the blood-vessels filled.

(17) Large enemata, except by the drop method, should never be given in the presence of peritonitis.

(18) All practitioners of medicine and surgery, as well as the general public, should be impressed with the importance of prohibiting the use of cathartics and food by mouth, as well as the use of large enemata, in cases suffering from acute appendicitis or peritonitis.

(19) It should be constantly borne in mind that even the slightest amount of liquid food of any kind by mouth may give rise to dangerous peristalsis and may change a harmless, circumscribed into a dangerous, diffuse peritonitis.

(20) The most convenient form of rectal feeding consists in the use of 1 ounce of any of the various concentrated liquid predigested foods in the market, dissolved in 3 ounces of warm normal salt solution, introduced slowly through a soft catheter, inserted into the rectum a distance of 2 to 3 inches.

(21) This form of treatment cannot supplant the operative treatment of acute appendicitis, but it can and should be used to reduce the mortality by changing the class of cases in which the mortality is greatest into another class in which the mortality is very small after operation.

(22) It is important to bear in mind the fact that this treatment is always indicated without regard to whether an immediate operation is or is not contemplated.

(23) It is further important not to be deceived by the very rapid improvement of apparently serious cases, into the belief that the case is not a gangrenous or perforative appendicitis, because such patients may easily be killed by food or cathartics.

(24) In acute appendicitis which has been carried through an attack without an operation, it is well to confine the patient absolutely to a liquid diet until his appendix has been removed.

(25) In case of severe pain in acute appendicitis after gastric lavage has been made, from 10 to 30 drops of deodorized tincture of opium should be added to each rectal feeding, until there is no longer any pain.

(26) Placing these patients in the Fowler position greatly increases their safety.

(27) The application to the abdomen of a large, hot, moist dressing of equal parts of the saturated solution of boric acid and alcohol greatly increases the comfort of these patients and prevents harm from manipulations.

(28) The repetitions in these conclusions are intentional, because it has seemed worth while to cover every possible point so completely that no one taking the time to read these conclusions carefully could be in doubt. They are all based upon the observation of a very large number of cases; they are not in any way theoretical, but all have an intensely practical foundation.

APPENDICOSTOMY.—The appendix is drawn out through a very small incision, fixed to the skin by suture, its tip cut off, and through its lumen the bowel is irrigated by means of a small rubber tube or catheter. By this procedure intractable cases of chronic colitis and dysentery have been cured.

APPETITE, LOSS AND EXCESS.—See Anorexia, and Bulimia.

APRAXIA.—See Aphasia.

APROSEXIA.—Inability to concentrate the attention. This condition is often due to the presence of adenoids.

AQUA.—See Water.

Nomenclature.—**A. Fluvialis,** river-water; **A. Pluvialis,** rain-water; **A. Fontana,** spring- or well-water; **A. Marina,** sea-water; **A. Carbonata,** carbonated water, soda-water; **A. Destillata,** distilled water; **A. Bulliens,** boiling water; **A. Fervens,** hot water; **A. Communis,** common water.

Aquæ, *waters*—are aqueous solutions of volatile substances, which may be solids, liquids or gases, dissolved by solution in cold or hot water, by filtration through an absorbent powder, by percolation through cotton saturated with the substance, or by distillation. The official waters are 18: **Aqua Ammoniæ.** Contains 10 percent ammonia gas by weight. Externally stimulant, irritant or caustic. Internally antacid and stimulant. Average dose, 15 minims. Should be largely diluted when taken internally. Useful in heartburn, sick headache, syncope. Slowly injected into a vein, a powerful stimulant to heart and respiration. **A. Ammoniæ Fortior** (stronger ammonia water). Contains 28 percent gas by weight. Used for making aqua ammoniæ, or properly diluted (4 or 5 to 8) as a rubefacient, vesicatory, or escharotic. Apply on cotton confined in top of a pill box. **A. Amygdalæ Amaræ** (0.1 percent). Useful vehicle. Average dose 1 dram. **A. Anisi** (0.2 percent oil). Useful vehicle. Average dose, 4 drams. **A. Aurantii Florum,** prepared by diluting the stronger water with equal volume of distilled water; it is used as a vehicle. Average dose, 4 drams. **A. Aurantii Florum Fortior** (triple orange flower water). Water saturated with the volatile oil of

fresh orange flowers, obtained as a by-product in the distillation of the oil of orange flowers. Vehicle. Average dose, 2 drams. **A. Camphoræ,** camphor 0.8 dissolved in alcohol and afterward triturated with purified talc. Vehicle. Average dose, 2 drams. **A. Chloroformi,** a saturated solution with excess of chloroform present. Antiseptic vehicle. Average dose, 4 drams. **A. Cinnamomi** (0.2 percent). Vehicle. Use cautiously in inflammatory affections. Average dose, 4 drams. **A. Creosoti,** 1 percent creosote. Antiseptic. Stimulant externally. Local nerve paralyzant. Average dose, 2 drams. **A. Destillata,** 800 parts from 1000 of water. Used for preparing the official diluted acids, for absorbing gaseous ammonia, for preparing nearly all the official aqueous solutions, and for compounding prescriptions. **A. Fœniculi** (0.2 percent). Vehicle. Average dose, 4 drams. **A. Hamamelidis** (so-called distilled extract of witch hazel, or Pond's extract). Average dose, 2 drams. **A. Hydrogenii Dioxidi** (solution of hydrogen peroxid). 3 percent by weight of pure hydrogen dioxid. Oxidizer, deodorant, disinfectant. Coagulates the albumin of tissues. Also used in the arts for bleaching purposes. Average dose, 1 dram. **A. Menthæ Piperitæ** and **Aqua Menthæ Viridis** (0.2 percent) are useful vehicles. Average dose, 4 drams. **A. Rosæ** (rose water). Prepared by mixing equal volumes of triple rose water and distilled water. Vehicle. Average dose, 4 drams. **A. Rosæ Fortior** (triple rose water). Water saturated with the volatile oil of rose petals, obtained as a by-product in the distillation of oil of rose. Average dose, 2 drams.

ARBUTIN.—See Uva Ursi.

ARCUS SENILIS.—A grayish-white opacity, extending around the edge of the cornea, about 1.5 millimeters from the sclerocorneal junction. Between it and the periphery the cornea is transparent. It is chiefly seen in old persons, and has been called both a fatty and a hyaline degeneration. It is often indicative of similar senile changes elsewhere. On account of its peripheral location it causes no visual disturbance. See Old Age.

ARGENTAMIN.—A solution of 10 parts of silver phosphate in a 10 percent aqueous solution of ethylene diamin. It has been recommended as a substitute for other silver compounds, on account of its great antiseptic power and astringency; but it is irritant. Aqueous solutions of various strengths, from 1 in 5000 to 1 in 1000, have been used as urethral injections in gonorrhea.

ARGENTUM.—See Silver.

ARGONIN.—A mixture of silver nitrate with sodium and casein. It is a valuable antiseptic, particularly against the gonococcus. A 2 percent solution is practically unirritating to the mucous membrane of the urethra. The drug is somewhat expensive to use for irrigation. Its solutions should be protected from the action of light.

ARGYLL ROBERTSON PUPIL.—A pupil responding to accommodation but not to light. It is of diagnostic value in locomotor ataxia. It is also seen in paretic dementia, in some cases of encephalomalacia, senile brain atrophy, syphilis, hydrocephalus, etc. See Pupil.

ARGYRIA.—A form of chloasma or discoloration of the skin and mucous membranes produced by the prolonged administration of nitrate of silver, the molecules of silver being deposited in much the same position as those of the natural pigment of the skin. It may be *general,* from internal administration, or *local,* from its local application. It is said that the administration of 450 grains of silver nitrate has caused it; and in the prolonged use of this drug much care must be taken to prevent argyria. Iodids in large doses have been suggested, but treatment for the removal of the pigment is usually unavailing.

ARGYROL.—Silver vitellin, a compound of a proteid and silver oxid containing 30 percent of silver, and is very soluble in water. It is painless and nonirritant, even in concentrated solutions on the conjunctiva. Solutions of 2 to 10 or 25 percent strength are used as local astringents, of 1 in 1000 for irrigating the vagina, bladder, and urethra. It is strongly bactericidal and has great penetrative power.

ARISTOCHIN. Diquinin Carbolic Acid Ester.—A white, tasteless powder insoluble in water, soluble in alcohol and in chloroform, and containing 96 percent of quinin. It is said to be free from the unpleasant effects of quinin, producing neither gastric irritation nor cinchonism, though twice as powerful against protozoa and twice as efficient in malarial fever. Dose, 8 to 15 grains, thrice daily; for children, 1 to 5 grains, according to age.

ARISTOL.—A combination of iodin and thymol. An amorphous, odorless, unstable, nontoxic powder, of fawn color, insoluble in water or glycerin, freely so in ether, chloroform, and fatty oils, and only sparingly soluble in alcohol. It is used as a substitute for iodoform. No heat should be used in mixing it or in its use; nor should alkalies, metallic oxids, or starch be mixed with it. It is of use in the local treatment of ulcers, wounds, and other breaches of tissue; in the treatment of indolent soft ulcers, lupus, psoriasis, syphilitic ulcerative processes, eczema, severe burns, affections of the ear, nose, and throat, in gynecologic and dermatologic practice, being nearly, if not quite, as effective as iodoform.

It is best applied in powder, in solutions in oil and ether (5 to 10 percent), or in ointment, with a base of lanolin or vaselin (5 to 10 percent).

A liniment is thus made:

℞. Alcohol, Ether,	each,	ʒ j
Aristol,		gr. v
Soft soap,		ʒ j.

Mix well and rub in part.

An ointment:

℞. Aristol,	gr. x
White vaselin,	ʒ ss.

Mix well and apply.

ARM, AMPUTATION.—The circular method usually gives excellent results; but skin flaps with circular division of the muscles, or one of these in front and a short transfixion flap behind, may be

adopted instead. In this amputation, as in all others through the shaft of a bone, the periosteum should be divided some little distance below the bone, so that it may invest and adhere to the face of the section. See AMPUTATION.

ARM, DISLOCATION.—See ELBOW, SHOULDER.

ARM, FRACTURES. Fractures at Upper End of Humerus.—Fracture of the anatomic neck is rare. It is sometimes entirely intracapsular, sometimes is just without, generally is partly within and partly without, the capsule. In the first instance the vitality of the fragment is doubtful, but in the last instance the attachment to portions of the capsule provides nourishment.

The cause is nearly always direct force. The head may be impacted between the tuberosities, or the upper diaphyseal end be driven into the cancellous structure of the head. The displacement, generally very slight, may be very great, the shaft being shifted inward, upward and forward.

The symptoms are usually little marked. In case of impaction the diagnosis is more probable than certain; deep palpation of the bony points under an anesthetic may demonstrate crepitation and abnormal mobility, making the diagnosis certain. A skiagraph should always be made if possible and another one taken after reduction of the fracture.

Treatment consists of rest in bed with extension of the arm downward and outward by means of weights, a pad or pillow being inserted in the axilla. Sometimes additional traction becomes necessary, acting laterally at the upper end of the humerus. If impaction exists, no effort should be made to separate the fragments. Passive movements should be begun early.

Fracture at the surgical neck, just below the tuberosity or penetrating it, is a frequent injury. The upper fragment may remain under the influence of the muscles attached to the tuberosity. Usually due to a fall upon the shoulder in elderly persons, it may result from a fall on the hand or elbow. The fragments may be fixed by impaction, or very marked displacement may be present, the upper end of the shaft of the humerus being frequently shifted forward, inward and upward.

The symptoms of abnormal mobility and crepitation, determined by palpation, together with the presence of the head of the bone in its proper position, and sometimes the occurrence of shortening, usually suffice for purposes of diagnosis. When the fragments are impacted, the diagnosis is not so easy, but exclusion of a dislocation should always be possible. The fracture may also be associated with and complicated by a dislocation of the head of the bone.

Treatment.—If displacement is present, reposition must be carefully effected. The upper fragment is so short that when there exists a marked tendency to displacement, the reposed fragments are held in place with difficulty. Ordinarily, splint dressings, with an axillary pad and a shoulder-cap, fixing the whole arm with the shoulder region as far back as the neck, suffice; when marked tendency to displacement exists, this serious injury is best treated by rest in bed, with permanent extension by weight and pulley in the longitudinal direction of the arm, together with an axillary cushion. It is better still to employ a second extension apparatus acting on the upper end of the shaft. This apparatus has the advantage of leaving the region of the shoulder bare and open to massage and the early careful use of passive movements, which are of value to prevent a tendency to ankylosis owing to the proximity of the joint. If reduction is difficult or impossible, operative interference to wire fragments is indicated.

Fracture of a tuberosity, especially the major one, may happen during the occurrence of a subcoracoid dislocation; also during the reduction of old luxations of the shoulder. The symptoms are not pronounced; the outer aspect of the shoulder may appear flattened, there are the signs of a contusion, and sometimes the mobility of the separated fragment can be made out.

Treatment is simple, having for its object the fixation of the arm, which is well accomplished by a simple spica bandage of the shoulder and a sling for the forearm.

Separation of the epiphysis at the upper end of the humerus occurs in young persons before the ossification of the epiphyseal cartilage, and is generally due to a fall upon the arm or shoulder. This injury is of great practical importance on account of the relative frequency of the injury and the possible interference with the growth and development of the limb as a result. The epiphyseal line is like a broad, reversed V, with the open end down, separating the head and tuberosities above from the diaphysis below. This gives the diaphyseal end a pointed extremity with lateral declivity.

EXTRACAPSULAR FRACTURE OF THE HUMERUS. (*After Gray.*)

The symptoms point to a separation of bone, as in fracture of the surgical neck. Abnormal mobility and crepitation can be determined under anesthesia if the displacement be slight; but the crepitation is soft—cartilage-crepitation rather than bone-crepitation. Frequently, the displacement is considerable, the lower fragment being displaced downward and inward; in this situation it causes an angular prominence, which is best seen and determined from a point above and behind the patient, and by comparison with the opposite side. Sometimes the displacement is so severe as to elude reposition under an anesthetic. In such cases it becomes necessary to cut down and separate directly the interfering soft parts. After reposition, treatment is essentially that of fracture of the surgical neck of the humerus.

This injury is a very serious one, because of the danger of interference with the further growth and development of the limb, which is almost sure to take place unless reposition is perfectly effected.

Fractures of the Diaphysis of the Humerus.—These occur as a result of direct or indirect vio-

lence, and present the common signs of fracture in a way readily determined—abnormal mobility, crepitus, various forms of displacement, etc. If the break occurs below the point of attachment of the deltoid muscle, the latter is likely to lift the upper fragment outward. On account of the close contact of the musculospiral nerve with the bone, it is liable to injury at the time of fracture, or to suffer later from inclusion in the callus formation, where it is often embedded as in a deep groove. Such an injury produces a typical paralysis (drop-wrist), and should be carefully borne in mind from the beginning, in order to avoid blundering in the prognosis.

Pseudarthrosis is relatively more common in this locality than elsewhere in the long bones of the body.

Treatment is best effected by means of an internal angular splint (of leather or heavy cardboard), and an external splint extending down to the elbow and capping the shoulder (of leather, felt, metal, or cardboard). These splints are to be well padded and held in place by cotton bandages, and over all starched bandages. The forearm must be carefully supported in a sling, whether the patient is lying in bed, or standing up, as its weight, if unsupported, is almost sure to produce some angulation at the point of fracture. Plaster of Paris is not suited to the treatment of this fracture ordinarily. If there exists much tendency to displacement, permanent traction may be an indispensable adjunct to the dressing.

Fractures at the Lower End of the Humerus.—These are supracondylar fracture, T-fracture, fracture in the epiphyseal line, oblique fracture through the articular extremity, and isolated fracture of the internal or external condyle. These fractures are frequent, and are of great importance, as they are, in fact or in effect, articular fractures.

Supracondylar fracture is due to a fall on the elbow or hand, and happens most frequently to children.

The T-fracture is a longitudinal splitting of the lower fragment. On fracture, the triceps pulls the lower fragment backward and upward in a distinctive way, which may be confused with luxation of the forearm. The injury is determined by grasping the condyles and demonstrating abnormal mobility. If, in case of T-fracture, the shaft of the humerus penetrates between the two portions of the lower fragment, the entire articular end is widened.

Treatment.—Under anesthesia, thorough reposition is followed by fixation in angular splints applied on the inner and outer sides, or by a single stiff angular splint applied on the flexor aspect of the arm. There is more or less danger, in such a fracture, of some stiffness or of complete ankylosis resulting. Therefore, the forearm had best be held, if possible, in a position of flexion, beyond a right angle, unless there are special local conditions that demand that it be kept more or less extended. Recent practice has demonstrated that in practically all fractures in and about the elbow the fragments are brought into the best position possible by a position of *acute flexion*. The tendency to stiffness and ankylosis is also reduced by this position.

Fractures of the condyles occur isolated or as complications of luxations.

Palpation shows displacement and mobility of the fragments.

Treatment consists of fixation by dressings and early passive movements.

Oblique Fracture of the Articular Extremity and Separation of the Epiphysis.—These articular fractures are frequently associated with marked displacement of the forearm at the elbow-joint. It is sometimes difficult to diagnose the exact condition; but careful palpation under an anesthetic, together with comparison with the uninjured side, will generally furnish an adequate idea of the nature of the injury. The prognosis of these fractures is less favorable than of supracondylar fracture, as some displacement of fragments is likely to persist and to diminish normal mobility by the formation of irregular bony prominences. Lateral deviation of the fragments may give rise to varus and valgus positions to the elbow.

What has been said about the **treatment** of supracondylar and T-fractures is applicable here; while the exigencies of the particular case may demand fixation in a more or less extended position, it will usually be best to fix the elbow in a position of acute flexion.

In the treatment of all these fractures at the lower end of the humerus it is necessary to change and replace the dressings every few days at first, and later on the dressings should be changed every other day. This plan permits very early and persistent passive motion and massage, which are the surest and only safeguards against a resulting ankylosis. The value of the anterior angular hinged splint with the Strohmeyer screw for the purpose of maintaining function must be remembered. This permits movement without removal of dressings. See AXILLA.

ARNICA.—The dried flower heads of "leopards'-bane." The flowers are used in medicine. Its properties are probably due to an alkaloid, *trimethylamin*, $(CH_3)_3N$. In small doses it is a cardiac stimulant; in large doses, a depressant. In toxic doses it frequently causes death. It is a popular remedy, when locally applied, for sprains, bruises, and surface wounds, and is valuable also in typhus and typhoid fevers as an antipyretic. **A., Infusum** (no longer official), 20 parts flowers, 100 parts water. Superior to the tincture for local use. **A., Tinct.**, 20 percent. Dose, from 5 to 30 minims. *Trimethylamin.* Unof. Dose, from 2 to 3 grains in syrup.

AROMATICS.—Substances characterized by fragrant, spicy taste or odor, as cinnamon, ginger, the essential oils, etc. They are generally stimulant to the mucous membrane of the gastrointestinal tract. **Aromatic powder** has of cinnamon 35, ginger 35, cardamom 15, and nutmeg 15, triturated into a fine powder. The dose is from 10 to 30 grains.

Aromatic fluidextract is a solution of aromatic powder in alcohol. Its dose is from 10 to 30 minims.

A grateful aromatic in flatulency:

℞. Powdered ginger root, ℥ jss
Boiling water, O ss.

Macerate for 2 hours in a closed vessel and strain

Add:

Tincture of ginger, } each, ʒ ss.
Syrup of ginger, }

The aromatic oils are local irrtiants. Internally, in large doses, they cause burning pain in the stomach, an increased circulation, and a species of intoxication. Their influence is more powerful and more transient than that of the simple bitters, and only temporarily increases digestive power. They are chiefly employed as carminatives to stimulate the intestines to contract upon and expel flatus, to disguise the taste of medicines, to make nauseating drugs acceptable to the stomach, and to prevent the griping of purgatives.

Some tonic drugs have, besides a volatile oil, a bitter principle that modifies their action. They are known as aromatic bitters.

The chief contraindication to the use of aromatics is inflammation of the stomach or bowels.

The principal aromatics are cinnamon, cloves, nutmeg, pimenta or allspice, cardamom, ginger, black pepper, red pepper, oil of cajuput, oil of sassafras, bitter orange peel, sweet orange peel, essence of spearmint, essence of peppermint, rosemary, sage, balm, lemon peel, orange-flower water, oil of anise, spirit of anise, oil of fennel, oil of caraway, oil of coriander, oil of lavender, oil of peppermint, oil of spearmint, oil of gaultheria, calamus, compound spirit of lavender, peppermint water, spearmint water.

ARRHENAL.—Disodic-methyl arsenate. Though similar in properties it is said to be more efficient than the cacodylates, especially in chronic malaria. Dose, 1/3 to 1 grain. See CACODYLIC ACID.

ARRHYTHMIA.—See HEART-DISEASE, Functional.

ARROW-ROOT.—A kind of starch derived from *Maranta arundinacea* of the West Indies, Southern States, etc. It is widely used as a food and is a popular remedy for diarrhea. The best variety comes from Bermuda. The secret of properly prepared preparation of arrow-root is in having the first mixture with milk absolutely smooth and free from lumps.

ARSACETIN.—Sodium-acetyl-paramidophenlyarsonate. Sodium acetyl arsanilate. A substitute for mercury in the treatment of syphilis, similar to atoxyl, but less tonic and more stable. It is used in 10 or 15 percent solution, 0.6 grains (6 c.c.) of a 10 percent solution, *i. e.*, 9 grains being injected in two consecutive days each week. Even with this drug, however, there is danger of serious toxic results, a case of optic atrophy having been reported. See ARYLARSONATES.

ARSENIC.—As = 75; quantivalence III, V. A nonmetal having a metallic luster and crystalline structure. In small doses it is a stomachic and general tonic, promoting appetite and cardiac action, and stimulating mental activity. It is of great value in irritative dyspepsia, and is sometimes used internally to blanch and clear the skin. In larger doses it creates skin-eruptions and behaves as a violent corrosive poison, acting with cumulative effect. Externally, it is a powerful escharotic, used in cancer. Only the salts and oxids are used in medicine.

Therapeutics.—Arsenic is especially useful in irritative dyspepsia, gastralgia, regurgitation of food without nausea, diarrhea coming on immediately after taking food, the vomiting of drunkards, and in chronic alcoholism.

Arsenic has proved of signal service in the commencement of phthisis, and in catarrhal pneumonia, probably by causing fatty degeneration of the exudation in the alveolar cavities, thus breaking it up and quickening its absorption. It is often very serviceable in chronic bronchitis with copious expectoration, in acute catarrh, hay-fever, whooping-cough, asthma, chorea, epilepsy angina pectoris, and other spasmodic nervous disorders. In many forms of neuralgia it often gives prompt and permanent relief, especially in cases due to malarial poisoning. As an antiperiodic it has high rank, being, however, of particular value in chronic malarial poisoning, and as an adjunct to quinin in the intervals between the paroxysms of intermittents. Anemia and chlorosis are remarkably benefited by it, and in rheumatic arthritis and chronic rheumatism it is sometimes of great service. In chronic scaly and papular skin-diseases its value is very great, but it is not serviceable in acute forms, and the more chronic the cutaneous affection, the more likely it is to be amenable to arsenic. Epithelioma may be retarded by small doses long continued, and it has certainly been useful in delaying the progress of other cancers, particularly scirrhus of the stomach and uterine carcinoma. Hypodermically, its solutions have been extremely efficient in histrionic spasm, local chorea of the head and neck, obstinate cases of general chorea, and in lymphadenoma. The so-called bromid of arsenic, in the form of Clemens' solution, has rendered good service as a remedy for diabetes mellitus of hepatic origin. Cupric arsenite is being highly recommended in typhoid fever.

Secret "cancer cures" have arsenic trioxid for their bases. In the form of a paste, arsenic has been used as a depilatory, and as an escharotic in cancer, but is exceedingly painful.

To avoid arsenic poisoning, full doses (10 minims of Fowler's solution) should be used at commencement, taken on a full stomach. The dose should then be steadily reduced. Tincture of opium will often give tolerance to the drug in susceptible persons, if given with each dose.

To remove morbid growths:

℞. Arsenic trioxid, ʒ j
Sulphur, ʒ j
Spermaceti cerate, ʒ j.

Mix into a paste and allow to remain in contact with the morbid growth for 24 hours.

In diabetes mellitus:

℞. Salicylate of sodium, ʒ iij
Solution of potassium arsenite, ʒ j
Glycerin, ʒ j
Cinnamon water, enough to make ʒ iij.

Mix and give a dessertspoonful 3 times daily.

In anemia and chlorosis:

℞. Arsenic trioxid, gr. j
Dried iron sulphate, ʒ ij
Powdered black pepper, ʒ j
Pill of aloes and myrrh, ʒ j.

Mix and divide into 40 pills. Give 1 pill twice daily, after meals.

Magnesia, lime, and solutions containing salts of iron or tannic acid are incompatible with arsenic.

Poisoning is either acute or chronic, and the anatomic characteristics are the same by whatever means or channel the poison has gained access to the system.

Acute poisoning usually ensues upon the nefarious administration of arsenic, generally the oxid. The prominent symptoms come on in from half an hour to an hour after taking; and the quantity taken has relation to the time of onset, and also to its state of solubility. The vomiting should be differentiated from bilious vomiting by the persistence in the latter of the symptoms after the removal of the apparent cause, and by the symptoms intermitting and again coming on after taking water or food. Choleraic diarrhea does not appear so suddenly, the stools are "rice-water" in character and the skin is livid, and the symptoms yield to treatment. In arsenic poisoning there is greater tenderness over the epigastrium, the diarrhea is less passive and is accompanied by more tenesmus, the stools are more bloody, and nervous symptoms more pronounced. The mucous membrane, moreover, is stripped off in threads, and so appears in the bowel discharges. About the third day after poisoning remission is likely to occur in the symptoms, only to be followed by a return then. Death generally occurs about the fourth or sixth day. A skin eruption is likely to appear on or about the third day, which may take any character. Fatty degeneration of all the tissues nearly always follows acute arsenic poisoning not speedily recovered from. Multiple neuritis may ensue.

Treatment of acute poisoning consists in applying external heat and stimulants, washing out the stomach, generally with a stomach-tube, and the administration of one of the antidotes. Only those antidotes having the freshly precipitated and hydrated sesquioxid of iron are of value. A fluid preparation of iron, such as the tincture of perchlorid of iron, must have added to it some alkali to precipitate the iron. If ammonia is used, the precipitate must be washed repeatedly to remove the ammonia. Magnesia is a better precipitant, because it not only throws down the iron, but is an antidote in itself. Monsel's solution, or the dialyzed tincture of iron, may be used instead of the tincture of the chlorid of iron. The former, however, is irritating, and so readily does dialyzed iron precipitate that it may be given pure.

The official antidote to arsenic of the U. S. P. is the ferri hydroxidum cum magnesii oxido. It should be kept on hand for immediate use, and is thus prepared:

℞. Solution of ferric sulphate, 40 c.c.
Water, 125 c.c.

Mix and keep in a well-stoppered bottle.

℞. Magnesium oxid, 10 grams.
Water, 750 c.c.

Mix the latter solution slowly with the iron preparation, and shake together until a homogeneous mass results.

Should be given in large doses (ʒ iv), and frequently repeated.

The following is a simple method of preparing hydrated oxid of iron, the antidote for arsenic, one of its chief advantages being that the ingredients are always easily obtained: Take tincture of iron chlorid, 4 ounces; mix in a vessel of 12 ounces capacity, and add aqua ammoniæ, 1 dram. Shake well, pour it on a large wet muslin drainer, wring out the water and alcohol, and wash with fresh water. The stomach having been evacuated by emetics while the antidote was being prepared, give 4 fluidounces at once, to be followed by an emetic. Then give 2 ounces every 10 minutes.

Opium is to be given in the after-treatment, to allay pain and irritation, and plenty of fresh water given, to dilute the poison and to flush the kidneys.

Chronic poisoning is generally accidental, from the inhalation of arsenic vapors in factories, or from green or other wall-papers, and in manufacturing artificial flowers. It shows itself by nervous symptoms due to inflammation of different nerve-structures, such as anesthetic areas, gradually extending loss of muscular power and paralyses, by suffusions of the eyes, a peculiar appearance of the conjunctiva, by irritation of the bronchial air-passages, diseases of the kidneys, and pigmentation of the skin. Asthma is often brought about by arsenic. The peripheral neuritis, paralyses and the anesthetic areas are generally confined to the lower extremities.

Treatment of chronic arsenic poisoning requires, first, the withdrawal of the source of the poisoning or absolute withdrawal therefrom. Tonics and attention to the digestive tract, removal to fresh country air, the administration of some form of iron, of quinin, etc., soothing lotions for the skin, and attention to ulcers are advisable measures. Potassium iodid will aid in eliminating the arsenic from the system. Warm baths and shampooing form the best treatment for the paralytic lesions.

Preparations.—**Arseni Trioxidum**, *Arsenic Trioxid* (*Arsenous Acid*), As_2O_3, is a heavy, white solid, occurring as an opaque powder, or in semi-transparent masses having usually a striated appearance, soluble in 30 to 80 of water at 59° F., the solubility varying with its physical condition, also soluble in 15 of boiling water, in alkalies and their carbonates, in hydrochloric acid and in glycerin. It is volatilized at 424.4° F., without melting, and when thrown on ignited charcoal it emits an alliaceous odor. It floats when sprinkled on

water, though its weight is about 3 1/2 times that of the corresponding bulk of the fluid on which it rests. Dose, 1/50 to 1/10 grain; average, 1/30 grain.

Liquor Acidi Arsenosi, *Solution of Arsenous Acid,* is a 1 percent solution in HCl and distilled water. Dose, 2 to 6 minims, thrice daily in water after meals. Average dose, 3 minims.

Liquor Potassii Arsenitis, *Solution of Potassium Arsenite* (*Fowler's Solution*), is a 1 percent solution, prepared by boiling together arsenous acid 1, potassium bicarbonate 2, compound tincture of lavender 3, and distilled water to 100. Dose, 2 to 6 minims (average, 3) in water thrice daily after meals.

Sodii Arsenas, *Sodium Arsenate.* Occurs in colorless prismatic crystals, of feebly alkaline taste and reaction, soluble in 4 of water at 59° F., very soluble in boiling water, hardly soluble in alcohol. Dose, 1/16 to 1/8 of a grain.

Sodii Arsenas Exsiccatus, *Exsiccated Sodium Arsenate,* an amorphous, odorless, white powder, very poisonous. Dose, 1/30 to 1/15 of a grain.

Liquor Sodii Arsenatis, *Solution of Sodium Arsenate* (*Pearson's Solution*), is a 1 percent solution of the dried arsenate in distilled water. Dose, 2 to 6 minims (average, 3) in water after meals.

Arseni Iodidum, *Arsenic Iodid,* AsI_3, occurs in glossy, orange-red crystalline masses or scales, gradually losing iodin by exposure to the air, soluble in 7 of water and in 30 of alcohol at 59° F.; is gradually decomposed by boiling water and by boiling alcohol, and is completely volatilized by heat. Dose, 1/20 to 1/8 grain; average, 1/10 grain.

Liquor Arseni et Hydrargyri Iodidi, *Solution of Arsenic and Mercuric Iodid* (*Donovan's Solution*), has arsenic iodid and mercuric iodid, of each 1 part in 100 of distilled water. Dose, 1 to 5 minims in water after meals.

Also, arsacetin, arsenobenzol, atoxyl, soamin, arrhenal, and cacodylic acid (*q. v.*).

The tests for arsenic are Fleitmann's, Marsh's, and Reinsch's. **Arrhenal** and **Cacodylic Acid** (*q. v.*).

A. Paste (*Pâte Arsenicale*), a French composition, used as application for destroying the pulps of decayed teeth:

℞. Arsenic trioxid, gr. v
Acetate of morphin, gr. x.

Mull in mortar; moisten cotton pellet in oil of cloves, eugenol, oily carbolic acid, or dental aconite, and dip into powder.

ARSENOBENZOL.—("606") Ehrlich's new specific for syphilis. See SYPHILIS.

ARTERIES, TABLE OF PRINCIPAL.

ARTERIES, TABLE OF PRINCIPAL

NAME.	ORIGIN.	DISTRIBUTION.	BRANCHES.
Acromiothoracic (thoracic axis).	Second branch of first part of axillary.	Shoulder, arm, upper anterior part of chest, and mammary gland.	Acromial, humeral, pectoral, clavicular.
Alar thoracic.....	Second part of axillary.	Lymphatic glands in axilla.	
Anastomotic (of external plantar).	External plantar.....	Outer border of foot.....	Anastomoses with the tarsal and metatarsal branches of the dorsalis pedis.
Anastomotic (of internal plantar).	Internal plantar.....	Inner side of foot.....	Anastomoses with internal tarsal branch of the dorsalis pedis.
Anastomotic (of middle meningeal), also called *perforoting.*	Middle meningeal.....	Around greater wing of sphenoid..	Anastomoses with deep temporal.
Anastomotic (of sciatic).	Sciatic	External rotator muscles of thigh ..	Assists in the formation of the crucial anastomosis.
Anastomotica magna (of brachial).	Brachial.....	Elbow.....	Posterior and anterior.
Anastomotica magna (of superficial femoral).	Superficial femoral (in Hunter's canal).	Knee.....	Superficial and deep.
Angular.....	The termination of the facial.	Lacrimal sac and lower part of orbicularis palpebrarum.	Anastomoses with infraorbital.
Anterior (of corpora quadrigemina).	Posterior cerebral.....	Anterior portion of corpora quadrigemina.	
Anterior (of receptacle).	Internal carotid.....	Dura mater of cavernous sinus and adjacent parts.	
Aorta, abdominal.....	Thoracic aorta.....	Two common iliacs.....	Phrenic (right and left), celiac axis, suprarenal or capsular (right and left), superior mesenteric, lumbar (four pairs), renal (right and left), spermatic (right and left), inferior mesenteric, right and left common iliac, middle sacral.
Aorta, arch.....	Left ventricle of heart....	Thoracic aorta.....	Two coronary, innominate, left common carotid, left subclavian.

ARTERIES, TABLE OF PRINCIPAL

Name.	Origin.	Distribution.	Branches.
Aorta, thoracic	Arch of aorta	Abdominal aorta	Two or three pericardiac, three bronchial, four or five esophageal, twenty intercostal, subcostal (or twelfth dorsal), diaphragmatic, aberrans.
Appendicular	Ileo-colic	Mesentery of vermiform appendix.	
Articular, middle (of knee).	Popliteal	Crucial ligaments and joint.	
Articular, superior external (of knee).	Popliteal	Crureus and knee.	
Articular, superior, internal.	Popliteal	Knee.	
Auricular, posterior	Fifth branch of external carotid.	Back of auricle, scalp, and part of neck.	Parotid, muscular, stylomastoid, anterior terminal or auricular, and posterior terminal or mastoid.
Axillary	Subclavian	Brachial and seven branches	Superior thoracic, acromiothoracic, long thoracic, alar thoracic, subscapular, anterior and posterior circumflex.
Basilar	By confluence of right and left vertebral.	Brain	Transverse (or pontile), internal auditory, anterior cerebellar, superior cerebellar, two posterior cerebral.
Brachial	Axillary	Arm and forearm	Superior and inferior profunda, anastomotica magna, nutrient, muscular, radial and ulnar.
Buccal	Facial	Muscles of cheek	Anastomoses with buccal branch of internal maxillary, the transverse facial and infraorbital.
Buccal	Internal maxillary	Buccinator muscle and mucous membrane of mouth.	Anastomoses with the buccal branch of the facial, the transverse facial and infraorbital.
Calcanean, external and internal.	Peroneal	Over the os calcis and surrounding soft parts.	
Calcanean, inferior (of external plantar).	External plantar	Over inner surface of os calcis.	Anastomoses with internal calcanean of peroneal.
Calcanean, middle	Posterior tibial	Os calcis.	
Cardiac	Gastric	Cardiac end of stomach.	
Carotid, common	*Right side*, innominate; *left side*, arch.	External and internal carotid	External and internal carotid.
Carotid, external	Common carotid	Anterior part of neck, face, side of head, integuments and dura mater.	Ascending pharyngeal, superior thyroid, lingual, facial, occipital, posterior auricular, temporal, internal maxillary.
Carotid, internal	Common carotid	Greater part of brain, the orbit, internal ear, forehead, and nose.	Tympanic, vidian, arteria receptaculi, pituitary, gasserian, meningeal, ophthalmic, posterior communicating, anterior choroid, anterior cerebral, middle cerebral.
Carpal	Radial	Branches to lower end of radius, wrist- and carpal-joints.	Enters into formation of anterior carpal rete.
Carpal	Ulnar	Carpus	Enters into formation of the posterior carpal rete.
Celiac axis	Abdominal aorta	Stomach, duodenum, spleen, pancreas, liver and gall-bladder.	Gastric, hepatic, splenic.
Cerebral, anterior	Internal carotid	Anterior portion of cerebrum	Anterior communicating, ganglionic (or central), commissural, hemispheral (or cortical).

ARTERIES, TABLE OF PRINCIPAL

Cerebral, inferior	See *Cerebral, posterior.*		
Cerebral, middle	Internal carotid	Middle portion of cerebrum	Ganglionic (or central), hemispheral (or cortical).
Cerebral, posterior	Basilar	Temporosphenoidal and occipital lobes.	Ganglionic (or central), and hemispheral (or cortical).
Cervical	Uterine	Cervix uteri.	
Cervical, ascending	Inferior thyroid	Deep muscles of neck and spinal canal.	Muscular, spinal and phrenic.
Cervical, deep	Superior intercostal	Deep muscles of neck and spinal canal.	Muscular, anastomotic, vertebral (or spinal).
Cervical, descending	Deep cervical	Tissues of neck.	
Cervical, superficial	Transverse cervical	Trapezius, levator anguli scapulæ, splenius muscles and posterior chain of lymphatic glands.	
Cervical, transverse (transversalis colli).	Thyroid axis	Posterior cervical and scapular regions.	Posterior scapular and superficial cervical.
Circular, of uterus	Uterine	Cervix uteri.	
Circumflex, anterior (of axillary).	Axillary	Pectoralis major, biceps, and shoulder-joint.	Bicipital and pectoral.
Circumflex, external	Profunda femoris	Muscles of thigh	Ascending, transverse, and descending.
Circumflex iliac, deep	External iliac	Upper part of thigh and lower part of abdomen.	Muscular and cutaneous.
Circumflex iliac, superficial.	Common femoral	Iliacus and sartorius muscles, inguinal glands, and skin of thigh.	
Circumflex, internal	Profunda femoris	Muscles of thigh.	
Circumflex, posterior (of axillary).	Axillary	Deltoid, teres minor, triceps, and shoulder-joint.	Nutrient, articular, acromial, muscular.
Coccygeal	Sciatic	Integument over lower part of sacrum and coccyx.	
Colic, left	Inferior mesenteric	Colon, descending.	
Colic, middle	Superior mesenteric	Transverse colon.	
Colic, right	Superior mesenteric	Colon, ascending.	
Colic, transverse	Colic, middle	Transverse colon.	
Communicating	Dorsalis pedis	Enters into formation of plantar arch.	The fifth plantar digital, or princeps hallucis.
Communicating	Occipital	Muscles of posterior part of neck	Anastomoses with branches of the vertebral.
Communicating (or perforating).	Deep palmar arch	Join proximal ends of metacarpal and second and third dorsal interosseous arteries.	
Communicating	Peroneal	Anastomoses with communicating branch of posterior tibial.	
Communicating	Posterior tibial	Anastomoses with communicating of peroneal.	
Communicating, anterior.	Anterior cerebral	Assists in formation of anterior boundary of circle of Willis; sends branches to caudate nucleus.	
Communicating, posterior.	Posterior cerebral	Enters into formation of circle of Willis; uncinate convolution and optic thalamus.	Uncinate, middle thalamic.

ARTERIES, TABLE OF PRINCIPAL

Name.	Origin.	Distribution.	Branches.
Coronary. See *Gastric*....			
Coronary, inferior.....	Facial.....	Lower lip.	
Coronary, left.....	Left anterior sinus of Valsalva.	Heart.....	Left auricular, anterior interventricular, left marginal, terminal.
Coronary, right.....	Right anterior sinus of Valsalva.	Heart.....	Right auricular, preventricular, right marginal, posterior, interventricular, transverse.
Coronary, right, of stomach. See *Pyloric.*			
Coronary, superior.....	Facial.....	Upper lip.....	Arteria septum narium.
Cremasteric.....	Deep epigastric.....	Cremaster muscle.	
Cremasteric.....	Spermatic.....	Cremaster muscle.....	Anastomoses with cremasteric from deep epigastric.
Diaphragmatic.....	Thoracic aorta.....	Diaphragm.	
Digital.....	External plantar.....	Outer side of the 2d and 3d, 4th and 5th toes.	
Digital, palmar.....	Superficial palmar arch..	Both sides of little, ring, and middle finger and ulnar side of index finger.	
Digital, plantar. See *Communicating, of dorsalis pedis.*			
Digital, superficial.....	Internal plantar.....	Toes.	
Dorsal.....	Intercostal.....	Spine and muscles of throat	Spinal and muscular.
Dorsal.....	Lumbar.....	Muscles of back.	
Dorsal, interosseous.....	Radial.....	Contiguous of 2d, 3d, 4th and 5th toes.	
Dorsal (of penis).....	Termination of pudic....	Penis.	
Dorsal (scapular).....	Subscapular.....	Muscles of scapula and shoulder-joint.	Infrascapular.
Dorsal of tongue.....	Lingual.....	Dorsum of tongue, tonsils, and epiglottis.	
Dorsalis hallucis.....	Continuation of dorsalis pedis.	Great and second toe.	
Dorsalis indicis.....	Radial.....	Index finger.	
Dorsalis linguæ.....	Lingual.....	Mucous membrane of tongue, pillars of fauces and tonsils.	
Dorsalis pedis.....	Continuation of anterior tibial.	Assists to form plantar arch.....	Tarsal, metatarsal, dorsalis hallucis, communicating.
Dorsalis pollicis.....	Radial.....	Thumb.	
Duodenal, superior, right. See *Pancreatico-duodenal, superior.*			
Duodenogastric.....	See *Gastroduodenal.*		
Dural.....	See *Meningeal.*		
Epigastric, deep (or inferior).	External iliac.....	Abdominal wall.....	Cremasteric, pubic, muscular, cutaneous, terminal.

ARTERIES, TABLE OF PRINCIPAL

Name.	Origin.	Distribution.	Branches.
Epigastric, superficial	Common femoral	Inguinal glands, skin, superficial fascia, and abdominal wall.	
Epigastric, superior	Internal mammary	Abdominal wall and diaphragm, liver and peritoneum.	Phrenic, xiphoid, cutaneous, muscular, hepatic and peritoneal.
Epiploic	Right and left gastro-epiploic.	Omentum.	
Esophageal	Gastric	Esophagus.	
Esophageal	Inferior thyroid	Esophagus.	
Esophageal	Left phrenic	Esophagus.	
Esophageal (4 or 5)	Thoracic aorta	Esophagus.	
Esophageal, inferior	Coronary (of stomach)	Esophagus.	
Ethmoidal, anterior	Ophthalmic	Part of anterior portion of brain, nose, frontal sinuses and skin of face.	Ethmoidal, meningeal, nasal, frontal, cutaneous.
Ethmoidal, posterior	Ophthalmic	Posterior ethmoidal cells, dura mater, nose.	Ethmoidal, meningeal, nasal.
Facial	Third branch external carotid.	Pharynx and face	Ascending, or inferior palatine, tonsillar, glandular, muscular, submental, masseteric, buccal, inferior labial, inferior and superior coronary, lateralis nasi, angular.
Facial, transverse	Temporal	Parotid gland, masseter muscle, skin of face.	
Femoral, common	Continuation of external iliac.	Lower part of abdominal wall, upper part of thigh and genitalia.	Superficial epigastric, superficial circumflex iliac, superficial external pudic, deep external pudic, profunda.
Femoral, profunda	Common femoral	Muscles of thigh	External circumflex, internal circumflex and three perforating.
Femoral, superficial	Continuation of common femoral.	Muscles of thigh and knee-joint.	Muscular, saphenous, anastomotica magna.
Fibular, superior	Anterior or posterior tibial or popliteal.	Soleus and peroneus tertius muscles and integument.	
Of the frenum linguæ	Sublingual	Frenum of tongue.	
Gastric (or coronary)	Celiac axis	Stomach, liver, and esophagus	Esophageal, cardiac, gastric, and hepatic.
Gastroduodenal	Hepatic	Stomach and duodenum	Right gastroepiploic and superior pancreatico-duodenal.
Gastroepiploic, left	Splenic	Stomach and omentum.	
Gastroepiploic, right	Gastroduodenal	Stomach and omentum.	
Gastrohepatic	See *Coronary, of stomach.*		
Gluteal	Internal iliac, posterior division.	Pelvic and glutei muscles, etc.	Muscular, superficial and deep.
Gluteal, deep	Gluteal	Deep muscles of posterior gluteal region.	
Gluteal, inferior	Sciatic	Gluteus maximus.	
Gluteal, superficial	Gluteal	Gluteus maximus and integument over sacrum.	
Gluteal, superior	Deep gluteal	Muscles adjacent.	

ARTERIES, TABLE OF PRINCIPAL

Name.	Origin.	Distribution.	Branches.
Hemorrhoidal, inferior (or external).	Pudic	Sphincter muscle, levator ani.	
Hemorrhoidal, middle (rectal, middle).	Internal iliac, anterior division.	Middle part of rectum.	
Hemorrhoidal, superior.	Inferior mesenteric	Upper part of rectum.	
Hepatic	Celiac axis	Liver, pancreas, part of duodenum, and stomach.	Pancreatic, subpyloric, gastroduodenal, right and left terminal.
Hepatic	Gastric	Left lobe of liver.	
Hepatic	Right phrenic	Liver.	
Hepatic	Superior epigastric	Liver.	
Hepatic, right	Hepatic	Liver substance	Cystic.
Humeral, thoracic	Acromio-thoracic	Pectoralis major, deltoid and adjacent integuments.	Anastomoses with anterior and posterior circumflex.
Humeral, transverse. See *Suprascapular.*			
Hypogastric	Continuation of anterior branch of internal iliac.	Vesical branches, impervious in the adult.	
Ileocolic	Superior mesenteric	Cecum and adjacent bowel.	
Iliac, circumflex deep. See *Circumflex iliac, deep.*			
Iliac, circumflex, superficial.	See *Circumflex iliac, superficial.*		
Iliac, common	Terminal branch of abdominal aorta.	Peritoneum, superitoneal fat, ureter, and terminates in external and internal iliac.	Peritoneal, subperitoneal, ureteric, external and internal iliac.
Iliac, external	Common iliac	Lower limb	Deep epigastric, deep circumflex iliac, muscular, and continues as femoral.
Iliac, external, small. See *Circumflex iliac, external.*			
Iliac, internal	Common iliac	Pelvic and generative organs, and inner side of thigh.	Anterior and posterior trunk.
Iliac, internal, anterior trunk.	Internal iliac	Pelvic and generative organs and thigh.	Hypogastric, superior middle and inferior vesical, middle hemorrhoidal, uterine, vaginal, obturator, sciatic, internal pudic.
Iliac, internal, posterior trunk.	Internal iliac	Muscles of hip and sacrum	Iliolumbar, lateral sacral and gluteal.
Ilio-lumbar	Internal iliac, posterior trunk.	Muscles of pelvis and pelvic bones.	Iliac and lumbar.
Infraorbital	Internal maxillary	Upper lip, lower eye-lid, lacrimal sac, side of nose.	Orbital, anterior dental, nasal.
Infrascapular	Dorsal scapular	Subscapularis, scapula, and shoulder-joint.	
Innominate	Arch of aorta	Right side of head and right arm.	Right common carotid, right subclavian, occasionally thyroidea ima.
Intercostal, anterior	Internal mammary	Intercostal muscles, ribs (upper 5 or 6), and pectoralis major.	
Intercostal, anterior	Musculophrenic	Lower 5 or 6 intercostal spaces.	

ARTERIES, TABLE OF PRINCIPAL

Name.	Origin.	Distribution.	Branches.
Intercostal, aortic. 10 pairs.	Thoracic aorta	Lower intercostal spaces	Dorsal, intercostal collateral, pleural, muscular, lateral cutaneous, mammary glandular.
Intercostal, first	Superior intercostal	First intercostal space.	
Intercostal, superior	Subclavian	Neck and upper part of thorax	Deep cervical, first intercostal, arteria aberrans.
Interosseous, common	Ulnar	Interosseous membrane and deep muscles of the forearm.	Anterior and posterior interosseous.
Interosseous, dorsal (3)	Metatarsal	Contiguous sides of 2d and 3d, and 4th and 5th toes.	
Interosseous, dorsal	Posterior radial carpal.	Dorsal aspect of fingers.	
Interosseous, palmar (3).	Deep palmar arch	Interosseous muscles, bones, and 2d, 3d, and 4th lumbricales.	
Interosseous, plantar	Plantar arch	Toes.	
Interosseous, posterior (forearm).	Common interosseous	Muscles, back of forearm	Posterior interosseous recurrent.
Interosseous, recurrent	Interosseous, posterior	Elbow-joint.	
Labial, inferior	Facial	Muscles and integuments of lower lip.	
Labial, superior	See *Coronary, superior.*		
Lacrimal	Ophthalmic	Lacrimal gland, muscles of eye and cheek, and upper and lower eyelids.	Recurrent lacrimal muscular, palpebral, malar, ciliary.
Lingual	External carotid	Tongue	Hyoid, dorsalis linguæ, sublingual, ranine.
Lingual	Mandibular	Lingual nerve.	
Lumbar (4 pairs)	Abdominal aorta	Bodies and ligaments of vertebræ, lumbar muscles, and capsules of kidneys.	Vertebral, muscular, dorsal, renal.
Lumbar	Iliolumbar	Psoas muscle, quadratus lumborum, and spinal canal.	
Malleolar, external	Anterior tibial	External portion of ankle.	
Malleolar, internal	Anterior tibial	Internal portion of ankle	
Malleolar, internal	Posterior tibial	Internal malleolus.	
Mammary, external. See *Thoracic, long.*			
Mammary, internal	Subclavian	Structures of thorax	Superior phrenic, mediastinal (or thymic), pericardiac, sternal, anterior intercostals, perforating, lateral infracostal, superior epigastric, internal mammary.
Maxillary, internal (maxillary group).	External carotid	Structures indicated by names of branches.	Deep auricular, tympanic, middle meningeal, mandibular, small meningeal.
Maxillary, internal (pterygoid group).	External carotid	Structures indicated by names of branches.	Masseteric, posterior deep temporal, internal and external pterygoid, buccal, anterior deep temporal.
Maxillary, internal (sphenomaxillary group).	External carotid	Structures indicated by names of branches.	Posterior dental (or alveolar), infraorbital, posterior (or descending) palatine, vidian, pterygopalatine, nasal, or sphenopalatine.
Mediastinal, anterior (or thymic).	Internal mammary	Connective tissue, fat and lymphatics, in superior and anterior mediastina, thymus gland.	

ARTERIES, TABLE OF PRINCIPAL

Name.	Origin.	Distribution.	Branches.
Mediastinal, posterior (several).	Thoracic aorta	Glands and loose areolar tissue in mediastinum.	
Mental	Facial	Muscles of chin and lower lip.	
Mesenteric, inferior	Abdominal aorta	Lower half of large intestine	Left colic, sigmoid, superior hemorrhoidal.
Mesenteric, middle	Common iliac (occasional branch).	Transverse and descending colon.	
Mesenteric, superior	Abdominal aorta	Whole of small intestine and upper half of large.	Inferior pancreatico-duodenal, middle right and ileocolic, vasa intestina tenuis.
Musculophrenic	Internal mammary	Diaphragm, fifth or sixth lower intercostal spaces, oblique muscles of abdomen.	Phrenic, anterior intercostals, muscular.
Nasal	Ophthalmic	Lacrimal sac and integuments of nose.	Lacrimal, and transverse nasal.
Nasal	Sphenopalatine	Turbinated bones, lateral walls of nose, ethmoidal and frontal sinuses and lining membrane of antrum.	
Nasal, lateral	Facial	Integuments, muscles and cartilage of nose.	
Obturator	Anterior division, internal iliac.	Pelvis and thigh	Iliac (or nutrient), vesical, pubic, external and internal pelvic.
Obturator, external	Obturator	Muscles about obturator foramen.	
Occipital	Fourth branch of external carotid.	Muscles of neck, and scalp	Sternomastoid, posterior meningeal, auricular, mastoid, princeps cervicis, communicating, muscular, terminal.
Ophthalmic	Internal carotid	The eye, adjacent structures, portion of face.	Lacrimal, supraorbital, central artery of retina, muscular, ciliary, posterior and anterior ethmoidal, palpebral, frontal, nasal.
Ovarian	Abdominal aorta	Ovary, ureter, Fallopian tube, uterus.	Ureteral, Fallopian, uterine, ligamentous.
Palatine, ascending (or inferior).	First branch of facial	Upper part of pharynx, palate and tonsils.	Palatine, tonsillar.
Palatine, descending (or superior).	Internal maxillary	To soft and hard palate	Anterior and posterior.
Palatine, posterior or descending.	Internal maxillary	Hard palate	Anterior and posterior.
Palmar arch, deep	Radial and communicating of ulna.	Palm and fingers	Princeps pollicis, radialis indicis, palmar interosseous (3), recurrent carpal, posterior perforating.
Palmar arch, superficial	Ulnar and superficialis volæ.	Palm and fingers	Digital (4), muscular, cutaneous.
Pancreaticoduodenal (inferior).	Superior mesenteric	Pancreas and duodenum.	
Pancreaticoduodenal (superior).	Gastroduodenal	Duodenum and pancreas.	
Perineal, superficial	Pudic	Muscles of perineum and integuments of scrotum.	Transverse perineal.
Perineal, transverse	Perineal, superficial	Muscles and integuments of perineum.	
Peroneal	Posterior tibial	Muscles and integument of leg and foot.	Anterior peroneal, muscular, medullary, communicating, cutaneous, external calcaneum, terminal (or posterior peroneal).

ARTERIES, TABLE OF PRINCIPAL

NAME.	ORIGIN.	DISTRIBUTION.	BRANCHES.
Pharyngeal, ascending....	First branch external carotid.	Pharynx, soft palate, tympanum, posterior part of neck, and membranes of brain.	Prevertebral, pharyngeal, palatine tympanic, meningeal.
Plantar arch.....	External plantar artery...	Anterior part of foot and toes.....	Articular and plantar digital.
Plantar, deep.....	Metatarsal.....	Assists in formation of plantar arch.	
Plantar, digital (4).....	Plantar arch.....	Third, fourth and fifth toes, and outer side of second.	
Plantar, external.....	External, tibial.....	Sole and toes.....	Muscular, calcaneal, cutaneous, anastomotic, posterior perforating, plantar arch.
Plantar, internal.....	Posterior tibial.....	Inner side of foot.....	Muscular, cutaneous, articular, anastomotic, superficial digital.
Plantar, interosseous. See *Interosseous, plantar.*			
Plantar, metatarsal See *Interosseous, plantar.*			
Popliteal.....	Continuation of femoral.	Knee and leg.....	Cutaneous, muscular (superior and inferior) or sural, articular, superior and inferior external, superior and inferior internal and azygos, terminal (anterior and posterior tibial).
Princeps cervicis.....	Occipital.....	Muscles of neck.....	Superficial and deep.
Princeps hallucis.....	Communicating (of dorsalis pedis).	First and second toes.	
Princeps pollicis.....	Radial.....	Thumb.	
Profunda (or deep femoral).	Femoral.....	Thigh.....	External and internal circumflex, three perforating.
Profunda, inferior.....	Brachial.....	Triceps, elbow-joint.	
Profunda, superior.....	Brachial.....	Humerus, mucles and skin of arm.	Ascending, cutaneous, articular, nutrient, muscular.
Pudic, external, deep (or inferior).	Femoral, common.....	Skin of scrotum (or labia in female).	
Pudic, external, superficial (or superior).	Femoral, common	Integument above pubes and external genitalia.	
Pudic, internal.....	Internal iliac, anterior division of internal branch.	Generative organs.....	External (or inferior) hemorrhoidal, superficial perineal, muscular, arteries of bulb, crus, and dorsal of penis.
Pyloric, inferior.....	Gastroduodenal or right gastroepiploic.	Pyloric end of stomach.	
Pyloric, superior.....	Hepatic.....	Pyloric end of stomach.	
Radial.....	Brachial.....	Forearm, wrist, hand.....	Radial recurrent, muscular, anterior and posterior radial carpal, superficial volar, metacarpal, dorsalis pollicis, dorsalis indicis, deep palmar arch.
Radial carpal, anterior and posterior.	Radial.....	Wrist and carpal joints.	
Radial, profunda.....	Superior profunda of arm.	Back of elbow.	
Radial recurrent, anterior.	Radial.....	Elbow-joint and muscles of forearm.	

ARTERIES, TABLE OF PRINCIPAL

Name.	Origin.	Distribution.	Branches.
Radial recurrent, posterior.	Posterior interosseous (forearm).	Elbow.	
Radialis indicis	Radial	Index finger.	
Ranine	Lingual	Tongue and mucous membrane of mouth.	
Renal	Abdominal aorta	Kidney	Inferior suprarenal, capsular (or perirenal), ureteral.
Sacral, lateral (1 or 2)	Internal iliac, posterior division.	Structures about sacrum	Spinal, rectal, muscular.
Sacral, middle	Continuation of aorta	Sacrum and coccyx.	
Scapular, dorsal	Subscapular	Muscles of infraspinous fossa	Infrascapular.
Scapular, posterior	Continuation of transverse cervical.	Muscles of scapular region	Supraspinous and infraspinous, subscapular, muscular.
Sciatic	Internal iliac, anterior division.	Pelvic muscles and viscera, and branches.	Coccygeal, inferior gluteal, muscular, anastomotic, articular, cutaneous, comes nervi ischiadici, vesical, rectal, prostatic, etc.
Sigmoid	Inferior mesenteric	Sigmoid flexure.	
Spermatic	Abdominal aorta	Scrotum and testis	Ureteral, cremasteric, epididymal, testicular.
Spermatic, external	Deep epigastric	Cremaster muscle, and spermatic cord.	
Splenic	Celiac axis	Spleen, pancreas, part of stomach, omentum.	Small and large pancreatic, left gastroepiploic, vasa brevia, terminal.
Sternal	Internal mammary	Sternum and triangularis sterni.	
Sternomastoid (or middle mastoid).	Superior thyroid	Sternomastoid, and other muscles of neck.	
Sternomastoid, inferior	Suprascapular	Sternomastoid muscle.	
Stylomastoid	Posterior auricular	Mastoid cells, tympanic cavity, etc.	Meatal, mastoid, stapedic, tympanic, vestibular, terminal.
Subclavian	Right, innominate. Left, arch of aorta.	Neck, thorax, arms, brain, meninges, etc.	Vertebral, thyroid axis, internal mammary, superior intercostal.
Sublingual	Lingual	Sublingual gland, side of tongue, and floor of mouth.	Artery of frenum.
Submental	Facial	Tissues under jaw	Muscular, perforating, cutaneous, mental.
Subscapular	Axillary	Subscapularis, teres major, latissimus dorsi, serratus magnus, axillary glands.	Dorsal and infrascapular.
Supraorbital	Ophthalmic	Orbit, frontal sinuses, diploë and upper eye-lid.	Periosteal, muscular, diploic, trochlear, palpebral.
Suprascapular (or transversalis humeri).	Thyroid axis	Muscles of shoulder	Inferior sternomastoid, subclavian, nutrient, suprasternal, acromial, articular, subscapular, supraspinous and infraspinous.
Tarsal, external and internal.	Dorsalis pedis	Skin and joints, etc., of foot.	
Temporal	External carotid	Forehead, parotid gland, masseter, ear.	Parotid, articular, masseteric, anterior auricular, transverse, facial, middle temporal, and anterior and posterior terminal.

ARTERIES, TABLE OF PRINCIPAL

Name.	Origin.	Distribution.	Branches.
Temporal, posterior....	Superficial temporal.....	Side of head and vertex.	
Thoracic, acromial (thoracic axis).	Axillary.....	Muscles of shoulder, arm, and chest.	Acromial, humeral, pectoral, clavicular.
Thoracic, alar.....	Axillary.....	Axillary glands.	
Thoracic, long (external mammary).	Axillary.....	Pectoral muscles, serratus magnus, mammary and axillary glands.	
Thoracic, short (or superior).	Axillary.....	Intercostal muscles, serratus magnus.	
Thyroid axis.....	Subclavian.....	Shoulder, neck, thorax, spine, cord.	Inferior thyroid, suprascapular and transverse cervical.
Thyroid, deep.....	Arch of aorta, innominate (occasional branch).	Same as inferior thyroid.	
Thyroid, inferior (ascending).	Thyroid axis.	Larynx, esophagus and muscles of neck.	Muscular, ascending cervical, esophageal, tracheal and inferior laryngeal.
Thyroid, superior (descending).	External carotid.....	Omohyoid, sternohyoid, sternothyroid, thyroid gland.	Hyoid, sternomastoid, superior laryngeal, cricothyroid.
Tibial, anterior.....	Popliteal.....	Leg.....	Posterior and anterior tibial recurrent, muscular, internal, and external malleolar.
Tibial, anterior, recurrent.	Anterior tibial.....	Tibialis anticus muscle.	
Tibial, posterior	Popliteal.....	Leg, heel and foot.....	Peroneal, muscular, medullary cutaneous, communicating, malleolar, calcanean, internal and external plantar.
Tibial, recurrent, posterior.	Anterior tibial.....	Back of knee-joint.....	Anastomoses with the inferior articular arteries of knee.
Tonsillar.....	Ascending palatine.....	Tonsil and Eustachian tube.....	
Tonsillar.....	Facial.....	Tonsil and root of tongue.	
Tracheal.....	Inferior thyroid.....	Trachea.	
Transversalis colli.....	Thyroid axis.....	Neck and scapular region.....	Superficial cervical and posterior scapular.
Ulnar.....	Brachial.....	Forearm, wrist, and hand.....	Anterior and posterior ulnar recurrent, common interosseous, muscular, nutrient, anterior and posterior ulnar carpal, palmar arch.
Ulnar carpal, anterior and posterior.	Ulnar.....	Carpal region.	
Ulnar, recurrent, anterior and posterior.	Ulnar.....	Muscles of arm and elbow-joint.	
Ulnocarpal, anterior....	Ulnar.....	Muscles of hand.	
Uterine.....	Internal iliac, anterior branch.	Uterus.....	Cervical, vaginal, azygos.
Uterine.....	Ovarian.....	Uterus.	
Vaginal (2 or 3).....	Internal iliac, anterior division.	Vagina.	
Vaginal azygos.....	Uterine.....	Vagina.	
Vasa brevia.....	Splenic.....	Stomach.	
Vertebral.....	Subclavian.....	Neck of cerebrum.....	Lateral spinal, muscular, anastomotic, posterior meningeal, posterior and anterior spinal, posterior cerebellar.

ARTERIES, TABLE OF PRINCIPAL

Name.	Origin.	Distribution.	Branches.
Vesical, inferior	Internal iliac, anterior division.	Bladder, prostate, seminal vesicles, and vagina (in female).	
Vesical, middle	Superior vesical	Bladder.	
Vesical, superior	Internal iliac, anterior division.	Bladder	Differential, uracheric, ureteric, middle vesical (occasionally).
Volar, superficial	Radial	Ball of thumb	Enters into formation of superficial palmar arch.
Volar, superior. See *Volar, superficial.*			
Xiphoid	Superior epigastric	Ensiform cartilage.	

ARTERIES, INJURIES.—**Contusion or bruising** of an artery without laceration or other injury of its coats occasionally occurs, and is said to be followed by contraction and permanent diminution in the size of the vessel, and even by gangrene of the limb.

Rupture or subcutaneous laceration of an artery is perhaps most often due to the passage of a wheel over a limb, incautious attempts to reduce an old dislocation of the shoulder, and excessive violence in breaking down adhesions in stiff joints.

1. The rupture may be *partial*—*i. e.*, only the internal and middle coats may be torn. In such a case the external coat may subsequently yield to the pressure of the blood, thus laying the foundation of an aneurysm; or the internal and middle coats may be folded inward into the interior of the vessel, obliterating its caliber and causing gangrene of the limb.

2. The rupture may be *complete*—*i. e.*, all the coats may be torn across. Gangrene may ensue, especially if the vein is also ruptured and the injury occurs in the lower extremity. Sometimes the extravasated blood is encysted.

Symptoms.—When the main artery becomes occluded, there will be pain at the seat of rupture and cessation of the pulse below, while gangrene will probably ensue later; or, if the artery is patulous, blood in large quantities will escape into the tissues, giving rise to a rapidly increasing swelling, in which no pulsation can be detected. When the extravasation is very large, constitutional symptoms of hemorrhage will also be present. Gangrene, if the ruptured artery is in the lower limb, will probably soon supervene. On the other hand, should the blood become encysted, the swelling will slowly assume the characters of an ordinary aneurysm.

Treatment.—(*a*) *When the artery is occluded,* all that can be done is to endeavor to prevent gangrene occurring by maintaining the warmth of the limb until the collateral circulation has had time to become established. Should gangrene occur, amputation must be performed as soon as a line of demarcation has formed. (*b*) *When blood in large quantities is extravasated into the tissues,* the treatment will depend on the situation of the ruptured artery. Thus, in the case of the popliteal, amputation is usually called for, especially if the vein is also ruptured, as gangrene will almost invariably ensue if the main artery is tied either above or at the seat of rupture.

Treatment of Wounded Arteries.—The following are the rules of Walsham:

1. When an artery is seen spouting in an open wound, a ligature should at once be applied to the bleeding end.

2. When the end of a large artery is seen pulsating, but not bleeding, in consequence of having been *torn* across, it is wise to apply a ligature to it as a precaution.

3. When an artery is exposed for some distance in its continuity, two ligatures, as a rule, had better be applied and the artery divided between them, especially if it is notched or bruised.

4. When an artery has ceased to bleed, even though the hemorrhage may have been sharp, the wound should on no account be enlarged for the purpose of tying the bleeding vessel, unless it can be seen or felt; for not only may it not bleed again, but as the bleeding has ceased, it may also be difficult or impossible to find it. In such a case, however, especially if the patient is much collapsed, he should be watched for the first sign of any return of the hemorrhage, firm pressure in the meantime being applied over the wound, and, when practicable, over the course of the main artery, above and below.

The whole limb, moreover, should be carefully bandaged from below upward.

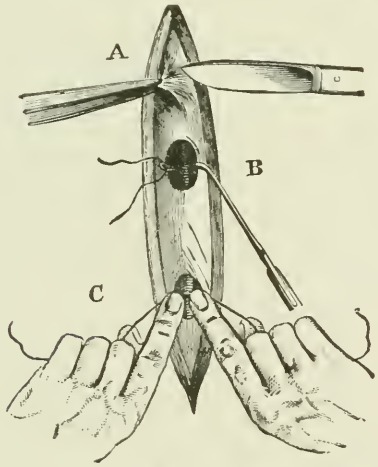
5. When the hemorrhage is moderate and clearly arterial, the external wound small, and the artery not visible, pressure should be applied in the way previously mentioned, and will probably suffice.

6. When the bleeding is severe and evidently arterial, and the external wound is still open, whether the wound is deep, recent, inflamed, or sloughing, the well-established rule—to which, however, there are, of course, exceptions—is to cut down upon the bleeding point and apply a ligature to each end of the artery if divided, or above and below the wound if the artery is punctured or only partially cut across. To do this it is generally sufficient to enlarge the wound in the soft tissues; but when the wound is on one side of the limb, and

the bleeding apparently comes from an artery on the other, a probe should be passed through the wound, its projecting point cut down upon, and the bleeding artery sought through this incision and tied. The object of this procedure is to prevent the necessity of making a very large wound.

While cutting down upon a bleeding artery, hemorrhage should be restrained by the use of an Esmarch bandage, or by the tourniquet, or the fingers applied to the main artery above the wound; in the case of a wound of the external iliac or gluteal, Davy's lever should be passed up the rectum and made to compress the common iliac. When it is impracticable to control the bleeding in any of these ways, the wound, if necessary, should be sufficiently enlarged to admit one or two fingers, and the bleeding vessel, having been recognized by the escape of warm blood, should then be compressed by the finger, the wound further enlarged, and the artery secured with the aid of an assistant before the finger is removed from the bleeding spot. Should gangrene ensue after ligation and spread rapidly, amputation must be performed at the seat of ligation; but if it involves only one or two fingers or toes, or spreads slowly, a line of demarcation should be awaited before amputating. See ARTERIES (Suture of).

ARTERIES, LIGATION. General Rules for Ligating.—(1) The incision is generally to be made parallel to the course of the artery, and the skin divided evenly to promote union by first intention



THIS DIAGRAM REPRESENTS THREE DISTINCT OPERATIONS: *A*. Opening the sheath. *B*. Drawing ligature round the artery. *C*. Tying artery.—(*Moullin.*)

(2) Each successive cut through the underlying tissues should be made the same length as that through the skin, and bruising of the parts avoided as much as possible. (3) The sheaths of muscles and tendons should not, if avoidable, be opened. (4) The sheath of the vessel having been exposed and the artery felt pulsating with the index-finger, the sheath should be pinched up with forceps, and opened by cutting with the blade of the knife on the flat. (5) The sheath being opened, it must be separated from the artery in the whole of its circumference, either by careful dissecting with the knife turned with its edge from the artery, or by the director insinuated by a gentle to-and-fro movement between the sheath and the artery. If this part of the operation is not done very delicately, too much of the sheath in the long axis of the artery will be separated, and there will be danger of secondary hemorrhage from cutting off of the blood supply which the vessel receives from its sheath. (6) Having separated the sheath, one side of it should be seized with the forceps and the needle passed, unthreaded, between it and the artery, and the point, by a gentle to-and-fro movement, carried around the vessel without injuring or including any of the contiguous structures. Save in exceptional cases, which will be mentioned, it should be passed from the side on which the vein lies. (7) When the point of the needle projects on the opposite side, it should be cleared of any loose cellular tissue of the sheath it may have carried before it, by scratching with the finger-nail or cutting on the needle with the edge of the scalpel directed from the artery. (8) The artery should be gently pressed between the curve of the needle and the finger, to ascertain that no other structure is included, and that pressure controls the pulsation in the aneurysm. (9) The needle should now be threaded with the ligature, which is carried around the artery as the needle is withdrawn; the ligature should then be tied in a reef knot and its ends cut off short. (10) Should much of the sheath have been unavoidably separated from the artery, two ligatures should be passed, and the artery divided between them. (11) Some form of aseptic ligature should be used, as silk, chromicized catgut, ox-aorta, or kangaroo-tail tendon, but the most suitable material can hardly be said to have been determined. (12) The wound should be accurately united, and if it is a deep one, it should be drained, and finally dressed antiseptically (Walsham).

Ligation of Special Arteries.—The common carotid artery may require tying for: (1) Wound of the artery; (2) a punctured wound near the angle of the jaw or tonsil; (3) aneurysm of the upper part of the artery or of one of its branches; (4) orbital, intracranial, or cirsoid aneurysm; and (5) aneurysm at the root of the neck (distal ligation). The artery may be tied either above or below the omohyoid. When practicable, it should be tied above, as it is here more superficial, and the risk of suppuration extending beneath the deep fascia into the chest is avoided.

The high operation, or ligation above the omohyoid: Make an incision 3 inches in length, with its center opposite the cricoid cartilage, along the anterior edge of the sternomastoid muscle—*i. e.*, in a line drawn from the sternoclavicular articulation to a point midway between the angle of the jaw and the mastoid process. Divide the skin, superficial fascia, platysma and deep fascia. Draw the anterior edge of the sternomastoid gently outward, and the artery will be felt pulsating in the angle formed by the omohyoid with the sternomastoid. Open the sheath on its inner side, and pass the aneurysm needle from without inward to avoid injuring the vein, which slightly overlaps

the artery on its outer side, and keep its point close to the vessel, lest the pneumogastric nerve be included in the ligation. The small descendens noni nerve runs superficial to the sheath, and, if seen, should be avoided. The superior thyroid, lingual, and facial veins cross the artery to open into the internal jugular vein. Should they impede the operation, divide them, having first applied two ligatures.

The low operation, or ligation below the omohyoid: Make an incision in the same line as for the high operation, but lower in the neck. Draw the sternomastoid outward and the sternohyoid and -thyroid inward, and the artery will be felt beating in the angle formed by the omohyoid with the sternothyroid. Pass the needle as before, from without inward, taking especial care not to injure the vein that on the left side slightly overlaps the artery. The head should be kept fixed, after ligation, by sand-bags or some form of splint.

The chief dangers after ligation are: (1) Cerebral disturbance from partial cutting off of the blood supply to the brain; (2) a low form of pneumonia from interference with the blood supply of the pneumogastric center; (3) suppuration descending into the mediastinum; and (4) suppuration of the sac when tied for aneurysm. The *collateral circulation* is carried on by the anastomosis of: (1) The vertebral with the opposite vertebral; (2) the inferior with the superior thyroid; (3) the internal carotid with the opposite internal carotid through the circle of Willis; (4) the deep cervical with the princeps cervicis of the occipital; (5) branches of the external carotid with the corresponding branches of the opposite side across the middle line of the neck.

The external and internal carotid arteries may be tied by an incision similar to that for the common carotid, but higher in the neck. A point to remember is that the internal carotid is in position at first external to the external carotid and that it is of larger size.

The lingual artery may require ligation for hemorrhage in cancer of the tongue, and as a preliminary to excision of the tongue. Make an incision along the greater cornu of the hyoid bone; divide the skin, superficial fascia, and platysma; hook up the submaxillary gland, and a few strokes of the director will expose the triangle, bounded below by the anterior and posterior belly of the digastric and above by the hypoglossal nerve. Scratch cautiously through the muscular fibers of the hyoglossus, which forms the floor of this triangle, taking care not to injure the lingual vein, which is superficial to the muscle; the lingual artery will be seen or felt lying upon the middle constrictor of the pharynx. The vessel, however, is often abnormal, and consequently may not be found in the usual situation.

The facial artery is readily tied at the anterior edge of the masseter, where it can be felt beating. It lies anterior to its vein. It is frequently tied in its course through the neck, in the removal of glands from that region.

The superior thyroid artery seldom requires tying, except for wounds of the neck, as "cut throat," and as a preliminary to removal of the thyroid body.

The temporal artery may require ligation for cirsoid aneurysm or a wound of the vessel. It may be readily secured at the spot where it is felt beating, as it crosses the zygoma just in front of the external auditory meatus.

The subclavian artery may be tied in the *third part of its course* for: (1) Axillary aneurysm; (2) aneurysm at the root of the neck (distal ligation);

Incision for the ligature of arteries in the neck. a. The temporal; b. the facial; c. the external carotid; d. the lingual; e. the common carotid; f. the third part of the subclavian.—(*Spencer and Gask.*)

(3) ruptured axillary artery; (4) secondary hemorrhage after amputation at the shoulder-joint; and (5) as a preliminary to the last-named operation. The head having been drawn well back, the face turned to the opposite side, and the shoulder depressed, draw down the skin over the clavicle, make an incision along the middle third of that bone through the integuments and platysma, so as to avoid injuring the external jugular vein, and let the tissues slip up again. Next divide the deep fascia on a director, and the posterior edge of the sternomastoid will be exposed. Hold aside, or divide if necessary, the external jugular or any other vein that may be in the way, but do not injure the suprascapular artery, as this is one of the chief vessels by which the collateral circulation will subsequently be carried on. Search with the finger and director for the scalene tubercle in the triangle bounded by the omohyoid above, the clavicle below, and the scalenus anticus on the inner side; the artery will be felt pulsating behind the tubercle. It has the vein in front of it, but on a lower plane, and the brachial plexus above it. Pass the needle from above downward. The artery, if necessary, may be tied in *the second part of its course* by extending the incision inward and partially dividing the scalenus anticus. Ligation of *the first part* has been so uniformly fatal hitherto that it will not be described. The *principal accidents* that may occur during ligation of the subclavian in the third part

of its course are: (1) Injury of the external jugular vein or other veins, and profuse venous hemorrhage; (2) wound of the sac of the aneurysm; (3) puncture of the pleura; (4) inclusion of a cord of the brachial plexus; (5) injury of the phrenic nerve. The *chief dangers after ligation* are pleurisy, secondary hemorrhage, and suppuration of the sac. The *collateral circulation* after ligation of the third portion is carried on by (1) the suprascapular and posterior scapular arteries anastomosing with the infrascapular, subscapular, and dorsalis scapulæ arteries; (2) the internal mammary, superior intercostal and aortic intercostal arteries anastomosing with the long and short thoracic arteries.

The axillary artery seldom requires ligation except for wound or rupture. In its continuity it may be tied in the first, second, and third parts of its course. In *the third part* it may readily be secured by making an incision, with the arm raised, through the skin and fascia along the inner border of the coracobrachialis and biceps (*b*). In *the first and second parts* of its course it lies below the pectoral muscles, and to expose it so deep a dissection is required that ligation of the subclavian is preferable. The *collateral circulation* after ligation of the first portion of the axillary is carried on by the same vessels as after ligation of the third part of the subclavian. After ligation of the third part of the axillary it is carried on chiefly by the anastomosis of small branches of the subscapular and circumflex above, with similar branches of the superior profunda below.

Lines of Incision for Ligation of Arteries of the Upper Extremity.

The brachial artery may require ligation for: (1) Wound of the artery; (2) aneurysm at the bend of the elbow; (3) wound of the palmar arch. It may be tied in any part of its course. Make an incision (*c*) along the inner edge of the biceps, in a line drawn from the anterior fold of the axilla to the middle of the bend of the elbow, through the integuments and deep fascia, avoiding the basilic vein, which lies over the course of the artery but superficial to the fascia. The median nerve crosses the artery along the middle of its course, from without inward. At the *bend of the elbow* make the incision obliquely from within outward (*d*), and divide the semilunar fascia of the biceps; the artery will be found between the tendon of the biceps on the outer side and the median nerve on the inner side. The *collateral circulation* when the artery is tied above the superior profunda is the same as that after ligation of the third part of the axillary. When tied below the superior profunda, it is carried on chiefly by the anastomosis of this vessel with the radial and interosseous recurrent and the anastomotica magna; when tied below the inferior profunda, by the additional anastomosis of this vessel with the posterior ulnar recurrent.

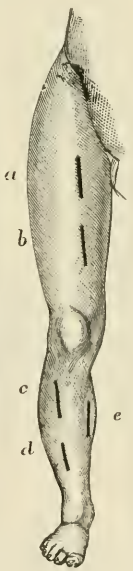
The radial and ulnar arteries may be tied for (1) aneurysm of either vessel or (2) wound of the palmar arch, but it is a question whether ligation of the brachial is not preferable in the latter case, as the anastomosis between the radial and ulnar and the carpal and interosseous arteries is so free. Both arteries, in the case of a wound of the palmar arch, must be tied. This is best done *at the wrist*, where they are superficial and can be felt pulsating. The radial lies between the supinator longus and the flexor carpi radialis; the ulnar between the innermost tendon of the flexor sublimis digitorum and the flexor carpi ulnaris, by which latter tendon it is slightly overlapped. An incision about an inch long through the integuments and deep fascia, parallel to the course of either vessel, is all that is necessary to expose them (*g*, *h*). In the case of the ulnar, however, the flexor carpi ulnaris may need to be held aside. The aneurysm needle should be passed from the ulnar to the radial side to avoid the nerve, which lies to the ulnar side. In the case of the radial, the needle may be passed either way, as the radial nerve at the wrist is not in contact with the artery. No harm will ensue if the venæ comites are tied with their respective vessels. *The radial artery in the upper third* lies deeply between the supinator longus and the pronator radii teres. Make an incision (*e*) in a line drawn from the middle of the bend of the elbow to half an inch internal to the styloid process of the radius. Separate the muscles, and the artery will be exposed. The radial nerve in this situation lies some distance to the outer side of the artery. *Ligation of the ulnar in the upper third* is more difficult, as it lies beneath the superficial flexor muscles. Make an incision (*f*) 4 inches long in a line drawn from the front of the internal condyle to the radial side of the pisiform bone. Seek the interval between the flexor carpi ulnaris and the flexor sublimis digitorum. Separate these muscles, and the ulnar nerve will be seen. Operate superficial to the nerve, and the artery will be found between the flexor sublimis and flexor profundus digitorum.

The external iliac artery may require ligation for: (1) Aneurysm in the groin; (2) secondary hemorrhage from the femoral; (3) a wound of the vessel itself. A line drawn from half an inch below and a little to the left of the umbilicus to the middle of Poupart's ligament indicates its course. Make a curved incision, beginning a little external to the center of Poupart's ligament, upward and outward for about 3 inches, toward the anterior superior spine of the ilium. Divide the skin, superficial and deep fascia, and the aponeurosis of the external oblique; cut more carefully through the internal oblique and transversalis muscles, and the fascia transversalis will be exposed. Divide this on a director, taking care not to injure the peritoneum. Separate the peritoneum gently from

the psoas muscle, and let an assistant press it carefully upward and inward. The artery will now be felt beating at the inner part of the wound, along the inner border of the psoas. Pass the aneurysm needle from within outward, to avoid injuring the vein, which lies to the inner side of the artery. The small crural branch of the genitocrural nerve lies on the artery, and the circumflex iliac vein and vas deferens cross it just before it passes under Poupart's ligament. The *chief accidents* that may occur during ligation are: (1) Injury of the peritoneum; (2) wound of the vein; (3) wound of the spermatic cord; (4) wound of the epigastric artery; and (5) puncture of the circumflex iliac vein. The *chief dangers* after ligation are: (1) Gangrene of the limb; (2) peritonitis; (3) secondary hemorrhage. Should secondary hemorrhage occur, carefully applied pressure must be tried. If this fails, no alternative remains but the desperate one of cutting down on the bleeding vessel and trying to secure it. Davy's lever should be used to control the hemorrhage during the operation. The peritoneum will probably be opened, and success will be problematic. The *collateral circulation* is carried on chiefly by the anastomosis between the internal mammary and deep epigastric; the iliolumbar and circumflex iliac; the gluteal and external circumflex; the obturator and internal circumflex; the sciatic and the superior perforating and internal circumflex.

The common iliac artery has been ligated for aneurysm of the external iliac and for gluteal aneurysm; the **internal iliac artery** also for gluteal aneurysm. Both arteries may be reached by prolonging the incision for ligation of the external iliac, and both have recently been tied through the peritoneum. Both operations were formerly attended with the most unfavorable results, but of late there have been several successful cases in which the abdomen has been opened in the middle line, the intestines drawn aside, and the vessels exposed by scratching through the peritoneum.

The superficial femoral artery may be ligated for: (1) Wound of the artery itself; (2) popliteal aneurysm; (3) hemorrhage from a wound of one of the tibials. The ligature may be applied either in Scarpa's triangle or in Hunter's canal. *In Scarpa's triangle* the artery is usually tied at the apex, where the sartorius touches the adductor longus. If necessary, the liné of the sartorius may be marked on the skin with lunar caustic by putting the muscle in action before the patient is anesthetized. Slightly flex the leg, and place the thigh on its outer side in a position of slight abduction and flexion. A line drawn from a point midway between the symphysis pubis and the anterior superior iliac spine to the adductor tubercle in this position indicates the course of the artery (*a*). Make an incision about 3 inches long in this line, beginning about 4 inches below Poupart's ligament; cut through the skin and superficial fascia, and divide the deep fascia on a director. Draw the sartorius gently *outward*, and the sheath of the vessel will be exposed. Open this in the usual way, avoiding the small branch of the internal cutaneous nerve, which crosses the artery at this spot. Pass the aneurysm needle from within outward, to avoid injuring the vein, which lies to the inner side of, and a little posterior to, the artery. *In Hunter's canal* the same line as the preceding indicates the course of the vessel (*b*). Place the limb as before, and make an incision 3 to 4 inches long in the line of the artery, in the middle third of the thigh. Divide the superficial and deep fascia, and the sartorious will be exposed. It may be recognized by its fibers running downward and inward. Draw the muscle to the *inner* side, and the aponeurotic covering of Hunter's canal (recognized by its strong transverse fibers) will be seen. Divide it on a director, and the artery will be found lying between the vastus internus on the outer side and the adductors longus and magnus on the inner side. The vein is behind and a little external to the artery. The long saphenous nerve crosses the artery from the outer to the inner side. Pass the aneurysm needle from without inward, keeping the point well applied to the vessel, as the vein in this situation is usually very adherent to the artery. The *chief dangers* after ligation are: (1) Gangrene; (2) secondary hemorrhage; (3) phlebitis and pyemia, from pricking the vein. The *collateral circulation* is carried on by the anastomosis of (1) the perforating branches of the profunda with the articular branches of the popliteal; (2) the descending branch of the external circumflex with the external articular branches of the popliteal and tibial recurrent; and (3) the artery of the great sciatic nerve with the internal articular branches of the popliteal.



Lines of Incision for Ligation of Arteries of Lower Extremity.

The popliteal artery may be ligated in its upper part for popliteal aneurysm. Place the limb on its outer side and make an incision about 4 inches long at the upper part of the popliteal space over the course of the artery. Divide the deep fascia and locate the pulsation of the vessel at the inner margin of the semimembranosus. Hook the nerve outward or inward, and open the sheath well to its inner side to avoid the vein.

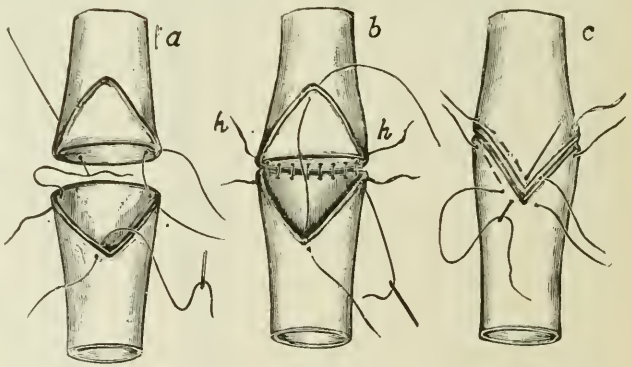
The Posterior Tibial Artery.—*In the upper third:* Place the limb on its outer side, and make an incision 4 inches long parallel with, and one-half of an inch posterior to, the inner border of the tibia (*c*). Divide only the skin and the superficial fascia in the first incision, to avoid injuring the long saphenous vein. Then divide the deep fascia and draw the gastrocnemius, if seen, backward; cut through the tibial origin of the soleus, and the intermuscular fascia will be exposed. Divide this on a director, and the artery will be found lying on the tibialis posticus, with the posterior tibial nerve to its outer side. Ligation of the posterior tibial in its upper third can hardly be required, except for a

wound, which should then be enlarged longitudinally until sufficient room is obtained. *At the ankle:* Make a curved incision over the artery a finger's breadth behind and below the internal malleolus. Divide the superficial and deep fascia and the internal annular ligament, and the artery will be found between the tendons of the flexor longus digitorum and flexor longus hallucis, with the nerve to its outer side.

The Anterior Tibial Artery.—A line drawn from the inner side of the head of the fibula to midway between the two malleoli indicates the course of the vessel. *In the upper third* make an incision about 5 inches long in the line of the artery (*c*), through the skin and superficial fascia, and look for the innermost white line, which indicates the cellular interval between the tibialis anticus and the extensor longus digitorum. Divide the deep fascia over this line on a director; hold the muscles apart by retractors, and the artery will be found on the interosseous membrane, with the nerve to its outer side. *In the middle third* the artery lies between the tibialis anticus and extensor proprius hallucis, and the nerve lies on the artery. *In the lower third* the artery lies between the extensor proprius hallucis and the extensor longus digitorum, with the nerve on its outer side. An incision in the line of the artery (*d*) and the separation of the muscles is all that is necessary to expose the vessel in any of these situations.

The dorsalis pedis artery may require ligation for a wound on the dorsum of the foot or for aneurysm of the vessel itself. Make an incision in a line drawn from midway between the two malleoli to the interval between the great and second toes; divide the skin and the superficial and deep fascia; the artery will be found between the extensor proprius hallucis and the innermost tendon of the extensor longus digitorum. As the artery sinks into the sole, it is crossed by the innermost tendon of the extensor brevis digitorum. The anterior tibial nerve is on the outer side.

ARTERIES, SUTURE.—This is carried out by means of a small round needle (No. 12) and fine silk (No. 000) by passing the sutures through all the coats. The glovers' in-and-out suture must be used so that the walls of the vessel shall pout out a little; this brings the endothelium accurately into contact and leaves no roughened surface within the lumen. For end-to-end union of a completely divided artery, the circular or oval cut section is drawn into the shape of a triangle by three equidistant fixation sutures. Then the three points of one triangle are approximated to the three points of the other by tying together the fixation sutures, while between the points in-and-out sutures are inserted as noted above. Implantation of the cut end of a vessel into the continuity of another may be done on the same lines, by first inserting fixation sutures to form two triangles.



ARTERY SUTURE.—*a*. Insertion of three fixation sutures so as to draw the divided ends into triangles. *b*. Approximation by the fixation sutures *h*, *h*, and suturing together of one side of each triangle. *c*. Suturing of a second side (*Spencer and Gask.*)

ARTERIOSCLEROSIS. **Synonyms.** — Atheroma. Chronic endarteritis. Anteriocapillary fibrosis. Arteriofibrosis. Angiosclerosis.

Definition.—A chronic inflammatory process, localized or diffuse, that takes place in the intima, producing a proliferation of round cells with wandering cells, and causing a distinct hardness and loss of tone in the arterial system.

Etiology.—Arteriosclerosis is a physiologic accompaniment of old age and it is often herditary. Rheumatism, syphilis, alcohol, heart-disease, and kidney-disease, gout, diabetes, excessive muscular or mental strain, lead-poisoning, toxins of acute infectious diseases, are the most common causes. "Time, tension, and toxins."

Pathology.—There is an inflammatory proliferation of the cells of the outer coat of the intima, which finally affects the adjacent coats. Often there is a tendency for the process to become localized, and this is termed **atheroma.** In atheroma the areas are at first whitish, but later undergo fatty degeneration and become yellowish or opaque. There is usually a tendency for certain portions of the area to undergo calcareous degeneration, with the formation of atheromatous plates. This process is very frequently seen in the arch of the aorta, thoracic aorta, coronary artery, and cerebral arteries. In the more diffuse form in advanced stages, the media and adventitia are invaded and the capillary walls are also thickened.

Results.—The process may affect the valves of the heart, setting up disease of these parts. Sudden distention may rupture the smaller vessels in the brain, giving rise to apoplexy; or, if in the larger vessels, an aneurysm may ensue.

Symptoms.—Slow rate and increased tension in the pulse, "pulsus tardus," causing a hardness, often feeling like "pipe stems." From the increased pressure in the arteries the heart must do more work, and often great hypertrophy of the cardiac muscle ensues. The coronary arteries may be involved, leading to fibroid degeneration, fatty degeneration, and the symptoms of angina pectoris, absence of compensation, dyspnea, scanty urine, and other symptoms.

Intermittent claudication (Charcot's symptom) may be observed. It is apparently due to the

deficient blood supply and is characterized by lameness, tingling, and other sensory disturbances, numbness, weakness and pain in the muscles of the legs upon the slightest exertion.

The cerebral arteries may be involved, indicated by headache, vertigo, insomnia, mental sluggishness, and hence apoplexy is common. The kidneys may next suffer, giving rise to interstitial nephritis or contracted kidney. The Stokes-Adams syndrome may be found. The arcus senilis is frequently present. (See BLOOD PRESSURE.)

Sequels.—Apoplexy, atheroma of coronary artery or chronic myocarditis, angina pectoris, interstitial nephritis, aneurysm, gangrene of the extremities by reason of embolism or thrombosis of the terminal arteries.

Prognosis.—A person with arteriosclerosis may live until late in life, and then he may be struck dead with apoplexy without any warning whatever, especially if suffering from organic disease of the heart or kidney, so that the prognosis is indefinite, depending upon hereditary influences and mode of life of the individual.

Treatment.—Seek diligently for any predisposing cause. Alcohol in any form should be absolutely interdicted. Attacks of gout and rheumatism should be prevented as far as possible by the restriction of animal foods, tea, and coffee. In these cases a vegetable diet is best. If due to heart-disease, kidney-disease, or syphilis, each will require its special line of treatment. The iodid treatment is commonly used. The iodid of potassium should be given in moderate doses long continued. Cardiac tonics are indicated. When hypertension exists, erythrol tetranitrate should be given in doses of 1/10 to 1/2 grain or glyceryl nitrate in doses of 1/100 to 1/50 grain. Recently Trunecek's artificial serum has been used. It contains the normal blood salts. It is given in tablets, 2 thrice daily, each of which contains sodium chlorid 6 1/4 grains, sodium sulphate 5/8 grain, magnesium phosphate and sodium carbonate of each 1/4 grain, sodium phosphate and calcium glycerophosphate of each 1/5 grain. Lacto-serum, serum of milk, sterilized without heat, in daily injections of 10 c.c. into the thigh, is reported to have been of marked value in arterial hypertension. The kidneys may be kept active by diuretics, such as:

℞. Lithium citrate, ʒ iss
Spirit of nitrous ether, ʒ iv
Solution of potassium citrate, ʒ ij
Water, enough to make, ʒ iij.

Two teaspoonfuls every 3 or 4 hours.

Benzoate of lithium may also be given in combination with the foregoing, or separately in doses of 5 grains every 4 hours. At the same time the skin should be kept active by proper amount of exercise, hot baths, and thorough massage.

ARTHRALGIA.—A general term used to indicate pain in a joint. It is sometimes used as a synonym for gout, rheumatism, or arthritis, to signify the pain attendant thereto. It is specifically used to mean neuralgia of a joint. It is extremely rare as an independent affection, but common as a complication. The pain is more often superficial or around the joint, than in it. The pain may be referred and unattended by local lesion, as is the case with hip-joint disease, in which the pain is referred to the knee, or as in chronic myelitis, or in locomotor ataxia, in which there are various referred joint-pains. Neuralgia of a joint may indicate some obscure lesion, as chronic inflammation of the bone. Irritation from the ovaries, the uterus, and the rectum may give rise to reflected joint-pains. The pain itself may be dull and aching, but is more often sharp and shooting. It may come in storms at periods, or be continuous and persistent.

Soreness of the joint on movement, some slight redness and heat, and swelling, with slight fixity of the joint, may be attendants. The redness and swelling, however, will generally be found to have been the result of friction or of the use of irritants. The suddenness of the onset, the absence of constitutional symptoms, the free mobility of the joint, especially under ether, and the condition and temperament of the patient must be considered in differentiating the character of the joint-affection. Disease or injury to the central nervous system, rheumatism, gout, syphilis, malaria, hysteria, neurasthenia, and neuritis may give rise to arthralgia.

The treatment of this condition is directed to the causes. Phenacetin is useful during the attacks, but morphin with his knowledge should not be given to the patient, even in severe cases. Hexamethylenamin (urotropin) in full doses, 10 grains every three hours, is sometimes effective in cases of gonorrheal or septic origin. Locally, external heat, warm flannel cloths, alone or with soap liniment, aconite, laudanum, or chloroform thereon, sometimes friction, may give relief. If any tendency to stiffness results, friction, the hot and cold douche, passive motion, and daily massage should be employed. Neurectomy and nerve stretching are last resorts. The condition of the general health should be kept in mind. See GOUT, JOINTS (Diseases), RHEUMATISM.

ARTHRECTOMY.—See EXCISION OF JOINTS.

ARTHRITIS.—A generic term signifying any disease involving a joint, but more strictly an articular inflammation. All the structures composing and surrounding a joint, including the synovial membrane, are embraced in the inflammation. It may be traumatic, rheumatic, syphilitic, suppurative, tuberculous, gonorrheal, or due to typhoid infection, to gout or to spinal lesions. It occurs as acute and chronic arthritis. See JOINTS (Diseases).

ARTHRITIS DEFORMANS. See JOINTS (Diseases).

ARTHROPATHY.—A peculiar disease of the joints similar to rheumatoid arthritis, but, according to Charcot, a distinct disease. It belongs to the prodromal stage of tabes, rapidly destroys the joint, is painless, without fever or inflammation, prefers the large joints, and is connected with hydrarthrosis and swelling of the joints. See JOINTS (Diseases).

ARTIFICIAL ANUS.—See Anus (Preternatural), Intestines (Surgery).

ARTIFICIAL EYE.—A shell of glass, made to imitate the anterior portion of the eyeball and retained in place behind the eyelid. After the healing of an enucleation a deep furrow results, into which the upper and lower rims of an artificial eye are inserted. The deeper this furrow, the better. Cicatrization may make it so shallow that it becomes impossible to wear an artificial eye. An artificial eye moves conjointly with the other eye, but its excursions are shorter.

An artificial eye may be worn 2 or 3 weeks after operation, all inflammation having subsided, and early use is advisable to prevent absorption of the orbital fat. The orbit is very tolerant of foreign bodies, but the shell should not be worn more than an hour or two at a time for the first few days.

To insert the shell, place the left hand flat upon the forehead, with fingers downward; with the two middle fingers raise the upper eyelid toward the eyebrow. With the right hand push the upper edge of the eye beneath the upper lid, which may now drop. Support the eye with the middle finger of the left hand, while the lower eyelid is raised over the lower edge with the right hand.

To remove the eye, draw down the lower lid with the middle finger of the left hand. With the right hand steady the lower edge of the eye, and gently raise forward over the lower lid. Care must be taken that the eye does not fall to the ground. An artificial eye should be taken from its orbit every night, cleansed, and placed in water overnight. In time it loses its luster, and should be replaced by a new one.

ARTIFICIAL FEEDING.—See Infant Feeding, Milk, Modified Milk, etc.

ARTIFICIAL LIMBS.—It is best to have instrument-makers take their own measurements, but the following data may be given by the patient, and may suffice for directions to make an artificial limb:

1. State whether a right or a left limb is desired.
2. Give the full measurements of the sound limb.
3. State in inches the exact spot where the amputation has been done.
4. Give a complete series of measurements (with diagram) of the stump.
5. Indicate the exact position of each joint by measurements, when the growth of one limb has not been equal to that of the other.
6. Tracings of the sound stump (hand or foot) should be given.

After Chopart's amputation of the foot, or when the thumb, a finger, or a hand is needed, a cast of the stump may be required. After Syme's operation a tracing may suffice. A boot is serviceable.

In taking measurements of the sound leg the knee should be in extension. Girths should be taken: one around the ankle and one around the calf and between the two; one should be taken between the calf and the knee, one of the knee, two of the thigh, and one of the wrist, and in each case the exact height, in inches, of each girth taken should be given. A shoe or a shoemaker's measurements should be sent, and will be of much service.

Of perpendicular heights, the height from the fork of the leg or body to the ground, that from the summit of a bent knee to the ground, and that from the middle of the calf to the ground should be taken. In the arm the elbow-joint is to be used as a fork, and as the place from which measurements are to be taken, both internally and externally.

The simpler an appliance, as a rule, the more useful it is. Especially is this so with regard to the lower extremity. The ignorant usually believe the contrary, and experience alone will convince. Elaborate and expensive artificial limbs for growing children are not to be advised. They require bucket-legs, stump-boots, etc., which may be frequently adjusted to their growing height, and suit play-ground proclivites.

ARTIFICIAL PUPIL.—See Iridectomy.

ARTIFICIAL RESPIRATION.—Methods of exciting and maintaining chest movements so as to supply air to the lungs; most useful in cases of drowning, in asphyxia in accidents during anesthesia administration, and in asphyxia of the new-born.

Precautions Necessary.—See that the air-passages are free for the admission of air, and to this end clothing that constricts the neck, chest, or abdomen must be loosened, the tongue must not be allowed to lie back to occlude the pharynx or press down the epiglottis, foreign bodies must be removed, and the trachea and bronchi should be free from fluids. The head should be turned upon one side, and generally lower than the pelvis, to provide against the inhalation of vomitus; the mouth or nares must be kept clear and open, and the tongue pulled forward. For the mechanic expulsion of fluids in the trachea or bronchi, place the patient on the face, see that the trunk is higher than the mouth, the mouth kept open and tongue forward. Exert steady, firm pressure around the margin of the thorax and the upper part of the abdomen, to expel the fluids. This should be done thoroughly and quickly, the patient on the ground, or, better, on a table of convenient height.

A knife-handle placed between the teeth will make a ready and useful gag to keep the mouth open. A button-hook is sometimes serviceable in the absence of forceps. The use of a cloth wound round a stick will, by rotatory motion, help to remove mucus and vomited matter.

Artificial respiration is a purely mechanic act, and one in which, efficiently performed, air must enter the lungs. It is most important that it is not performed too quickly nor too violently. Twelve to 16 respiratory acts a minute are sufficient. When pressure is employed on the chest-walls, it must be certain and steady.

There are five principal methods: Sylvester's method, Howard's method, Marshall Hall's method, Schaefer's method, and the method of mouth-to-mouth insufflation.

Sylvester's method is performed by grasping

the arms of the patient lying prone—or, better, with head lower than the body—above the elbows, drawing the arms steadily upward above the head, and keeping them so stretched for from 3 to 4 seconds. Next turn the arms downward, and press them firmly against the sides of the chest for from 2 to 3 seconds. These movements are to be repeated from 15 to 20 times a minute, with perseverance, if needful, for from 1 to 2 hours. An assistant may aid by pressing upon the lower ribs and the diaphragm at the same time that compression is made by the arms. If much congestion exists about the head and face, the external jugular vein may be opened. When natural respiration has been established, a warm room, a warm bed, an enema of brandy, and beef-tea may be employed, and but little water given by the mouth.

Prone Pressure Method of Artificial Respiration.

Howard's Method.—The respiratory and alimentary tracts are first cleared, as follows: The patient is placed face downward, with a pillow or roll under the pit of the stomach, the head resting upon the forearm. The attendant stands over the patient and then places his left hand on the lower and back part of the left side of the chest, while the right hand is laid upon the spinal column, about on a line with, or a little above, the left hand; firm pressure is then made, and continued while three is counted slowly, and ended with a vigorous push. These movements are repeated as long as fluid flows from the mouth.

The patient is now turned upon his back, face upward, and a roll placed under his shoulders. The hands are carried above the head and tied together. The attendant kneels astride the patient's hips and presses with his open hands upon the lower borders of the chest slowly and firmly upward and inward, with his body thrown forward until his face almost touches the patient's face. A sharp push is then made, bringing the attendant to the upright position. A rest of 2 or 3 seconds should then follow, and the movement be repeated. These measures should not be abandoned for two hours.

Marshall Hall's method is performed by placing the patient on one side and alternately rolling him on his face to compress the chest, and on his back to allow the elasticity of the ribs free movement to draw air into the lungs. The arm of the side rolled upon may be drawn above the head. Either side may be used.

Schaefer's Method, also called the prone pressure method.—This method is extremely simple, does not give rise to any complications, affords the entry of more air into the patient's lungs, and requires less physical effort on the part of the operator. There can be no doubt that this is the best method yet devised, and the technic should be acquired by all. The patient is placed on the ground, with his face downward, and with a thick folded garment or pillow under the lower part of the chest. Care must be taken that the entrance to the mouth and nose is clear. The operator places himself in a kneeling posture astride of the patient, facing the patient's head, his knees being opposite the patient's hip. He then places his hands flat over the back of the lower ribs, one hand on each side, and gradually throws the weight of his body forward, so as to make firm pressure on the lower ribs. By this means the chest is compressed and air is forced out of the lungs. The operator then brings his own body up into the semi-erect position, but still retaining his hands in position, thereby relaxing the pressure on the ribs, and enabling air to be drawn into the lungs by the elastic reaction of the chest wall. The process is repeated regularly about 15 times a minute, and should be continued for at least half an hour. The advantages claimed for this method by its originator, are: (1) Its relative efficiency; (2) the ease with which it is carried out; (3) the absence of risk of injuring the liver or fracturing the ribs; (4) the facilities afforded for the escape of fluid from the mouth, and (5) the natural tendency of the tongue to fall forward.

Mouth-to-mouth insufflation is not to be depended upon, for it is difficult to keep the larynx open or to prevent the air passing down the esophagus.

Instruments have been devised for the performance of artificial respiration, but they interfere with the first faint return movements of natural respiration.

Oxygen is indicated in many cases of artificial respiration, but its results are not satisfactory.

Tracheotomy is not to be considered in any case in which air can be made to pass, even in small quantities, through the trachea.

For **resuscitation of the new-born,** see Asphyxia Neonatorum, New-born Infant (Asphyxia), Pulmotor.

ARYLARSONATES.—Arsenical compounds used as substitutes for mercury in cases in which the latter is not tolerated. See Arsacetin, Atoxyl, Soamin.

ASAFETIDA.—A gum-resin obtained by incision from the living root of *Ferula fœtida*. It occurs in whitish tears embedded in a grayish sticky mass, of alliaceous odor and taste, soluble in alcohol to at least 60 percent, and when triturated with water it yields a milk-white emulsion. Its principal constituent is a *sulphuretted volatile oil*, consisting chiefly of allyl sulphid. It also contains a gum and a resin, with ferulaic, malic, acetic, formic, and valeric acids. Dose, 2 to 8 grains.

It is a mild stimulant to the circulatory and nervous systems, and an excellent carminative. It is also a stimulating expectorant, tonic, laxative, diuretic, emmenagog, aphrodisiac, and anthelmintic. The disgust generally felt for this drug makes its use restricted. Its odor and taste are extremely nauseous and persistent. The emulsion is highly useful in the flatulent colic of infants. The pill form is the best for administration in nervous excitement and hysteria. A suppository may be used in infantile convulsions and in the restlessness of low fever:

℞. Pulverized asafetida, 5 j
Quinin sulphate, gr. xxx
Oil of theobroma, to make 12 suppositories.

One may be used every 3 or 4 hours.

Preparations.—**Tincture of Asafetida.** Dose, 10 to 30 minims. **Emulsion of Asafetida** (*Milk of Asafetida*). Strength, 4 percent in water. Dose, 2 to 8 drams. **Pills of Asafetida.** Each pill has 3 grains of asafetida, and 1 grain of soap. Dose, 1 to 4 pills. **Mixture of Magnesia and Asafetida** (*Dewees' carminative*) has of magnesium carbonate 5, tincture of asafetida 7, tincture of opium 1, sugar 10, distilled water to 100 parts. Dose, 1/2 to 4 drams.

ASCARIS.—See Worms.

ASCITES. Definition.—An accumulation of fluid in the peritoneal cavity. Ascites is a symptom and not a disease.

Etiology.—(1) Nephritis; (2) diseases of the liver, especially atrophic cirrhosis; (3) heart-disease; (4) pressure of an abdominal tumor; (5) chronic peritonitis; (6) tuberculosis.

Symptoms and Clinical Course.—Abdominal distention, great exhaustion, dyspnea, feeble pulse, scanty urine, constipation, and generally edema of the lower extremities.

Inspection.—The abdomen is distended, the navel projects, the abdominal veins are enlarged, especially noticeable around the region of umbilicus, producing the *caput medusæ*. When the patient assumes the dorsal decubitus, the flanks project on each side.

Palpation elicits fluctuation.

Percussion confirms palpation. The fluctuation is more readily detected by having the patient press downward with the hand placed vertically below the region of the umbilicus while the examiner's hands are on each side making gentle percussion.

Movable dulness is also present. To detect this the patient should first lie on one side, when percussion is made in lower flank, and on turning to the other side the fluid gravitates, giving place to a tympanitic note where dulness previously existed.

Aspiration.—There is withdrawn a clear amber-colored fluid, of a specific gravity from 1012 to 1016.

Diagnosis.—

Ascites.	Ovarian Tumor.	Pregnancy.	Distended Bladder.
1. Frequently associated with heart- or kidney-disease.	1. Heart and kidneys normal.	1. Same as ovarian tumor.	1. Heart normal; urine suppressed.
2. Navel often protrudes; caput medusæ present.	2. Same as ascites.	2. Abdominal veins enlarged.	2. Abdominal veins normal.
3. Percussion note gives dulness, more perceptible in flanks or lower abdominal region, where the fluid gravitates; movable dulness.	3. Percussion note gives dulness rather high up; dulness not movable.	3. Same as ovarian tumor suppression of menses.	3. Dulness immovable; catheter confirms diagnosis.
4. Tumor develops from below and extends upward.	4. Tumor develops to right or left of median line.	4. Enlargement develops in area of uterus.	4. Enlargement develops in region of bladder.

Treatment consists in absolute rest in bed and a diet composed of soft-boiled eggs, beef-juice, underdone steak, stewed fruits, and vegetables. Some cases do well upon a strictly milk diet. Compound jalap powder (1/2 dram) may be given 3 times daily to produce thorough catharsis. Magnesium sulphate, 4 drams, dissolved in quarter of a glass of water may be taken daily before breakfast. Liquids should be restricted as much as possible. Should these measures fail to give relief, paracentesis abdominis may be done to withdraw the fluid.

Method of Tapping.—The bladder should first be emptied. The patient sits on the edge of the bed, or is propped up by means of pillows. The operator, after anesthetizing the parts, makes a short incision about 1 1/2 inches below the umbilicus, dividing the superficial tissues; then with a quick motion thrusts in a trocar and cannula (a sufficient distance, varying in different individuals); the trocar is then withdrawn, allowing the fluid to escape.

Pressure over the abdomen may be made by means of a 4-tailed bandage to prevent collapse. Whisky (1/2 of an ounce) may also be given while the fluid is draining away.

Any sign of faintness on the part of the patient is an indication that the operation should cease.

The operation may be repeated frequently. See PERITONITIS.

ASEPSIS.—The condition of nonputrefaction; the absence of all septic material or of pathogenic organisms. It is especially necessary in surgery and obstetrics. In surgery the method should be used only in uninfected areas. It consists of the use of moderate heat, chemic germicides, or both, to prepare the instruments, hands of operators, and the field of operation. No chemic germicide, however, is used after incision is made. If no irrigation is employed during the operation, the method is known as the "dry" method, simple sterilized sponges being used. If irrigation is employed, boiled water is used. It is impossible to render a large field of operation absolutely aseptic by any known method.

A description of the technic of **aseptic surgery** is given under ABDOMINAL SECTION (*q. v.*).

ASEPTIC FEVER. (Reactionary, simple traumatic, or resorption fever) is seen after subcutaneous injuries, such as contusions, fractures, and sprains, and after aseptic operations. It is due to the absorption of sterile products of cellular disintegration, chiefly fibrin ferment, from extravasated blood or from exudate, hence is apt to be of greater degree after the use of strong antiseptics. The only symptom is a slight rise in temperature, rarely more than 101° F., which disappears by the end of the second or third day. If the fever persists beyond this time, especially if other symptoms appear, it is almost surely due to some other cause, most likely infection of the wound. The erythematous and urticarial rashes which are sometimes described in connection with this condition are probably due to intestinal derangement, as they subside after the bowels have been freely evacuated. Aseptic fever requires no treatment.

ASPARAGIN.—See ALTHÆA.

ASPERGILLOMYCOSIS.—See PARASITES (Vegetable).

ASPHYXIA.—A term signifying, literally, pulselessness, but generally understood as the condition resulting from the interruption of the function of respiration. Apnea signifies not only the condition of suspended animation from respiratory failure, but also arrested respiration from an excess of oxygen in the blood. Asphyxia may arise from the inhalation of gases, such as carbonic acid gas, charcoal fumes, or sulphuretted hydrogen; by strangling or throttling; by the impaction of foreign bodies in the larynx or trachea; by failure of the respiratory apparatus, as in fractures of the spine above the origin of the phrenic nerve; and from poisoning with strychnin or curare, or from anesthesia, from compression of the chest, etc.; but by far the most common cause is drowning.

Death is sudden when the obstruction to respiration is complete, but otherwise it is gradual in its onset.

The excess of carbon dioxid in the blood at first stimulates, then paralyzes, the respiratory center in the medulla. Artificial respiration is therefore required in cases of sudden asphyxia. Lividity is the most prominent symptom of asphyxia, although convulsive twitchings about the mouth and limbs and prominence of the eyeballs are noticed. The lividity is most marked in the lips and tongue, which, just before death, become almost black. The heart continues beating after all signs of respiration have ceased. This has led to the various means of artificial respiration. See ARTIFICIAL RESPIRATION, DROWNING, etc.

ASPHYXIA NEONATORUM.—A pulseless condition of the new-born, generally due to mechanic interference with the circulation of the oxygenated blood in the fetus, as may happen from flooding; from premature detachment of the placenta; from pressure upon the cord, resulting in premature stimulation of the respiratory centers from the accumulation of carbon dioxid in the fetal blood; or from the inherent debility of the child from any prenatal cause.

There are two varieties. In **asphyxia livida** we have cyanosis; injected conjunctivæ; protuberant eyes; strong cardiac action; slow, full pulse; cutaneous sensation; tense musculature; umbilical pulse; intermittent respirations, with generally a favorable prognosis.

In **asphyxia pallida** we find death-like paleness; relaxation; minimum heart-beat; no umbilical pulsation; diaphragmatic respiration poorly established; sphincter paralysis; conjunctival and cutaneous insensibility, also of the palate, which, when it fails to respond to tickling with a finger, indicates an unfavorable prognosis.

Prognosis.—According to Bouchut, if careful auscultation for five minutes fails to reveal any heart-sounds, the case is hopeless; otherwise persevere so long as any action of the heart can be detected, though the duration and degree of the compression endured determines the danger of the asphyxia. It must also be remembered that even when life is preserved, there is subsequent danger from pneumonia or cerebral compression, which may produce permanent paralysis or idiocy later in life.

Prophylaxis, whenever possible, should be attempted, especially in breech presentations and prolapse of the cord, by methods described in the standard text-books on obstetrics.

Treatment.—1. When there has been premature inspiration, remove all foreign substances from the mouth and trachea, if necessary, by aspiration through a flexible catheter thrust into the windpipe.

2. Stimulate respiration by slapping the child's back and buttocks, or by sprinkling alternately with hot and cold water, or immersing in hot and cold baths alternately. The administration of brandy, ammonia, or Hoffmann's anodyne, and electric stimulation, are valuable.

3. So long as any motion of the heart can be detected, artificial respiration should be persisted in by means of either Marshall Halls', Schultze's, or Byrd's method, at the rate of not more than sixteen forced respirations a minute. See NEW-BORN INFANT (Asphyxia), PULMOTOR.

ASPIDIUM (Male Fern).—A genus of ferns the properties of which are due to a resin containing filicic acid; and valuable chiefly as a vermicide against the tape-worm.

The active principle is *filicic acid,* which is extracted in the oleoresin. It also contains a green, fatty oil, a volatile oil, resin, tannin, etc. Dose, 1/2 to 1 1/2 drams in a single dose, fasting, or in divided doses at short intervals, followed by a purgative.

The oleoresin of aspidium is an acetone extract and deposits filicic acid on standing. It should be well shaken before being used. Dose, 20 to 60 grains, in capsules, repeated every 3 hours for 2 or 3 doses.

Aspidium is an efficient vermicide against tapeworm, particularly the unarmed variety (bothriocephalus latus). The oleoresin is the best form; the patient having fasted for the previous day, or used only a milk diet, 1 dram may then be given in 4 doses 1/4 hour apart. This may be repeated the next morning and followed by three drops of croton oil in emulsion. This is one of many methods. Cusso may be combined with it advantageously. See ANTHELMINTICS.

ASPIRIN. Acetyl-salicylic Acid.—A white powder, soluble in 100 of water. It is said to be more efficient than the salicylates, producing less of the undesired side effects because of the slow liberation of the salicylic acid. It passes unchanged through the stomach, decomposition taking place in the intestine. It is most efficient in acute articular and muscular rheumatism, tonsillitis, influenza, gout, pleurisy, polyneuritis, chorea, and neuralgia. Dose, 5 to 15 grains, thrice daily.

ASTASIA ABASIA.—A symptom consisting in inability to stand or to walk in the normal manner. The condition forms a symptom-group, not an entity, and is probably a functional neurosis. As a rule, patients, though able to move the feet and legs perfectly in bed, are either unable to walk properly or cannot stand at all. Patients generally recover, especially if young persons, and relapses are not uncommon. Static electricity and the rest treatment are advised.

ASTEREOGNOSIS.—The inability to recognize objects, their nature and uses, by touch. It is usually associated with intractable hemiplegia or brain tumor.

ASTHENOPIA. Definition.—Weakness or speedy fatigue of the ocular muscles or visual powers, due to eye-strain.

Causes.—Errors of refraction, excessive use of the eyes, muscular insufficiency, and constitutional denutritive processes, such as anemia.

Varieties.—1. **Accommodative asthenopia,** generally due to hyperopic astigmatism, or to simple hyperopia, producing strain of the ciliary muscle.

2. **Muscular asthenopia,** due to weakness, incoordination (heterophoria), or strain of the external ocular muscles. Myopia, by necessitating extreme convergence and straining of the internal recti, is a common cause.

3. **Retinal or nervous asthenopia** is a rare variety caused by retinal hyperesthesia, anesthesia, or other abnormality, or by general nervous affections. In over-worked school children it is manifested by complaint of haziness and dimness of the letters, occasional diplopia, photophobia, lacrimation, and local ocular pain. In neurasthenic and hysteric adults all these symptoms are aggravated, and these patients constitute very troublesome cases.

Symptoms.—Symptoms of asthenopia are of such diversity and differ so in degree that a thorough discussion of the effects of eye-strain would necessitate a volume in itself.

As a causative factor in the production of headache, eye-strain is by far the most important. Anorexia, dyspepsia, constipation, heartburn, nausea, repeated attacks of vomiting, etc., represent some of the gastric reflexes. Amenorrhea and dysmenorrhea are menstrual anomalies sometimes caused by eye-strain. Insomnia, nightmare, chorea, nocturnal enuresis, and even epilepsy, have often owed their existence and perpetuation to uncorrected eye-strain in some form. The multiformity of the effects of eye-strain can only be properly realized when we understand how vital the function of vision is to every act, emotion, and thought. The visual centers are in the closest connection with the other brain-centers, and the slightest disturbance of the visual mechanism produces sympathetic irritation in the entire motor, sensory, and psychic systems. Happily, the manifold effects of eye-strain, so long ignored, are being appreciated and recognized more and more every day. Besides the reflex symptoms, which are often remote and only brought out by careful questioning (the usual complaint in asthenopia is discomfort in near work), the patient complains of inability to read or sew for any length of time; the print "runs together," there is heaviness of the lids, and often excessive lacrimation. Local congestion soon produces conjunctivitis or blepharitis, and it is our duty to examine the refraction in all cases of chronic conjunctival and palpebral inflammation, instead of carelessly dismissing the patient with a time-worn formula for an ointment or a wash. So long as uncorrected ametropia exists, there will be recurring attacks of inflammation.

A peculiar **rule in asthenopia** is that the amount of local or constitutional reflex is in direct proportion to the debility or neurotic tendency of the patient. Strong, vigorous men may, by accommodative and muscular effort, overcome ametropia to so great a degree as to entirely mask the condition, and such a patient may go all his life without experiencing a single uncomfortable reflex; on the other hand, a nervous school-girl or a neurasthenic woman may suffer severest headaches, or be the victim of anorexia, nausea, dyspepsia, etc., from the slightest astigmatic error. There is also noticed an **interchangeability of reflexes.** When the vision continues normal in spite of the ametropia, reflexes are present; if the vision suffers, reflexes are less conspicuous. Also intense local symptoms are usually unattended by severe reflex symptoms, and vice versa.

Diagnosis rests on a careful examination of the refractive condition of the eye and of the muscular power and muscle equilibrium. In all cases in which there is presumed to be retention of accommodative power, a mydriatic must be used.

Treatment.—In the accommodative form, rest of the eyes, abstinence from excessive near work,

and constant use of correcting lenses are necessary. Constitutional and hygienic treatment must be urged. If there is any muscular anomaly, it must be corrected by gymnastic exercise with prisms, constant wearing of prisms, or in extreme cases tenotomy and advancement. For nervous asthenopia near work must be reduced to a minimum, and outdoor exercise, good food, the administration of tonics, massage, or electrotherapy, are indicated.

ASTHMA, BRONCHIAL.—The term asthma is still loosely employed to designate dyspnea with cough. Accordingly we speak of cardiac asthma in heart-disease, renal or uremic asthma in chronic renal disease. It is doubtful whether there is any etiologic difference between cardiac and renal asthma; the shortness of breath in both forms being immediately dependent upon engorgement of the pulmonary capillaries due to failing heart action. Much confusion would be avoided by limiting the use of term to designate the disease known as bronchial or spasmodic asthma. In this sense the term is used here exclusively.

Asthma is an expiratory dyspnea that occurs paroxysmally. The dyspnea is due to a diminished caliber of the smaller bronchial tubes. As the paroxysms of asthma are often sudden in onset, last for 1 or 2 hours, cease, and leave the patient apparently in perfect health, they must be due to a lesion less slow in onset and less persistent than either inflammation or edema of the bronchioles. Sudden acute engorgement of the bronchioles might produce this dyspnea, and laryngoscopic examinations have shown that the bronchi are congested during asthmatic attacks. Spasmodic contraction of the bronchioles may also produce the symptoms. The possession by the bronchioles of an anatomic structure that makes such contraction possible has led the majority of clinicians to believe that spasm of them is the cause of asthmatic dyspnea. Whether asthma is due to active congestion or to bronchial spasm matters not; it is universally admitted that either the vasomotor nerves or nerves supplied to the bronchioles control the phenomena. An acute and temporary general emphysema is produced during each paroxysm.

Symptoms.—Asthmatic dyspnea lasts for from a few minutes to several hours. It often recurs nightly for a few days or 1 or 2 weeks consecutively, and, ceasing, does not reappear for weeks, months, or sometimes years.

Most sufferers from this malady have no premonition of their attacks. A few will be warned by symptoms that are peculiar to each, such as unusual sneezing or flatulence.

The onset is commonly sudden. The attacks occur almost exclusively at night, and generally between 2 and 4 o'clock in the morning. The patient is awakened by dyspnea. To make his breathing as comfortable as possible he soon learns to sit or stand so as to brace his shoulders, that the unusual muscles of respiration may act the better. In order that air may enter the air-passages as readily as possible, he will hold his head back and straighten his neck. When dyspnea is intense, the patient's countenance expresses both distress and anxiety. At first a warm perspiration, which becomes cold and clammy when cyanosis develops, breaks out because of the labor for breath. The temperature of the patient remains normal. His pulse becomes rapid and sometimes small, soft, and irregular.

The dilatation of the nostrils with each inspiration, the swollen cervical veins, the distended thorax, and the lifting of the whole thorax with each inspiration at once attract the attention of onlookers. Respiration is not much hurried, frequently not at all, but is very labored. The intercostal spaces are widely distended. In other words, the thorax is constantly in the position of deep inspiration. Inspiration is short, produced by the sudden lifting of the whole chest; expiration is much prolonged. In children the lower part of the thorax is often retracted during inspiration. Percussion reveals no change in resonance or a moderate increase. The area of pulmonary resonance is enlarged by the downward displacement of the liver, and by the displacement of the heart and overlapping of its edges by the distended lungs. It is not necessary in most cases to place an ear to the patient's chest to hear the noisy breathing, which is usually described as crowing or whistling or a combination of both. The short inspiratory sound and prolonged whistling expiratory one can often be heard many feet from the patient.

In frankly spasmodic cases of asthma coughing does not occur until near the end of the paroxysm. A few small, glossy plugs of mucus may then be coughed up and expectorated. If they are examined microscopically, in addition to a few epithelial cells, numerous eosinophile cells will generally be seen, and often Charcot-Leyden crystals and spiral threads, known as Curschmann's spirals.

In the intervals between paroxysms respiration, the bronchial tubes, and lungs seem to be normal.

Many cases are associated with coryza and bronchitis. When the latter is present, dyspnea is likely to be more persistent, because the bronchioles are narrowed simultaneously by spasm and by inflammation of their walls.

Diagnosis is not difficult, as a rule; sudden attacks of dyspnea of short duration leaving the air-passages normal are not produced by any other malady. It may be distinguished from capillary bronchitis by the persistence of dyspnea, the hurried breathing, and increased temperature that occurs in the latter. Chronic emphysema is not paroxysmal. In it dyspnea is constant. Stenosis of larynx or trachea causes inspiratory, not expiratory, dyspnea. In cardiac dyspnea the characteristic sibilant râles are not present and the vesicular character of the breath sounds is at first unaltered. If pulmonary edema develops fine moist râles are heard usually limited to the inferior-posterior portions of the lungs. The dyspnea is not predominantly expiratory. It must be remembered that asthma and cardiac dyspnea may be associated.

Asthma occurs at all ages, but most frequently

between the twentieth and fortieth years. Men are somewhat oftener affected than women. A neurotic temperament is very evident in most sufferers. The malady is occasionally hereditary, appearing in many generations, and sometimes in several individuals of each generation.

Etiology.—The immediate exciting cause of asthma is commonly irritation of the nasal, pharyngeal, or bronchial mucous membrane, or rarely of the stomach or uterus. The dyspnea is provoked reflexly by such irritation. In a few instances attacks have been known to have a mental origin. Certain objects—for instance, a painted flower as readily as a real one—will suggest, and therefore provoke, a paroxysm of asthma in certain individuals.

A large number of cases of asthma are provoked by irritation of unusually sensitive erectile tissue in the nose or throat. The irritant may be a certain odor to which the sufferer possesses an idiosyncrasy, or some odorless dust. The destruction of this tissue will then prevent the recurrence of asthma.

Those individuals who are liable to asthma at certain seasons—as, for instance, fall or spring, when they are attacked by coryza or bronchitis or both—should seek, by change of climate, to escape the primary catarrh. If it is hay-fever that provokes asthma in any individual, he must be advised, during August and at least the first half of September, to reside where this latter malady is unknown. In the eastern United States, the White Mountains are surer to give immunity than any other locality. Mackinac, the neighboring shore of Michigan, and many places along the shores of Lake Superior afford immunity to residents of the Central States. Very many are unaffected so long as they remain in Colorado or New Mexico. See HAY-FEVER.

Prognosis in asthma is favorable as to life, but a permanent cure is exceptional except by an entire change of climate, or a surgical operation in those cases which are dependent upon an intranasal condition. Only in the worst cases is asthma the immediate cause of death. Much discomfort is caused by the disease, which, however, may be mitigated or cut short by appropriate treatment.

Treatment.—Two indications guide the treatment of asthma: First, prevent the development of dyspnea; second, relieve it when it is established. To meet the first, drugs must be given during the intermissions of attacks. The iodid of sodium or potassium is of the greatest help in many cases. It is especially useful in averting attacks that complicate bronchitis. The drug is usually efficacious in doses of 5 to 10 grains. The following formula may be recommended as routine during intervals between attacks:

℞. Potassium iodid, 10 grams
Tincture of belladonna leaves or Tincture of hyoscyamus, 15 grams
Syrup of sarsaparilla, 30 grams
Water, enough to make 100 grams.

One teaspoonful in water 3 times a day after meals.

It must sometimes be given in twice or three times this amount. Arsenic, either in the form of arsenous acid or Fowler's solution, will prevent recurrences in a few cases. It does not act promptly. Its dose must be gradually increased to near the point of beginning intolerance of it. A number of fluidextracts that are more or less useful to relieve dyspnea have been used to avert asthma, with varying results, sometimes appearing to be helpful, at other times useless. Among these are senecio aureus, grindelia robusta, euphorbia pilulifera. They may be used as adjuvants when an iodid or arsenic is given. Just how any of them acts to prevent dyspnea is not known.

The following is a useful formula:

℞. Sodium iodid, 10 grams
Fluidextract of euphorbia pilulifera, 60 grams
Water, or simple elixir, add sufficient to make 120 grams

Of this, 1 teaspoonful may be given 3 or 4 times daily.

If, as rarely happens, the fermenting contents of stomach or intestines provoke an attack, when dyspnea starts, these organs should be promptly emptied.

When irritability of the nasal or pharyngeal mucous membranes makes one liable to asthma, it may often be aborted and sometimes avoided by the application of local anesthetics, such as cocain or eucain. A solution of cocain in water of from 2 to 4 per cent. strength, sprayed into the nostrils and pharynx, sometimes affords relief at once. In severe cases the relief is temporary, and if the spraying is frequently repeated, the toxic effects of cocain may be developed. Eucain is safer, far less poisonous, but it is slower in producing its effects, and must be used in stronger solutions. If morphin is combined with cocain, the anesthesia is prolonged. Instead of an aqueous solution of these drugs, they may be diluted by starch-powder and blown into the throat and nose. Holocain has not yet been used to relieve asthma. As it is an efficient local anesthetic, does not apparently produce toxic effects, it may yet be found useful.

Suprarenal extract should be tried, as it is often effective, both in cutting short an attack and during intervals between attacks. It is given hypodermically (10 minims of adrenalin chlorid) in solution or by inunction to the nasal mucous membrane (10 per cent. suprarenal ointment); or in triturates with sugar of milk, which are allowed to dissolve in the mouth, so as to permit absorption by the mucous membrane.

Rheumatic or gouty individuals are most promptly relieved by salicylic acid or the salicylates. An abundance of milk and water should be given, so that elimination by the kidneys will be increased. A regimen such as is essential to the treatment of these dyscrasias should also be prescribed.

When dyspnea is great and cyanosis is marked, it is best to administer a little chloroform or ether, as they lessen the sensitiveness of the nervous sys-

tem at once and cut short the paroxysm. In most cases sufficiently prompt results may be obtained from chloral administered by the mouth. It is best for an attendant to awaken the patient an hour before an expected attack, and then to give 20 grains of chloral. If necessary, a half or third of this dose may be given 1 or 2 hours later. If the patient awakens with dyspnea, a full dose of chloral should be given at once. Morphin may be given hypodermically instead. Its usefulness is increased by combining atropin with it. It will often give the greatest possible relief. These drugs undoubtedly produce their good results by benumbing the central nervous system.

Some years ago Fraser demonstrated the prompt and great good afforded by the nitrites in relieving the dyspnea of asthma. In from 2 to 5 minutes after inhaling nitrite of amyl dyspnea lessens, and in from 15 to 20 minutes often disappears. The effects of nitrite of amyl are very transitory. Those of nitroglycerin are as prompt if it is given hypodermically, and more prolonged. The effects of nitrite of sodium and erythrol tetranitrate are still more persistent. They are given in solution by the mouth in doses of from 1 to 4 grains. In most cases of asthma relief is afforded quite as quickly by the nitrites as by chloroform. They benumb the endings of sensory nerves and thus break the reflex arc, the integrity of which is necessary for the production of most cases of asthma.

Belladonna and stramonium have a similar mode of action, but produce little effect unless used in doses that will cause mild poisoning—that is, excessive dryness of skin and mouth, and obscured vision because of dilatation of the pupils. These drugs, therefore, are used as adjuvants, but are not depended upon for relief. They are sometimes given by the mouth, as in this formula:

℞.	Sodium nitrite,	2 grams
	Tincture of stramonium,	20 grams
	Fluidextract of grindelia,	30 grams
	Glycerin,	5 grams
	Water, enough to make	60 grams.

Of this mixture a teaspoonful may be taken once in an hour or an hour and a half until 2 or 3 doses have been taken, if more than 1 is needed to abort the paroxysm. Instead of nitrite of sodium, chloral may be used in this formula.

Very frequently stramonium is administered by inhalation, the leaves being mixed with tobacco or wrapped in paper and smoked, or made into pastils, burned upon a plate, and the smoke inhaled. Cigars, cigarets, and pastils are rendered much more effective if paper or some other absorbent, saturated with a strong solution of niter, is added to the stramonium leaves. When burned, the niter is converted into a nitrite.

The following are favorite formulas: Thirty grams of dry leaves of Datura stramonium are added to a solution of 2 c.c. of the aqueous extract of opium in 25 c.c. of water. When the leaves have again been dried, they may be rolled in cigaret paper and smoked.

Cigarets may be made still more effective by saturating the stramonium leaves with an 8 per cent solution of nitrite of potassium, and a solution of arsenite of potassium, of such strength that each cigaret will contain about 0.05 gram. Frequently, a mixture of stramonium, hyoscyamus, and belladonna leaves is used as a basis for these cigarets, and sometimes tobacco is mixed with them.

The inhalation of compressed air in the pneumatic cabinet is efficacious. See PNEUMOTHERAPY under TUBERCULOSIS, PULMONARY. The new treatment by vaccines, preferably autogenous, seems encouraging. See VACCINE THERAPY.

ASTIGMATISM. Definition.—An error of refraction usually due to some irregularity of the curvature of the refracting surfaces of the eye. The cornea is most often the faulty structure, but lenticular astigmatism is not uncommon; in fact, it is said that all eyes possess some irregular astigmatism in the lens, and for this reason the point of light at a great distance is not seen as a point, but as a star. However, it must be remembered that light coming from the heavens travels through media of different refractive powers. In simple myopia or hyperopia, while the refraction is faulty, the corneal meridians are all of equal curvature. In astigmatism the curvature of the meridians is different; one principal meridian may be of proper curvature while the other is markedly defective. It must be remembered that astigmatism does not depend upon the length of the globe, but upon the curvature of the cornea and lens.

Varieties.—**Regular astigmatism** is present when the two principal meridians—*i. e.*, those of greatest and least curvature—are at right angles to each other.

Irregular astigmatism is a condition in which the unequal curvatures of the cornea bear no definite relation to each other. There are no principal meridians, and different parts of the same meridian may have different refractive powers. This form of astigmatism is usually due to cicatrices of the cornea following injuries, surgical operations, or destructive inflammations. If the cornea is clear and apparently regular, we are safe in attributing irregular astigmatism to a difference in the refractive power of the different sectors of the lens, or to its oblique position.

Causes of Regular Astigmatism.—As previously stated, the chief factor in the production of regular astigmatism is imperfect curvature of the cornea. Regular astigmatism may be congenital or hereditary. Congenital malformation of the cornea may be a part of a general anatomic defect in the bones of the face and skull.

The causes of acquired regular astigmatism are not exactly understood, but as almost every person is slightly astigmatic, among civilized nations regular curvature of the corneal surface is the exception rather than the rule. However, the excessive use of the eyes in modern life is attended by so much muscular and accommodative effort that it seems probable that both tension on and torsion of the coats of the eyeball by the muscles are

prime factors in the meridional change in corneal curvature. Pressure of the lids, particularly in ametropia and when they are hypertrophied and uneven after some marked conjunctival inflammation, is often suggested as a cause. Finally, after operations on the cornea or sclerotic, the subsequent changes during cicatrization may produce a high degree of astigmatism.

Disadvantages.—An astigmatic eye sees a point as a line; hence images are distorted and marked visual disturbance results. It is believed that there is an involuntary effort on the part of the ciliary muscle, and even the external muscles, and to remedy the astigmatic defect. By constant unequal contraction the ciliary muscle partly compensates for moderate inequalities in the curvatures of the cornea. Such continuous and unequal accommodative effort must result in eye-strain and consume much of the normal nervous energy, eventually producing reflex manifestations of disturbance of the nervous equilibrium. Therefore, an astigmatic person may be able to improve his vision only at the expense of his health. Uncorrected astigmatism, particularly in delicate and nervous women, results in the worst forms of reflex asthenopic symptoms.

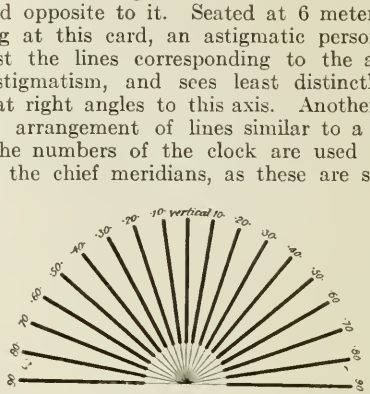
Symptoms.—Nearly every person consulting the ophthalmologist for refraction is more or less astigmatic, and in the majority of cases part of the astigmatism is masked by the accommodative effort of the ciliary muscle. Under this natural correction the visual acuity is more or less undisturbed, and in the moderate degrees of astigmatism the reflex symptoms are the most prominent signs. The patient complains of headache, nausea, anorexia, indigestion, inability to perform continuous near work, etc. In reading the letters often fade out and seem to run together. There is significant confusion of such letters. Commonly there will be noticed an inclination of the head to one side, the patient saying that he can see better with his head in that position. In very high degrees of astigmatism the pupil may be oval, and the symmetry of the cornea may be detected by simple inspection.

From the preceding remarks as to the involuntary correction action of the ciliary muscle, the use of a mydriatic in determining the full degree and correct axis of the astigmatism is necessary.

Tests for astigmatism are very numerous; there are a dozen or more valuable methods of qualitative and quantitative diagnosis of astigmatism. The astigmatic cards and dials, the stenoepic disc, and the keratoscope furnish us easy methods for simple diagnosis, while the ophthalmoscope, ophthalmometer, retinoscope, and test-lenses are valuable methods for the more exact determination of the kind and degree of astigmatism. Besides these tests we have the perforated chimney disc, the cobalt glass, etc.

The diagnosis of astigmatism by the ophthalmoscope, by the retinoscope, and by the test-lenses is described in the sections dealing with these instruments, and only those instruments especially designed for the detection of astigmatism will be here described.

Astigmatic cards and charts are of several varieties. **Snellen's cards** consist of a series of equally colored dark lines arranged like the spokes of a wheel, with the angle of inclination of each line marked opposite to it. Seated at 6 meters and looking at this card, an astigmatic person sees clearest the lines corresponding to the axis of his astigmatism, and sees least distinctly the lines at right angles to this axis. Another form is the arrangement of lines similar to a clock-dial; the numbers of the clock are used to indicate the chief meridians, as these are so well



Snellen's Card for Testing Astigmatism.

known by the patient, and can be easily indicated by him to the physician.

Pray's astigmatic letters are formed of equally black lines inclined at different angles. The letter seen the blackest is the one formed of lines at an angle corresponding to the axis of the patient's astigmatism. Many other forms of cards and charts have been suggested.

The stenopeic disc consists of a round disc of metal or hard rubber containing in one of its diameters a fine, linear, slit-like opening. It is mounted in a test-lens cell for use in the trial-frame. One eye is excluded from vision with an opaque disc, and the stenopeic *slit* is placed before the other. The patient is directed to look at the test-letters or astigmatic chart. The stenopeic disc is then rotated in the trial-frame until it reaches the position in which the letters are most distinctly seen, or in which the lines on the chart are of nearest equal distinctness. The angle marked on the trial-frame corresponding to the inclination of the *slit* indicates the least defective meridian, and also the axis of the necessary correcting cylinder, as such a cylinder would correct only the defect of the meridian at right angles to its axis (the most defective meridian). The convex or concave glass that gives the best vision is put down as the refraction of the first meridian. The *slit* is turned exactly 90°, and the second meridian is similarly refracted. If both meridians are hyperopic or myopic, the refraction of the first meridian represents the spheric defect, and the difference between them is the cylindric defect at the axis of the first meridian. If the *slit* was preferred in the vertical meridian (axis 90°), and the refraction of this meridian was +1.00 D., and the refraction of the horizontal meridian (axis 180°) was +2.00 D., the defect would be expressed thus: +S. 1.00 +C. 1.00 ax. 90.

If the refraction of the first meridian was myopic, say, −1 D., and the refraction of the 180 meridian hyperopic, say, +2 D., the defect could be expressed either −S. 1.00 +C. 300 ax. 90, or +S.

2.00 — C. 3.00 ax. 180. The first would be the better formula to use, as the meridian of least defect is generally taken for the spheric correction.

The stenopeic disc furnishes a simple means of refracting astigmatic eyes, but it is not always accurate. It is of greatest value in cases of mixed astigmatism. It has the advantage of not requiring cylindric lenses in refraction.

A ready means of detecting astigmatism is the application of a low degree cylinder before the eye, which, if preferred in any special axis, gives a strong reason to suspect astigmatism in that axis or at right angles to it.

Treatment of regular astigmatism consists in using the proper correcting glasses. The full astigmatic correction should be ordered, and, in the compound or mixed forms, combined with the spheric correction. If the degree of defect is high, or if there are symptoms of accommodative asthenopia, the glasses should be worn constantly. The patient should be urged to wear spectacles, for eye-glasses frequently get out of shape, and it is not possible to know whether the glass is applied to the eye at the proper axis. In very sensitive eyes the slightest tilting of the axis of the cylinder is provocative of the most disagreeable asthenopic symptoms, and often a proper glass wrongly adjusted will aggravate the condition.

Treatment for irregular lenticular astigmatism is worthless. For **irregular corneal astigmatism,** generally due to a corneal cicatrix, stenopeic glasses—*i. e.*, discs having small holes in the middle to prevent the rays of light from being received on any but an extremely limited corneal area, the curvature of which may be regular—have been used. However, the field of vision is so limited in these cases that the glasses are of little value. By patiently applying the test-lenses to an irregularly astigmatic eye, a cylindric combination which at a particular axis seems to improve the vision may be found.

ASTRAGALUS.—See Ankle.

ASTRINGENTS.—Agents that produce contraction of muscular fiber and condensation of other tissues, the first probably by direct irritation, the second by precipitating their albumin and gelatin. They also lessen secretion from mucous membranes. The principal astringents may be enumerated as follows:

Acids, alcohol, alum, chalk, lime, creosote, carbolic acid, tannic acid, gallic acid, catechu, gambir, galls, kino, oak-bark, uva ursi, hematoxylon, bismuth subnitrate, etc., cadmium sulphate, copper sulphate, ferric chlorid, lead acetate, silver nitrate, zinc sulphate.

Sulphuric acid, gallic acid, and lead acetate are examples of remote astringents, acting on internal organs through the blood. Those that affect the part to which they are applied are local astringents, and include most of those previously enumerated.

The metallic astringents are used most frequently to reduce the size of wounds and ulcers, and to remove exuberant granulations and form a protecting pellicle over such. Astringents lessen congestion and secretion of mucous membranes, and are used in lotions to the eye and mouth, as gargles or sprays to the throat, as injections to the urethra, vagina, and the nose, and as suppositories to the rectum. In diarrhea they are serviceable, and in lessening hemorrhage, in the treatment of hemoptysis, hematuria, and hematemesis they are made use of internally. Gallic acid and lead acetate are most valuable in these conditions.

Three mineral astringents are not only astringent, but sedative, and may, therefore, be freely used in acute inflammations. They are silver nitrate, lead acetate or subacetate, and bismuth carbonate or subcarbonate. Most other astringents possess some irritant properties.

ATAXIA.—See Locomotor Ataxia.

ATELECTASIS.—Pulmonary collapse, with failure of the air to enter the vesicles. It may be either *acquired* (apneumatosis) or *fetal.* The condition is due not to disease of the lungs, but to nerve injuries, weakness, etc. In fetal cases the lung has never been inflated, while in apneumatosis it has been inflated.

There is intense dyspnea, cough, and clinical symptoms of bronchopneumonia, with which it frequently coexists.

The physical signs are the same as those of bronchopneumonia. Prognosis is unfavorable.

Treatment.—In the cogenital variety inflate the lung by means of a catheter placed in the larynx, artificial respiration, and application of heat to extremities. If the disease is due to bronchopneumonia, institute the treatment for that disease.

ATHEROMA.—Primarily, a soft encysted tumor (sebaceous cyst); more commonly, the fatty degeneration of the walls of the arteries in consequence of chronic arteritis, and called **atheromatous degeneration. Atheromatous abscess,** resulting from chronic arteritis, is a collection of soft matter beneath the intima, while an **atheromatous ulcer** is formed by the abscess breaking through the intima. See Arteriosclerosis.

ATHETOSIS.—A symptom most frequently occurring in children, and characterized by continual change of position of the fingers and toes, and inability to keep them quiet, save in sleep. It is due to some lesion or derangement of the brain or cord. It is also called "posthemiplegic chorea," from its occurrence after hemiplegia, in adults.

Strictly speaking, it is not a disease, but usually part of a symptom-group indicating some lesion of the cerebrum. The movements are difficult to describe, being commonly observed in one hand and its fingers, occasionally in both. It is most frequently congenital, occurring usually with some form of cerebral palsy. The movements are more or less rhythmic, do not cause the patient fatigue, can usually be controlled by the will, though modified by strategy, and, as a rule, do not impair sensation. Athetosis may be a sequel of poliencephalitis, and toxic agents may affect the motor cortex or subcortex. The dura is often adherent to the pia, and this is frequently

injected, infiltrated, and adherent to the cortex, which, with the subcortex, is softened and may include the whole of the gray matter. The diagnosis is not difficult. Its movements, when contrasted with chorea, though irregular and bizarre in themselves, have a certain regularity and monotony in their method of repetition. The prognosis is unfavorable. Hysteric athetosis is possible, has been observed, and has a favorable prognosis. Little can be done in the way of treatment. Nerve-stretching will temporarily stop the movements. Galvanism has frequently been employed, but is of little permanent value. Iodids, bromids, and mercury may be tried where meningitis is suspected. Conium, gelsemium, hyoscin, and opium are only of temporary value.

ATOPHAN.—Trade name of a preparation of phenyl-quinolin-carboxylic acid; it has been suggested as a substitute for the salicylates and also as an analgesic. Its main use, however, is in the treatment of gout, where its ingestion is followed by an increase in the output of uric acid and the urates. It checks the pain and inflammation, but is probably not more of a specific than colchicin. The usual dose is from 8 to 16 grains, combined with one dram of sodium bicarbonate; this should be followed by a glass of water. This dose may be given three or four times a day. See GOUT (Treatment of).

ATOXYL.—Sodium arsanilate. An amido-benzene compound of arsenic. It is claimed to be 40 times less toxic than Fowler's solution, and has the same action. It has proved a very efficient remedy for trypanosomiasis and it has been used with good results in syphilis. The use of this drug has, however, been abandoned by many because of the danger of optic atrophy. Dose, hypodermically, 1/10 to 1/2 of a grain, gradually increased up to 3 grains. See ARYLARSONATES.

ATROPHODERMA.—Atrophia cutis, atrophy of the skin, a wasting of the skin due to innutrition. **A. albidum,** a type of xeroderma in which the skin from the middle of the thigh to the sole, more rarely from the upper arm to the palm, is in places very white, stretched, and difficult to pick up, with the epidermis extremely thinned, faintly glistening, wrinkled, and peeling off in thin, shining flakes. There is extreme sensibility on the finger-tips, palms, and soles. The condition remains stationary from the earliest childhood. **A. neuriticum,** glossy skin; an atrophy of the skin in the area of a nerve affected by disease or injury. It chiefly attacks the extremities. The skin of the affected part becomes very dry, smooth, and glossy, like a thin scar; the fingers are tapering, hairless, and almost void of wrinkles, and of a pink or deep-red color. A severe and persistent buring pain precedes and accompanies this condition. The nails become curved both longitudinally and transversely, and there is some thickening of the cutis beneath the free end. **A. pigmentosum.** See XERODERMA. **A. striatum et maculatum,** an atrophic condition of the skin of adults characterized by streaks of a pearly or bluish-white color, glistening, scar-like, from 1 inch to several inches long, and a quarter of an inch or more wide, and which follow the natural cleavage of the skin, and are situated chiefly about the buttock, anterior border of the ilium, trochanters, and thigh. The "spots" are less common, small, usually isolated, and are usually seen on the trunk and neck.

ATROPIN, $C_{17}H_{23}NO_3$.—A crystalline alkaloid derived from *Atropa belladonna.* The sulphate is a white powder of bitter taste, neutral reaction, soluble in water. *Homatropin,* $C_{16}H_{21}NO_3$, is a derivative alkaloid, the hydrobromid being used by ophthalmologists as a mydriatic, principally because its effects pass off more quickly than those of atropin. Homatropin slows the heart; atropin quickens it. See HOMATROPIN. Atropin is an irritant narcotic, a mydriatic, antispasmodic, and anodyne; in small doses a cardiac, respiratory, and spinal stimulant; in large doses a paralyzant of the cardiac and respiratory centers, the spinal cord, motor nerves, and voluntary muscles. It produces congestion and dryness of the mucous membrane of the mouth, nose, pharynx, and larynx, at first lessening the gastric and intestinal secretion, to be followed by an increase of the same. It is extensively used in ophthalmic practice to dilate the pupil, paralyze accommodation, and also in various corneal, iritic, and other ocular diseases. The usual strength is 4 grains to 1 ounce of water. It is contraindicated whenever there is increased intraocular tension, and should not be used in persons over 40 years of age, or in gouty or rheumatic subjects, in whom its instillation may light up a laten or incipient glaucoma. Its therapeutic uses in general medicine are also manifold, *e. g.,* in inflammatory affections and the pain of cerebral and spinal hyperemia, atonic constipation, cardiac failure, hypersecretions, etc., and as a physiologic antagonist in opium-poisoning. Dose of atropin sulphate, 1/120 to 1/100 of a grain.

Atropin is used in poisoning by opium, physostigma, and hydrocyanic acid; in ptyalism from mercury, pregnancy, etc.; in the sweats of phthisis, in sudden cardiac failure, and by eye-surgeons to paralyze accommodation, dilate the pupil, contract the vessels, and lessen pain. In opium-poisoning it should be given in very small doses, and repeated for effect, as most of the unsuccessful cases of its use reported in this connection were due to overdosing with the antagonist, superinducing belladonna narcosis upon the opium narcosis. In cases of heart-failure from chloroform or ether inhalation, the hypodermic injection of atropin has saved lives when all other methods of resuscitation had failed. It is highly efficient in lead-poisoning, if used in combination with potassium iodid; and has given the most satisfactory results as a hemostatic in profuse metrorrhagia after abortion, in metrorrhagia of obscure origin, and in phthisical hemoptysis.

Symptoms of **poisoning** are those of belladonna —tickling and dryness in the throat, vomiting, diarrhea, redness of the face, and quick and irregular pulse. These symptoms are generally mild and of short duration, and are usually produced during mydriasis from the drug. Full doses of some preparations of opium are indicated as a physiologic antagonist. See BELLADONNA, MYDRIATICS.

In whooping-cough:

℞. Atropin sulphate, gr. 3/4
Pulverized sugar, white, ʒ ijss.
Give a grain and a half 3 times daily to a child of 5 years.

A sedative application:

℞. Atropin sulphate, gr. iv
Morphin sulphate, gr. viij
Rose-water, ʒ ss
Glycerin, ʒ iijss.
Mix into a liniment. Rub into the part.

In Iritis:

℞. Atropin sulphate, gr. iv
Water, ʒ j.
Make into an eye-wash. Instil a dozen drops during the day. Purge with calomel.

To produce mydriasis for refraction purposes:

℞. Atropin sulphate, gr. j
Distilled water, ʒ ij.
Instil 1 drop in each eye 3 times a day for 2 days.

AURA.—A sensation sometimes like a gentle current of air rising the limbs or body to the head; a frequent forerunner of an epileptic attack —*aura epileptica.* The term is also applied to any slight symptom preceding an attack of any disease or paroxysm, as the *aura hysterica, aura vertiginosa,* etc. See Epilepsy, Hysteria, etc.

AURANTIUM (Orange).—Aromatic and tonic, also more or less bitter, but has little action except a mild stimulant influence on the nervous system, due to its volatile oil. In medicine its use is chiefly for flavoring purposes. The bitter orange may be used as a gentle tonic and stimulant to the digestion, but usually with other more active agents. The tincture, water, and aromatic elixir are the favorite preparations.

Orange occurs in two official varieties of fruit and preparatons of their flowers, *Citrus vulgaris,* the bitter orange, and *Citrus Aurantium,* the sweet or Portugal orange. The official titles are: **Aurantii Amari Cortex,** *bitter orange peel*—the dried rind of the unripe fruit of *Citrus vulgaris,* characteristics well known. **Aurantii Dulcis Cortex,** *sweet orange peel*—is the fresh outer rind of the ripe fruit of *Citrus Aurantium.* It contains a volatile oil differing from that of the bitter orange, and less of the bitter principle.

Preparations.—Fluidextractum Aurantii Amari, *fluidextract of bitter orange peel.* Dose, 10 to 60 minims. **Tinctura A. Amari,** *tincture of bitter orange peel*—strength 20 percent. Dose, 1 to 2 drams. **Tinctura A. Dulcis,** *tincture of sweet orange peel*—strength 20 percent. Dose 1 to 2 drams. **Syrupus A.** Tincture of sweet orange peel 5, magnesium carbonate, 1 citric acid 5, sugar 82, water to 100. Dose, 1 to 2 drams. **Syrupus A. Florum,** *syrup of orange flowers*—sugar 85, orange-flower water to 100. Dose, 1 to 2 drams. **Spiritus A. Compositus,** *compound spirit of orange*—oil of orange peel 20, oil of lemon 5, oil of coriander 2, oil of anise 1/2, alcohol to 100. Dose, as for alcohol. **Aqua A. Florum Fortior,** *stronger orange-flower water*—is water saturated with the volatile oil of fresh orange flowers. Dose, indefinite. **Oleum A. Corticis,** *oil of orange peel*—a volatile oil, obtained by expression from the fresh peel of either orange. Is soluble in about 4 times its volume of alcohol, and is an ingredient of the official spirit of orange and also of spiritus myrciæ (bay rum). Dose, 1 to 5 drops. **Elixir Aromaticum,** *aromatic elixir (simple elixir)*—has of the compound spirit of orange 1.2, purified talc 3, syrup 37 1/2, alcohol and distilled water to 100. Dose, 1 to 8 drams or more.

AURICULO-VENTRICULAR BUNDLE (Gaskell's Bridge, Bundle of His).—The remains of the primitive cardiac tissue which passes from the auriculo-ventricular node to the right and left ventricles. See Heart Block.

AURICULO-VENTRICULAR INTERVAL.—The interval between the auricular and carotid waves in tracings of the jugular pulse. Normally it is equal to one-fifth of a second. See Pulse.

AURUM.—See Gold.

AUSCULTATION.—Listening to the sounds produced within the chest during the act of respiration, coughing, or speaking, furnishes the most reliable means of studying the condition of the lungs, and is, therefore, the most valuable method of discriminating between the various conditions that may affect the lungs.

Auscultation is either *immediate or mediate.*

It is *immediate* when the ear is applied directly to the chest, which may be either denuded or thinly covered.

It is *mediate* when the sounds are conducted to the ear by means of a tubular instrument, termed a *stethoscope.*

For ordinary purposes *immediate,* or direct, auscultation is sufficient, but when it is desirable to analyze circumscribed sounds, as in diseases of the heart, or when the patient objects to this method on the score of delicacy, or the auscultator objects on account of the uncleanliness of the person to be examined, the stethoscope is to be preferred. Moreover, there are certain parts of the chest that can be explored satisfactorily only by the aid of a stethoscope, and, again this instrument has the additional advantage of *intensifying* the sound.

In auscultation the following rules, formulated by Da Costa, should be observed.

"1. Place yourself and your patient in a position that is least constrained, and permits of the most accurate application of the ear or stethoscope to the surface. Above all avoid stooping, or having the head too low.

"2. Let the chest be bare, or, what is better, covered only with a towel or a thin shirt.

"3. If a stethoscope is employed, apply closely to the surface, but abstain from pressing with it. This may be obviated by steadying the instrument, immediately above its expanded extremity, between the thumb and the index finger.

"4. Examine repeatedly the different portions of the chest, and compare them with one another while the patient is breathing quietly. Making him cough or draw a full breath is, at times, of

service; especially the former, when he does not know how to breathe."

See CHEST (Examination).

AUTOINFECTION.—Infection resulting from a primary focus in the organism as, for instance, the dissemination of the bacillus of tuberculosis or diphtheria, or the metastatic abscesses of pyemia. See AUTOINTOXICATION.

AUTOINTOXICATION.—Autointoxication is, as the name implies, a poisoning caused by substances which are formed under the influence of the vital processes of the organism. Accepting this definition, then, intoxication by infection, by resorption of products of cryptogenetic infection, and by absorption of alimentary poisons (meat, sausage, fish poisons—ptomains) is not considered as an autointoxication. The substances causing autointoxication may be produced:

1. By the tissues and organs of the body.

2. By altered function in the gastrointestinal tract.

1. Under this heading are grouped manifestations of altered nuclein metabolism (gout, rheumatism), of altered fat metabolism (acetonuria), of altered carbohydrate metabolism (diabetes with resultant acidosis), also such obscure intoxications resulting from altered functions of organs as uremia (kidney), cholemia (liver), exophthalmic goiter, and myxedema (thyroid), tetany (parathyroids), acromegaly (hypophysis cerebri), Addison's disease (adrenals). The above are not regarded as autointoxications in the sense in which the term is ordinarily used.

2. Autointoxication as generally understood is spoken of wrongly as acidosis, acid intoxication, and properly as gastrointestinal autointoxicaton. It is an expression of qualitative or quantitative changes of normal digestion. The development of our knowledge of autointoxication has been the result of constant research on the part of the French school, at whose head Combe stands, as the champion of the subject.

The qualitative and quantitative alterations taking place in normal digestion, which produce symptoms of autointoxication, have been studied for the most part from the side of protein decomposition, carbohydrate and fat metabolism having been practically neglected. The changes normally undergone by the protein molecule under the influence of the various ferments in the gastrointestinal tract are:

Normal Digestion.—I. *Gastric Juice. Pepsin.*

1. Noncrystallizable bodies, albumose, peptone.
2. Ammonia.
3. Diamino acids—lysin, arginin, histidin.
4. Monamino acids.

a. Aromatic Series.—Phenylalanin, tyrosin, tryptophan.

b. Fatty Acid Series.—Leucin, glycocoll, alanin, serin, cystin, valin, prolin, oxyprolin, aspartic and glutamic acids.

II. *Intestinal Juice.*—The chief ferments of protein digestion are erepsin and trypsin.

1. **Erepsin.**—Its only function is to transform albumose and peptone into crystallizable bodies, and it has no action on native albumin.

2. **Trypsin.**—This ferment breaks down the albumin molecule into exactly the same split products as the gastric juice, only more quickly and more completely. It may be stated that normally the gastric juice conducts digestion of protein only as far as ablumin and peptone, at which stage the food is expelled into the intestine to be digested still further by erespin and especially trypsin.

Action of Bacteria on Food.—In addition to the change wrought in the food by enzymatic action, powerful alterations are produced by microbic activity. The split products of bacterial decomposition are of utmost importance in the causation of autointoxication and differ materially from those brought about by ferments. By bacterial action the following bodies are produced:

I. Albumose—peptone.

II. Ammonia.

III. Diamino Acids.—Lysin, arginin, histidin.

IV. Monamino acids:

1. Aromatic Series.—Phenylalanin, tyrosin, tryptophan.

2. Fatty Acid Series.—Leucin, glycocoll, alanin, serin, cystin, valin, prolin, oxyprolin, aspartic and glutamic acids.

V. Fatty Bodies.

1. Butyric, caproic and valeric acids.
2. Ptomains.

VI. Aromatic Bodies.

1. Oxyacid Group.—Paraoxyphenylacetic and paraoxyphenylpropionic acids.
2. Phenol Group.—Phenol, paracresol.
3. Indoxyl Group.—Indol, skatol.

VII. Gases.

Methane, hydrogen, carbon dioxid, hydrogen sulphid, methylmercaptan.

Fate of Products of Digestion.—Under normal conditions, the carbohydrates and nitrogenous substances are broken up by bacterial action in the small intestine and large intestine respectively, but when putrefaction is intense, proteolysis may be carried on in the small intestine. The end-products of digestion included under headings I, II, III, and IV are capable of being utilized by the body to cover its nitrogen losses, and they assist in the maintenance of nitrogen equilibrium. The substances under V, VI, and VII are dead losses to the organism, and hence bacterial decomposition must be regarded both as a needless waste of protein material and as a generator of toxic agents. It would lead too far afield to discuss the place of origin, the toxic action and the portal of excretion of each one of the toxic agents included under V, VI, and VII, but information can be obtained from some of the larger works on the subject.

The outline of the chief split products of protein digestion given above, shows that nitrogenous food, broken down under the action of ferments, is completely utilized and to a certain extent the same is true of the split products of bacterial decomposition. However, there are substances formed under the influence of microbic activity which are decidedly toxic to the organism when produced in excess or when the power of the organism to overcome the same is weakened.

Defenses of the Body Against Autointoxication.—As is the case with all injurious substances, the products of bacterial decomposition are opposed in the body by an elaborate system of defense, which is fully able to cope with the poisons, so long as these poisons are not produced in too large quantities. The defensive means of the body, limiting the formation of autotoxins, are three in number:

I. **Line of Defense within the Intestinal Canal.**
1. Acidity of gastric juice.
2. Bile
3. Pancreatic juice.
4. Bacterial flora of small intestine.
5. Acidity of small intestine.
6. Flora of large intestine.

II. **Line of Defense Immediately Surrounding Intestinal Canal.**
1. Mucosa of intestine.
2. Liver.
3. So-called Antitoxic Glands—thyroid, hypophysis, suprarenals.

III. **Line of Defense apart from Gastrointestinal Canal.**
1. Respiratory tract.
2. Saliva.
3. Sweat.
4. Urine.
5. Feces.

Causes of Autointoxication.—It will readily be seen that the causes of autointoxication are easily grouped under two headings:

1. Those which have to do with excessive formation of the toxins.

2. Those which cause a diminution of the factors of safety.

I. **Increased function of toxins** is seen in any condition of the gastrointestinal tract whereby food is improperly digested, improperly absorbed, or remains an abnormally long time in the stomach or intestines. The protean manifestations of such disturbance are usually called dyspepsia or indigestion, either gastric or intestinal in origin, but, were such cases more closely observed, it would be seen that the cause of the dyspepsia could be covered by one or more of the following: Too frequent, too rapid, and too free eating; bad quality of food—too coarse, too rich, bad cooking; insufficient digestive juices; gastric stasis—dilatation from any cause; intestinal stasis, ptosis, constipation, dilatation of colon, inflammation of gastrointestinal tract.

Diseases of the nose and throat, and intestinal parasites are other causes responsible for increased production of toxins.

II. **Diminution of Factors of Safety.**—Under this heading are grouped diseases which primarily or secondarily cause alteration of function in the structures constituting the three lines of defense of the organism.

Symptoms of Autointoxication.—As is the case with any school that is eagerly and enthusiastically publishing researches and claims in favor of a new symptom-complex, the French school has seen fit, satisfactorily to itself, to group under the diagnosis autointoxication, every conceivable manifestation of alteration in nervous, respiratory, digestive, muscular, urinary, cardiac and vascular function. To give in detail the various symptoms for which autointoxication has been held responsible, would be to reproduce any book on symptomatology. There is no need to lean to the extreme views of the French; but in obscure cases of any disease of any part of the body—eye, nervous system, cardiac, etc.—for which treatment based on symptoms alone, is not beneficial, it is believed that careful study of the excretions will, in many cases, clear up some indefinite diagnosis.

Diagnosis of Autointoxication.—The diagnosis of autointoxication is based essentially on the result of the urine examination. The first definite investigation was undertaken by Bouchard who attempted to show that the toxicity of the urine increased in cases of autointoxication, that is, that it took smaller quantities of urine to kill an animal, than when the urine was obtained from a healthy person. His work will always remain a classic, but it led to nothing except to stimulate research in the direction of urinary chemistry as applied to autointoxication.

Without attempting to trace the historical development of the subject, it may be said that in view of our present knowledge, the most important qualitative changes in the urine, occurring in autointoxication, are the presence of indican, urobilin, and phenol. Besides these, albumin and casts, in the presence of indican, without any further evidence of nephritis, are seen quite frequently, and disappear coincidently with the disappearance of the indican. Acetone has also been found, but seems to indicate faulty fat metabolism or ordinary inanition rather than gastrointestinal autointoxication.

Of the quantitative changes, increase in the amount of volatile fatty acids is a quite constant finding. A most important factor is that described by Baumann and called the "Coefficient of Baumann." Normally the ethereal sulphates (B) are to the total sulphates (A) as one to ten, that is, if there are 1.50 grams of total sulphates, the ethereal sulphates should be 0.150 grams. In autointoxication, this factor is disturbed so that instead of being A : B : : 1.50 : 0.150, the following may be seen: A : B : : 1.50 : 1.00.

Another factor is the "Coefficient of Amann," which supposes in health that the ethereal sulphates should be to the total nitrogen as 1 is to 1.4. This also is sometimes altered.

The chemical examination of the feces has not made important strides.

Bacteriological examination is out of the question, and the suggestion that the dried bacteria normally should bear a certain ratio to the dried feces, and that any variation speaks for autointoxication, has not always been borne out.

The degree of fermentation has been studied by Schmidt and Strassburger by means of a very simple apparatus, which measures the amount of fermentation by the amount of water displaced. It gives no more information than does mere physical examination of a very malodorous, frothy stool.

The best way of arriving at an opinion regarding the state of the digestion is to examine microscopically the stool of the patient on an ordinary diet. Should anything be found abnormal with the protein, carbohydrate or fat metabolism, as shown by undigested meat, starch, or much neutral fat or fatty acid crystals (in place of the normally present soap), then a test diet such as devised by Schmidt should be ordered:

Morning.—Pint of milk, tea or cocoa. One roll with butter, one soft-boiled egg, a plate of oatmeal cooked with milk.

Afternoon.—A quarter pound of Hamburg steak (rare inside), fairly large portion of mashed potatoes, roll and butter, and a pint of milk, tea or cocoa.

Evening.—A pint of milk, roll and butter, and two scrambled eggs. At the time of taking this a 5-grain carmine capsule should be given, with directions that that stool be saved which immediately follows the red colored stool. The test diet should of course be continued until the examination of the stool has been completed.

By means of this test meal or diet, a fairly accurate idea of the state of digestion can be attained.

The presence of undigested starch granules is important. These are easily recognized by dropping on the feces on a slide, a drop of Lugol's solution. On microscopic examination, the poorly digested starch will be found blue. An acid stool is usually associated with faulty carbohydrate digestion.

Treatment.—Remembering that autointoxication is due in part to nitrogenous putrefaction in the intestines, and in part to decrease in the activities of the three lines of defense of the organism, the therapeutic indications are:

I. 1. To diminish nitrogenous putrefaction in the intestine in order to bring it to the normal grade, if the defenses of the organism are functionating properly.

2. To decrease the nitrogenous putrefaction *below* normal if the defenses are insufficient.

II. To stimulate the factors of safety, when they are performing their functions imperfectly.

1. Since putrefactive changes are due to decomposition of protein by bacteria, the main object to achieve is to modify the bacterial culture. This may be approached from any or all of five sides.

A. By proper dieting.

B. By introducing organisms which are antagonistic to the intestinal flora.

C. By using yeasts of various kinds.

D. By the use of intestinal disinfectants.

E. By mechanically removing the bacteria and their products (lavage).

A. Of the nitrogenous foods which increase intestinal putrefaction, meats and the leguminous vegetables (lentils, peas, string beans, lima beans) are to be put in the first rank, and to a much less degree, the whites of eggs. Fatty food increases to a great extent nitrogenous putrefaction, and even cream and butter have the same effect except that it is much less pronounced.

Of the foods which of themselves do not favor intestinal decomposition, may be mentioned milk, skimmed milk, centrifugalized milk, sour milk, butter milk, whey (from pressed cheese), curdled milk (natural or artificial), fresh cheese (cream cheese), koumys, kefir. Carbohydrate foods also tend to diminish intestinal putrefaction, and in this group are sugar, glycerin, and farinaceous foods.

To make up a diet suitable for a case of autointoxication, the following general rules may be formulated:

1. Diminish as far as possible nitrogenous food.
2. Exclude absolutely the nitrogenous foods which are most conducive to putrefaction.
3. Eggs are the best of the nitrogenous foods to use, although the whites should not be eaten.
4. Avoid fatty foods except fresh butter.
5. Use as much farinaceous food as possible.
6. Use skimmed milk, butter milk, curdled milk, and fresh cheese, starting with small amounts.
7. A diet of cereals and milk is the diet par excellence.
8. Eat slowly and masticate thoroughly.
9. Do not drink with meals, or eat when drinking.
10. Eat small amounts of food at a time, and alternate meals of liquid and meals of solid food.
11. Rest flat on the back for an hour after each solid meal, but do not sleep.

B. **Introduction of Organisms Antagonistic to Those Causing Intestinal Putrefaction.**—1. In autointoxication the intestinal flora changes its characteristics so that in this condition there is a diminution of the carbohydrate-splitting organisms and a great increase in proteolytic bacteria. The latter have a natural enemy in those organisms which ferment sugar and produce lactic acid, and it has been found that by their introduction the actively proteolytic bacteria are held in abeyance.

Yoghourt or milk curdled with the Bulgarian lactic acid bacillus is one of the most valuable means of introducing lactic acid bacilli in autointoxication, but it should not be prescribed in enteritis. The amount taken is usually 300 grams (10 ounces) taken twice a day, either fasting or with breakfast, and again in the afternoon or at bedtime.

Metchnikoff has modified the yoghourt and suggests instead pure cultures of lactic acid bacilli. Of the latter, one is especially recommended, and is called the Bulgarian bacillius, or the bacillus of Massol (isolated from yoghourt by Prof. Massol of Geneva). This does not exist normally in the intestine, but once introduced is able to combat most effectually the nitrogen putrefaction. To overcome the disagreeable odor of suet or tallow imparted by it to the milk, Metchnikoff combines with it the Bacillus acidi lactis aerogenes. The combination of these two organisms is called Lactobacillin (Metchnikoff), and may be given as such or in milk. There are now on the market innumerable preparations of the lactic acid organism in the form of tablets to be taken in that form, or as fermented milk, or as powders or tablets from which milk may be made.

Other preparations, less widely known, are:

a. Biolactyl of Fournier, which combined the

bacillus of Massol with the lactic acid streptococcus.

b. Paralactic Bouillon of Tissier. This is a mixture of the Bacillus paralactici, and the Bacillus acidi bifidus Tissier.

C. **Yeast** has for a long time been used in autointoxication, and as a treatment of furunculosis, brewer's yeast (Saccharomyces cerevisiæ) has achieved some reputation. Used in the former condition yeast attenuates the autotoxins, favors phagocytosis and intestinal fermentation, and is of great value in autointoxication. The only contraindication to the use of yeast is in gouty states, since it contains large quantities of xanthin bases. It may be used either fresh or in the dried state. In the latter form it comes in 20-centigram doses of which from 2 to 8 are to be taken in the twenty-four hours. Fresh brewer's yeast is usually given by mouth, a half teaspoonful three times a day to children, and to adults a teaspoonful three times a day before meals.

The yeast of grapes (Saccharomyces ellipsoidæus) has been recommended by Jacquemin, and it has been found to have an antibacterial action, although ephemeral. It is prescribed in doses of 4 to 6 teaspoonfuls a day before meals.

D. **Use of Intestinal Disinfectants.**—Diet of milk and cereals alone is of prime importance in decreasing the action of proteolytic bacteria, but it is incomplete and after a time there is a reaccumulation culminating in a discharge of symptoms from the side of the gastrointestinal tract of nervous system. Recourse, in addition to diet, must be had to drugs which, while improperly called disinfectants, do, nevertheless, have some effect in diminishing the number and virulence of the bacteria, temporarily at least.

Attention has been called in a preceding paragraph to the influence of disordered gastric states on the production of autointoxications, so that antiseptic drugs should be considered from two sides:

1. Gastric antiseptics.
2. Intestinal antiseptics.

1. Of these the most valuable are hydrochloric acid (40 to 60 drops a day), menthol (0.15 to 0.20 t. i. d.) and ichthyol (0.10 to 0.20 in pills t. i. d.).

2. **Intestinal Antiseptics.**—Of the intestinal antiseptics, calomel is by far the best, and below this rank creosote, salicylic acid preparations (sodium salicylate, salol, betol, eucalyptol), the last three in doses of 0.15 to 0.25 every two hours. Bismuth salicylate is also an excellent antiseptic, as is also betanaphthol. The following prescriptions will be found of service:

℞.	Bismuth salicylate,	ʒ ij
	Salol,	gr. lxxij
	Betanaphthol,	ʒ j.

Make 24 capsules and take one four times a day after meals. Two grains of menthol or one grain of thymol in capsules t. i. d., the latter to be taken with a glass of milk, are also recommended.

Free use of castor oil and of saline purges should be made.

E. **Use of Mechanical Means of Removing Bacteria.**—Lavage of the intestine with physiological salt solution (7 grams of sodium chlorid to a liter of sterile water), heated to body temperature should be employed. Contraindications are: Severe grade of enteroptosis when the water enters but there is no return; intestinal irritation. Irrigation of the intestine with drugs has been practised. Of these the best is ichthyol 10.15 grams of a 1 percent solution in 1 liter of water.

II. The emunctories must be stimulated by proper measures, bathing, exercises, diaphoretics, etc.

AUTOPSY.—See Postmortem Examination.

AUTOSUGGESTION.—A term suggested by Page for that peculiar mental condition often developing after railway accidents; it is intimately associated with the hypnotic state. In both of these conditions the mental spontaneity, the will, or the judgment is more or less suppressed or obscured, and suggestions become easy. Thus, the slightest traumatism to any member may cause a paralysis, a contracture, or an arthralgia. It is also called *traumatic suggestion*. See Railway Injuries.

AUTOTRANSFUSION.—The transfer of the blood of the body to the brain and other central organs by depressing the head, by elevating the hips and legs, and by the use of elastic bandages on the limbs. The object of the transfusion is to raise blood-pressure in the vital centers and to maintain the vital functions in shock or after severe hemorrhage. Bottles of hot water should be applied to the feet and the calves of the legs, and the temperature of the elevated portions must be maintained. See Transfusion.

AVOIRDUPOIS WEIGHT.—The common English weight used for all commodities except precious metals, gems, and medicines. The pound is equal to 7000 grains troy, or 453.54 grams, or 16 ounces. The ounce is divided into 16 drams, each of 437.5 grains. See Weights and Measures.

AVULSION.—A traumatic or surgical tearing or wrenching away of a part, as a polypus or limb, etc.

When a limb is entirely torn away from the rest of the body, various tissues of the parts give way at different levels. Skin usually separates at the highest point; muscles protrude, and appear to be tightly embraced and almost strangulated by the skin; tendons, vessels, and nerves hang out of the wound, and are of varying lengths; and the bone, shattered, forms the apex of the ragged conic stump. Hemorrhage is comparatively small in such conditions, but occasionally, as in avulsion of an entire upper limb, including the scapula or clavicle, it is directly or indirectly fatal.

Treatment.—Avulsed tissues in flaps should be cleansed, trimmed, replaced and supported, warmth being furnished. Great caution is necessary in the use of sutures in avulsed or lacerated wounds. The general principles of treatment of lacerated and contused wounds obtain. See Wounds.

AXILLA (Armpit).—The pyramidal space situated between the upper and lateral part of the chest and the inner side of the arm, the apex being directed upward toward the root of the neck, the base directed downward and formed by the in-

tegument and fascia, the anterior boundary formed by the pectoral muscles, costocoracoid membrane and clavicle, and the posterior boundary, lower than the anterior, formed by the subscapularis, teres major, and latissimus dorsi muscles. It is best demonstrated on the living body by the abduction of the arm to a right angle with the chest. Its numerous and important blood-vessels, cellular tissue, glands, and nerves make it especially important in surgery. The skin, at its base, contains thin, long, fine hairs, and is abundantly supplied with sebaceous and sweat glands, which, from their situation and structure, are the frequent seats of boils and superficial abscesses and of inflammatory eruptions, and a lurking-place for parasites.

Wounds.—Serious direct and penetrating wounds of the axilla are rarely encountered. If hemorrhage is spontaneously arrested, it is best not to interfere, but to watch carefully and keep the sufferer quiet and at rest. Pressure, if used, must be gentle and carefully maintained. Free bleeding from a wound of the axilla requires prompt securing of the bleeding point, either directly through the wound or by operation. The difficulty of finding a wounded artery is great. Ligation of the subclavian artery in the third part of its course may be necessary, and even ultimate amputation at the shoulder-joint may give the only chance for life from wounds of the artery. Wounds of the axillary vein are dangerous, not only because of the hemorrhage, but also from the entrance of air into the vein. This vessel is generally wounded or torn during removal of tumors from the axilla. A ligature should be applied immediately upon the detection of profuse venous bleeding. Phlebitis and pyemia may result if antisepsis is not obtained, which may not be practicable in an emergency.

Wounds of the large axillary vessels often result from attempts to reduce dislocations of the head of the humerus. The heel of a boot placed in the axilla to give counterextension in attempts at reduction of dislocations has caused fatal injury to the vessels in the axilla; and paralyses have resulted from injury to the brachial plexus. The vascular injury may be due to direct action of the head of the humerus, to unnecessary violence in reduction, or to puncture by the sharp end of a fragment of bone in fracture. In some cases so rapidly does the blood pour out into the soft parts of the axilla and of the chest and back, that death ensues in an hour. In other instances an aneurysm develops within a few hours or days, and in others, swelling from effused blood may take place very gradually and after a considerable time.

The prognosis in injuries of this space is most unfavorable, especially in those in advanced age, and when the injury has been of long standing. Acute cellulitis of the axilla occurs, with cellulitis of adjacent parts, and is usually rapid in its progress and needs prompt treatment to prevent septicemia. Superficial abscesses may be due to local irritation, lymphangitis, or intense cachexia, and require early opening to prevent penetration of pus into the deeper portions of the axilla and the formation of a sinus.

Glandular swellings in the axilla are those of acute and chronic adenitis, of strumous and syphilitic enlargements, of secondary cancerous infiltrations, and of lymphadenoma. Acute inflammatory swellings usually give evidence of some lesion of the lymphatics of the hand or of the thoracic and abdominal walls, and do not necessarily go on to suppuration. Chronic adenitis is usually attended by marked cachectic conditions. The dissection and removal of enlarged strumous and other glands is tedious and difficult. The knife should be discarded as soon as possible, and the blunt dissection continued, tearing being done in no rash manner, nor with too great force. The great danger is wound of the axillary vein or of some large tributary. In carcinoma of the breast careful dissection of the axillary cavity and removal of all enlarged and apparently healthy glands should be done.

Tumors of the cavity are chiefly of glandular origin—some of new growths, and some of nerve tissue. In large or rapidly developing tumors the symptoms are usually those due to compression of the blood-vessels and of the cords of the brachial plexus.

AXILLARY ANEURYSM.—This form of aneurysm is not uncommon as the result of sprains or of attemps to reduce long-standing dislocations of the shoulder.

The diagnosis, as a rule, presents no difficulty, unless the aneurysm has become diffused, when it may be mistaken for abscess.

Treatment.—(1) When the aneurysm is spontaneous, small, and well circumscribed, pressure or ligation of the third part of the subclavian should be practised. (2) When more or less diffused, as when the result of an injury to the artery in the reduction of a dislocation, the aneurysm should be cut down upon, the clots turned out, and the vessel secured above and below. If this operation is decided on, an incision should be made over the subclavian artery through the skin and fascia, so that pressure may be made on it more directly, and the circulation through the aneurysm during the subsequent operation better controlled. A small incision is then made over the aneurysm, two fingers are introduced into it, and placed on the bleeding spot in the artery, which may be known by the hot arterial blood issuing from it. An assistant in the meantime enlarges the wound, turns out the clots, and helps the surgeon to tie the artery above and below the rupture before the fingers are removed. This method is less dangerous than that practised by Syme, who made a free incision over the aneurysm, rapidly turned out the clots, and seized with forceps the bleeding point in the artery. (3) When the aneurysm is of great size and involves the subclavian, Macewen's method may be employed or the first part of the subclavian or the innominate may be ligated, or iron wire introduced, galvanopuncture or manipulation tried, or amputation at the shoulder-joint performed. All these methods, with the exception of Macewen's, are desperate expedients. See ANEURYSM.

BACK, INJURIES. Sprains and Wrenches.—These are very common, especially in the flexible parts—the cervical and lumbar regions; sometimes they are chiefly muscular, as in cases of overwork, lifting heavy weights, or in sudden awkward twists; at times, when due to external violence, they involve the fibrous textures—the ligaments, fascia, and synovial membranes—as well, the muscles either being caught unawares by the unexpected jerk or being overpowered. The worst occur in railway collisions, when every muscle or ligament that has an attachment to the spine may be strained or hurt. For various reasons the spinal cord itself escapes more frequently than might be expected; it lies in the central axis, so that in all movements it occupies neutral ground; it is separated by some distance from the walls; around it there is a waterbed, probably always filled with fluid; and in the lumbar region, where the range of movement is as great, perhaps greater, than elsewhere, its place is taken by the cauda equina.

The extent of injury in these cases is extremely variable. No structure is always exempt, but probably the muscles and fibrous tissue are the greatest sufferers. In some cases the spinal nerves are hurt—stretched, possibly, as they pass out through the foramina, or compressed by extravasation—so that the effects are referred to distant parts of the body. Even the bones and joints do not escape, for, though it is rarely possible to prove the existence of definite injury at the time, it is certain that inflammation may break out in them afterward.

The complications that follow these injuries depend largely upon the state of the patient's health. Stiff neck, lumbago, and chronic rheumatism occur in some, particularly after middle life; synovitis and osteoarthritis, leaving the spine rigid, ankylosed, and perhaps distorted, occur in others; caries is exceedingly common, especially in children and young adults; and, what is still more serious, if the ligaments have been torn and hemorrhage has taken place in the vertebral canal, inflammation of the membranes or of the cord itself may follow. In most cases this is very insidious; softening sets in slowly, and steadily grows worse; in a few rare instances it is acute, suppuration commencing externally in the broken-down blood-clot or in the joints, and spreading through a rent in the membranes or along the lymphatics, until the sheath of the dura mater is involved.

Sprains of the back have acquired a peculiar significance from their frequency in railway collisions, and attempts have been made to distinguish them, when they occur under these conditions, from others. Except, however, for their severity, and for the fact that they are always associated with a very grave degree of shock that is certainly not without influence upon the subsequent progress of the case, there is no reason for such a step. See Railway Injuries.

Symptoms.—The chief are pain and stiffness; these are never absent. The former may be immediate and severe, as when the head is twisted round to look in some awkward direction, and a muscle or tendon is caught or displaced; or it may be dull and aching, not coming on for hours. Very often it is especially severe at night, when the patient is warm in bed; and usually the skin over the painful part is exceedingly tender, as it always is over muscles that have been overstrained or overworked. If the nerves are injured in the foramina, the pain runs round the trunk like a girdle, or extends into the limbs; sometimes it is attended by formication. Very often patients imagine they are paralyzed, mistaking the difficulty of movement arising from the pain for actual loss of power; this may be very misleading. It is not uncommon to find after a strain of the loins that defecation and micturition are difficult, not because the spinal cord has been injured (though it must never be forgotten that this may be the case), but because these actions depend so largely upon the integrity of the muscles that support the back. The same occurs in lumbago, when it is due to cold, without any suspicion of injury; but it cannot be denied that, especially after railway accidents, it is a very disquieting symptom.

Swelling is not common in accidents of this kind, unless there is a considerable extravasation; it may follow the outline of the muscles, as in the neck, or simply form a smooth, rounded elevation. The skin, as already mentioned, is often very tender, but, as a rule, firm pressure gives relief. Redness is seldom seen, and it rarely happens that the temperature is raised.

Hematuria is not an uncommon occurrence after sprains of the lumbar region; the urine is bright red for a day or two, and sometimes there is sufficient blood to form a clot in the ureter; then it gradually becomes smoky, until, as a rule, the whole has disappeared in about a week. It is seldom serious, but may be fatal, from rupture of one of the larger arteries.

Treatment.—Rest is the first consideration, to limit the amount of extravasation and hyperemia that follows, and then gentle passive movement, to assist in absorption and to restore the function and nutrition of the part. If there is one spot especially tender, or one particular movement that causes pain, immediate relief may sometimes be obtained by suddenly throwing the muscles concerned into vigorous action. Subcutaneous injections of morphin must generally be used, as the pain is often so severe that the patient has not the power to make this effort. In twists and strains of the neck

and loins this plan may be tried at once. When the aching, stiffness, and pain on movement are more general, and it is clear that the symptoms are due to chronic changes in the joints and muscles, and that the spinal cord is not involved, counter-irritants may be employed. Hot baths, shampooing, friction with stimulating liniments, ironing, blisters, acupuncture, and galvanism with slow interruptions of the current, are of the greatest value, but constitutional treatment must not be neglected, especially if there is any evidence of gout or rheumatism. Muscles and joints are intended for work; it they are injured, they require rest, it is true; but as soon as the damage is repaired, they become stiff and waste unless they are used; the longer they remain at rest, the stiffer they become.

In cases of more severe injury, when there is either shock or excitement, the patient should be placed in bed, and kept warm and as quiet as possible until they have entirely passed away. The urine may have to be drawn off, especially after railway accidents or other severe injuries; the bowels are almost sure to be constipated, and should be opened by a calomel purge; stimulants, unless the pulse is very feeble or actually failing, do more harm than good. Then, as soon as the acute symptoms have subsided, when the patient begins voluntarily to change his position in bed, gentle passive motion, bending the spine backward and forward, and massage may be commenced, to prevent the muscles becoming rigid. If the depression continues, or if, some weeks after the accident, the patient does not begin to rally, the prognosis becomes very grave. There is evidence than that the nervous system has been seriously affected; and in patients of a neurotic temperament, or when there is any hereditary taint, it is impossible to predict what may happen. Perfect rest for mind as well as body is essential; everything that worries or annoys must be carefully kept away, and the attention must be diverted as much as possible by change of scene or occupation. Good food, fresh air, and a moderate amount of such exercise as the patient can be induced to take are the best remedies; stimulants should be avoided. The only drugs of any service are those that improve the appetite and help to keep up nutrition; potassium bromid and sedatives or narcotics usually do harm. See SPINE (Injuries, Curvature), SPRAINS, etc.

BACTERIAL VACCINES.—See SERUM THERAPY AND VACCINE THERAPY.

BACTERIOLOGY, EPITOME.

CLASSIFICATION.

According to morphology	1. Microbacteria—short rods.	Bacilli.
	2. Desmobacteria—long rods.	Bacilli.
	3. Spherobacteria—globules—cocci.	
	4. Spirobacteria—spirals—spirilla.	
According to biology	1. Saprophytic.	
	2. Parasitic.	
According to necessary medium.	1. Aerobic.	
	2. Anaerobic.	
According to virulence	1. Pathogenic.	
	2. Nonpathogenic.	
According to manner of division.	1. Diplococci.	
	2. Streptococci.	
	3. Staphylococci.	
	4. Leptothrix, etc.	
According to sporulation	1. Endospore.	
	2. Arthrospore.	
According to color	1. Chromogenic.	
	2. Nonchromogenic.	
Organisms that contain no chlorophyl (fungi).	1. Hyphomycetes.	
	2. Saccharomycetes.	
	3. Schizomycetes.	

Conditions Necessary for Growth of Bacteria.—1. **Oxygen.**—Most bacteria require this element for their existence, and those that cannot be deprived of it without destroying life are called *aerobic* bacteria. Those microorganisms that can grow without its presence are called *anaerobic*.

2. **Nutriment.**—Organic and inorganic substances are required for the growth of bacteria. Of the organic materials, the albumins furnish the most essential principles.

MICRO-COCCI. BACILLI. SPIRILLA.

3. **Moisture.**—A certain degree of moisture is essential. All bacteria are destroyed by prolonged heat, or even by prolonged sunlight.

4. **Reaction of Medium.**—Most bacteria require a slightly alkaline medium.

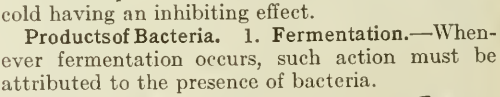
5. **Light.**—Unlike the higher forms of organisms, bacteria do not depend upon this condition for life. Many grow in abundant light, while most of them grow luxuriantly in an incubator from which light is excluded.

6. **Electricity.**—A certain amount of electricity is doubtless required for the existence of bacteria. A high current may destroy them.

7. **Movement.**—Rest is required for the best development of most microorganisms, prolonged agitation inhibiting their growth.

8. **Temperature.**—Most bacteria grow best at the normal temperature of the body, excessive heat or cold having an inhibiting effect.

Products of Bacteria. 1. **Fermentation.**—Whenever fermentation occurs, such action must be attributed to the presence of bacteria.



STAPHYLOCOCCI. STREPTOCOCCI. DIPLOCOCCI. TETRADS. SARCINÆ.

2. **Putrefaction** is a condition similar to fermentation, but occurring in highly nitrogenous or albuminous material, while fermentation occurs in carbohydrates. During the process of putrefaction certain animal alkaloids are produced called *ptomains*, many of which are violent poisons, while others are wholly inert substances. Allied to the ptomains are other products of microorganismal life entitled *tòxins* and *toxalbumins*. These bodies are highly complex molecules, and their exact formulæ or chemic composition are unknown. Certain toxins, upon introduction into the system,

are capable of producing very pronounced symptoms or death itself.

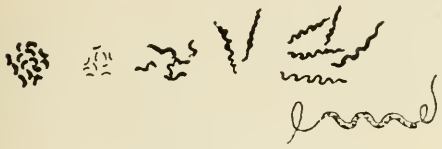
3. **Chromogenesis.**—Distinct color is produced in the medium upon which certain bacteria are growing, and these are denominated "chromogenic," in

Bacilli of Various Forms.

contradistinction to others that are "nonchromogenic."

4. **Liquefaction of Gelatin.**—Most bacteria during their artificial cultivation bring about liquefaction of this culture medium.

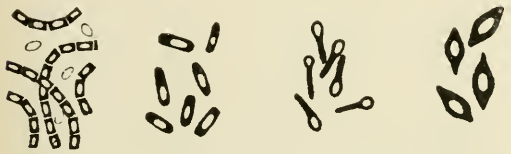
5. **Production of Gases.**—Certain gases, such as



Spirilla of Various Forms.

H_2S, NH_3, CH_4 and CO_2, are given off during the growth of many microorganisms.

6. **Production of Acids and Alkalies.**—Most microorganisms have a tendency to bring about a change in the normal reaction of the medium upon which they grow—most commonly an acid condition.



Bacteria with Spores.

7. **Production of Odors.**—Frequently, odors are eliminated during the growth of bacteria, most commonly from H_2S and NH_3.

8. **Phosphorescence.**

9. **Production of Nitrites.**

10 **Peptonization of Milk.**

Bacteria Showing Flagella.

11. **Production of Disease.**—That property of the life of bacteria which most concerns mankind is in the production of diseases, many of which are due to certain definite forms, entitled "pathogenic" bacteria, in contradistinction to others that have not this tendency, and called "nonpathogenic."

To Prove that a Given Microorganism is the Cause of a Disease. *Koch's Postulates.*—(1) The microorganism must be found in the tissues, blood, or secretions of a person or animal sick or dead of the disease; (2) the microorganism must be isolated and cultivated from these same sources; it must also be grown for several generations in artificial culture media; (3) the pure cultures, when thus obtained, must, on inoculation into a healthy and susceptible animal, produce the diseases in question, and (4) the same microorganisms must again be found in the tissues, blood or secretions of the inoculated animal.

Characteristics of Bacteria.—During the life of bacteria every form preserves certain characteristics as to shape, size, motility, manner of reproduction, and staining properties. In this way we are able to separate them into classes and to group them.

By this inherent action each form preserves its distinct identity and never changes its type. Under certain conditions, such as a change in the proportion of various ingredients in the culture medium, one type of organism may change its form to a certain extent, but never its type. Thus, the common colon bacillis may be altered in motility to an extent depending upon its age and upon the reaction of the culture medium, but never merges or becomes a coccus or spirillum; it remains a bacillus. Bacteria are named as follows: A "coccus" may be described as a single round cell. When two are grouped together, it is spoken of as "diplococcus." If in the shape of a bunch of grapes, the term "staphylococcus" is given, or if in chains, "streptococcus." Cocci that are of minute form, and can only be observed by means of a microscope, are spoken of as "micrococci.

For assistance in diagnosis the accompanying illustrations of the prominent bacilli are given.

Cultivation of Bacteria.—For the proper study and isolation of the different forms of bacteria we resort to the **culture method,** first proposed and used by Robert Koch. At the present day the original formula has undergone many changes, but the principle remains the same as formerly. According to this formula, 500 grams of finely chopped lean beef, free from fat and tendons, is to be soaked in 1000 c.c. of water for 24 hours. During this time it should remain in the ice-chest or be placed on ice. It is then strained through a coarse towel and pressed until 1000 c.c. of fluid has been obtained. To this add 10 grams (1.0 percent) of dried peptone and 5 grams (0.5 percent) of common salt (NaCl). Render neutral or slightly alkaline with a few drops of a saturated solution of soda. Keep the flask in which the fluid is contained in a steam sterilizer or water-bath, and at a boiling temperature until all the

albumin is coagulated and the fluid portion is of a clear, pale straw color. It is then to be filtered through a paper filter and sterilized in the straw sterilizer by the fractional method.

Nutrient Gelatin.—To 1000 c.c. of the meat infusion, prepared as previously directed, 10 grams of peptone, 5 grams of sodium chlorid (NaCl), and 100 grams of gelatin ("Gold Label" brand) are added, and the mixture boiled for an hour over a moderately hot flame, stirring occasionally. The liquid is then cooled and neutralized with sodium carbonate solution, using phenolphthalein as an indicator.

Agar-agar.—To 1000 c.c. of bouillon as prepared by the method of Koch add 10 grams of agar-agar and boil for an hour or two. Cool and neutralize, using phenolphthalein as an indicator.

Glycerin, agar-agar, blood-serum, potatoes, milk, and peptone solution are all used as culture media for bacteria. Culture media are used to isolate the bacteria for the purpose of studying the characteristics of each type of microorganism in a **pure culture.** This is made possible by proceeding according to any of several methods, such as **plate culture** (in Petri dishes, preferably) or **Esmarch tube.**

Bacteria with Capsules

The microorganism may then be thoroughly studied in the fresh specimen, either by means of the **hanging drop** or by different methods of **staining.**

Hanging-drop Method of Examination.—A hollow-ground slide is used, and by means of a camel's-hair brush apply a ring of vaselin about the outer edge of the concave surface. A drop of material is placed in the center of the depression upon the slide and examined.

Methods of Staining and Special Characteristics.—The reader is referred to the article upon Pathologic Technic, and under the special headings for descriptions of the most important bacteria.

BAG OF WATERS.—The fetal membranes inclosing the amniotic fluid and projecting through the os uteri early in labor. See Amnion.

BALANITIS.—An inflammation of the mucous membrane of the glans penis. Simple uncleanliness may cause it, but it is generally one of the complications of the increasing stage of gonorrhea. There are redness and other signs of inflammation, which may end with exfoliation of the epithelium and leave the glans eroded or ulcerated. Sometimes crops of vesicles appear, which may be taken for chancres. Balanitis may be caused by syphilitic chancrous erosion; in such case the absence of urethral discharge, the defined ulcer, and the induration, especially the history of the time of incubation, may show the diagnosis. It is when phimosis exists that there is difficulty in making a correct diagnosis. The scalding urine, the presence of chordee, the unmixed purulent discharge, lead to the belief that gonorrhea is the cause of the balanitis. The history of a sore, a painful and indurated spot beneath the prepuce, the mixture of blood with the discharge, and the enlargement of the inguinal glands, with the absence of chordee and scalding, would indicate a preputial chancre.

The course of balanitis is from 3 to 4 days.

The treatment must be according to the cause. Cleanliness, by washing with warm water upon retraction of the prepuce, and dusting with a powder made of equal parts of boric acid and starch, and then replacing the prepuce, will suffice. Simple cleanliness and the use of the powder, or the insertion of dry lint between the glans and prepuce, changed often, may effect a cure. Borated talc, or boric acid and subnitrate of bismuth in proportion of 1:6, are useful. Excoriations may be touched with a solution of silver nitrate of the strength of 10 grains to the ounce. See Gonorrhea, Syphilis.

BALANOPOSTHITIS.—Inflammation of the glans penis and prepuce. The treatment is the same as that of simple balanitis.

BALDNESS.—See Alopecia.

BALLOTTEMENT.—A method of diagnosing pregnancy from the fourth to the eighth month. A push is given the uterus by the finger inserted into the vagina, and if the fetus is present, it will rise and fall again like a heavy body in water. See Pregnancy (Diagnosis).

BALSAM.—**B. of Peru,** obtained from *Toluifera Pereiræ.* A thick brown liquid with an odor of benzoin and vanilla, soluble in 5 of alcohol, almost insoluble in water. It is not a true balsam, as it contains no volatile oil. Dose, 10 to 25 grains in emulsion. *Incompatibles* are ferric salts, iodoform, and hydrogen peroxid. It is antiseptic, stimulant to the circulation, and sedative to the nervous system; acting chiefly on the mucous membranes, it is tonic and expectorant, diuretic and diaphoretic. In large doses, it causes gastralgia, nausea and vomiting, colic and diarrhea. It is used locally in chronic skin diseases of inflammatory type and sore nipples, to relieve itching, cleanse bed-sores, promote the healing of wounds and ulcers, and to kill the acarus scabiei, being considered by some authorities the best of all applications in itch. Internally, it is used as a stimulant and disinfectant expectorant in chronic bronchitis and asthma, as well as in gonorrhea, gleet, leukorrhea, and other discharges from mucous membranes. **B., Canada,** a turpentine gathered from the natural blisters of the bark of *Abies balsamum.* It is much used as a mounting medium by microscopists. **B. Dipterocarpi, Gurjun balsam,** wood oil, an oleoresin similar in properties to copaiba, but it is less disagreeable and less apt to upset the stomach, also less actively diuretic. It has been used with good success in leprosy, given internally in full doses and used locally at the same time. Mixed with 4 parts of lime-water it is useful in chronic eczema, lupus and psoriasis. **B. of Fir.** Same as B., Canada. **B., Friar's.** See Benzoin. **B. of Gilead,** an oleoresin obtained from the *Balsamodendron gileadense.* **B. of Tolu,** obtained from *Toluifera balsamum.* Its properties are due to a volatile oil, *toluene.* It possesses an agreeable odor, and is a

basis for many cough-mixtures. It is a fair expectorant. *Tincture of tolu* contains 20 percent of the balsam, in 80 percent of alcohol. Dose, 20 to 40 minims. *Syrup of tolu*, tincture of tolu, 5 percent. Dose, 1 to 6 drams.

BANDAGES.—Bandages are usually strips of muslin or other material, of varying widths and lengths, used in surgery for the purpose of protecting, compressing, etc., a part, or for the retention of dressings and applications. A **simple bandage** or **roller** consists of one piece; a **compound,** of two or more pieces. *Starch, plaster-of-Paris, silica, dextrin, tripolith,* etc., are used or recommended for making stiff and **immovable dressings or bandages.** According to their direction, bandages are classed as: (1) **Circular,** circular turns about the part; (2) **figure-of-eight,** the turns crossing each other like that figure; (3) **oblique,** covering the part by oblique turns; (4) **recurrent,** the turns returning successively to the point of origin; (5) **spica,** the turns resembling the arrangement of the husks of an ear of corn; (6) **spiral,** each turn covering one-half of the preceding; (7) **spiral reverse,** the bandage is reversed in order to better adapt it to the part. Bandages are also classed according to the part to which they are applied.

Bandages are made of unglazed muslin, flannel, linen, calico, cloth, or india-rubber, in lengths of from 2 to 10 yards, and in widths to suit the purposes for which they are needed; ordinarily, unbleached muslin is preferred.

A bandage should have a width of 3/4 of an inch for the fingers or toes, from 2 to 2 1/2 inches for the upper limbs, 3 inches for the lower limbs, and 6 inches for the body.

When applying a bandage, the dresser should grasp the roller in one hand, holding the loose end in the other; apply it to the limb so that the *outer surface* may be against the skin, and so that the bandage will lie close to the limb.

The spiral bandage is most frequently employed in the treatment of affections of the extremities or trunk. In applying the *spiral* each turn must cover at least one-third of the one below. Owing to the enlargement of the limbs at the outer part, it is impossible to apply the bandage without making "turns" in it; such a turn is called a "reverse," which is the folding of the bandage upon itself, so that it will fit snugly to the limb. To divide this properly, it is well to remember that a turn should never be made over a prominence of bone, and, if possible, it should be made on the outside of the limb; also, that when making the reverse, the bandage should be held quite loosely, so that with a single movement of the wrist the turn can be made, carrying the hand from supination to pronation. In making the turn the hand should be held slightly above the level of the limb, and great care must be taken not to unroll more bandage than is actually required.

Figure-of-eight bandages are made by passing the roller alternately upward and downward as it enwraps the limb. They are used when the enlargement is too great and too irregular for reverses to lie evenly, as over the ankle- and elbow-joints.

A cylindric portion of the body is covered by a circular bandage, each turn covering the previous one by overlapping it about one-third of its width. A conic part is covered by a spiral bandage. Each turn of a spiral bandage is tighter at its upper part and loose at its lower edge, to correct which the reverse spiral bandage is used. To make this spiral reverse bandage, with about 6 inches of slack, holding the roller in the right hand, place the thumb of the left hand across the fresh turn, turning and folding down the bandage with no traction until the turn is well around the limb. The figure-of-eight bandage is used to cover a projecting point, also the groin, breast, shoulder, or axilla, each turn covering about two-thirds of the previous one. The peripheral turns should be tighter than those nearer the body in bandaging an extremity. A tight bandage applied to a leg or an arm should include the foot or hand. A finger or toe should be left exposed in firm dressings to indicate the state of the circulation in the part.

Bandages should be firmly and evenly applied, and care should be taken to place the part in the position it is intended to occupy. Generally, a bandage should run from the inner to the outer side as it passes over the anterior surface of a limb.

To remove a bandage, the terminal portion of it should be taken up by one hand and passed behind to the other, taking in the slack as it is transferred from one hand to the other.

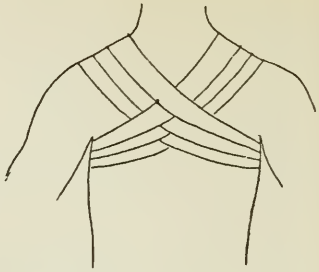
The **triangular** or **Esmarch bandage** is made by cutting diagonally across a piece of calico, or like material, about 40 inches square. The longest side is called the lower border. It is very useful on account of its wide applicability as a temporary bandage: *e. g.*, to make a sling, or shawl-cap, to retain dressings on the breast, etc.

Two important rules in bandaging are: (1) Bandages should not be permanently applied about joints until all swelling has subsided; (2) in bandaging a limb always avoid circular compression and rely on lateral compression over splints.

The bandages for the head are: (1) *Circular, of the forehead,* to retain dressings upon the head. (2) *Circular, of the eyes.* (3) *Crossed, of the eyes,* to hold dressings upon one or both eyes. (4) T, *of the eye,* a small piece of muslin cut in the shape of a right-angled triangle, and sufficiently large to cover the eye, is sewed by its base, with the perpendicular toward the ear, to a horizontal strip of a length to encircle the head. The apex of the triangle is sewed to a vertical strip long enough to pass under the jaw and meet the horizontal strip on the opposite side. (5) *Crossed, of the angle of the jaw,* to support the parts in fracture of the angle of the jaw. (6) *Knotted, of the head,* a double-headed roller with compress, to make compression in wound of the temporal artery. (7) *Recurrent, of the head,* a single-headed or double-headed roller, to retain dressings upon the head. (8) *Four-tailed, of the head,* a piece of cloth 8 inches wide and long enough to pass over the head and under the chin, is torn from each end to within 3 or 4 inches of the middle. The body of the bandage is placed on the top of the head, the posterior ends are tied under the chin, and the two anterior ends carried backward and tied at the nape of the neck. (9)

Crossed bandage of both eyes.

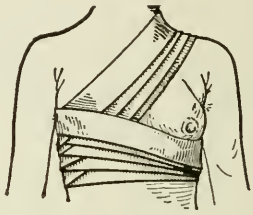
Barton's bandage.



Posterior figure-of-eight bandage of the chest.

T-bandage of the eye.

The six-tailed bandage of Galen.



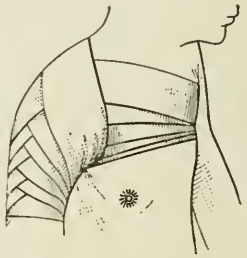
Suspensory and compressor bandage of the breast.

Recurrent bandage of the head.

Transverse recurrent of the head

Four-tailed bandage of the head.

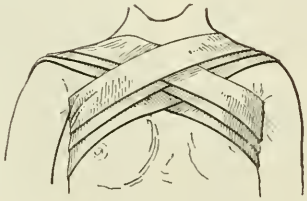
Agnew's bandage.



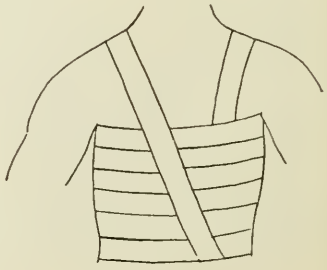
Spica bandage of shoulder.

Four-tailed bandage of the head.

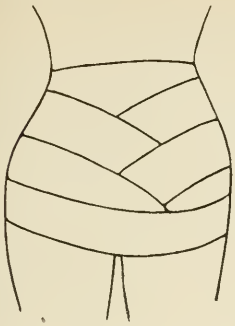
Gibson's bandage



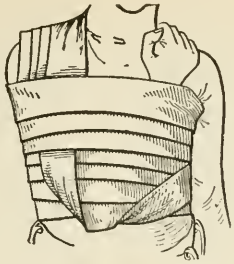
Anterior figure-of-eight bandage of the chest.



Spiral of the chest.

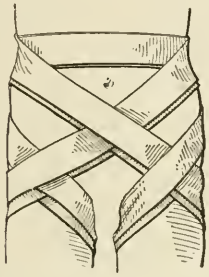


Eight-tailed bandage of the abdomen.

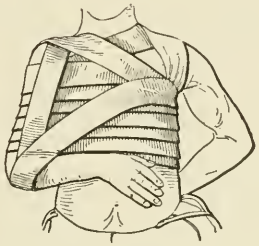


Velpeau's bandage.

Gauntlet bandage.

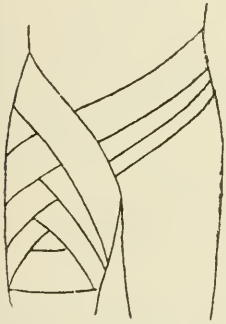


Double spica bandage of the groins.

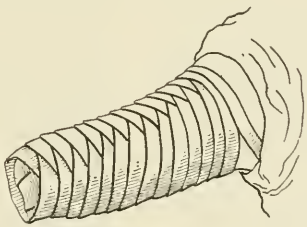


Desault's bandage.

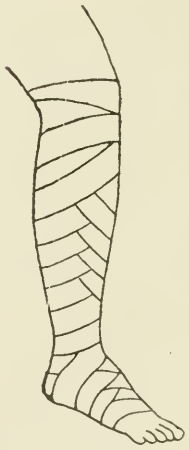
Demigauntlet bandage



Ascending spica of the groin.



Recurrent bandage of stump.



Modified figure-of-eight bandage of the lower extremity.

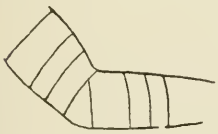


Figure-of-eight of the elbow.

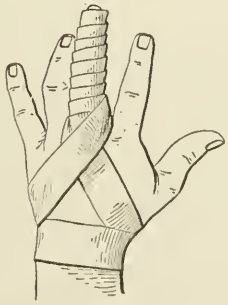
Spiral reversed of the forearm (or leg).



Spiral bandage of the finger

Spica of the foot.

Gibson's, for the body of the lower jaw, to support the parts in fracture. (10) *Rhea Barton's,* for the same purpose. (11) *Capeline* or *mitra Hippocratis,* made by a *double-headed roller* (one which is rolled from each end, the two heads lying on the same side of the bandage and being of equal size). One roll being taken in each hand, the intervening strip is applied low down over the center of the forehead, and the bandage unrolled on each side until the two heads meet posteriorly below the occipital protuberance. From this point the two rollers are applied in different directions, one passing continuously around the head in a circle, the other forward and backward over the cranium until the latter is entirely covered. (12) *Galen's six-tailed bandage;* the bandage is so arranged that it has 3 strips at each end. The middle portion is placed on the crown of the head, the anterior ends are tied at the back of the neck, the middle under the chin, and the posterior at the forehead. (13) *Garretson's,* a bandage for the lower jaw, passing above the forehead and back again, to cross under the occiput, and finally ending in front of the chin. (14) *Pressure-bandage,* an eye-bandage applied with a considerable degree of firmness in order to afford pressure. (15) *Protective bandage,* a bandage for the eye, lightly applied. (16) *Hamilton's,* a form of compound bandage for the lower jaw, consisting mainly of a firm leather strap to support the jaw. (17) *Liebreich's,* a variety of bandage for the eye, made from a knitted cotton band. (18) *Thillaye's,* a compound bandage for joining the edges of the wounds in harelip operation.

The bandages of the trunk are: (1) *Circular, of the neck;* (2) *figure-of-eight, of the neck and axilla,* to retain dressings upon the shoulder or in the axilla; (3) *anterior figure-of-eight, of chest,* to draw the shoulder forward and to retain dressings on the anterior surface of the chest; (4) *posterior figure-of-eight, of chest,* to draw the shoulders back in fractured clavicle, or to retain dressings on the posterior surface of the chest; (5) *crossed, of one or both breasts,* to support the breasts in excessive lactation or in mammary disease; (6) *spica, of shoulder,* to retain the head of the humerus in place after dislocation; (7) *spiral, of the chest,* to make compression in fracture of the sternum or ribs; (8) *circular, of the abdomen,* to support the abdominal walls; (9) *spiral, of the abdomen,* to compress the abdominal walls or to retain dressings; (10) *spica, of one or both groins,* to compress groin or retain dressings; (11) *spiral reverse, of the penis,* to retain dressings upon this organ.

The bandages of the arm are: (1) *Circular, of the wrist.* (2) *Figure-of-eight, of wrist,* to compress the joint or retain dressings. (3) *Figure-of-eight, of elbow.* (4) *Circular, of arm or forearm.* (5) *Oblique, of arm or forearm.* (6) *Spiral, of arm,* to retain dressings. (7) *Spiral reverse, of upper extremity,* to support the arm in dislocations, fractures, etc. (8) *Velpeau's,* used to support the arm in fracture of the clavicle, the neck, or acromial process of the scapula. The hand of the injured side being placed on the sound shoulder, an oblique turn is made from the axilla of the sound side, across the back of the chest to the opposite shoulder, covering the fracture, down under the elbow in front to axilla of the sound side, then across the back over the outside of the point of the elbow to the axilla of the sound side, thus continuing the oblique and circular turns alternately, and advancing over the arm until it is held firmly. (8) *Desault's apparatus* consists of an axillary pad held by tapes around the neck, a sling for the hand, and two single-headed rollers. The forearm is placed at right angles with the humerus, held in place by many circular and oblique turns about the shoulder and body. (10) *Boyer's,* a form of apparatus consisting of a chest-belt, an arm-belt, and an axillary pad. It is used in treating fractured clavicles.

The bandages of the hand are: (1) *Spiral, of the finger;* (2) *spiral, of all the fingers,* or *gauntlet;* (3) *spiral, of palm,* or *demigauntlet;* (4) *spica, of thumb.* All the bandages of the hand are used in cases of fracture or to retain dressings.

The bandages of the lower extremity are: (1) *Figure-of-eight, of ankle,* to cover the part or retain dressings; (2) *figure-of-eight, of knee,* to cover the part or compress it; (3) *figure-of-eight, of thighs,* to compress the part after wounds or operations; (4) *spica, of instep,* to compress the parts; (5) *spiral reverse, of whole lower extremity,* to support the limb after fracture, etc.; (6) *Baynton's,* a series of straps of adhesive plaster used in the treatment of chronic leg ulcers; (7) *Ribbail's,* a spica bandage of the foot.

BANTING TREATMENT.—A treatment, named after its inventor, for the reduction of corpulence or obesity by the withdrawal of the starches and farinaceous articles of food and the use of a diet of nitrogenous food. See OBESITY.

BANTI'S DISEASE.—The terminal stage of splenic anemia (*q. v.*), associated with cirrhosis of the liver and ascites. The disease may be prolonged for ten or more years.

BARBADOS LEG.—See ELEPHANTIASIS.

BARBER'S ITCH.—See RINGWORM OF THE BEARD.

BARIUM.—Ba = 136.8; quantivalence II. A metal of the alkaline group, of pale yellow color, characterized by a strong affinity for oxygen. Neither the metal nor its salts are much employed in medicine, all are poisonous; none of the salts are official, but the chlorid, dioxid, and sulphid are occasionally used. **B. chlorid,** $BaCl_2.2H_2O$, soluble, used as a reagent, and also as a cardiac and vasomotor stimulant in the treatment of aneurysm, and for mitral insufficiency. Dose, 1/2 to 2 grains. **B. dioxid,** BaO_2, used for making aqua hydrogenii dioxidi. **B. sulphid,** BaS, is occasionally used as a depilatory.

Incompatible with barium salts are: Carbonates, chlorates, oxalic acid, oxalates, phosphoric acid, phosphates, sulphuric acid, sulphates, tannic acid, tartaric acid, tartrates.

BARLEY-WATER.—A decoction made by pouring a pint of cold water over a tablespoonful of washed pearl barley, boiling for two hours and adding boiling water as needed to maintain the original quantity. After adding a pinch of salt, the decoction is strained and kept on ice until

wanted. Barley-water makes a nutritious, demulcent drink in fevers and inflammatory conditions, especially when the gastric mucous membrane is involved. Its principal use is as a temporary substitute for milk in enterocolitis of infants.

BARRENNESS.—See STERILITY.

BARTHOLIN'S GLANDS.—Two small mucous glands, about the size of a pea, situated on each side of the vagina just posterior to the bulbs. They terminate by a narrow duct about half an inch in length that has its orifice in front of the hymen, about the middle of the vaginal ostium.

Inflammation and suppuration of Bartholin's glands constitute a rather common affection. It is most frequently gonorrheal in origin, although it may be the result of other forms of infection. It is accompanied by severe pain, and, finally, swelling and edema. The swelling is pear-shaped, with the large end toward the perineum. There may be fever, and, later, fluctuation may be obtained. Spontaneous evacuation may occur, resulting in one or more persistent fistulas.

In the chronic state the gland is indurated, hypertrophied, and contains a few drops of greenish pus. Usually but one side is affected.

The treatment in the acute stage consists in early incision and drainage. The incision should be made in the lower part of the swelling, at the junction of the skin and mucous membrane; the pus should be evacuated; the cavity irrigated and packed with gauze. Healing by granulation will take place in the course of a week or ten days.

Should the abscess return, or should it be chronic in character when first seen, the entire gland must be dissected out and the wound closed with a few interrupted stitches.

Cysts of Bartholin's glands may be the result of inflammation, or they may be primary in origin. The duct of the gland becomes occluded and the contents are retained. The cyst is filled with a colorless fluid, although at times it may be dark, and rarely exceeds the size of an egg.

Treatment consists in evacuation and packing, or, better, in complete extirpation of the gland.

BASEBALL FINGER.—This is the result of a blow of a baseball on the palmar surface or, more frequently, on the end of the finger. The injuries may be divided into two groups. In the first, one of the interphalangeal joints is tender and swollen, and a fusiform enlargement persists long after the injury. The lesion may be a sprain or a dislocation, but in many instances there is a fissured fracture of the end of one of the phalanges, hence a skiagram should always be taken. The *treatment* is the reduction of any deformity that may be present, a palmar splint for three weeks, and later massage. In the second group (*mallet finger*) the extensor tendon is stretched or torn, as described in the next paragraph.

Mallet finger is a drooping of the distal phalanx as the result of rupture or overstretching the end of the extensor tendon, such as may be caused by sudden and violent hyperflexion of the end of the finger. In the early stages it is treated by the application of a splint. If the deformity persists, the tendon may be sutured to the periosteum (Stewart).

BASEDOW'S DISEASE.—See EXOPHTHALMIC GOITER.

BASHAM'S MIXTURE.—A solution of iron and ammonium acetate, officially known as *liquor ferri et ammonii acetatis*, forming a very useful and elegant preparation of iron, acting as a diuretic, diaphoretic, and chalybeate, and very useful in Bright's disease. It is made as follows:

Tincture of the chlorid of iron,	2 parts
Dilute acetic acid,	3 parts
Solution of ammonium acetate,	25 parts
Aromatic elixir,	6 parts
Glycerin,	6 parts
Water,	to 50 parts

The dose is from 2 to 6 drams, well diluted, and taken through a glass tube or quill, to protect the teeth. See IRON.

BATH.—A medium in which the body is wholly or partly immersed. As therapeutic agents, baths are classified accordingly as water, vapor, air, etc., is used; according to the temperature, as hot, tepid, cold, etc.; according to the end desired, as nutritional, medicinal, stimulant, etc.

Special Forms of Baths.—B., Acid, add 1 1/2 ounces of nitric acid and 1 to 3 ounces of hydrochloric acid to 30 gallons of warm water in a wooden or earthenware vessel, and immerse the patient in this for from 10 to 20 minutes. For a foot-bath, add 1/2 ounce of nitric acid and 1 ounce of hydrochloric acid to 4 gallons of warm water. This is said to be useful in cases of dyspepsia with sluggish liver and constipation. **B.s, Acratothermal,** baths prepared from natural mineral waters of high temperature, but in which the gaseous and saline constituents are small in quantity and of feeble therapeutic action. Syn., *indifferent thermal baths; simple thermal baths; unmixed thermal baths.* **B., Air-,** a bath in which but little water is employed, the body being exposed freely to the air. It is employed in those cases in which there is a tendency to catch cold on slight exposure. **B., Alcohol,** one in dilute alcohol, used to reduce temperature in fever. **B., Alkaline,** add 3 ounces of potassium carbonate, or 6 of sodium carbonate, to 25 or 30 gallons of hot water. It is used in chronic squamous skin diseases, chronic rheumatism, and lithemia. It should be taken in a wooden, earthenware, or enameled tub. **B., Animal.** 1. One prepared from dung of cattle or the contents of the first stomach of a freshly slaughtered ox. 2. The introduction of the whole body or the part affected with rheumatism into the body-cavity of an animal just slaughtered. **B. Antimonial,** one containing 1 to 2 ounces of tartar emetic; it is used in skin diseases. **B., Antirheumatic,** one containing, in sufficient water for the purpose, 100 grams of oil of turpentine, 10 grams of oil of rosemary, 50 grams of sodium carbonate. **B., Antisyphilitic,** a solution of 15 grams of mercury bichlorid in 500 grams of water, to be added to the bath at the time of using. **B., Astringent,** one prepared with tannin or other astringents, to control sweating or in the treatment of skin diseases. **B., Astringent, Most's,** a bath for extensive burns, con-

sisting of a solution of 200 grams of alum in 6 to 8 pailfuls of cold water and 1 pailful of curdled milk. **B., Balsamic,** one containing tar, turpentine, or the buds and bark of terebinthaceous plants. **B., Blanket,** a method employed in chronic nephritis to stimulate the diaphoretic action of the skin. The patient is placed in bed and closely wrapped in blankets, a hot poultice being applied at the same time to the loins, and renewed as often as it becomes cool. **B., Bog,** a bath formed by mixing bog earth (generated by the decomposition of plants in the presence of water, and found at iron and sulphur springs) with warm water to form a pulpy or mushy consistence. This is used as a mud bath. **B., Borax,** borax, 4 ounces; glycerin, 3 ounces; water, 30 gallons. It is used in the same class of cases as bran bath. **B., Bran,** boil 1 pound of bran in 1 gallon of water, strain, and add 30 gallons of water. This is a soothing and emollient bath, and is of service in squamous and irritable conditions of the skin. **B., Brand,** cold bath. The tub is filled with water at 68° F. The patient is given a stimulant of from 1/2 of an ounce to 2 ounces of brandy, the face and chest are laved with ice-water, an ice-cap applied to the head, and then he is gently placed in the water. The attendants should gently pass the flattened outstretched hands over successive parts of the body to dilate the superficial cutaneous vessels. Remove the patient as soon as his teeth begin to chatter, or if cyanosis of the lips or face appears. Usually, the bath should be continued 15 minutes. The patient is then placed wet on a sheet and quickly wrapped from head to foot. After drying, hot water is applied to the feet. See Typhoid Fever. **B., Buff,** one in which the bather is nude. **B., Chemic,** in chemistry, an apparatus for regulating the temperature of chemic processes by surrounding the substance with water, sand oil, or mercury, through which the heat is communicated. **B., Cold,** a bath of cold water, the temperature of the latter varying from 32° to 70° F. It is used to reduce fever, and as a general stimulant. See Bath (Brand). **B., Dipolar,** a hydroelectric bath in which the patient does not come in contact with either of the electrodes, but these are immersed in the water at each end of the tub. **B., Effervescent,** a liquid bath containing a free gas, which is given off with effervescence. **B., Egyptian,** a modification of the Turkish bath, with rise of temperature to the maximum point, followed by lowering of temperature to the initial point. **B., Electric,** one in which the medium of the bath and the bather's person are included in the circuit of a galvanic current. **B., Electric-light,** exposure in a closed chamber to the rays from an arc light. See Phototherapy. **B., Electrotherapeutic,** a bath furnished with suitable electrodes and used in the application of electricity for curative purposes. **B., Electrothermal,** a hot bath combined with exposure to the influence of electricity. **B., Foot-,** a bath for the feet, used as a derivative agent in cases of cold, etc., **B., Fucus-,** one containing seaweed, or a decoction of it, imparting sodium chlorid and a small percentage of iodin. **B., Full,** one in which the patient's body is entirely covered by water, so that his chin just clears it. **B., Gas-,** one in which a gas is applied to the entire body or an affected part by means of a closed cabinet. **B., Gelatin,** dissolve 1 pound of common glue in hot water, and add the solution to the plain bath, or to the bran bath; it may be used for the same class of cases. **B., Graduated,** one in which the temperature of the water is gradually lowered by the addition of cold or ice water. **B., Half,** the patient is seated in a tub containing from 8 to 10 inches of water of a temperature suited to the case. A wet towel is tied around the head, and the bath water is poured and dashed over the back, head, and shoulders with the attendant's right hand while friction is practised with the left, and the patient does the same on the anterior portion of the body. The temperature of the water may be lowered if a more decided impression is desired. The bath is continued for from 5 to 20 minutes, with active friction. It is indicated in all fevers with a depressed nervous system, as shown by ataxia, delirium, or coma. **B., Herb-,** made by using the extract of pine-needles or of some aromatic herbs; used as a tonic. **B., Hip-.** See Bath (Sitz-). **B., Hot,** the temperature ranges from 104° to 110° F. It acts upon the skin, producing free perspiration, and accelerates the pulse and respiration. **B., Hot-air,** Turkish bath; the patient is placed in a box (French method), his head being outside, and the box is filled with hot air furnished by a lamp. In the ordinary Turkish bath the patient is compelled to inhale the air within a closed compartment. A much higher temperature may be borne in hot-air baths than in vapor baths. They provoke more profuse sweating, and raise the temperature of the body to a greater extent. They are useful as a diaphoretic and in catarrhal, neuralgic, and rheumatic conditions. They are contraindicated, as is also the vapor bath, in fatty degeneration of the heart. **B., Hydroelectric,** a water-bath charged with electricity. **B., Hydrostatic,** a variety of permanent water-bath in which the patient is supported without total immersion. **B., Indian,** massage in combination with a Turkish bath. **B., Internal,** lavage of the stomach or rectum. **B., Iodin-,** one to which is added a solution of 8 grams of iodin and 16 grams of potassium iodid in 600 grams of water. **B., Kinetotherapeutic,** a water-bath in which specified movements are carried out. **B., Light-.** 1. See **B., Sun-.** 2. Exposure of affected parts to rays of light by means of various apparatus; also of the whole body for inducing perspiration. **B., Lime-,** a bath to which slaked lime is added at the time of using; it is used in gout and in treatment of itch. **B., Medicated,** a bath in which medicinal substances, as mineral salt, sulphur, etc., are dissolved or held in suspension. **B., Mercurial,** for the treatment of syphilis. Calomel, 20 to 60 grains, or a mixture of 15 grains of calomel and 20 grains of cinnabar are fused over a water-bath. The patient is stripped and enveloped in one or more blankets or in a mackintosh or india-rubber blanket lined with flannel. The lamp and mercury are placed under his chair and the former lighted. In a few minutes perspiration is induced, and the

sublimed calomel is deposited upon the body. Twenty to thirty minutes are sufficient for a bath after which the patient is allowed to cool off slowly. The bath is best taken before retiring. **B., Milk,** a bath in milk, for nutritive purposes. **B., Mineral.** 1. The water of a mineral spring used as the medium. 2. One to which a solution of mineral substances has been added. **B., Monopolar,** a hydroelectric bath in which the wall of the metal tub is utilized as a large electrode. The current entering here is conducted to the entire surface of the body in contact with the water, and passes out by means of a large metal electrode the edges of which are covered by a rubber pillow so placed that the patient can lie upon it without coming in contact with the metal. See B., Dipolar. **B., Moor,** a bath in water mixed with the earth of moors. **B., Mud,** a bath prepared by mixing well-seasoned earths containing more or less mineral matter, with water containing the same substances. The body is surrounded with this mixture at various temperatures from 90° to 100° F. The patient is then rinsed with warm water. This is of value in some uterine diseases and in obstinate rheumatism. **B., Mustard,** made by inclosing from 2 to 4 ounces of ordinary mustard in a piece of muslin or thin linen, and hanging it in about 4 gallons of hot water until the latter becomes yellow. It is used as a general bath for infants in collapse, convulsions, or severe bronchitis, the child remaining in until the skin becomes ditinctly reddened. It is also used as a foot- or sitz-bath in amenorrhea. **B., Nauheim,** a natural thermal effervescent (gaseous muriated) bath. See Heart-disease, Schott Treatment. **B., Needle.** See B., Rain-. **B., Nutritive,** one containing wine, milk, or any nutritive ingredient. **B., Oxygen-,** an inhalation of oxygen to correct inadequate aeration of the blood; also a local application of oxygen gas to gangrenous ulcers. **B., Ozone-.** See B., Fucus-. **B., Pack** or **Sheet,** one in which the body is wrapped in wet cloths. See B., Sheets. **B., Peat-,** an application of bog-earth containing much vegetable matter and used in gout and rheumatism. **B., Permanent.** See Bath (Warm). **B., Pine,** prepared by adding a decoction of pine-needles, or some pine extract, to hot water. It is mildly stimulating, and is employed in hysteria, gout, and rheumatism. **B. of Plombières,** a bath to which a solution of 100 grams of powdered gelatin in hot water is first added and afterward a mixture of 100 grams of sodium carbonate, 20 grams each of sodium chlorid and sodium bicarbonate, and 60 grams of sodium sulphate. **B., Plunge-,** a bath, hot or cold, into which the patient plunges. **B., Rain,** consists of from 4 to 6 three-fourths circles of pipes secured together at a distance of 2 to 3 inches. Each pipe has 3 lines of fine perforations, from which the stream issues under pressure, striking the body of the patient at all points with considerable force. This may be used as a substitute for the dripping sheet. **B., Russian,** one in which the air of the room is saturated with steam by throwing water upon heated mineral or metallic substances, after which the bather is rubbed down, finishing with a cold douche. See Bath (Vapor). **B., Sand,** the body of the patient is surrounded in a tub with a layer of dry, warm sand that has been naturally or artificially heated, the temperature ranging from 95° to 120° F. The duration of the bath is from 1 to 1 1/2 hours. The head is wrapped in a wet towel and permitted to lie outside of the sand. The after-treatment is the same as that after a hot-air bath. This is of value as an emollient procedure. **B., Schott.** See Schott Treatment. **B., Seawater,** more stimulating and tonic in its effects than fresh water. It may be given cold, tepid or hot. It may be prepared artificially by dissolving bay-salt or rock-salt in fresh water, 4 to 9 pounds of salt to 30 gallons of water. It is useful in convalescence, chlorosis, and strumous diseases. See Sea-bathing. **B., Seaweed.** See B., Fucus. **B., Sheet,** the application of cold water to the body through the medium of a sheet or towel of fine or coarse texture, placed upon the skin. The patient is wrapped in a linen sheet, wrung not quite dry out of water at a temperture of from 63° to 70° F. A rubber cloth and a blanket are spread over the bed to protect it. As the sheet dries small quantities of water are poured with one hand from a vessel or sponge upon a limited part of the body, beginning with the chest. With the other extended hand rapid passes are made over this spot until it becomes a little warmer. Successive parts of the body are thus treated, except the forearms, hands, feet, and legs. The patient is then dried and made comfortable. This is applicable in all febrile affections with high temperatures, except in chest and abdominal diseases. **B., Shower,** a familiar form of the douche. The water is delivered from a nozzle with numerous perforations that may be attached to a hose, striking the body in a divided stream. **B., Sitz-,** one in which only the buttocks and hips are immersed in water, It is useful in pelvic inflammations, amenorrhea, and retention of urine. **B., Slime,** a bath in water mixed with the slimy deposit of organic matter found in rivers or ponds. **B., Sponge,** one in which the patient's body is rubbed with a sponge and water. It is used to reduce temperature. **B., Starch,** starch, 1 pound; water, 30 gallons. This is used as is the bran bath. **B., Sulphur,** contains potassium sulphid, from 4 to 8 ounces in 30 gallons of water; a small quantity of sulphuric acid may be added. It is used in certain skin-diseases, scabies, lead colic, and lead palsy. **B., Sulphurous-acid,** a means of applying the fumes of burning sulphur to the body. The patient is seated on a cane-bottomed chair, and a blanket or oil-cloth is placed around him, the head remaining uncovered. On the floor beneath the chair is a pan containing a little water, and in this is placed a smaller vessel containing small pieces of sulphur. A small quantity of spirit of wine is poured over this and ignited, and sulphurous acid gas is evolved. **B., Sun,** the therapeutic exposure of the naked body to the sun's rays. **B., Surprised,** an ancient and now obsolete form of bath for insane and hysteric patients, who were unexpectedly plunged into cold water. **B., Sweat, B., Sweating,** a bath to induce a free flow of perspiration; *e. g.*, a Turkish bath. **B., Tepid,** the tem-

perature of the water ranges from 85° to 95° F. It acts mainly upon the skin as a sedative, cleansing, and detergent agent; the pulse, respiration, excretion, secretion, and temperature are practically unaffected. **B., Turkish,** one in which the bather is placed successively in rooms of higher temperature, then shampooed or rubbed, and finally stimulated by a douche of cold water. See BATH, HOT-AIR. **B., Vacuum,** the treatment of parts by subjecting them to a partial vacuum. **B., Vapor,** Russian bath; this may be given, like the Turkish bath, in a box, by permitting steam from a pipe to permeate it, providing for its escape; or the patient may inhale the vapor within a closed compartment, the whole surface being at the same time exposed to its influence. A higher temperature can be borne than in the hot-water bath, though for a shorter time. It is useful to provoke profuse perspiration. It should be followed by brisk frictions. **B., Warm,** the tub is filled with water at any temperature near that of the body—say, 90° to 104° F. The patient lies quietly in it, and obtains the effect of warmth, moisture, and water-pressure. It is used to calm the nervous system, produce sleep, and allay reflex instability. The *continuous warm bath,* called by Hebra the *permanent bath,* is made by suspending a sheet in the tub as a hammock. The patient lies upon this surrounded by water that is kept at an equable temperature (warm) by a proper arrangement of in-and-out flow. It is used in the treatment of extensive burns and wounds. **B., Water-,** a bath of water. It may be cold (60° to 75° F.), tepid (85° to 95° F.), or hot.

BATTERY.—This term is usually applied to a series of cells producing electricity (voltaic or galvanic battery); also frequently to a single cell. The way in which the cells are coupled depends upon the nature of the current that is desired and the relation between the external and internal resistance. For example if the cells are arranged, in series—the copper of the first with the zinc of the next, and so on—the result is to give the maximum electromotive force; on the other hand, if the zincs are connected and the coppers connected, the electromotive force is the same as for a single cell, but the internal or battery resistance is diminished, and hence the strength of the current or the quantity of electricity may, under certain conditions, be much increased. The first method is popularly spoken of as the arrangement for intensity; the second, as the arrangement for quantity. A primary battery is a combination of a number of primary cells that form a single battery. A secondary battery is a combination of a number of storage cells to form a single electric source. In the following table the storage or secondary batteries are not included. The common form of these is a series of lead plates carrying masses of lead oxid. See ELECTRICITY.

NAMES, ELEMENTS, FLUIDS, ETC., OF THE PRINCIPAL BATTERIES

NAME OF CELL.	POSITIVE ELEMENT.	NEGATIVE ELEMENT.	EXCITING AGENT.	DEPOLARIZING AGENT.	E. M. F. IN VOLTS
Beetz	Zinc	Copper	Zinc sulphate in plaster-of-Paris.	Copper sulphate in plaster-of-Paris.	1.04
Bunsen	Zinc	Carbon	Sulphuric acid, dilute	Nitric acid	1.75 to 1.96
Callaud	Zinc	Copper	Solution of zinc sulphate.	Cupric sulphate	1.0 to 1.14
Daniell	Zinc	Copper	Zinc sulphate	Cupric sulphate	1.0 to 1.14
Edison-Lelande	Zinc	Cupric oxid and carbon.	Potassium hydroxid	Cupric oxid	0.75
Fuller	Zinc	Carbon	Zinc chlorid	Potassium dichromate and hydrochloric acid.	1.5
Gaiffe	Zinc	Silver	Zinc chlorid	Silver chlorid	1.02
Gravity. See *Callaud*					
Grenet	Zinc	Carbon	Sulphuric acid and potassium dichromate.	Chromic acid	2.0
Grove	Zinc	Platinum	Sulphuric acid, dilute	Nitric acid.	1.94 to 1.97
Latimer-Clark	Zinc	Mercury	Mercuric sulphate	Mercuric sulphate	1.436
Leclanché	Zinc	Carbon	Ammonium chlorid	Manganese dioxid	1.42
Lelande Chaperone	Zinc	Copper or iron	Potassium hydroxid	Cupric oxid	0.98
Maische	Zinc scraps n a bath of mercury.	Platinized carbon.	Common salt solution	None separate	1.25
Marié Davy	Zinc	Carbon	Sulphuric acid, dilute	Mercuric sulphate	1.52

NAMES, ELEMENTS, FLUIDS, ETC., OF THE PRINCIPAL BATTERIES.—*Continued.*

BEARBERRY.—See Uva Ursi.

BEARING-DOWN PAINS.—The true pains of labor. They become most marked and assume their characteristic bearing-down quality during the second stage of labor. See Labor.

BECHTEREW'S DISEASE.—Osteoarthritis of the spine. See Spondylitis Deformans.

BECQUEREL'S RAYS.—Radiation given off by uranium and some of its compounds. They are luminous, actinic, and skiagraphic. They may give rise to a dermatitis.

BED-SORES.—Local patches of moist gangrene caused by undue pressure and irritating secretions; a crease or fold in a sheet, a crumb of bread, a feather, or a bit of string on the sheet may cause them. Especially is this so when the skin is irritable from excessive perspiration, inefficient washing, or involuntary passages of urine. Bed-sores are particularly common in spinal disease and injuries, and in all wasting diseases.

Treatment consists in reducing the pressure, careful repeated washing, drying, and dusting with zinc oxid, and subsequent protection with lint or cotton-wool, etc. Leather-backed adhesive plaster may be applied over bony prominences, or, if seen early, collodion may be used. Frequent rubbing with alcohol, and changing the position of the patient may prove a preventative. When congestion appears, a water-bed or air-cushion may be used. Spirit of camphor or glycerol of tannin may be rubbed in twice daily, to harden the skin. Other preparations are salt and alcohol (2 drams to 1 pint), or the following:

℞. Powdered alum, ℥ ss
Tincture of camphor, ℥ ij.
Whites of 4 eggs.

℞. Corrosive sublimate, gr. ij
Alcohol, ℥ j.

℞. Oil of copaiba, } equal parts.
Castor oil, }

A solution of silver nitrate may be used when the skin is about to break, in the strength of 20 grains to the ounce; and in solution of 10 grains, daily, when the skin breaks. The sloughs should be removed as fast as they form. Stimulation, good nourishment, and sleep are valuable in treatment.

BEEF.—The flesh of domestic cattle. Good beef should be of red color, possess firm texture, and be free from unpleasant odor. Beef consists of albuminoids, 20 3/4, fat 2 3/4, extractives 1 1/2, salts 1 1/2, water 73 1/2, and also a minute quantity of creatin.

Beef-essence or **extract** is made by pouring 8 ounces of soft water upon 1 pound of finely chopped, fresh beef, free from fat, adding 5 or 6 drops of hydrochloric acid and from 50 to 60 grains of salt, stirring well, and leaving in a cool place for 3 hours. Pass through a hair sieve, pressing the meat slightly, and adding, gradually, 2 ounces of water. It is of red color, has the taste of soup, may be taken cold or warm, a teacupful at a time.

Beef-tea is made by putting a pound of minced lean beef into a pint of tepid water in an earthen jar, where it is left for an hour. It is then strained, and the juice squeezed out of the meat, placed on the fire and slowly brought to the boiling-point, being stirred all the time. Season to taste.

Or, in 3 ounces of cold water place 2 pounds of meat, lean and boneless, in a jar, which may be placed in a saucepan of water and allowed to simmer for 4 hours.

BEE-STING.—See Bites and Stings

BELCHING.—See Eructations, Flatulence.

BELLADONNA (Deadly Nightshade).—The *Atropa belladonna* is a herbaceous, perennial plant, having dark-purple, bell-shaped flowers, and glossy, purplish-black berries about the size of cherries. It is indigenous in the mountainous districts of central and southern Europe and Asia, and is cultivated in Europe and in the United States. It contains the official alkaloid *atropin;* also the alkaloids *belladonnin, hyoscyamin, hyoscin,* and *atropamin.* It also contains albumins, gums, and a coloring principle, *atrosin.*

Belladonna leaves are ovate and tapering, brownish-green above, grayish-green below, of faint odor, and bitter, disagreeable taste. Stram-

onium leaves are more wrinkled, hyoscyamus leaves are more hairy. Dose, 1/2 to 1 1/2 grains gradually increased.

Belladonna root is seen in cylindric, tapering, wrinkled pieces, 1/2 to 1 inch thick, nearly odorless, taste bitter and acrid. Dose, 1/2 to 1 grain, cautiously increased.

Therapeutics.—Belladonna is used to relieve pain, relax spasm, to allay excessive secretion, as a valuable vasomotor stimulant, and as a mydriatic. In asthma, with morphin, it is a sovereign remedy as a prophylactic and as a cure. It is of great service in intestinal spasm, griping, and cramps, spasm of the sphincter ani or of the urethra and bladder, chordee, dysmonorrhea, hiccough and whooping-cough, sore throat, and exophthalmic goiter. It is especially useful in the pain of inflammation, particularly that of rheumatism, gout, neuralgia due to peripheral disturbance, sciatica, cancer, and pelvic affections. In cerebral and spinal hyperemia, congestive headaches, encephalitis, meningitis, and myelitis it proves one of the very best remedies. In erysipelas of superficial and nonvesicular character, and when cerebral, it is really curative administered locally and internally. Inflammations of the lungs, iris, bladder, kidneys, and breasts are all treated with it. In constipation from atony of the bowels it is remarkably efficient, and in the enuresis of children it is equally so, if used freely—10 to 20 drops of the tincture thrice daily.

Its local application is efficient in ulcers of the rectum, anal fissure, abscesses, boils, carbuncles, and other superficial inflammations. In scarlet fever it relieves many of the symptoms, and is especially indicated in this disease when the rash is imperfect, the pulse feeble, and the condition one of adynamia. Its prophylactic power against scarlet fever is believed in by many of our best practitioners, though questioned by many others.

Its chief active principle is the alkaloid *atropin* which is insoluble in water. Atropin is used to obtain the same effects as belladonna. See Atropin.

Poisoning.—Belladonna in full doses produces flushing of the face, dryness of the fauces, dilated pupils, and sometimes an erythematous rash resembling that of scarlet fever, and slight delirium. It excites the brain and spinal cord, quickens the pulse, raises arterial pressure, increases intestinal peristalsis, and checks all the secretions except the urine. It is especially well borne by children. It is rapidly diffused and quickly eliminated, particularly by the kidneys.

Opium is the physiologic antagonist to the effects of belladonna on the cerebrum, pupil, heart, respiration, arterial tension, and kidneys. Physostigmin, aconite, pilocarpin, and quinin are each antagonistic to some of its effects; muscarin, to most of them. In poisoning by this drug tannic acid and emetics should be used; then morphin, physostigmin, or pilocarpin for the nervous disturbance. Caustic alkalies decompose atropin, and are therefore incompatible with the preparations of belladonna.

Poisoning by belladonna is treated by the application of external heat if collapse ensues, and by the use of strychnin if respiration fails. The physiologic antagonist (opium) should be given in small graded doses, especially when respiration is faulty.

Incompatible with **Belladonna** or **Atropin** are: Alkaloidal precipitants, alkali hydrates, or acids with heat, tannic acid, vegetable decoctions or infusions. Physiologically incompatible are: Aconitin, bromal hydrate, chloral hydrate, hydrocyanic acid, jaborandi, morphin, muscarin, physostigmin, phytolacca, pilocarpin, quinin.

Preparations.—The preparations of the **leaves** are: **B., Extractum.** Dose, 1/10 to 1/2 grain. **B., Tinct.,** 10 percent. Dose, 1 to 15 minims. **B., Unguent.,** contains extract 10, dilute alcohol 5, benzoated lard 65, hydrous wool-fat 20 parts. **B., Emplast,** contains 30 percent of the extract.

From the root are prepared: **B., Fluidextractum.** Dose, 1/2 to 2 minims. **B., Linimentum,** fluidextract 95, camphor 5.

Atropin. Dose, 1/160 of a grain. **Atropin Sulphate.** Dose, 1/200 to 1/100 of a grain. See Atropin. **Oleatum Atropinæ,** a 2 percent solution of the alkaloid in alcohol, 2, oleic acid 50, and olive oil to 100. Dose, 1/200 to 1/60 of a grain.

BELL'S PALSY.—See Facial Paralysis.

BENDS, THE.—See Caisson Disease.

BENEDICT'S TEST FOR SUGAR.—See Urine (Examination).

BENEDIKT'S SYNDROME.—This consists of: (1) Hemiplegia on one side of the body; (2) oculomotor paralysis of the opposite side; and (3) a tremor on the hemiplegic side. It is found in diseases of the midbrain.

BENZIN.—A distillate from petroleum, consisting of hydrocarbons, chiefly of the marsh-gas series; a transparent, diffusive, inflammable liquid, soluble in about 6 of alcohol, readily soluble in ether, chloroform, etc., insoluble in water. Its vapor, mixed with air and ignited, explodes violently. **B. Purified.** A valuable solvent for oils fats, resins, caoutchouc and some alkaloids, and a vermicide against tape-worm. Dose, 5 to 10 drops, on sugar or in mucilage.

BENZOIN.—A resin obtained from *Styrax benzoin,* a tree native to Sumatra and Siam. It is composed of resins 80 percent, benzoic acid 10 to 20 percent, and a trace of volatile oil. Some varieties also yield cinnamic acid. It is sparingly soluble in water, cold alcohol, and ether, and crystallizes in shining prisms, melting at 134° F. It is used as a remedy for bronchitis and in making court-plaster. It occurs in tears consisting of several resins agglutinated by a balsam. It yields benzoic and cinnamic acids, is antiseptic and disinfectant, and is used mainly as a stimulant expectorant in chronic bronchitis. Sodium and potassium compounds are sometimes used in place of like salicylic acid compounds. They render the urine acid and increase its quantity. Benzoin is irritant to the fauces, and the powder inhaled excites sneezing and coughing. Benzoin is principally used as a stimulant expectorant, especially in the chronic

bronchitis of the aged, and by atomization in laryngeal affections. The compound tincture, 1 dram to 1 ounce in a pint of boiling water, is a useful sedative inhalation. For sore nipples and chapped hands, 1 part of the compound tincture to 4 parts of glycerin and water, is useful. As a cosmetic, to remove freckles and other skin affections, and in urticaria, it is of service. In foul-smelling wounds it is excellent. *Benzoic acid* is used to acidify the urine, and is, therefore, useful in cystitis, phosphatic deposits, excessively alkaline urine, and, rarely to remove phosphatic calculi. Benzoin has the property of preventing rancidity in ointments. It is an ingredient in cosmetic washes, in aromatic or fumigating pills or pastils, and in court-plaster or black sticking-plaster.

Incompatibles with *Benzoin*, alkalies, acids, and water; with *Benzoates*, acids, ferric salt.

Preparations.—**Adeps Benzoinatus,** benzoinated lard, contains 2 percent of benzoin. **B., Tinct.,** 20 percent of the resin in alcohol. Dose, 10 to 20 minims. **B., Comp. Tinct.,** friar's balsam, benzoin 10, Aloes 2, storax 8, balsam of tolu 4, alcohol, to 100 parts. Dose, 10 to 40 minims. **Benzoic Acid,** $H.C_7H_5O_2$, alcohol the best solvent. A constituent of opii tinct. camphor. Dose, 5 to 10 grains, in wafers. **Ammonium Benzoate,** water the best solvent. Dose, 5 to 30 grains. **Lithium Benzoate.** Dose, 5 to 30 grains. **Sodium Benzoate,** water the best solvent. Dose, 5 to 30 grains.

BENZONAPHTHOL.—Prepared from beta-naphthol by the action of benzoyl chlorid; it occurs as a white, tasteless powder, almost insoluble in water. It is used as an intestinal antiseptic and disinfectant in typhoid and tropical dysentery. Dose, 5 to 15 grains.

BENZOSALIN.—Methyl benzoyl salicylate. After passing unchanged through the stomach it is said to be split up into benzoic and salicylic acid in the intestines. It is said to have the same action as its constituents without producing any unpleasant by-effects. Dose, 7 to 15 grains.

BENZOSOL.—Benzoyl guaiacol. Guaiacol benzoate. It is split up in the intestines into guaiacol and benzoic acid which are absorbed and excreted in the urine. Compared with guaiacol, this agent has the advantage of being almost tasteless; hence it can be given in large doses without digestive disturbance and disagreeable eructations, and without the local irritant effect. In doses of 4 grains, gradually increased to 12 grains, thrice daily, it is said to give as good results as creosote in the treatment of pulmonary tuberculosis.

BENZOSULPHINID.—See Saccharin.

BERBERIS (Barberry).—The root of the common barberry. Its properties are due to an alkaloid, *berberin*. It is an astringent, bitter tonic; in large doses, a cathartic. It is used locally in conjunctivitis, and internally in malarial and typhoid fevers. **B. Fluidextract.** Dose, 10 to 40 minims. *Berberin*, the alkaloid, is a tonic to the capillary vessels, and increases the blood-pressure. It is recommended as a tonic and an antiperiodic, and is an ingredient of various lotions for the mucous membranes; it is useful in nasal catarrh, etc. Dose, 1 to 10 grains. The hydrochlorid is an efficient injection in gonorrhea.

BERI-BERI (Kakké).—A disease of certain tropical regions, believed by some to be excited by a microorganism, and by others regarded as a specific multiple neuritis, resembling that of lead and alcohol, and of a peripheral character. Poor diet is a marked etiologic factor. Deficiency of the vitamines is now believed to be the real cause of the disease. Beri-beri resembles pernicious anemia. The general symptoms are those of anemia and anasarca.

Symptoms.—There are 4 forms: (1) An incompletely developed or rudimentary form; (2) an atrophic form; (3) a dropsical or dropsical and atrophic form; and (4) an acute pernicious or cardiac form. The rudimentary form may set in insidiously, with or without prodromes, while catarrhal symptoms are frequently present, soon followed by weakness in the lower extremities, numbness, and edema. Days, weeks, or even months may thus ensue with gradual recovery. In the atrophic form the onset may be insidious or abrupt, consisting in loss of power and wasting of the affected muscles. Improvement takes place slowly. The dropsical form is characterized by general and widespread anasarca, involving the serous cavities as well as the subcutaneous tissues. Recovery is gradual. The acute pernicious form attacks preferably young, robust persons, and is characterized by acute cardiac insufficiency.

The most conspicuous and most constant symptom of beri-beri is the impairment of motion. This begins in the lower extremities, and is of ascending type and of variable degree. The paretic muscles waste. Cutaneous anesthesia or hyperesthesia is of variable distribution. Paresthesias are common and varied, as hyperesthesia is uncommon. There is little pain, either spontaneous or induced. Palpitation of the heart, oppression and dyspnea, epigastric pulsation, precordial distress, acceleration of pulse, diminution of arterial tension, cardiac hypertrophy and dilatation, and functional cardiac murmurs are common. The blood shows no distinctive alteration.

The usual termination of the disease is in recovery. In chronic cases death may take place from general exhaustion.

The **prognosis** is uncertain, and must be based upon the circulatory condition.

Treatment.—The first measures are attention to diet and to clothing, protecting against changes of temperature and against wet and cold. The dropsy is treated on general principles with potassium acetate, digitalis, and squill, and occasionally calomel, etc. The chief indications are to regulate intestinal function, to remove edema, to increase the action of the skin, and to give tone and vigor to the muscular fiber. Change of climate is of great importance. Elevation is to be preferred, and a sea voyage may be curative. Laxatives have always been looked upon as serviceable. In acute cases salicylic acid and sodium salicylate have been strongly recommended. Digitalis is an indispensable remedy. In acute cases with

cardiac insufficiency venesection may be resorted to. In chronic cases arsenic, iron, and quinin are indicated. In atrophic cases subcutaneous injections of strychnin are useful, and the pareses may be materially improved by electricity. With regard to the diet, Stitt says: "It must be remembered that not only is rice, from which the neuritis-preventing vitamine has been removed by excessive milling, productive of beri-beri but that the same applies to other cereals which have been similarly deprived of their vitamines. The same result may be obtained by the employment of excessive sterilization for canning. Fresh meat is as valuable as fresh vegetables in prophylaxis, but if either kind of food be subjected to excessive heat, as in the case with tinned meats, etc., they not only do not prevent beri-beri but in a negative way are beri-beri producing."

BETANAPHTHOL (Naphthol).—A derivative of naphthalene, or naphthalin, a hydrocarbon product of coal-tar; feebly soluble in water, but freely so in alcohol, ether, and chloroform. It is a white, crystalline powder, of phenol-like odor and pungent taste. It is an efficient antiseptic and parasiticide. It is used to dress wounds and ulcers, and is employed in skin diseases, such as ringworm, psoriasis, scabies, and eczema, in the form of an ointment of 30 to 60 grains to the ounce. Internally, it may be used in diarrhea, dysentery, enteric fever, and in cholera. In the summer diarrheas of children, in the dose of 1/6 to 1/4 grain, every 2 or 4 hours, it is useful. It is given in emulsion or as a powder, with sugar, in wafers or capsule, and is flavored with oil of bergamot. To prevent intestinal fermentation it should be taken after meals. Dose is from 3 to 6 grains in pill.

BETANAPHTHOL BENZOATE.—Benzonaphthol. It is used as an intestinal antiseptic in typhoid fever and diarrhea. Dose, 3 to 8 grains.

BETOL.—Salicylate of betanaphthol, of alleged value in rheumatism, cystitis, intestinal catarrh, and gonorrhea. It resembles salicylic acid in its properties. Dose, 2 to 8 grains.

BIER'S HYPEREMIC TREATMENT.—Upon the theory that increased blood supply means destruction of bacteria and their products, increase in the opsonic index and regeneration of tissues, Bier has made use of hyperemia as a curative agent, both in the active and passive form. When treating chronically diseased joints alternately by active and passive hyperemia, Bier discovered that by hot-air hyperemia the edema sometimes occurring after constriction hyperemia rapidly vanished. This result led him to use hot-air hyperemia in the treatment of elephantiasis, and in the edema that is present after healed fractures of the extremities. This treatment by hyperemia has an action on the tissues that is not only solvent, absorbent, nutritive, and bactericidal, but also analgesic.

Active hyperemia as produced by the hot-air treatment is advocated in sciatica, lumbago, neuralgia, sprains, traumatic synovitis, chronic rheumatic arthritis, and rheumatoid arthritis, thrombosed varicose veins, fractures, especially Colles' and Pott's. It is claimed to be beneficial in treating gangrene, diabetic or senile. The part affected is placed within a box of proper shape and size into which a current of hot air (144 to 230° F.) is conducted through a tube, the degree of heat being regulated and not so high as to be painful. In neuralgias and threatening gangrene, the Bier-Eschbaum hot-air douche is used. Unpleasant after-effects in weak patients can be avoided by applying a cold compress to the forehead during the treatment, and by avoiding the exposure of large surfaces to the hot air. Hot air should not be applied for longer than one hour in the day. Treatment should not be given during the menstrual period. Hot air is contraindicated in joint tuberculosis as it provokes abscess formation.

The indications for passive hyperemia cover a wider field than the active by reason of the great nutritive and especially the bactericidal effect.

For the production of passive hyperemia, Bier has adopted (1) constriction and (2) suction—the elastic bandage and the vacuum cup respectively. Careful and correct technic is requisite for the success of the treatment.

(1) Applied correctly the venous outflow of the parts is obstructed by pressure on the veins while the pressure is insufficient to affect the arteries. The bandage is especially adapted to diseased joints and should be applied firmly but not too snugly for a definite length of time, depending on the case, one hour being the maximum. Abscesses should first be incised. Constriction hyperemia has been used with success in joint affections such as tuberculosis, rheumatoid arthritis, acute gonorrheal arthritis, acute and chronic gout, infective inflammations, cellulitis of the arm, beginning whitlow, septic wounds of the head and extremities, tenosynovitis, osteomyelitis, lymphangitis, lymphadenitis. Contraindications are advanced tuberculosis, large abscesses, beginning amyloid disease, heart disease, arteriosclerosis. Hydrops tuberculosis is first treated with iodoform injections until the hydrops disappears.

(2) In acute lymphadenitis, mastitis especially, boils and small carbuncles, contusions or black eyes, sinuses, abscesses as of the axilla, acute purulent otitis, etc., glass caps are used from which the air is exhausted by means of a rubber bulb or suction pump. They are made of various shapes to fit different regions. The treatment is intermittent, 5 minutes on and 3 minutes off, for 3/4 of an hour daily. See HOT-AIR TREATMENT, INFLAMMATION, JOINTS (Diseases).

BILHARZIASIS.—See SCHISTOSOMIASIS.

BILIARY CALCULI.—See GALL-BLADDER (Diseases).

BILIOUS FEVER.—See MALARIAL FEVERS.

BIMANUAL EXAMINATION.—See GYNECOLOGIC EXAMINATION.

BIRTH.—See LABOR.

BIRTH-MARK.—See NEVUS.

BIRTH, PREMATURE.—See ABORTION, LABOR, MISCARRIAGE, NEW-BORN INFANT.

BIRTH, STILL.—See VIABILITY.

BISKRA BUTTON.—See FURUNCULUS ORIENTALIS.

BISMUTH.—Bi = 210; quantivalence I, III, V. A pinkish-white crystalline metal, not used in medicine in its metallic form. Its commercial salts are likely to contain arsenic. The insoluble salts of bismuth are feebly astringent, and are useful in disordered digestion, diarrhea, acne, eczema, etc.

The action of bismuth salts is chiefly a local one, they being sedative to the end-organs of the nerves. They are also feebly astringent, and produce constipation after a time, coloring the stools and tongue a dark clay color from their conversion in part into the sulphid. Toxic effects, when occurring, are ascribed to arsenic, with which the commercial preparations may be contaminated. The bismuth salts, however, have toxic powers of their own.

Bismuth as an intestinal sedative should be given in large doses—from 20 to 30 grains. An antiseptic, like carbolic acid, creosote, salol, etc., may be combined advantageously with it. It is given in pills, in powders, and suspended in mucilage of acacia. Freely given, the odor of garlic is imparted to the breath.

Bismuth subnitrate is used locally in skin-diseases. Dermatol, or bismuth subgallate, is a fine yellow powder, unaffected by exposure to light and air, entirely odorless, astringent in action, and antiseptic. It is less poisonous than iodoform, which it was intended to supplant. It is of use in skin-diseases in which there is much secretion—as weeping eczemas—as a dusting-powder or in ointment.

Preparations.—**B. Citras**, a white, amorphous powder, odorless and tasteless, insoluble in water or alcohol, soluble in water of ammonia. Used only for pharmaceutical purposes. Dose, 1 to 3 grains.

B. et Ammonii Citras, a combination of the citrate with aqua ammoniæ, and has no definite chemical composition. Small, pearly scales, very soluble in water, sparingly in alcohol. Dose, 1 to 5 grains.

B. Subcarbonas, a white or yellowish-white powder, of somewhat varying chemical composition, tasteless and odorless, insoluble in water or alcohol. Dose, 5 to 20 grains in powder or emulsion.

B. Subnitras, a heavy, white powder, of somewhat varying chemical composition, odorless and almost tasteless, of slightly acid reaction; insoluble in alcohol, almost insoluble in water. Dose, 5 to 20 grains several times a day, in powder, pill, or milk; often combined with opium, morphin or belladonna.

B. Subgallas (*Dermatol*), fine, odorless, saffron-yellow powder, insoluble in all ordinary solvents. Dose, 5 to 20 grains.

B. Subsalicylas, should yield not less than 80 percent of pure bismuth oxid; almost insoluble in water, insoluble in alcohol. Dose, 5 to 15 grains.

B. betanaphtholate. See ORPHOL.

B. oxyidogallate. See AIROL.

B. tetra-iodo-phenol-phthalein. See EUDOXIN.

B. tribrom-phenol. See XEROFORM.

For persistent nausea and vomiting:

℞. Bismuth subnitrate, ʒ iij
Tincture of aconite, ʒ j.

Divide into 10 capsules. Give 1 every half hour.

℞. Carbolic acid or creosote, gtt. x to xx
Bismuth subnitrate, ʒ iij.

Divide into 10 capsules. Give 1 every hour.

For choleraic diarrhea in children:

℞. Bismuth subcarbonate, ʒ ij
Syrup of acacia, } each, ℥ ij.
Cinnamon water, }

One teaspoonful every hour.

For acute gastrointestinal inflammation:

℞. Morphin sulphate, gr. j
Bismuth subnitrate, ʒ ss
Creosote, gtt. vj.

Divide into 12 powders. Give 1 powder every 2 or 3 hours.

For chapping of hands or cheeks from exposure:

℞. Bismuth subnitrate, } each, ʒ iij
Oleate of zinc, }
Lycopodium, ʒ ij.

BITES AND STINGS.—These are usually punctured, sometimes also lacerated, poisoned wounds, the treatment of which depends upon the individual case; that is, whether the bite was by a dog, cat, rat, or venomous serpent, etc., or whether the sting was by a tarantula, scorpion, centipede, or spider, bee, wasp, etc.

If the patient is otherwise in good health, a **dog bite** needs the simplest antiseptic treatment, with no probing of the wound. If there is cause for suspicion, in addition to cleansing the wound an application of ammonia may be made, and the wound may be scrubbed and soaked under hot water, and the Pasteur treatment should be instituted at once. Dog bites should never be cauterized with silver nitrate. Sucking the wound is a foolish custom, and is often the origin of infection. It is most foolish immediately to kill a dog that has bitten anyone. Observation of the animal only is desirable. Hydrophobia has been said to exist exactly in proportion to the common belief in it and the public discussion of the subject. Very many of the cases reported as hydrophobia are perhaps not hydrophobia at all. See HYDROPHOBIA.

The treatment of bites by **cats and rats** consists of simple cleansing, and, perhaps, squeezing the wounds under hot water. Subsequent inflammation requires general treatment.

Stings of Bees, Wasps, etc.—There sometimes remains in the flesh the sting or a portion of the body of the insect, appearing as a black speck at the seat of the bite. This may be removed by pressing over it with a watch-key, or by pulling or sucking. Death has followed a bee-sting. A few drops of ammonia and water may be applied with relief. Camphorated chloral will arrest the severe pain. Cold and wet applications—even wet earth—are soothing.

Mosquito Bites.—A weak solution of carbolic

acid is an excellent preventive agent, not only as regards the mosquito, but also one tending to keep off numerous other pests—ticks, fleas, lice, horse-flies, etc. Carbolic-acid soap may suffice.

If resorted to before retiring, the protection usually lasts during the sleeping hours. An emulsion of common kerosene or petroleum is an excellent substitute. A few drops of petroleum held in an open receptacle a few inches under the insect causes the latter to drop dead.

A 1:1500 solution of potassium permanganate, distributed in mosquito-haunted marshes or grasses, will render the development of the larvæ impossible.

An ointment containing 1/2 of a dram to the ounce of betanaphthol reduces the irritation caused by the bites and stings of any insect.

Aqua ammoniæ does not penetrate the tissues, but it reduces the suffering. Menthol may be rubbed over the surface.

Neal recommends the following mixture for local application:

℞. Pulverized ipecacuanha, ℥ ss
Alcohol, } each, ℥ ss.
Ether, }

Ottinger affirms that the best results are obtained from the application of ichthyol.

Brocq and Jacquet recommend the following:

℞. Camphorated oil of camomile, 100 parts
Liquid storax, 20 parts
Peppermint essence, 5 parts.

Also,

℞. Peruvian balsam, 5 parts
Storax ointment, 25 parts
Olive oil, 20 parts.

When violent local tumefaction and congestion result, a cold lead-water poultice forms a very soothing application. Lemon-juice is also useful.

Gnats.—The remedial and preventive measures recommended for mosquito-bites are equally useful for gnat-bites.

Leech-bites.—The Philippine Islands are infested with a blood-thirsty land-leech, most tormenting, but not dangerous, whose attacks in certain districts are not to be avoided except by the use of stout, tight-fitting, canvas leggings. The whites are obliged to protect themselves by means of leech-gaiters, the cloth being woven so closely as to be absolutely impermeable. In those of robust health, leech-bites merely cause annoyance, the only difficulties sometimes encountered are the bleeding, slight inflammation, and itching like that experienced from mosquito-bites; but in those of degraded habits, with the germs of tropical fever in their blood, the punctures, if rubbed or scratched, are liable to degenerate into ulcers that may lead to loss of limb or life.

Chigoe.—An insect that, in Cuba, Porto Rico, and the West Indies generally demands to be specially guarded against in the chigoe, or jigger. It is the female only that is annoying, and she is especially likely to work her way beneath the skin of the feet. Having buried herself, an intolerable itching results, at first rather agreeable than otherwise, but after a few hours merging into most violent pain. At the same time a small, white, bladder-like tumor, about the size of a pea with a dark spot in the center, develops under the skin.

Mexican guides apply a lighted cigaret to the spot, the heat of which penetrates sufficiently to destroy the insect. Negro women remove the skin from the little ball with a fine needle, making pressure with the thumbs, squeezing out the sac of eggs; the cavity is then filled with snuff or tobacco. The unacclimated persons and all new-comers are especially subject to the attacks of the chigoe. Excruciating, violent inflammation and even gangrene have resulted from neglected chigoe-sores.

Vivigagua.—An ant that lives in the West Indies, chiefly in and about the sugar-cane fields. This insect bites with great fierceness, producing the impression that one has been pierced by a red-hot needle. There is no protection to be had from its onslaughts, or those of the ticks and *Diablito colorado*, except by carefully burning over the ground before camping, or using a liberal sprinkling of insect-powder, or of poke-root and borax mixed. A certain amount of immunity may be secured by wearing tight, closely-woven canvas leggings or high-topped boots.

Ticks.—Blood-sucking ticks bury the whole head in the flesh, and any attempt at removal leaves the head behind to create trouble.

The head should be removed with needle or knife and the wound subsequently dressed antiseptically. Turpentine applied to the rear end of the insect sometimes causes it to loosen its hold. Again, a drop of chloroform injected with a hypodermic syringe frequently brings about the same result.

Spiders.—Corrosive sublimate solution, 1:500 or 1000, and keeping the wounds constantly wet with the same, is advised. A liniment made of ordinary ammonia-water, olive oil, and laudanum, well rubbed over the bitten part, and a few drops of the ammonia water in a tumbler of water, if administered internally, is also useful. Guaco is a remedy of some repute. Ipecac paste or poultice proves a perfect specific. Any of the preparations recommended for mosquito-bites are also useful for spider-bites. In severe cases the local injection of a 5 percent solution of potassium permanganate may prove advantageous, the patient's strength being simultaneously sustained by means of strychnin and, if need be, stimulants. Strong coffee is considered valuable.

Scorpions.—Scorpions are peculiar to the tropics and subtropics, and are equally abundant in the Philippines, Canaries, Porto Rico, and Cuba. They generally hide under stones, fallen tree-trunks, in roofs, cracks in the walls, thatch and dark corners of deserted huts, and obscure parts of inhabited dwellings; they have an unpleasant way of hiding overnight in one's boots, stockings, or trousers. Scorpion-stings, though painful, are not dangerous to a person in good health, and are easily relieved by camphor, rum, lemon-juice, or solution of carbolic acid, though inflammation

may persist, sometimes with slight fever, for several days.

No specific has been found. As a means of overcoming the distressing, burning pain so common in scorpion-stings, chloral hydrate, used locally by rubbing into the affected part, proves most efficacious.

Cocain has been used with magic relief. One grain of the drug in from 10 to 15 drops of pure water is given hypodermically in the neighborhood of the bite. Camphorated chloral (equal parts of camphor and chloral hydrate) gives almost instant relief from the acute pain produced by the venom of the scorpion. For the collapse that supervenes in some cases, milk and brandy are recommended.

Aromatic spirit of ammonia in 30 minim doses in very hot water every half hour is a valuable remedy.

Centipede.—Its bite is about as venomous as the sting of the scorpion, and may prove serious in children and persons weakened by excessive fatigue, disease, and the inordinate use of alcohol.

The centipede in our country is harmless, and, in fact, as its aim is to destroy cockroaches and feed upon them, it may be regarded as a welcome visitor rather than as an enemy. The venomous species may be recognized by the legs, which are quite short, and each segment of the body bears a single pair of legs.

The treatment of centipede-bites is the same as that of the sting of the scorpion.

Snakes.—Venomous snakes are generally nocturnal or crepuscular or both, and when encountered during the daytime, their presence is due to accident. No venomous serpent will ever be found in or on a tree, and most of them have clubbed, instead of slender, tails. Rattlesnakes prefer, as a rule, the more dry, elevated, and stony districts.

Rattlesnake wounds are not so universally fatal as is popularly believed. The prevailing physiologic views are those of Weir Mitchell and Reichert, who consider that the blood is rendered uncoagulable, the blood-corpuscles being disintegrated through the destructive influence of the venom upon protoplasm. Blood-extravasation occurs as a result; there is profound depression of the respiratory nerve-center, medullary hemorrhage, etc.

The first step is to apply a ligature—a tightly tied and twisted cord or handkerchief—about the bitten part, and above the wound, and then as soon as possible seek the services of a medical man. As the poison exerts its chief effect upon the brain and nervous centers, every effort should be made to combat the two former and sustain the heart and respiration, which is best done by violent exercise. Not only will this sustain the heart and respiration, but it will tend to increase the cutaneous elimination of the toxic products. Alcohol, except when given by a medical man to stimulate and sustain a flagging heart and circulation, is detrimental rather than beneficial. Large drafts of strong coffee are, on the contrary, of great value.

Suction is considered dangerous by some observers. The dry cup instead of the mouth is preferable. Serious effects may follow in a person who performs suction of a poisonous wound.

Hypodermic injections of strychnin in large doses are useful. Its action is regular and prompt, and after a time ceases entirely, but it should not be employed until unmistakable symptoms of snake-poison are perceptible. The patient must be watched for 24 hours after the disappearance of the last symptoms, in order to be able to combat, in time, a sudden relapse.

The conclusions reached by Duke are that the hypodermic injection of strychnin is the only remedy to be relied upon; it must be carried out with boldness, but only after the symptoms of snake-poison have become pronounced. If a proper amount of snake-poison to counteract the strychnin is not present in the blood, the latter may itself cause death. If the patients are moribund when seen—*i. e.*, pulseless, and respiration has ceased—the intravenous method may be adopted. A remedy now considerably employed in the treatment of venomous bites is a 1 percent solution of permanganate of potassium.

Antivenene is serum taken from an immunized ass or a horse. If injected in sufficient quantity into persons bitten by snakes, it prevents the action of the venom of all snakes, provided intoxication is not too far advanced. It must be injected as soon as possible after the bite. Generally it is efficacious an hour and a half after the bite in adults. Usually, 2 1/2 fluidrams are sufficient for children under 10 years, and 5 fluidrams for adults. When the bite is that of a very dangerous species, it is advisable to give one single injection of a double dose at once. The wound is washed with a solution of hypochlorite of lime diluted to 15 1/2 grains to 2 fluidounces of water previously boiled. The dose of serum must be injected into the subcutaneous cellular tissue in the right or left side of the abdomen, and with the usual antiseptic precautions. Then, with the same syringe, 2 or 2 1/2 fluidrams of the 1:60 solution of hypochlorite of calcium are to be injected in the different parts surrounding the bite and into the bite itself. These injections are intended to destroy, in and around the wound, the venom that has not yet been absorbed. After these procedures the bandage may be removed from the limb, the patient rubbed, given coffee or tea, and warmly covered, so as to cause abundant perspiration. The administration of ammonia or alcohol must be avoided. Cases in which the use of chlorid of lime produced favorable results have also been reported. See Serum Therapy.

BLACK DRAUGHT.—See Senna.

BLACK DROP.—See Opium.

BLACK EYE.—This may be the result of traumatism directly to the lids or adjacent structures, or may be due to injury to remote parts, such as fracture of the orbit or of the lower skull. In the last case the hemorrhage does not appear until some time after the injury, and occupies particularly the edges of the upper lids.

Treatment is not absolutely necessary; the extravasated blood will disappear of itself in a few weeks. If the contusion is seen soon after the

injury, ice-cold applications should be ordered to prevent extravasation. If seen after the stage of effusion, hot compresses, lead-water and laudanum, or a pressure bandage, may be ordered. Incising very puffy lids is a bad practice, as the swelling soon disappears of itself, or, at least, on the application of heat and pressure. For cosmetic effect, the discolored lid may be painted a flesh tint.

BLACK VOMIT.—See YELLOW FEVER.

BLACK WASH.—See MERCURY.

BLACK-WATER FEVER.—See MALARIAL FEVERS (Hemoglobinuria).

BLADDER, ATONY AND PARALYSIS.—Both terms are applied to insufficient contractile power in the muscular coat to expel the contents of the bladder; but in atony the want of power is the result of loss of tone in the muscular fibers, while paralysis is due to the failure of nervous influence. Both conditions must be distinguished from the mere inability of the bladder to empty itself on account of obstruction to its outlet. See URINE (Retention).

Atony may be due to: (1) Simple overdistention (2) gradual distention owing to enlarged prostate or stricture; (3) cystitis.

Symptoms.—The patient complains of inability to hold his urine, or that it constantly dribbles away, or that he has to pass it very frequently. The involuntary flow occurs at first during sleep; afterward on any exertion causing contraction of the abdominal muscles. These symptoms, although often improperly spoken of as incontinence, are really those of retention, the bladder being fully distended, but unable to empty itself, and the excess flowing involuntarily away.

The treatment consists in passing a catheter at regular intervals, and as often as may be necessary to empty the bladder completely, while, in the meantime, the condition leading to the atony must be treated by appropriate measures. Thus, if the result of overdistention, strychnin and galvanism may be tried; if the result of gradual distention from enlarged prostate or stricture, these conditions must be treated in the way mentioned under their respective heads. In both paralysis, and atony, cystitis, dilatation of the ureters, pyelitis and disorganization of the kidney rapidly ensue if the cause of the bladder disturbance cannot be relieved.

True paralysis of the bladder is nearly always the result of disease or injury of the brain or spinal cord and does not occur except in general paralysis. The bladder, being paralyzed, cannot empty itself, and becomes distended as in atony; and when it can hold no more, the excess overflows through the sphincter, which is also paralyzed.

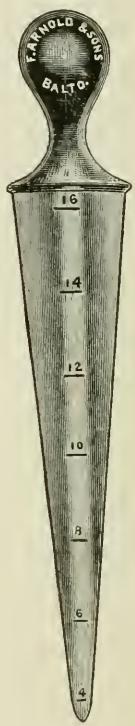
Reflex paralysis, however, often occurs after an injury or surgical operation, especially that for hemorrhoids. The local treatment consists in the regular passage of a catheter 2 or 3 times daily.

BLADDER, EXAMINATION.—In the female the bladder and urethra may be examined in the following manner: The woman is placed on the table in the lithotomy position, with the hips elevated 15 to 20 inches by means of pillows; the urine is drawn off with a catheter, and the urethra is anesthetized by the application of a solution of cocain, 10 grains to 1 fluidounce. The urethra is gently dilated—by the instrument shown in accompanying illustration—up to about 12 mm. The vesical speculum is next introduced; the obturator is withdrawn, and the examiner inspects the interior of the bladder by means of reflected or direct light. As the urine accumulates in the bladder, it is removed by means of small balls of absorbent cotton held in longtoothed-forceps. The elevated position of the hips allows air to enter the bladder as soon as the urethra is dilated, and thus the walls are separated, which permits thorough inspection of every part of the organ.

As the speculum is withdrawn, the walls of the urethra may be examined.

In the Male.—For inspection of the urethra and bladder see ENDOSCOPE and CYSTOSCOPE.

BLADDER,EXTROVERSION.—The malformation in which, in consequence of arrested development, the posterior wall of the bladder is pushed forward by the pressure of the abdominal viscera, and protrudes as a red, velvety tumor. It is associated with epispadias, and with failure of union of the pubic bones at the symphysis. The testicles are frequently retained. It is attended with extreme discomfort from the constant dribbling of the urine.



URETHRAL DILATOR; THE FIGURES INDICATE DIAMETER IN MILLIMETERS.

Treatment.—Many operations having for their object the closing-in of the bladder by flaps of skin taken from the adjacent abdominal wall have been performed. Various attempts have also been made to turn the ureters into the colon or rectum, but without success. Recently, Trendelenburg has succeeded in reducing the gap between the pubic bones by separating the sacroiliac synchondroses, so that he was enabled at a subsequent sitting to bring the margins of the mucous surface of the bladder in contact, and then to unite them by a plastic operation. The newly formed bladder is in this way lined with mucous membrane instead of having its front wall closed in by skin. The objection to the skin flap is the growth of hair into the bladder at puberty, and its incrustation with phosphates. If no operation is undertaken, a properly shaped urinal must be worn.

BLADDER, FOREIGN BODIES.—Under the head of foreign bodies in the bladder are included every kind of solid substance introduced into the bladder from without. Renal and vesical calculi are not included.

They are more common than would at first glance seem possible. Among them are included: (1) Various surgical instruments, such as portions

of catheters, sounds, bougies, or portions of any of the ordinary instruments used in operations within the bladder; (2) substances introduced through perverted sexual instinct into the bladder by way of the urethra; (3) projectiles thrown from firearms or cannon; and (4) foreign bodies entering the bladder by means of a fistulous opening from adjacent tissue or organs.

These foreign substances rarely become encysted, but usually soon become incrusted with the urinary salts, and thus form the center of a vesical calculus.

Symptoms.—The symptoms depend somewhat upon the mode of entrance, but if external or fistulous wounds are closed, they differ in no particular from those of ordinary calculus.

The diagnosis is greatly facilitated by the use of the cystoscope, but the presence of foreign bodies may be detected by the sound.

The treatment necessarily depends on the manner of introduction of the foreign body and the sex of the patient. In the female the urethra may usually be dilated sufficiently to allow the removal of the foreign body through the natural channels. In the male, extraction is performed by means of the lithotrite or cystoscopic forceps. In this way, pieces of catheters, bougies, threads, rubber and other small objects are in most instances readily removed. This procedure is contraindicated when the foreign body has become incrusted with salts or is so large that its withdrawal would injure the urethra. Under such circumstances suprapubic cystotomy is the proper procedure.

BLADDER, INFLAMMATION.—See Cystitis.

BLADDER, INJURIES.—The bladder may be injured by stab or gunshot wounds through the abdominal walls, the rectum, or the vagina; it has been punctured through the sacrosciatic foramen; it may be torn by one of the pubic bones in fracture of the pelvis, or wrenched from the triangular ligament by separation of the symphysis; it may be bruised to such an extent in parturition, or by the presence of the retroverted uterus, that the wall sloughs and gives way; and when it is distended, it may be ruptured by compression. If the tissues are healthy, the force necessary to effect rupture must be considerable; if, on the other hand, they are diseased in any way, it may be altogether insignificant; even muscular action is enough. Rupture of the bladder, therefore, is said to be either traumatic or idiopathic.

The most frequent cause of bladder injury is a blow upon the lower part of the abdomen, but rupture may be produced by contraction of the abdominal muscles, as in lifting heavy weights; and perhaps, for the same reason, by violence applied to the back. In one or two instances in which it has been due to a fall in a sitting position, it was probably the result of a sudden impact of the fluid against the base. The bladder must be distended, or it cannot be torn, though it may be punctured; and partly for this reason, partly because in alcoholism the protecting influence of the muscles is in abeyance, it is peculiarly likely to occur in drunken men. The rupture may be either intraperitoneal or extraperitoneal.

Symptoms.—The typical symptoms are the feeling as of something giving way, collapse, severe pain, inability to stand upright or walk, and desire, but want of power, to urinate. No one of these symptoms is invariably present, and the only evidence that can be relied upon is that obtained by passing a catheter; the bladder either contains only blood, or a small quantity of blood-stained urine. Collapse may be absent. Inability to urinate cannot be relied upon, for partial and even complete power has been retained, especially in extraperitoneal cases. Sometimes there is no pain; and, particularly when the accident has occurred during drunkenness, so that no history can be obtained, and it is merely a matter of conjecture whether the bladder was full at the time or not, the diagnosis may be a matter of the greatest difficulty, especially during the period when treatment is most valuable.

1. **Intraperitoneal Rupture.**—Immediately after the accident the bladder collapses, and the urine enters the peritoneal cavity, collecting at first at the lower part, but soon becoming diffused by the movement of the intestines. Healthy urine does not immediately give rise to peritonitis; the abdomen has been opened on several occasions, more than 24 hours after extravasation, without any evidence of inflammation. If, however, urine is retained, or if it comes from a bladder already inflamed, as when the wall of a sacculous slough or a cancerous ulcer gives way, peritonitis sets in within a very few hours, and becomes general, the abdomen becoming distended, the face pinched and drawn, and the pulse rapidly failing.

2. **Extraperitoneal Rupture.**—In this the urine is poured out either into the loose tissue that lies in front of the neck of the bladder, or behind, between the bladder and the rectum or the uterus. Sometimes there is a free exit, the perineum or the vagina or the rectum being torn as well. If there is no exit, the ordinary symptoms of extravasation of urine set in, and inflammation, followed by sloughing and septic poison, spreads rapidly into the iliac fossæ, the front wall of the abdomen, and even ino the scrotum, through the inguinal canal. Generally, the peritoneum becomes involved as well before the patient dies.

Prognosis.—Gunshot injuries are not so fatal as might be supposed; the urine escapes through the wound, and retention and decomposition are prevented. The same occurs when the bladder is wounded by foreign bodies pushed into it through the rectum or vagina, or when it sloughs in consequence of pressure during parturition. When there is no external wound or easy exit for the urine, it accumulates, decomposes, and acts as a virulent poison.

Treatment.—The first indication is to remove the urine that has already escaped; the second is to close the rent in the bladder so as to prevent further extravasation. The patient is placed under an anesthetic; a rubber bag is introduced into the rectum to raise and fix the floor of the bladder; and an incision made in the middle line, ending just below the upper border of the pubic symphysis. The extraperitoneal portion of the

bladder is examined first by gently pushing the folds of peritoneum upward. If there is no extravasation of blood there, or evidence of bruising, the peritoneal cavity itself is laid open and the rest of the bladder carefully examined. If there is a rupture, the edges are steadied and drawn forward by hooking up the nearer end with a blunt and rounded retractor (a suture is unnecessary, and only inflicts further injury), and then a series of Lembert sutures passed close together, commencing in the sound tissue beyond each end of the rent, being careful to avoid including any of the mucous membrane. Grieg Smith recommends a double row, one to transfix the cut muscular surface, the other (Lembert's) outside this; and that all should be passed before being tied. The intestines are held back out of the way, in the meantime, with a soft, flat sponge. Then the abdominal cavity is cleared of all blood-clot and urine that may have found their way in, and irrigated either with warm water—temperature, 100° F. (37.7° C.)—or with a dilute solution of some nonpoisonous antiseptic. The wound should be closed in the usual way, introducing a drainage-tube only when peritonitis is already present. If there is any doubt as to the security of the sutures in the walls of the bladder, they may be tested first by distending the cavity, with milk, through a catheter. Silk is the best material, and the sutures should not be more than 1/8 of an inch apart; catgut, even if it were as certain, is difficult to knot securely when the wound lies deep in the cavity of the pelvis. In one or two cases the difficulty has been so great that it was necessary to make a short transverse incision through the peritoneum on each side.

After the operation the bag in the rectum is emptied and withdrawn, a suppository or a hypodermic injection of morphin given, and the patient kept warm and quiet in bed, receiving no food but a small quantity of ice to suck or a few teaspoonfuls of milk. At first there is very little urine secreted, and if the sutures are sufficiently closed, there is no need to pass a catheter, much less to tie one in or to perform cystotomy; the bladder is able to empty itself without risk.

Extraperitoneal rupture must be treated on the same principles. If the rent can be secured from the front, an opening should be made over the pubes, and Lembert's sutures passed as before; but as it is impossible to remove the urine from the loose cellular tissue around the bladder, the abdominal opening should not be closed and a large drainage-tube should be inserted. Wounds involving the rectum or vagina, if not very large, may remain untreated for a time; very frequently they close in or contract so that the resulting fistula is much smaller. Wounds in other parts are usually complicated by other injuries (Moullin).

BLADDER, PARACENTESIS.—This may be needed either as a temporary measure, to give relief until the natural passage can be reopened, or as a permanent means of exit in impermeable stricture or enlargement of the prostate. It may be performed either over the pubic symphysis, through the perineum (going either through or behind the prostate), or through the rectum. Of these three methods, the first named is the only one recognized at present. In exceptional instances when, as in cases of extravasation of urine or advanced cystitis, the object is rather to drain the bladder than to relieve retention, the prostatic portion of the urethra may be opened in the middle line, at the apex of the gland (*la boutonnière*); and sometimes this is done in case of stricture (Cock's operation).

Suprapubic Paracentesis.—This may be performed either with an aspirator or with an ordinary, but somewhat curved, trocar and cannula. When the bladder is distended, there is abundant room, but, especially in old cases of cystitis, the posterior surface of the symphysis must always be followed. If the relief required is only temporary, the aspirator may be used, a small incision being made in the skin with a scalpel, and the trocar pushed through it into the bladder, downward and backward. No extravasation follows, as the mucous membrane glides upon the muscular coat when the bladder collapses, and the orifice becomes valvular. If necessary, this may be repeated 2 or 3 times without much danger; but if it is continued, there is always a risk, either of leakage taking place through the wall of the bladder or, without any direct opening being present, of an abscess forming in the loose cellular tissue, between the layers of the transversalis fascia, possibly due to the escape of irritating material from the end of the cannula as it is withdrawn.

When a permanent opening is required, a large trocar (with a linear, not a triangular, cutting-edge) and cannula may be introduced in the same way. On withdrawing the trocar, a soft india-rubber tube is passed down the cannula, and left when this is removed. The other end of the tube may be carried under the bed clothes to a receptacle. After a few days the tissues become consolidated and form a short, straight canal, which can be fitted with a rubber tube and stop-cock. Owing to the contraction of the sinus there is no leakage.

In exceptional cases, after suprapubic cystotomy for enlargement of the prostate or tumor of the bladder, the opening has been allowed to contract to a sinus and the same arrangement made use of.

BLADDER IN PREGNANCY.—Certain diseases of the bladder and abnormalities of the urine at times complicate pregnancy; the most important are the following:

Irritability of the Bladder.—This is a frequent complication of early pregnancy. It is purely functional in character, and is caused by pressure of the gravid uterus. Occasionally it may be neurotic.

If **treatment** is demanded, it should consist in the administration of nerve sedatives, such as the bromids and chloral. If the condition is due to a displacement of the uterus, this should be corrected.

Retention of Urine.—This usually occurs in the early months of gestation, and is caused by a retrodisplacement of the uterus; occurring later, during the last month of pregnancy, it may be due to pressure caused by the descent of the presenting

part of the child and lower uterine segment into the pelvis (subsidence of the uterus).

As the urine accumulates in the bladder, it is gradually expelled drop by drop through the urethra. This is called the *incontinence of retention.*

Treatment should consist in relieving the cause as quickly as possible; a backward displaced uterus should be replaced; later in pregnancy an abdominal binder may relieve pressure and thus do good. Sometimes catheterization becomes necessary; this should be done under the strictest aseptic precautions.

Vesical Hemorrhoids.—This condition is due to pressure upon and engorgement of the pelvic blood-vessels. As a rule, no symptoms arise unless rupture of a small vessel occurs, when hematuria will be present. If this should become annoying, rest in bed, free purgation, and the administration of gallic acid by the mouth (20 grains) 3 times daily will usually effect a cure. Occasionally it may be necessary to irrigate the bladder with some astringent solution.

Vesical Calculi.—These may be present before, or they may originate during, pregnancy.

It is important that they be recognized and removed before labor, as otherwise a vesicovaginal fistula may be formed from sloughing of the tissue compressed between the calculus and the advancing head.

Cystitis.—This is a somewhat rare complication of pregnancy. Its causes, symptoms, and treatment are the same as in nonpregnant patients.

Albuminuria.—This occurs in about 6 percent of all pregnant women. See NEPHRITIS OF PREGNANCY.

Glycosuria.—This is a rather common affection, occurring in from 15 to 50 percent of cases. Usually it is lactose absorbed from the breasts, and is therefore found just before and after labor. Diabetes mellitus may occur, being intensified in all its symptoms and frequently producing abortion.

Treatment should consist in the ordinary management of these cases uncomplicated by pregnancy, aided by the induction of abortion should the patient's condition become critical.

Polyuria, lipuria, chyluria, peptonuria, and **hematuria** may occur, but their pathologic significance is slight, and treatment is, as a rule, not demanded.

BLADDER, RUPTURE.—See BLADDER (Injuries).

BLADDER, STONE.—**The causes** are not entirely known, but residence in certain districts or countries, poor living, abuse of alcohol (especially in the form of malt liquor), excess of nitrogenous food, want of sufficient exercise, and anything that induces the excessive formation of uric or oxalic acid in the urine are regarded as predisposing causes. Retention of urine from prostatic enlargement and the presence of a foreign body in the bladder are exciting causes. In a few cases a nucleus has been formed for a calculus by a piece of necrosed bone that has reached the bladder from a fractured pelvis or carious spine.

Varieties.—The three most common varieties of calculi found in the bladder are the uric acid, the oxalate of lime, and the phosphatic. They may occur almost pure or they may be mixed. According to Sir Henry Thompson, the uric acid and urates form one-half of the number met with; the phosphatic, one-fourth; the mixed, one-fourth; and the oxalates only 3 percent of the whole. A description of the various forms of calculi is given under the head of URINARY CALCULI (*q. v.*).

The character of the stone may to some extent be determined by the state of the urine. Thus, if the urine is acid, it will probably be either oxalate of lime or uric acid; if alkaline, phosphatic. Calculi vary in size from that of a hemp-seed to a large mass weighing many ounces.

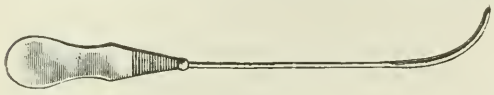
The calculus may be variously situated in the bladder. It is usually free just behind the prostate, but it may be in the upper fundus behind the pubes, or in one of the sacculi so often found in long-standing diseases of the bladder (encysted). Calculous matter may sometimes be deposited upon growths in the bladder or upon the ulcerated mucous membrane.

The Terminations of Stone.—If neglected, cystitis may set in, and inflammation may spread up the ureters to the kidney. In consequence, moreover, of the obstruction to the urinary outlet, the bladder may become hypertrophied, and the ureters and kidneys dilated.

Symptoms.—The three chief symptoms are: (1) Pain generally referred to the end of the penis, and worse after micturition, on account of the stone then falling on the sensitive trigone and the walls of the bladder contracting upon it; (2) frequent micturition; and (3) a little blood in the urine. These symptoms are increased on exercise, especially riding, and after the jolting of a railway journey, etc., and are least marked at night, when the patient is at rest. Other symptoms that may be present are the passage of gravel; sudden stoppage of the stream during micturition; the presence of mucopus in the urine owing to cystitis; piles in adults and prolapse of the rectum in children, due to straining; and elongation of the prepuce in boys, caused by the constant handling to relieve pain after micturition. Stone in the bladder may be simulated by cystitis, an enlarged prostate, a long or adherent prepuce, a narrow meatus, a growth in the bladder, calculous or other disease of the kidney, a peculiar choreic condition of the bladder, tubercle of the bladder, and ascarides in the rectum. An accurate diagnosis, however, can only be made by sounding the bladder, though in boys the stone may be felt by the finger in the rectum while pressure is made with the other hand above the pubes.

Sounding the Bladder.—The ordinary sound is a solid steel instrument with a short, bulbous beak. Thompson's sound is hollow, to allow some of the urine to be drawn off if desired, and has a handle like that of the lithotrite, to facilitate the necessary movements in the bladder. Having warmed and oiled the sound, pass it like a catheter, letting it glide into the bladder by its own weight without using any force. When the sound is in, gently push it onward to examine the posterior part of the bladder. Then turn the beak alternately to

either side, and depress the handle between the patient's thighs to search the upper fundus. Then turn the beak downward to examine the base or lower fundus. If the stone is not detected, allow a little of the urine to escape, or change the patient's position, or raise his pelvis and make an-



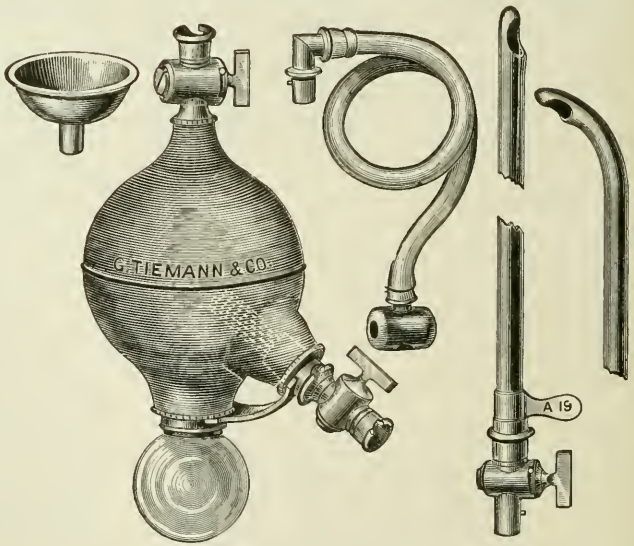
Stone Sound.

other effort. The stone may not be felt because of its small size, or because it has become encysted or entangled in a fold of mucous membrane. A guarded opinion, therefore, should be given, and a further examination made at a future time. A stone may be known to be present by the peculiar ring that is both felt and heard on striking it. This ring is quite unlike the sensation given to the sound by its coming into contact with phosphatic deposits on a roughened or fasciculated bladder, or with one of the pelvic bones. Having discovered a stone, the next care should be to determine approximately (1) its probable size and composition, (2) whether it is free or encysted, (3) whether there is one stone or more, and (4) the condition of the bladder and urethra. (1) The *size of the stone* may be roughly estimated by the amount of resistance offered on pushing it before the sound or by passing the sound over it, and by feeling it through the rectum with the other hand pressing on the hypogastrium. Its exact size can only be ascertained by seizing it with the lithotrite, the distance the blades are then apart being indicated by the scale on the handle. The *composition of the stone* may be approximately determined by (*a*) the character of the ring on striking it—the clearer the ring the harder the stone; (*b*) the condition of the surface, which is rough in the oxalate of lime, smooth in the phosphatic; (*c*) the reaction of the urine; and (*d*) the general health of the patient. (2) A *stone, when encysted,* is always felt at the same point in the bladder, and when seized with the lithotrite, cannot be moved. The sound cannot be passed all around it. There is no blood present, and the symptoms are usually less severe, and are not increased by exercise. (3) The *presence of a second stone* can only be determined with certainty by seizing one stone with the lithotrite and then striking the other (Walsham).

Treatment.—The stone may be removed by crushing (*lithotrity*) or cutting (*lithotomy*). In adults lithotrity, with but few exceptions, should be the rule. In children up to 12 or 14 years of age, lithotomy has hitherto been the recognized operation; even in very young children lithotrity, as in adults, will also be the rule, lithotomy, the exception. In adults lithotomy should be practised in place of lithotrity only when (1) the stone is very large and hard; (2) when the urethra is the seat of intractable stricture; (3) when the stone is encysted; and (4) when the bladder is sacculated. The conditions, however, most favorable for success in lithotrity are, as well expressed by Sir Henry Thompson, "a capacious urethra, a bladder capable of retaining 3 or 4 ounces of urine, absence of ordinary signs of renal disease, and fair general health."

Bigelow's Lithotrite.

Lithotrity, litholapaxy, or **Bigelow's operation** consists in crushing the stone in the bladder, and removing the *whole* of the fragments through a large evacuating catheter. To the late Professor Bigelow is undoubtedly due the credit of having enunciated the principle that the bladder is not so intolerant of instruments as was formerly supposed,



Bigelow's Evacuator.

and that it was to the presence of the fragments, rather than to the lithotrite, that the irritation, cystitis, etc., so common after the old method, should be ascribed.

The operation, as described by Walsham, is as follows: The patient having been prepared for the operation by careful attention to the general health, rest, and such local means for allaying

chronic cystitis as were pointed out under that head, should be placed under an anesthetic, with the pelvis raised a few inches, the thighs slightly apart, the knees supported on a pillow, and the body and legs well wrapped up in blankets to avoid a chill. The rectum should be emptied by a purge the day before, and by an enema on the morning of the operation. A few ounces of urine in the bladder are desirable. If necessary, incise the meatus (a stricture, if present, should have previously been dilated), warm and oil the lithotrite (Forbes' is by far the best instrument), and pass it with gentleness, letting it glide by its own weight through the spongy and membranous portion of the urethra, and do not depress the handle until the blades have reached the prostate. Then bring the shaft to an angle of 35° with the horizon, and it will glide through the prostatic urethra, over the trigone of the bladder, and may possibly be felt to graze the stone. The blades now rest in the lowest part of the bladder and point upward. Hold the handle tightly with the left hand, and, without moving the instrument, open the male blade by drawing out the wheel-shaped end with the right hand. Pause a few seconds to allow the currents set up in the urine by this movement to subside. Then gently press in the male blade, and the stone will probably be caught. If so, continue the pressure on the wheel to retain the stone between the blades, while the button is moved by the thumb to convert the sliding into the screw movement. Rotate the instrument slightly to make sure that the mucous membrane is not caught by the blades; depress the handle slightly to raise the blades from the walls of the bladder, and screw home. The stone will probably be felt to crack and break into fragments. If the stone cannot be seized in this way, systematically explore the bladder thus: Open the blades and rotate 45°; pause and close. Do this first to the right, then to the left. Then raise the blades slightly by depressing the handle; rotate alternately to right and left 90°; raise the blades further and rotate 135°. Finally, reverse the blades by rotating half a circle. In this way the stone will probably be found. In these maneuvers the blades should be opened before rotating them, in order that the stone may not be displaced by the male blade, and after rotating, a pause should be made before closing them to allow the currents to subside. Having crushed the stone and larger fragments, withdraw the lithotrite, first screwing tight home to insure complete closure of the blades, in order to prevent laceration of the urethra. Next introduce a large evacuating catheter (No. 16, or larger); let the urine escape, and inject 2 or 3 ounces of warm water. Attach the aspirator, previously filled with water at a temperature of 98°, and compress the india-rubber bulb, driving some of the water into the bladder. Let the bulb expand and the outward current will bring away some of the fragments and débris, which will fall into the receiver and be prevented from returning into the bladder by the trap on again compressing the bulb. Continue compressing and relaxing until fragments cease to come away. Then, if any are felt by the evacuating catheter, reintroduce the lithotrite, or a smaller one, and crush again and aspirate as before, repeating this *until all the fragments are removed.* The operation frequently lasts from an hour to an hour and a half or longer.

After-treatment.—Opium, if no serious kidney-disease is present, may be given; and hot hip-baths if there is much pain. If there is retention, the catheter should be used at regular intervals, or tied in if its passage causes much irritation and pain. Complete rest in bed for a few days or longer should be enjoined. If cystitis follows the operation, Sir Henry Thompson strongly recommends a weak injection of silver nitrate (1 grain to 1 fluidounce). As a rule, however, no after-treatment is required, even in young boys.

After-complications.—(1) Rigors and fever; (2) retention of urine; (3) acute cystitis; (4) prostatitis and abscess, and (5) orchitis and epididymitis, occasionally occur. More rarely, (6) hemorrhage; (7) suppression of urine, and (8) phlebitis of the prostatic plexus of veins, followed by pyemia. The impaction of a fragment of the calculus in the urethra (formerly common when the fragments were left in the bladder) cannot occur if the bladder has been thoroughly evacuated.

Causes of Death.—Death may occur from (1) acute nephritis, (2) pyelitis, (3) cystitis, (4) perforation or rupture of the bladder, (5) peritonitis, (6) sapremia or pyemia, or (7) exhaustion. A fatal termination is rare, except when there is some chronic kidney-disease.

Lithotomy, or cutting for stone, may be performed through the perineum or above the pubes. Perineal lithotomy is a slovenly and uncertain procedure, rarely practised at the present time. When a cutting operation is deemed advisable, it is best to resort to suprapubic lithotomy, which permits an adequate survey of existing conditions.

Suprapubic lithotomy consists in opening the bladder between the pubes and the peritoneal fold. It is the method that should be employed for the removal of very large stones, and for certain forms of tumor in the bladder. First, pass a Petersen's india-rubber bag into the rectum and dilate it with water, and distend the bladder with a weak antiseptic solution; it will then rise well into the abdomen and appear as a prominent tumor, dull to percussion above the pubes. Make an incision in the middle line immediately above the symphysis, and having divided with scissors the tissues forming the linea alba, expose the wall of the bladder by gently separating the fatty tissue that lies in front of it with the finger or director, avoiding the peritoneal fold, and, if possible, the large veins that ramify in this situation. The bladder having been fixed by inserting a sharp hook into its walls, make an incision into it; introduce the finger to ascertain the size of the stone; enlarge the wound, if necessary, by cutting toward the pubes, and extract the stone with the finger and scoop or with the forceps. After the removal of the calculus, the bladder is washed with silver nitrate solution and closed either entirely or with the exception of a small opening. If hemorrhage was not severe

and the bladder not badly infected it is better to close it completely and insert a retention catheter through the urethra.

BLADDER, TUBERCULOSIS.—Vesical tuberculosis is very intractable. It may be primary. or secondary to tubercle in other parts of the genito-urinary tract, especially the testicle and prostate. It is most often met with in boys and young adult males. The tubercle which is deposited in the submucous tissue soon caseates, leading to small multiple circular ulcers with undermined edges. There is pain, hemorrhage, irritability of the bladder and other signs of chronic cystitis; but the diagnosis will depend on the exclusion of other diseases such as stone, tumors, etc., and the presence of tubercle in other organs, and of the tubercle bacillus in the urine. With the cystoscope the ulcers may be seen especially in the area of the trigone. The general constitutional remedies for tubercle should be employed, together with such local remedies as are indicated for cystitis and for the assuaging of the pain. Iodoform emulsion may be injected into the bladder or lactic acid up to 20 percent. Guyon recommends instillations of bichlorid of mercury from 1:10,000 to 1:1000, and Rovsing employs injections of carbolic in the strength of 6 percent, using 50 c.c. These failing to relieve, suprapubic cystotomy may be done and the bladder washed out, and such caseous masses of tubercle as permit of it scraped away. In the female this may be done through the dilated urethra. Tuberculin is being used, both administered generally and injected into the bladder, with varying results.

BLADDER, TUMORS.—The tumors found in the bladder are: (1) *The fibrous*; (2) *the mucous*; (3) *the villous* or *papillomatous*; (4) *the malignant. The fibrous* and *mucous* spring from the submucous coat, and protruding the mucous membrane in front of them, assume a polypoid or warty shape. They are very rare. *The villous* or *papillomatous* spring from the mucous membrane, and appear as soft, flocculent growths resembling the villi of the chorion. They are the most common of the innocent growths. *The malignant* spring either from the mucous or the submucous coat, and may form a large mass, often nearly filling the bladder, or assume a villous appearance or merely infiltrate the walls. They have either a carcinomatous or a sarcomatous structure.

The symptoms common to all are those of a foreign body in the bladder, with hematuria and absence, on sounding, of stone. In using the cystoscope a measured quantity of fluid should be left in the bladder, which should be previously irrigated if the urine contains blood or pus, until the fluid returns clear. See Cystoscope.

Treatment.—The removal of the tumor, unless it is malignant, or is causing very little trouble, should generally be attempted. This may be done either through the operative cystoscope or through a suprapubic incision. If the pedicle of the tumor can be reached, the former method is preferable, provided of course that the services of a skilled cystoscopist are available. When suprapubic cystotomy is performed the growth may be removed by the cold wire or galvanocautery loop or by forceps, or may be burned off by the acutal or galvanocautery. Tumors infiltrating the anterior wall, if not too large, may be removed by raising the peritoneum, excising the growth with the infiltrated wall, and uniting the edges of the wound with sutures. When removal is contraindicated, relief, when there is obstruction to the urinary outlet, may be obtained by suprapubic puncture; hemorrhage should be restrained by astringents, and pain assuaged by opium.

BLADDER, ULCERS.—These may be due to tuberculosis, cystitis, injury, burning with the cystoscope, or malignant growths. Under the heading *simple ulcer* there has been described a solitary ulcer usually situated at the base of the bladder. It is most frequent in anemic women, occasionally perforates, and has been compared to a peptic ulcer. The **symptoms** of ulcer of the bladder are those of chronic cystitis, the diagnosis being made by the cystoscope. The **treatment** is that of chronic cystitis. Ulcers have been curetted and local applications made through an operating cystoscope. In progressive cases the bladder should be opened, the ulcers curetted and cauterized, and drainage established; perforation is treated in the same way as rupture of the bladder. See Bladder (Injuries).

BLASTOMYCOSIS.—A chronic infectious inflammation especially of the skin due to a yeast fungus, the blastomyces. The cutaneous lesions begin as small papules and become pustular. Secondary involvement of various organs may result. The lungs may be infected primarily by inhalation of the fungus. The symptoms are mainly respiratoy in the generalized type of the disease. The infection runs a protracted course, lasting 10 to 12 years as a rule.

Diagnosis is made by examination of the pus under the microscope.

Prognosis is good in the cutaneous type if treatment is begun early, 3 to 12 months sufficing for a cure. In the systemic type the prognosis is grave.

Treatment consists in large continuous doses of potassium iodid (1 to 1 1/2 drams daily) and local antiseptics, radium, the X-rays, and excision of subcutaneous abscesses. A vaccine made from autogenous filtrate has been used in a few cases, with apparently good results.

BLAUD'S PILL.—A pill of iron carbonate made by mixing about 2 1/2 grains of ferrous sulphate for each pill with potassium carbonate, sugar, tragacanth, althea, glycerin, and water. The dose is 1 or 2 pills after meals. It is largely used in amenorrhea and in the various forms of anemia. See Iron.

BLEACHING.—The most important bleaching agents are the following. *Acids:* hydrochloric, nitric, sulphuric; *carbonate of potassium* (K_2CO_3)—its value depends upon the percentage of carbonate it contains; *caustic soda* (Na OH), a coarse white powder; *chlorid of lime*, a white powder with a chlorinous odor—it is the most important of all; *hydrogen dioxid* (H_2O_2), a colorless, odorless liquid—it is called "Golden Hair-dye;" *permanganate of*

potassium ($K_2Mn_2O_8$); *soaps*—tallow, rosin, and olive oil; *soda ash* (Na_2CO_3)—its value depends on the amount of Na_2O it contains; *soda crystals* ($Na_2CO_3.10H_2O$).

BLEEDERS.—A popular term for those who are subjects of the hemorrhagic diathesis. See Hemophilia.

BLEEDING.—The artificial abstraction of blood from the body. When local or topical, it is done by **scarification, cupping,** and **leeching,** and is useful in certain inflammatory conditions, particularly about the eye and ear. When general, it is done by **venesection** or **phlebotomy,** and **arteriotomy.** Bleeding reduces the heart's action and diminishes the quantity of the blood in vessels.

In the early stages of pneumonia and other acute inflammation in which there is a strong, full pulse, blood-letting is very serviceable if done early. In apoplexy, except when the heart is enfeebled, it is serviceable. In eclampsia and venous engorgement, in uremia, in plethora, and in peritonitis when vigor is maintained, in pleurisy, in uremic asthma and in spasmodic bronchial asthma, in emphysema, in disorders of menstruation, in shock, fever and sunstroke, it has its uses. It is necessary always to bear in mind the age, the sex, the general temperament and condition of the individual in considering the expediency of blood-letting. The very young, the old, the feeble, and the cachectic do not bear it well. Hemophiles are a dangerous class to bleed. See Cupping, Leeching, Venesection.

BLENNORRHAGIA.—See Gonorrhea, Vaginitis.

BLEPHARITIS.—An inflammation of the free edges of the eyelids.

The synonyms are blepharitis simplex, blepharitis marginalis, blepharitis ciliaris, blepharitis ulcerosa, blepharitis hypertrophica, blepharadenitis, ophthalmia tarsi, tinea tarsi, sycosis tarsi, and eczema of the lid-edges.

Causes.—Uncorrected ametropia; some inflammatory process, such as conjunctivitis, keratitis, etc.; inflammation of the roots of the cilia; or the condition may be the result of strumous diathesis. The disease is said to accompany general disturbances of the sexual organs and syphilis. Lice are sometimes a cause. There is also reason to attribute it to special bacteria. Dirty children are very susceptible to blepharitis. Continued eye-strain undoubtedly lies at the bottom of many obstinate cases. Obstruction of the lacrimal apparatus is a cause not to be overlooked.

Symptoms.—The lid-edges are swollen and reddish, and may cause intolerable itching and soreness. There is a gummy and yellowish secretion in the lashes and on the skin near the lid-edge, which, when dried, deposits as scabs and crusts. The lids are glued together after being closed for some time, particularly in the morning. The eyes tire easily. Eczema may be present about the lid-edge, and possibly in other parts of the body. The cilia are often dwarfed or entirely absent, causing a disagreeable disfigurement. In the hypertrophic variety the lids may be everted, exposing the puncta lacrimalis and causing the tears to overflow, thus keeping up the condition, and, indeed, aggravating it, as the edge of the lower lid soon becomes water-soaked. The most annoying **sequel** of blepharitis is trichiasis, a condition in which the lashes become misplaced and scratch the cornea, and which leads to actual entropion.

Treatment.—As this is a frequent affection, it is well to thoroughly discuss the treatment. These cases are sometimes very obstinate, and despite all efforts at relief they cause the patient long years of discomfort, and produce a most annoying facial blemish. First of all, search for one of the causes enumerated. It is advisable to examine the refraction of the affected eyes, and be sure that the lacrimal apparatus is unaffected. Treat any possible cause. All the scales should be removed and the lid-edges kept clean and fresh. For this purpose warm water or a weak boric or bichlorid solution (1:5000) should be used. In the eczematous variety bichlorid in itself is an efficient remedial agent. The local treatment by massage, with a weak Pagenstecher ointment, is probably the best at our command. Ulcers may be painted with a 2 percent solution of nitrate of silver. The treatment of the trichiasis consists in epilation of the distorted cilia, their destruction by electrolysis, or operation. Disease of the conjunctiva and cornea should be treated simultaneously with the blepharitis.

℞. Yellow oxid of mercury, gr. j
Vaselin, ʒ iij.
Rub up well and put in a collapsible tube. Use at bedtime.

BLEPHAROPHIMOSIS.—See Eyelids.

BLEPHAROSPASM.—A spasmodic contraction, clonic or tonic, of the orbicularis, often affecting both eyes. In its mildest form it consists of fibrillary twitchings which may result from overexertions of the eyes or eye-strain. It is observed at times after the instillation of eserin. It is generally reflex, from irritation of the conjunctiva or cornea by a foreign body, or from inflammation of some kind in these regions. It is a disagreeable accompaniment of corneal ulcer. Often the irritation caused by an inverted eyelash is the cause of the trouble. Photophobia often leads to blepharospasm. If no local cause is discernible, ametropia is frequently the cause, or some reflex from a distant irritation, such as a decayed tooth. The spasm may be of central origin.

Treatment of the cause is the only way to attack the spasm. Pressure on the facial nerve at its exit at the styloid foramen is said to stop the spasm. Galvanism is useful. By all means examine the refraction. To examine the eyes of a child with corneal disease and consequent blepharospasm, it is sometimes necessary to plunge the face under cold water, or even to partially anesthetize.

BLINDNESS, CAUSES.—Partial or total loss of vision may result from toxic agents such as tobacco, lead, alcohol, quinin, salicylates, uremia, diabetes. Migraine and hysteria or severe hemorrhages may be responsible. Traumatism is some-

times the cause. The loss of sight may be found in one eye alone due to disuse by reason of high compound astigmatism or strabismus. Blindness is also due to corneal opacities, cataract, intraocular hemorrhage, disease of choroid and retina, neuroretinitis, retrobulbar optic neuritis, optic atrophy (which may be due to cerebral disease, pressure from tumors, embolus). The chief cause of blindness in children is ophthalmia neonatorum.

BLINDNESS, TESTS.—Hysteric amblyopia is not uncommon, but many cases so diagnosed are properly the sequence of asthenopia. Malingering by the declaration of amblyopia, or blindness, is usually found in insurance examination and in military life, and often to procure damages after alleged injuries. Many ingenious devices have been adopted to expose the simulant, all depending upon the fact that in ordinary visual perception there is no account taken of the exact participation of the two eyes. If a book is held before the patient's eye and a pencil is interposed in front of the eye supposed to be active, the reading will be slightly interrupted if the other eye is amblyopic; if, however, the amblyopia is feigned, the other eye will escape the pencil and the reading will be uninterrupted. Another way is to interpose a highly convex lens in front of the eye supposed to be well, and if test-type is removed beyond the focal distance of the lens and is still legible, we know that the other eye participates in vision. The production of double images by the interposition of prisms also proves binocular vision. Still another method depends upon colored letters placed upon a dark background, which cannot be seen through glasses of complementary colors. A person looking at green-blue letters on a dark ground through a red glass over the sound eye, and a white or green glass over the alleged blind eye, will be unable to see the letters if the allegation is true. See COLOR-BLINDNESS, FIELD OF VISION.

BLISTERS.—See COUNTERIRRITATION.

BLOOD, EXAMINATION.—**The specific gravity** varies from 1050 to 1060.

The constituents of the blood are the plasma (serum and fibrin) and the corpuscles and plates.

The red corpuscles (**erythrocytes**) are the oxygen carriers, and are present in healthy males to the number of about 5,000,000 to the cubic mm., and in females to the number of about 4,500,000.

The white corpuscles (**leukocytes**) number from 7000 to 9000 to the cubic mm. They are classified as follows: (1) **Large** polymorphonuclear neutrophiles (about 65 percent); (2) **small** lymphocytes (about 25 percent); (3) large lymphocytes and **transitional forms** (about 5 percent); (4) eosinophiles (0.5 to 5 percent); (5) basophiles, "mast" cells (0.1 to 0.5 percent). The last three forms are so called by reason of small bodies contained within them which have an affinity for eosin stains (**eosinophiles, acidophiles**), or for neutral violet stains (**neutrophiles**), or for basic anilin stains (**basophiles**). The basophile cells contain both coarse and fine granules. Pathologic blood may contain, in addition to the above in altered proportions, neutrophile myelocytes, eosinophile myelocytes, and basophile myelocytes. For detailed descriptions of the various types of leukocytes, the reader is referred to text-books on hematology.

The blood-plates occur in grape-like arrangement in masses to the number of 200,000 to the cubic mm.

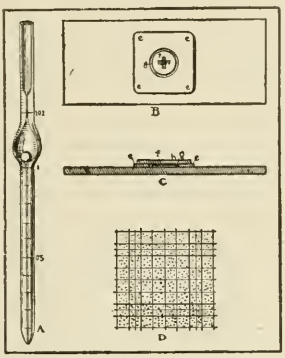
Diminution of the red corpuscles occurs in pernicious anemia, secondary anemia, leukemia, severe hemorrhage, advanced malignant disease, etc. This condition is known as **oligocythemia**, and may be so extreme as to show but 500,000 red corpuscles to the cubic mm. The opposite condition, **polycythemia**, sometimes occurs in health and forms part of a symptom-complex with cyanosis and splenic enlargement. (See POLYCYTHEMIA.) The red cells may number as much as 9,000,000.

Leukocytosis—increase of white corpuscles (especially of the polymorphonuclear form)—may be physiologic or pathologic. *Physiologic leukocytosis* occurs (1) during digestion; (2) after exercise, massage and cold bath; (3) during pregnancy; (4) in the new-born. *Pathologic leukocytosis* is observed (1) after hemorrhage; (2) in cachectic states, as certain forms of anemia, especially leukemia, carcinoma and sarcoma. In **leukemia** the increase is **permanent** and may be as high as 200,000 to the cubic mm. (4) Immediately before death, agonal leukocytosis, if death does not occur suddenly. (5) In **toxic conditions**, such as uremia, cholemia, prolonged chloroform or ether narcosis, ptomain poisoning, gas poisoning, quinin poisoning, and following the injection of tuberculin, thyroid and other animal extracts, and the intravenous injection of saline solution; and after the administration of certain drugs as antipyrin, salicylates, pilocarpin; (6) inflammation and suppuration.

Inflammatory leukocytosis is generally present in the following diseases; Lobar pneumonia, pericarditis, empyema, acute articular rheumatism, erysipelas, acute ulcerative endocarditis, cerebrospinal-meningitis, typhus fever, relapsing fever, Asiatic cholera, bubonic plague, yellow fever, and in septicemic and pyemic conditions; follicular tonsillitis, diphtheria, scarlet fever, small-pox; actinomycosis, trichiniasis, glanders, secondary syphilis; appendicitis, cholangitis and cholecystitis, empyema of the gall-bladder, acute pancreatitis, gonorrhea, abscesses, osteomyelitis; and in a number of inflammatory skin diseases; in herpes zoster, pellagra, etc. Leukocytosis usually signifies some pyogenic infection. In general, it represents the reaction of the individual to the disease. If the patient's resistance is poor, or the toxemia is intense, or the infection a very mild one, leukocytosis may be wanting.

Leukopenia.—The number of leukocytes is normal or diminished in malnutrition or starvation, and in certain infections and toxemias. Among these are typhoid fever, paratyphoid fever, Malta fever, malaria, influenza, measles, miliary tuberculosis and other forms of tuberculosis if unaccompanied by suppuration; pernicious anemia, splenic anemia, Hodgkin's disease, and following the continued use of certain drugs such as atropin, cocain, camphoric acid.

Counting the Corpuscles.—The apparatus most useful is the *Thoma-Zeiss hemacytometer*, an instrument almost universally adopted. It consists of a counting slide and one or two pipets, one for the red and the other for the white blood-corpuscles. The slide is of ordinary size, made of thick polished glass, having at its center a thin square of glass cemented on the surface. The latter has a central circular opening nearly filled in by another glass disc, 1/10 of a mm. thinner



Thoma-Zeiss Blood Counter, showing pipet, counting chamber and ruled field.—(*Greene.*)

than the square surrounding it, thus forming a chamber with a depth of 1/10 of a mm. The surface of the disc is divided by a series of microscopic lines into 400 squares, each having a square area of 1/400 of a mm. and a cubic capacity of 1/4000 of a mm. Each quadrant of 16 squares is inclosed by additional lines placed between the lines marking the square; in other words, 3 parallel lines on each side form the frame of a quadrant. The pipet consists of a graduated capillary tube expanded near its upper end into an ovoid chamber that contains a glass pearl for mixing the blood with the diluting fluid. The capacity of the tube is 1 mm., while that of the chamber, between the marks 1 and 101, is 100 mm. Thus, by drawing up the blood to the mark 1, a dilution of 1:100 is obtained, while when drawn up to the mark 0.5, the dilution is 1:200. The second pipet for counting the white blood-corpuscles is similarly constructed, except that the bore is larger and the tube is graduated for a dilution of 1:10 and 1:20. The instrument is also supplied with cover-glasses with ground surfaces.

To make a successful blood-count, strict attention must be paid to details. These are apparently insignificant, and yet failure will follow the efforts of the careless investigator who does not observe all the precautions here laid down: (1) Have everything ready for immediate use before you obtain the drop of blood. (2) Observe the most scrupulous cleanliness, not for aseptic purposes, but to prevent the smallest particle of dirt or any other foreign body from obscuring the field of vision, and thus interfering with counting. The diluting fluid, therefore, *must be filtered every time it is used* the slides washed in plain water and carefully dried (no alcohol or ether should be used, as the cement is likely to be dissolved out); the cover-glasses to be cleansed in acid alcohol; the pipet, above all, perfectly clean and dry. (3) Carry out the first stages of the procedure as rapidly as possible. The successive stages are as follows: (*a*) Clean the part from which the drop of blood is obtained with alcohol and ether. (*b*) Make a puncture either in the pulp of the finger or the lobe of the ear (in the case of children, the toe is to be preferred), free enough to allow a flow of two or three large drops. (*c*) Suck a drop into the capillary tube of the pipet up to the mark 0.5 to obtain a dilution of 1:200, or to 1 for a dilution of 1:100 if marked anemia is known to be present. (*d*) Having rapidly wiped off the end of the pipet, transfer it at once into the diluting fluid and draw up the latter to the mark 101. (*e*) Keeping the tips of the fingers on the ends to prevent spilling, shake the pipet vigorously for about 2 minutes. (*f*) Reject the first two or three drops, and then deposit one on the center of the disc, or, as some do, fill in the entire chamber. (*g*) Place the cover-glass on the fluid, carefully avoiding air-bubbles, and press firmly at the sides (not in the center) until you see Newton's rings. (*h*) Place the slide on the stage of the microscope and, after allowing a few minutes for uniform distribution of the corpuscles, take up the process of counting (Robin). Normally, the blood-corpuscles are so numerous and so tightly packed that to count them on so small an area as 1/4000 of a cubic mm. is absolutely impossible, not to mention the fact that the coagulated blood will form a layer of sufficient thickness to cover entirely the lines that mark the squares. It is therefore necessary to dilute the blood, for two reasons: (1) To prevent its coagulation, preserving the integrity and shape, as well as distinctness, of each corpuscle; and (2) to dilute it to a degree sufficient to permit the counting. For that purpose we use one of the following solutions:

Gowers' solution:

℞.	Sulphate of sodium,	gr. cxij.
	Acetic acid,	ʒ v.
	Water,	ʒ iv.

Hayem's solution:

℞.	Corrosive sublimate,	0.5 gm.
	Sodium sulphate,	5.0 gm.
	Sodium chlorid,	1.0 gm.
	Distilled water,	200.0 c.c.

Or **Toisson's solution,** prepared according to the following formula:

℞.	Methyl-violet,	0.025 gm.
	Chlorid of sodium,	1 gm.
	Sulphate of sodium,	8 gm.
	Glycerin (neutral),	30 c.c.
	Distilled water,	160 c.c.

The latter is the one universally preferred. It possesses the distinct advantage of staining the

white blood-corpuscles, thus enabling the beginner to avoid them in the count. Besides, in looking over the entire field with a low power, one may approximately judge of the proportion of the white corpuscles to the red.

Be careful to avoid any pressure on the parts, as it will dilute the blood by causing a transudation of serum. In sucking up the drop, always keep the point of the pipet under the surface, to prevent the entrance of air-bubbles. The latter should also be carefully avoided when the cover-glass is placed on the disc. For this purpose it is best to place it by a sliding motion, expelling the air-bubbles as the cover-glass is moved from right to left. Should any air-bubbles remain on the disc, the manipulation is repeated after cleaning the slide. Once the blood is mixed with diluting fluid, the counting may be done at leisure. The blood-corpuscles are best seen and most conveniently counted under a moderately high power (1/5 or 1/6 objective). The illumination should be adjusted to suit each case and conditions present. The position of the substage condensor, mirror, and diaphragm should be so modified as to render the squares distinctly visible, and, as a rule, a dark illumination is best.

Having placed the slide in position, locate first the squares. This can be done by the low power. Then find a quadrant of 16 squares inclosed within a frame made of 3 parallel lines, and commence counting from the left-hand upper corner. Count the corpuscles of each square of the upper row, then the lower from right to left, then the third from left to right, and, finally, the last from right to left. This order may be reversed either from the right first or from above downward. The number of corpuscles in each square should be marked down on the paper in the order in which the counting is done. This will not only relieve the memory, but will always show how many and which squares have been counted. Some of the corpuscles will be found astride on the line or slightly overriding it. To avoid counting these twice, make some rule by which to be guided. For instance, count all corpuscles within the square and all on the upper and left side border, not counting any on the lower or right side lines. Having counted 16 squares, divide the sum total by 16 in order to get the average of each; then multiply by the dilution, either 100 or 200, as the case may be, and, finally, multiply this by 4000, which will represent the number of corpuscles in each cubic mm. For example: The first square contained 12, second 10, third 11, fourth 9, and so on, the total number being 192. This, divided by 16, gives an average of 12 corpuscles to the square. The dilution, we may suppose, was 100; the number of corpuscles in 1 mm. will be $12 \times 100 = 1200$. Each square has a cubic capacity of 1/4000 of a cubic mm. Consequently, the number of corpuscles in a cubic mm. will be $1200 \times 4000 = 4{,}800{,}000$. This calculation can easily be remembered by the following formula:

$$\frac{\text{Corpuscles} \times \text{dilution} \times 4000}{\text{Number of squares counted}} = \text{corpuscles in 1 cubic mm.}$$

To obtain most accurate results, two or three quadrants of the same drop should be counted, or two or three fresh drops used. In the latter case the pipet should always be thoroughly shaken before a new drop is expelled.

A similar procedure is employed in **counting the white blood-corpuscles,** only the diluent fluid is 1/2 percent acetic acid, to which a little gentian-violet may be added if a stain is desired. Strict cleanliness at every step of the procedure is even more necessary in counting the leukocytes, than in the case of the red cells, in order to avoid clumping of the cells. The tip of the pipet must never be allowed to touch the finger, either of patient or physician, and must be wiped off with clean dry cotton, after drawing up the blood, and again after dilution has been made. The acetic acid destroys the red corpuscles, while the white become more prominent. In cases in which the question of expense enters largely into consideration, the counting of both red and white may be done at the same time; in this case the dilution should always be 1:200, and at least 256 squares counted. The white cells are stained, and, therefore, easily recognized, and the whole field can be gone over in a few minutes. Having determined the entire number of white corpuscles, proceed with the calculation in the manner previously described.

The normal proportion of red blood-corpuscles is 5,000,000 to the cubic mm., but this will vary under different circumstances, even in health, and a slight variation below or above the normal limit is not to be looked upon as pathologic. In this connection it is also well to bear in mind that after a severe diarrhea the number of red corpuscles is considerably increased, reaching as high as 7,000,000 to the cubic mm., this being due to the withdrawal of plasma from the blood. On the other hand, copious drinking may temporarily diminish the number of corpuscles by the reverse effect. The proportion of white blood-cells is normally even more variable, the variation extending from 1 to 300 to 1 to 700 red. Having completed the blood count, invariably clean the apparatus. *Never put away the pipets without thoroughly cleaning them.* To clean the pipet, first run through it distilled or clean water, then strong alcohol, then ether, and, finally, a current of dry air to evaporate the latter. (The pipet is dry when the glass pearl is freely movable and does not cling to the sides.) The washing and drying are best accomplished by a double bulb from an atomizer. This not only saves time, but also one's lungs. Should there still remain some particles of dirt, clean with some strong acid, alkali, or acid alcohol (Robin).

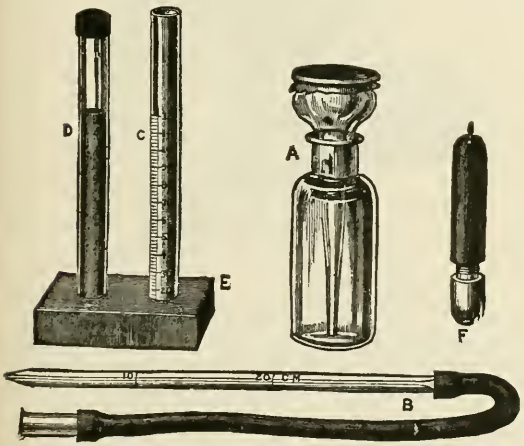
Hematocrit.—Another method for determining the relative proportion of red blood-corpuscles is by means of the hematocrit (Hedin-Daland). It consists of a metal frame in the shape of two arms, each carrying a small graduated capillary tube. One tube is completely filled with blood by means of a rubber tube connected with a dropper. Both ends of the tube are quickly covered with a little vaselin, so as to prevent the blood from adhering to the part of the frame with

which the terminal ends come in contact. The tube is then inserted in the arm. The whole is adjusted to a double-speed centrifuge, or an electric centrifuge and rotated at a speed of 70 revolutions of the crank, or 10,000 revolutions by the electric motor, a minute, for 2 minutes. The tubes are then removed and the percentage read

Hematocrit.

off, the scale being rendered visible by a magnifying lens front. The volume of the red blood-corpuscles will be seen as a red column, while the white occupy a shorter column above, being almost invisible, except in cases of leukocythemia. Each degree of the scale represents the percentage by volume, and is supposed to contain 100,000 red blood-corpuscles. Thus, if the red column reaches the mark 50, the volume is 50 percent, while the number of red cells is 5,000,000. In this way a rapid though rough and only approximately accurate blood-count may be obtained.

Estimation of Hemoglobin.—The simplest method is Tallqvist's. Comparison is made between the blood taken up by absorbent paper and a series of lithographed color bands. It is, however, quite inaccurate. The same objection applies to a similar color test, that of Wetherill. Until recently the instruments most generally used were those of Fleischl and Gowers. In Gowers' instrument a red



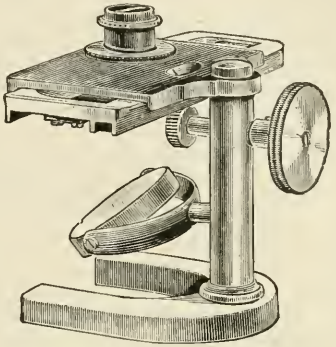
Gowers' Hemoglobinometer.

A. Pipet-bottle for distilled water. *B*. Capillary pipet. *C*. Graduated tube. *D*. Closed tube containing standard dilution. *F*. Lancet for pricking the finger.

solution (carmin-glycerin), corresponding in intensity to a 1 percent solution of normal blood, hermetically sealed in a small glass tube, is the standard used. To 20 cu. mm. of blood is added water until the color is exactly that of the standard.

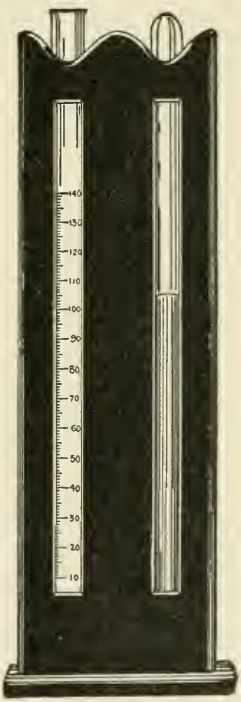
In making the comparison the tubes should be held in front of a white surface and the percentage will be shown on an accompanying scale. There is an error of about 5 percent.

Unfortunately, very accurate estimation is not always possible by either the Fleischl or Gowers instruments. In the former, approximately correct findings may be obtained by delimiting the field of observation and comparison.



Fleischl's Hemoglobinometer.

Sahli's hemometer is constructed on the same principle as Gowers' instrument, but differs from it in several important respects. The chief defect of Gowers' hemoglobinometer is the difficulty of determining when the proper dilution has been reached because the standard solution is of an entirely different color from that of blood and water. In order to appreciate slight differences in *shade* the solutions to be compared must contain the same coloring matter. Sahli, finding that solutions of hemoglobin were not permanent, devised the method of diluting the blood with 10 times its volume of 1/10 normal solution of hydrochloric acid. This forms a dark brown mixture containing in suspension minute particles of hematin hydrochlorid, to which the color is due. Such a mixture, sealed in a glass tube, is used as the standard solution in Sahli's instrument. A similar graduated tube, each division corresponding to 20 cu. mm., is filled to the mark 10 with 1/10 normal HCl solution, saturated with chloroform, which is supplied in a small stoppered vial protected by a hard-rubber capsule. With a capillary pipet 20 cu. mm. of blood are drawn up and introduced into the tube, and shaken up with the N/10 HCl until the color becomes a clear dark



Sahli's Hemometer.

brown, after which water is added until the shade of the mixture exactly corresponds to that of the standard solution, when the hemoglobin percentage may be read off, as in Gowers' instrument.

The standard solution is practically permanent. If the tube, however, remains in disuse for a long time, the suspended particles of hematin, which are not in solution, may adhere to the glass and the mixture may appear lighter in color. This is easily corrected by gently shaking and repeatedly inverting the tube to restore uniform distribution of the pigment particles.

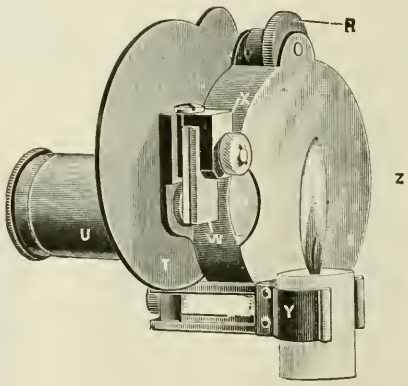
The **Hammerschlag specific gravity method** has been used also. As modified by Cabot, this method is as follows: Mix in a urinometer glass such quantities of benzol and chloroform that the specific gravity of the mixture taken by an ordinary urinometer is about 1059 (the normal specific gravity of the blood). Puncture the ear, draw a drop of blood into the tube of a Thoma-Zeiss pipet, a small medicine dropper, or any other capillary tube, and expel it again into the benzol-chloroform mixture. The blood does not mix with these liquids, but floats like a red bead. If it sinks to the bottom, add chloroform; if it rises to the top, add benzol, until finally the drop remains stationary in the body of the liquid, showing that its specific gravity is the same as the fluid in which it has been placed. Then take the specific gravity of the liquid in the same manner as that of urine. The result will also give the specific gravity of the drop of blood floating in the mixture. The chloroform-benzol mixture may be filtered and used over and over again indefinitely.

Table of specific gravity and hemoglobin (Hammerschlag):

Specific Gravity.		Hemoglobin.
1033–1035	=	25–30 percent.
1035–1038	=	30–35 percent.
1038–1040	=	35–40 percent.
1040–1045	=	40–45 percent.
1045–1048	=	45–55 percent.
1048–1050	=	55–65 percent.
1050–1053	=	65–70 percent.
1053–1055	=	70–75 percent.
1055–1057	=	75–85 percent.
1057–1060	=	85–95 percent.

Cabot adds the following precautions: (1) The inside of the urinometer glass should be perfectly dry and clean, otherwise the drop of blood may cling to it and flatten out against it. (2) It is usually well to have more than one drop of blood in the glass, in case any mishap occurs with the first. (3) Add the chloroform and benzol, a few drops at a time, and after each addition stir the whole mixture thoroughly with a glass rod. (4) If there is reason to believe that the blood will be lighter than normal—*i. e.*, the hemoglobin deficient—it saves time to start with a lighter mixture of chloroform and benzol. (5) Avoid admitting air within the blood-drop. This can be seen either in the capillary tube or after the drop is in the mixture. It is safer to take the *middle portion* of the blood drawn into the capillary tube, as both the first and the last portions of the column are more likely to have air in them. (6) The whole process should be done as quickly as possible, else the chloroform or benzol may work into the blood-drop and affect its weight. (7) It is better to have a urinometer with a scale running as high as 1070, but this is not essential, for the clinically important specific gravities are low, not high.

The above methods have largely been superseded by **Dare's** hemoglobinometer which affords a rapid, convenient, accurate and easy estimation. This instrument has the additional advantages of using undiluted blood and of an accurately standardized comparison scale. The film of fresh blood drawn by capillary attraction between two white glass plates, one transparent the other opaque, is compared with a circular disc of tinted glass representing the various color shades possessed by normal blood according to its hemoglobin concentration. The blood and color scale are illuminated by transmitted candle light. The observation is made through a camera tube, the instrument being pointed toward a dark object. The reading is indicated on the left side of the instrument by the beveled edge of the rectangular opening, the percentage beneath this edge representing the percentage of hemoglobin in the blood examined.



Dare's Hemoglobinometer.

U. Observation tube. *T.* Shield. *W.* Removable plate with capillary opening for holding blood. *X.* Thumb screw for holding same. *Y.* Candle holder and candle. *R.* Milled wheel for revolving color disc. *V.* Aperture for illumination and color comparison. *S.* Case inclosing color disc.

Variations in Hemoglobin.—Hemoglobin is diminished in chlorosis and in all forms of anemia, and may fall as low as 15 percent of the normal. This condition is called **oligochromemia.** It is usually proportionate to the reduction in the red cells except in chlorosis in which the hemoglobin equivalent of each cell is greatly reduced and pernicious anemia in which it is relatively in excess. The *color index* indicates the relation between the number of cells and the amount of hemoglobin. In other words, it is the quotient of the percentage of hemoglobin divided by the percentage of red cells.

Hemoglobin is increased in connection with pulmonary stenosis.

Further Microscopic Study.—A good microscope, a few cover-slips and slides, a bottle of good stain, on the one hand, a general knowledge of the morphology of the normal blood-corpuscles, and a memorized appreciation of the changes they present in different diseases, on the other hand, constitute the working material.

Under ordinary aseptic precautions the ear-lobule or finger-tip of the patient is pricked with a sterile needle; the droplet of blood that oozes out (no pressure should be exerted) is spread in a thin layer between two cover-slips and allowed to dry in the air.

"Ehrlich's triple stain" is prepared as follows: Concentrated watery solutions of orange G., acid fuchsin, and methyl-green are made; 40 c.c. of the orange G, 45 c.c. of the acid fuchsin, and 55 c.c. of methyl-green solutions are mixed with 50 c.c. of distilled water, 50 c.c. of alcohol, and 15 c.c. of glycerin, and the mixture allowed to stand a week in a cool, dark place.

The dried smear must first be "fixed" in one of the following ways: By heat, *i. e.*, by passing the cover-slip through a flame 30 to 40 times; by boiling one minute in absolute alcohol; by placing it in a 1 percent alcoholic solution of formalin; by formalin vapor.

A few drops of Ehrlich's triple stain are then placed upon the cover-slip and allowed to remain for about two minutes; then washed off with water, the slips dried between filter-paper, and mounted on a slide with a drop of Canada balsam. The slide is now ready for examination.

Examination of the Stained Specimen.—According to the selective affinity of the several constituents of the blood-cells for certain anilin dyes modern stains are acid, basic or neutral. *The basic dyes*, such as methyl-violet, methylene-blue or hematoxylin (chromatin stains), act chiefly upon nuclei. *Acid dyes*, such as eosin, orange G, or acid fuchsin, are protoplasm stains, while *neutral dyes* (resulting from the mixture of acid and basic colors in solution) color the "neutrophile" granules of the leukocytes. By using combinations one may in a single step attain differentiation.

Staining Solutions.—Ehrlich's triacid or triple stain has now been displaced by Wright's modification of Jenner's stain, an alkaline eosinate of methylene-blue, which, by at once *fixing* and *staining* the specimen, eliminates the laborious and delicate heating process of the older method.

Wright's Modifications of Louis Jenner's Stain.—The student or practitioner had best purchase a solution ready made; keep it tightly corked.

Technic of Staining.—(1) The dried but unfixed smear, completely covered with the stain for one minute. (2) Then distilled water is added drop by drop *until a greenish metallic scum appears and the margins show a reddish tint.* (3) After *three minutes* the stain is removed, *without washing*, and the film gently dried between filter-paper, and (4) mounted in balsam.

Results.—*Erythrocytes* appear orange or pink throughout. *Erythroblasts* show deep blue nuclei, *blood-plaques* purple, *mast cell granules* deep purple, *polymorphonuclear leukocytes* show lilac or blue nuclei, *neutrophile granules* lilac, *eosinophile granules* pink, fine *basophile granules* deep blue, *bacteria* and such organisms as malarial parasites blue.

For routine work the best stains are the Wright's, the eosin-methylene-blue and the eosin-hematoxylin, the last giving especially clearly defined pictures of the nuclear elements of the cells.

Eosin-methylene-blue Stain. Technic.—The smear is fixed in pure methyl-alcohol 3 minutes. Then it is stained 3 to 5 minutes in 1/2 percent alcoholic (70 percent) solution of Grübler's eosin. Then it is washed and dried. Next the slide is placed in a carefully made solution of 20 drops of 1/4 percent aqueous solution of methylene-blue, and 10 drops of the above eosin solution for 1/2 to 1 minute. Then it is washed, dried, and mounted if desired.

Eosin-hematoxylin Stain. Technic.—The specimen is stained with the eosin solution 1/2 minute. After washing it is placed in hematoxylin solution 1 to 3 minutes. Then it is washed, dried, mounted.

The red blood-corpuscles present themselves as round, discoid elements, with a central depression. They are arranged in rolls, have no nucleus, are uniform in size and shape, and their hemoglobin (with Ehrlich stain) is colored reddish-yellow, and forms a concentric ring around the central depression. Pathologically, five abnormalities must be observed: (1) They may be reduced in number; (2) they may have a nucleus (erythroblasts); (3) they may present differences in size; (4) they may present differences in shape; (5) the hemoglobin of the individual cell may be reduced; (6) the cells may be studded with bluish dots, so-called *basophilic* or *granular degeneration.* All these abnormalities may be determined by a glance at the blood-slide: reduction in number, by the fact that the blood-corpuscles are not, or only in part, arranged in rolls, and appear as individuals; the presence of a nucleus, by the appearance of a blue, circumscribed body within the cell; changes in size and shape are apparent, and the reduction of the hemoglobin may be determined with sufficient accuracy for diagnostic purposes by a narrowing of the concentric red ring previously described.

Basophilic degeneration is seen particularly in lead poisoning, but also in other severe forms of anemia, as in Hodgkin's disease, chlorosis, leukemia, pernicious anemia, splenic anemia, the secondary anemia of carcinoma and a number of diseases, among them pulmonary tuberculosis.

Diagnosis of the So-called Primary Anemias (Chlorosis and Primary Pernicious Anemia).—Clinically, they are very similar in their severer forms, and for prognostic purposes chiefly it becomes imperative to examine the blood carefully in these cases. The differentiation even here is not easy, and hinges practically on the following point: In both diseases, speaking of the severer form of chlorosis—we have marked decrease in the number, and pronounced changes in the size and shape, of the red blood-corpuscles, and, as a rule, in primary pernicious anemia, and sometimes in chlo-

rosis, red blood-corpuscles with nuclei. The changes in the leukocytes are varying and diagnostically insignificant. The differential diagnosis lies exclusively in the differences to be observed relative to the hemoglobin. In both diseases the hemoglobin is reduced considerably, but while in primary pernicious anemia the hemoglobin of the individual red blood-corpuscles appears normal, or, if anything, increased, under the microscope, in chlorosis the hemoglobin is greatly reduced in the individual corpuscle, sometimes presenting an appearance to the eye of a very fine ring around the periphery of the cell only. Herein lies an absolute differential diagnosis between the two diseases of great simplicity, the easy execution of which makes it most valuable.

The Leukocytes.—The characteristic features of the *normal white cell,* or leukocyte, are that it is larger than the red blood-corpuscle, has one or several nuclei, and a protoplasmic content that may be homogeneous or have fine or coarse granulations.

With the Ehrlich stain the nuclei are stained blue, the homogeneous protoplasm pink, the fine granulations violet, and the coarse ones bright red. A leukocyte with bright red, coarse granulations is called an eosinophile cell. The abnormalities observed are chiefly numeric—an increase of all or only some of the different kinds of leukocytes: that is, leukocytosis, lymphocytosis, or polynuclear leukocytosis. Normally, one leukocyte should be found, on an average, in every fifth field. When we find two or three in every five fields, we speak of slight leukocytosis, while one leukocyte to every field, or more, constitutes a severe leukocytosis. Especial attention should be paid to the absence, presence, or increase of eosinophiles.

Prince suggests the following mixture as giving the best results in staining the nuclei of the leukocytes clearly, and at the same time the granules of the neutrophilic, eosinophilic, and basophilic cells: Saturated solution of toluidin blue (Grübler), 1 part, 2 percent solution of eosin (Grübler), 2 parts. He mixes the solution in distilled water in the order given, agitates thoroughly for a few minutes, as the toluidin blue is precipitated by acid anilin dyes. He then employs the supernatant fluid only. Immediately after agitation the mixture is ready for use, and from 30 to 60 seconds is sufficient time for staining, although at the end of 10 or 12 weeks it requires 5 to 7 minutes to get a good result. He fixes in dry air at a temperature of 120° F. for nearly 20 minutes, although 128° F. will not bring disastrous results, and the time of fixation may be extended to several hours with a highly beneficial effect. Fixation with alcohol, or with a mixture of alcohol and ether, gives less satisfactory results, the granules not being satisfactorily separated out from their surroundings. After fixation the film on the cover-glass is covered with the stain, the solution being allowed to remain from 1 to 3 minutes, when the slip is washed thoroughly and rapidly in running water, and dried quickly in the air. After drying it is passed two or three times through a Bunsen flame and then mounted in balsam, when it is ready to be studied with a 1/12 of an inch immersion lens, with a flat mirror and open diaphragm. The nuclei of the small lymphocytes are stained a rather diffuse dark blue, with darker narrow bands of wavy outline interwoven throughout each nucleus, while the protoplasm is stained palè blue. The nuclei of the large lymphocytes stain deeply, with the same characteristics, the protoplasm staining faintly. Granules stained intensely blue are occasionally noted in the protoplasm and the nuclei of the large lymphocytes. In the polymorphonuclear cells the nuclei stain sharply and clearly and of a dark blue. The neutrophilic granules stain pink and are isolated from the protoplasm, which remains clear. Degenerative changes in the cells are distinguished by the faintness of the reaction in such cells. In the eosinophiles the nuclei stain greenish-blue and the granules a deep maroon. The erythrocytes react faintly or stain darkly a brownish-red stain, according as the spreads are stained for a shorter or a longer time. Nuclei in normoblasts stain deeply, exhibiting the karyokinetic tendency, when present. This stain shows the characteristics of leukemic blood very well, with better differentiations in the myelocytes, and the plasmodium malariæ stains turquoise-blue, and is therefore sharply differentiated from the cell in which it is inclosed.

Diagnosis of Leukemia.—The clinical symptoms of a case of leukemia are insufficient for a diagnosis, and a positive diagnosis of leukemia cannot be made without a differential count of the leukocytes. From a hematologic point of view we may conveniently describe two forms: *viz.,* mixed leukemia and lymphatic leukemia.

The former is a chronic disease, and gives a much better prognosis as to longevity than the latter, which runs a much more acute course, and is probably of an infectious nature, with an absolutely fatal prognosis. In mixed leukemia there is a "mixed" blood-picture, and the polymorphous character of the blood-slide is characteristic and diagnostic. All forms of polynuclear and mononuclear leukocytes in great number are found in each field—eosinophile cells, red blood-corpuscles that are decreased in number, changed in size and shape, with greatly reduced hemoglobin, and containing nuclei. A special pathologic leukocyte is noted, the myelocyte; it is a leukocyte with one nucleus, with fine or coarse granulations, and about three times as large as a normal leukocyte. For practical purposes and rapid diagnosis a single glance will make the diagnosis, if we will simply think of the polymorphous blood-picture and the myelocytes.

Lymphatic leukemia, on the other hand, shows a very uniform field; namely, a colossal increase in the small mononuclear leukocytes—lymphocytes. Sometimes there are more of these mononuclear leukocytes than red blood-corpuscles; nucleated red blood-corpuscles are sometimes found, but they have no diagnostic significance. Counting red blood-corpuscles and leukocytes or determining the hemoglobin in this disease is not necessary.

The following table (from Coplin) will aid in diagnosing the various anemias and leukemias.

TABULATION OF BLOOD CHANGES IN ANEMIAS AND LEUKEMIAS

	DISEASES.	Gross Appearance and Sp. Gr.	Hemoglobin and Color Index.	Number of Erythrocytes.	Size of, and Form Changes in Red Cells. Nucleated Cells.	Number of Leukocytes.	Large and Small Lymphocytes.	Polymorphonuclear Leukocytes.	Myelocytes.
PRIMARY ANEMIAS.	Chlorosis.	Blood flows readily Pale red, watery. Extravascular coagulation slow; intravascular, frequent. Sp. gr. of total blood decreased. Sp. gr. of plasma slightly increased.	Hemoglobin greatly reduced. Color index constantly low.	Normal or slightly reduced.	Decreased in size. Poikilocytosis only in severe cases and rarely marked. Nucleated cells rarely found. Normoblasts are present in severe cases.	Generally normal.	Occasionally relatively increased.	Normal or relatively diminished.	Rarely found.
	Pernicious Anemia.	Blood flows scantily, often difficult to obtain. Watery, pale red (often coffee color). Coagulation slow. Sp. gr. decreased.	Marked reduction in the amount of hemoglobin. Color index usually high.	Pronounced oligocythemia. Rouleaux-formation scanty or absent.	Marked variation in size. Macrocytes predominate. Poikilocytosis more marked than in any other anemia. Microblasts, normoblasts, and megaloblasts present. The latter most numerous.	A moderate leukopenia may be present.	Usually relatively increased.	Commonly decreased, relatively.	Small number nearly always found.
	Simple Primary Anemia.	Paler red than normal. Coagulation slightly more rapid. Sp. gr. decreased.	Hemoglobin moderately reduced. Color index normal or nearly so.	Moderately diminished.	Normal or slightly decreased in size. Nucleated cells only in severe cases.	Generally normal.	Sometimes increased relatively.	Sometimes decreased relatively.	Absent or rare.
Leukemia	Myelogenous Leukemia.	Light red or milky. Less fluid, coagulation slow. Sp. gr. decreased. Alkalinity usually diminished.	Hemoglobin slightly reduced. Color index below normal.	Usually only a slight reduction.	A slight reduction; poikilocytosis slight. Nucleated cells more frequent than in any other form of anemia. Normoblasts predominate.	Enormous increase. In no other anemia are leukocytes so abundant.	Increased, but relatively diminished.	Increased, but relatively diminished.	Myelocytes for a large percentage of the leukocytes, from 10 to 60 percent or more. (Basophilic cells included.)
	Lymphatic Leukemia.	Resembles myelogenous type, except that changes are not so pronounced. Alkalinity usually diminished.	Hemoglobin reduction more marked than in Splenomedullary type. Color index low.	Reduced. Always more pronounced than in myelogenous type.	Reduction in size and distortion more striking than in myelogenous type. Nucleated cells rarely present.	Greatly increased, but not to the extent found in the myelogenous type.	Greatly increased (as high as 90 percent or more). Sometimes small and other times large are increased.	Relatively decreased.	Absent or rare.
	Pseudoleukemia or Hodgkin's Disease.	Paler red than normal, depending on severity. Coagulation more rapid. Sp. gr. normal or slightly decreased.	Hemoglobin reduced, depending on severity and stage. Color index normal or low.	Diminished, depending on severity and stage.	May be undersized. Poikilocytosis in severe cases. Nucleated cells usually absent. May be present when disease is marked.	Normal or slightly increased.	Generally normal.	Generally normal.	Rarely found.

TABULATION OF BLOOD CHANGES IN ANEMIAS AND LEUKEMIAS—*Continued*

	DISEASES.	Gross Appearance and Sp. Gr.	Hemoglobin and Color Index.	Number of Erythrocytes.	Size of, and Form Changes in Red Cells. Nucleated Cells.	Number of Leukocytes.	Large and Small Lymphocytes.	Polymorphonuclear Leukocytes.	Myelocytes.
PRIMARY ANEMIAS.	Splenic* Anemia.	Pale red, more watery. Coagulation more rapid. Sp. gr. decreased.	Hemoglobin reduced. Color index normal or low.	Reduced sometimes to one-fourth of normal.	Normal; usually slightly reduced. Poikilocytosis seldom excessive. Nucleated cells rarely present.	Normal or slightly increased.	Generally normal. Usually increased if fever is present.	Generally normal.	Rarely found.
	SECONDARY ANEMIAS.	Pale red, depending on severity; watery. Coagulation usually rapid. Sp. gr. decreased.	Reduction varies, depending on severity. Color index usually below normal.	Diminution varies with condition.	Usually decreased. Poikilocytosis in a number of severe conditions. Nucleated cells rarely met with in mild anemias, but not uncommon in pronounced cases.	Generally increased. Seldom normal or decreased.	Usually diminished	Usually increased.	May be found in some cases.

* By some authors not recognized as a primary anemia.

The observations of the blood of diagnostic or prognostic importance in the cachexias, infectious fevers, various inflammations, etc., are treated of in the special articles on these various diseases.

Eosinophilia is the term applied to any increase in the cells containing eosinophilic granules. It is observed in filariasis, trichinasis, hydatid cysts, ankylostomiasis, osteomalacia, asthma, and certain skin diseases.

Poikilocytosis is a condition characterized by irregularities in the shape of the red blood-cells. It is seen in pernicious anemia and leukocythemia.

Microcythemia or microcytosis is the term applied to the condition in which the red blood-cells are markedly reduced in size. It accompanies the severe anemias and toxemias.

Macrocythemia or macrocytosis is the opposite condition, the size of the red blood-cells being greater than normal. It is associated with the severe forms of anemia, especially pernicious anemia.

Nucleated red blood-cells are abnormal constituents of the blood and are present in the grave forms of anemia.

Hydremia is an excess of the watery constituents of the blood, with a corresponding decrease of the cellular elements. It is present in anemia, in anasarca, and after the ingestion of fluids in large quantities.

Anhydremia is a condition in which the fluid portion of the blood is greatly diminished. It occurs after excessive drains on the system from any cause as in hemorrhage and cholera.

Melanemia is a rare condition characterized by the presence of black, brown, or yellow granules in the blood. It is observed in malaria, relapsing fever, melanosarcoma, and Addison's disease.

Lipemia is applied to the presence of fat in the blood. It may be detected by the microscope as minute fat globules or by its black coloration when stained with a 1 percent solution of osmic acid. Lipemia occurs in chronic alcoholism, chronic nephritis, diabetes, pulmonary tuberculosis, and after injuries to the bone-marrow.

Parasites are encountered in the blood in certain diseases. The principal animal parasites are filaria sanguinis hominis, plasmodium of malaria, spirocheta pallida, and distoma hematobium. The most important vegetable parasites are tubercle bacillus, streptococcus, staphylococcus, gonococcus, meningococcus, spirillum of relapsing fever, anthrax bacillus, typhoid bacillus, bacillus of glanders, colon bacillus, and the bacillus of tetanus, diphtheria, influenza, leprosy, glanders, bubonic plague, malignant edema. See Parasites.

BLOOD-LETTING.—See Bleeding, Cupping, Leeching, Venesection.

BLOOD-POISONING.—See Sepsis.

BLOOD-PRESSURE.—The clinical estimation of blood-pressure began more than two decades ago; but, until recently, was of little practical value, and failed to claim more than passing interest. This was because of the crudity of the apparatus and the impossibility of obtaining uniform and reliable records. Not until the adoption of the circular arm compression, suggested simultaneously by Riva Rocci and Hill, did sphygmomanometry obtain the recognition which it deserved.

Following the lead of Riva Rocci Hill, John W. Fisher and Clifford Allbutt, many investigators, in rapid succession, added numerous improvements and modifications to the earlier instruments, so that there are now several excellent models from which to choose—any of which may be relied upon for uniformly accurate figures. Among the modern instruments may be mentioned those of Cook, Janeway, Stanton, Faught, Rogers, Nicholson, Baum, Taylor and Erlanger.

The principle of modern sphygmomanometry is based upon: A means of circular compression (arm-band), applied to a superficial vessel (the brachial); means to produce pneumatic pressure (bellows or pump) within the encircling arm-band; and means to accurately measure the amount of this pressure (the mercury manometer), together with suitable tubes and connections to unite them.

Instruments.—Blood-pressure instruments have gone through various processes of evolution, and two general types are now employed; the mercury type and the aneroid. Many mercury instruments still have imperfections. The fundamental portion of the instrument is very simple; either a U-tube or a straight tube with a mercury reservoir, but the tube must be made of the proper quality of glass, accurately calibrated and the scale should be sufficiently large to be easily read. The small portable, mercury instruments are not practical and are seldom accurate. The early types of instruments have a redundance of stop-cocks and complicated attachments. The ideal mercurial instrument is one that is non-leakable, free from stop-cocks, the release of air being controlled by the valves in the pump.

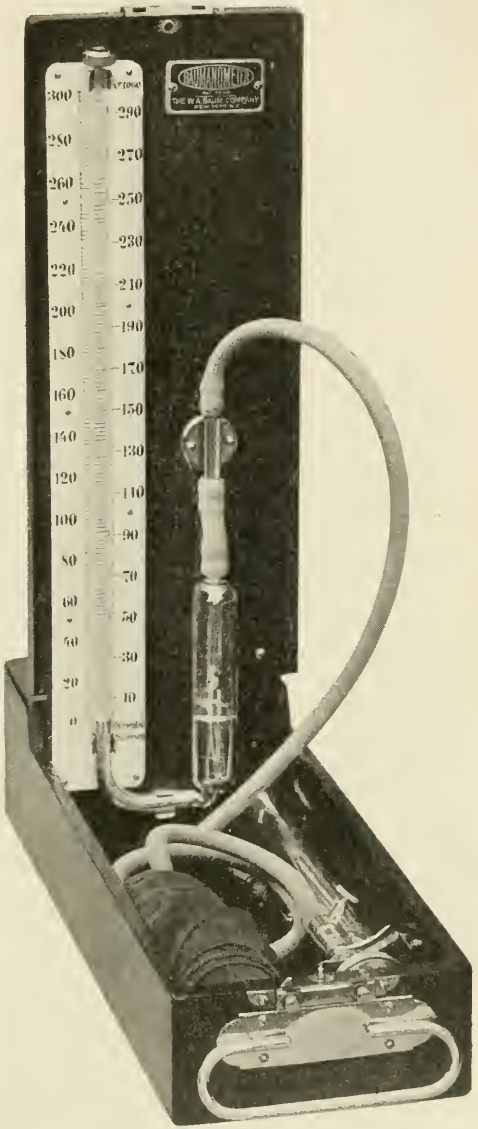
The following is an excellent type of such an instrument, evolved after experiencing many difficulties in securing accurate blood-pressure readings from a large staff of examiners.

The aneroid instruments are portable and elegant in appearance, but are not entirely dependable. They require frequent checking with the mercury manometer. They are useful for bedside work but the mercury instruments are more scientific and dependable for office work or for scientific work. Janeway says "no metal manometer can remain accurate."

The variations in blood-pressure, occurring with change in posture, constitute an important study in the examination of the heart affections, of the muscular variety particularly. In a normal individual, it should be found that, as the posture is changed from standing to reclining, the blood-pressure should increase, and the pulse rate decrease. For example: Standing, blood-pressure, 120 mm.; pulse, 72. Sitting, blood-pressure, 125 mm.; pulse, 70. Reclining, blood-pressure, 135 mm.; pulse, 64. Any change in this relation, tending toward an inversion of the ratio, is indicative of myocardial weakness or defective innervation or both.

(3) Temporary causes of variation, such as fatigue, mental excitement, or fear of the test itself, recent taking of alcohol, etc., should be eliminated, as much as possible, and for these and other reasons, *no single observation should be accepted, when it is possible to make several.* This is particularly so in cases under high nervous tension, where it is often noted that the mere change of the patient's current of thought will immediately be indicated by a change in the pressure level. The examiner will often find himself taxed to the utmost in his effort to control such variations, that he may arrive at proper deductions.

(4) Age and sex variation may be largely eliminated by the following simple rules: In children, 8 to 14 years, consider the maximum systolic pressure to be 90 mm. Hg., and in youth, up to 21 years, from 100 to 120 mm. Hg. (Brunton). Consider the average systolic pressure to be 120 mm. Hg., at the age of 20, then, for each year of life



BAUMANOMETER.

add 1/2 mm. Hg. to 120. Thus, at the age of 60, the average normal systolic pressure would be 140 mm. Hg. The figures obtained agree closely with those of Woley, Janeway and others. Women have a slightly lower blood-pressure than men, averaging about 10 mm. less for the same age.

There are several other minor factors that are believed to influence blood-pressure, namely:

Digestion, time of day, menstruation, etc.; but their effect is so slight that they need not be considered from the clinical standpoint.

In the estimation of blood-pressure, it is the usual practice to determine the systolic, the diastolic, the pulse pressure and the mean pressure.

Method of Taking Blood-pressure.—There is only one method that an up-to-date physician should follow and this is the auscultatory method. The method of palpation and the method of noting the diastolic pressure by the oscillation of the needle of an aneroid instrument or of the mercury column in mercurial types of instruments are crude and inaccurate. Any physician who has a blood-pressure instrument will surely have a stethoscope. The following method is adopted by the Life Extension Institute for reading and interpreting blood-pressure:

The systolic and diastolic blood-pressure should be taken preferably with a mercurial instrument and by the auscultatory method. In employing this method, the following points should be carefully borne in mind. The cuff should be applied preferably to the left arm, on a level with the heart, the subject sitting and the arm supinated and resting on a table. Place the stethoscope over the brachial artery just below the sphygmomanometer cuff, avoiding undue pressure (avoid indenting the skin). Inflate the sphygmomanometer bag until the heart sounds disappear Slowly release the air until the sounds reappear. The sounds elicited over the artery may then be distinguished as follows. *First*, a sound sharp and snappy in character. This is designated the *first phase* and = the **systolic pressure.** *Second*, succeeding the snappy sound one may usually distinguish a soft blowing murmur. This is termed the *second phase* and is not recorded in the reading. *Third*, succeeding the murmur is a return of the snappy sound, termed the *third phase;* also disregarded in the reading. *Fourth*, the snappy character continues for a varying number of beats and then becomes abruptly muffled. This point of muffling is the *fourth phase* and = the **diastolic pressure.** *Fifth*, the muffled sound finally disappears, constituting the *fifth phase*, formerly suggested as the diastolic pressure, but not so regarded by this Institute. CAUTION: If a leather cuff is used, the buckle should be watched for slipping, as this will greatly increase the reading. The normal pulse pressure (difference between the systolic and diastolic pressure) ranges between 30 and 55 mm.; a lower pulse pressure in an apparently active, healthy subject raises a question as to the accuracy of the reading or of the standard employed. The leather cuff is preferable to the cuff of silk or any other material.

The Pulse Pressure.—This is the variation in pressure occurring within the vessel during a cardiac cycle, and is obtained by subtracting the diastolic from the systolic pressure. A normal pulse pressure should be between 30 and 45 mm. Hg. by the auscultatory method. The pulse pressure is increased in generalized arteriosclerosis, aortic regurgitation; and is decreased in prolonged infections, valvular disease with loss of compensation, and in pure myocardial disease.

The *mean pressure* is determined by dividing the sum of the systolic and diastolic pressure by two, and is an index of the mean pressure of the circulation within the vessel at the time of observation.

The importance of the blood-pressure changes are often overestimated. The proper status of the blood-pressure test is that of a clinical sign, which attains its greatest value when taken in consideration with the clinical picture as a whole. The mistake is frequently made of placing too much stress upon the evidence of high blood-pressure, and of treating this symptom as the whole disease. This is dangerous! The fact must never be lost sight of that high blood-pressure is frequently a conservative act of nature to maintain a normal blood distribution in the face of increased peripheral resistance, in which case it would be the height of folly to blindly set about an energetic blood-pressure lowering campaign, without first carefully considering its cause and relation to the clinical picture.

Low Blood-pressure (Hypotension).—As yet, very little importance is attached to slightly lowered blood-pressure; though it has been noted with considerable constancy in tuberculosis, infectious fevers (particularly typhoid), in uncomplicated diabetes mellitus, etc. Most important is the marked fall of pressure occurring during prolonged anesthesia, when its detection should immediately suggest the employment of active stimulation, if not the speedy termination of the operation.

High Blood-pressure (Hypertension).—Several well-known pathologic conditions are associated with constant and marked elevation in blood-pressure, and in which regular observations with the sphygmomanometer are an important adjunct to treatment, and are worthy of more general adoption.

Chronic Interstitial Nephritis.—This condition, usually accompanied by general arteriosclerosis, is productive of some of the highest pressures seen. Faught has recently reported two cases where the pressure remained for many days above 300 mm. Hg. Both in chronic interstitial nephritis and in arteriosclerosis, the sphygmomanometer is valuable in following the effect of measures of relief. In *cerebral hemorrhage*, and in *apoplectic coma*, the sphygmomanometer will serve to distinguish them from embolism, when the pressure is low. *Uremia* is always preceded by a gradual but persistent rise in pressure. Here, systematic observations may, by giving timely warning, forestall the attack.

Eclampsia shows a very high blood-pressure, as illustrated by Hirst, who reports a pressure of 320 mm. Hg. The sphygmomanometer, used at regular intervals during pregnancy, may, at times, be even more valuable than urinalysis.

Blood-pressure and Arteriosclerosis.—There is much misapprehension even among the medical profession and especially among the laity as to the relationship of arterial tension and arterial thick-

ening. In fact they are spoken of at times in medical works as synonymous. The conditions are, of course, entirely different. An artery of gossamer thinness may show very high tension. There is no necessary relationship between high blood-pressure and arterial thickening. Thickening often follows high tension but advanced arterial sclerosis can exist and does exist in a large number of instances with lowered blood-pressure. The two conditions should be independently sought. Many physicians have reported to the Institute that arterial thickening cannot exist in either case because the blood-pressure is normal. Such comments display a fundamental ignorance of the pathological conditions referred to. As long as the splanchnic area is not extensively involved, very extensive thickening in other regions may have no effect on blood-pressure. The blood-pressure and the condition of the arteries should be separately determined in all physical examinations regardless of the age of the subject. This matter has been well covered by Dr. Clifford Allbutt in his classical work on Angina-Pectoris in which complete references to this subject will be found.

Finally it should be borne in mind that high blood-pressure or low blood-pressure is a symptom and not a disease. It may be a temporary manifestation of nervous failure or nervous excitement and repeated observations are necessary to determine the significance of any variations found.

The importance of the blood-pressure test to therapeutics of the circulation is a most important subject, as, by it, we are able to follow more intelligently our therapeutic endeavors, and to note their beneficial effects, or total failure. Much evidence is at hand to show that too great confidence has, in the past, been placed in the so-called blood-pressure reducers, chiefly comprising the nitrites; and, on the other hand, that more dependence should be placed on physical methods, such as massage, exercise, baths, etc., one of the most striking facts shown being the extremely feeble and evanescent effect of some of the old remedies, and the prolonged and marked benefit derived from purely physical measures. In the light of present knowledge, it is useless to continue the use of a remedy, when the sphygmomanometer fails to show the expected improvement. Neither is it a good practice to push a drug further when the sphygmomanometer shows that the effect has been obtained.

Life Insurance.—While British Life Insurance Companies have given little attention to blood-pressure, most American companies now require at least the systolic pressure as a routine measure in all examinations; and some companies are requiring also the diastolic pressure. The papers of Dr. John W. Fisher of the Northwestern Life Insurance Company, should be consulted for statistics giving the mortality experience of many thousands of cases. This experience has also been confirmed by investigations of the Prudential Life Insurance Company. From such experiences the following table has been derived showing the average blood-pressure among healthy males at each age period:

	Average Systolic Pressure, Mm.
Ages 15 to 20	120
Ages 21 to 25	123
Ages 26 to 30	124
Ages 31 to 35	124
Ages 36 to 40	127
Ages 41 to 45	129
Ages 46 to 50	131
Ages 51 to 55	132
Ages 56 to 60	135

Women 10 to 15 mm. less.

From a life insurance standpoint the principle has also been evolved that a persistent blood-pressure ranging of 15 mm. above the average for the age is attended by an increased mortality and warrants postponement or close study of the case.

BLUE MASS.—See Mercury.

BLUE OINTMENT.—See Mercury.

BLUE PILL.—See Mercury.

BLUE VITRIOL.—See Copper (sulphate).

B N A.—See Anatomic Nomenclature.

BOIL (Furuncle).—A boil is an acute circumscribed inflammation of a sebaceous or hair follicle, ending in suppuration and the extrusion of a central necrotic mass. It begins as a painful, deep-seated induration that gradually approaches the surface, showing itself as a rounded or acuminate reddish prominence. In the course of a few days softening takes place, with the formation of a central slough, or "core." The resulting depression heals up by granulation, with the production of a slight scar. When no suppuration or necrosis takes place, the lesion is termed a "blind boil."

Numerous satellites are likely to form around one furuncle as a focus. This may be due to external autoinoculation or to lymphatic transmission.

Furunculosis is a condition in which there are intermittent outbreaks of boils, extending over a period of weeks or months. This condition is not infrequently seen in diabetes and Bright's disease. Boils are due to the introduction of specific microbes into the hair or sebaceous follicles. Impoverished health renders the soil favorable, but it does not produce furuncles *per se*. Uncleanliness, itching dermatoses (promoting scratching), and certain occupations (tar and petroleum workers), all favor the development of boils.

The pathologic process consists of a dense leukocytic infiltration around a sebaceous or hair follicle, with thrombotic obstruction of the capillary blood-vessels and a central necrosis. The exciting organism is a pyogenic microbe, usually the staphylococcus pyogenes aureus.

The prognosis in single furuncles is good. Furunculosis may long remain refractory to treatment.

Treatment.—Single lesions should be incised as soon as the first evidences of suppuration occur.

Abortive applications—such as carbolic acid, nitrate of silver, tincture of iodin—fail, as rule, to abort, although they may do good as counterirritants. A 25 percent ichthyol plaster protects the boil and tends to prevent autoinoculation. An excellent method is to apply hot boric-acid com-

presses covered with oiled silk. The use of this lotion upon the surrounding skin lessens the liability to further follicular infection.

The following method for preventing the formation of boils is recommended by Robin: The patient should be given tar-water as a drink, and should take 3 capsules every day, each containing the following:

℞. Sublimed sulphur, gr. jss
Pulverized camphor, gr. 3/10.

Wherever there is any redness, or there are threatening indications of the formation of a boil, the spot should be painted with tincture of iodin, and in this way it may be arrested. When the boil has formed, the contents should be evacuated as completely as possible. When the core has been taken out, the following ointment is introduced into the wound by means of a brush:

℞. Sublimed sulphur, } each 150 grains.
Pulverized camphor, }
Glycerin, q. s.

The boil is then covered with a piece of linen on which this ointment has been spread. Afterward the entire region of the eruption should be sprayed with a solution of equal parts of carbolic acid and water four times a day, after the boil has been carefully washed with boric-acid water; then a dressing of the ointment is again applied.

Predisposing causes being removed, invigorating life, change of air, outdoor exercise, and bathing are to be employed. The urine should be carefully examined to determine whether or not diabetes or Bright's disease exists. The diet is to be attended to. A saline purge occasionally is beneficial. Quinin and iron chlorid, the former in 5-grain doses every 6 hours, then gradually lowered to 3 or 4 grains a day, may be given. If diabetes or nephritis exists, appropriate treatment should be given. Dilute sulphuric acid, 5 to 10 drops, with 1/2 of a dram of magnesium sulphate, will open the bowels. Sulphid of calcium, in 1/6 of a grain doses every hour or two, has been recommended. Tablespoonful doses of yeast, given 3 times a day, half an hour before meals, improve some cases. Benefit has resulted from 20 to 30 minim doses of dilute sulphuric acid in two ounces of water, every four hours.

Recently suction cupping has been used with success. See Bier's Hyperemic Treatment, Inflammation.

Furunculosis has been treated with excellent results by vaccine injections—preferably of autogenous material rather than stock. See Vaccine Therapy (Staphylococcus).

BONE, DISEASES.—Akromegaly is a strange progressive disease that is attended with symmetric enlargement of the bones as well as of the soft parts of the body. The bones commonly enlarged are those of the head and face; the lower jaw often projects beyond the upper; the hands and feet are often enormously enlarged, but the central viscera are, as a rule, unchanged. No treatment has yet been found to check this disease, which invariably ends in death. See Akromegaly.

Virchow's disease, or leontiasis ossea, somewhat resembles akromegaly. In this the enlargement begins in the upper jaw, and soon interferes with mastication, extends to the other cranial and facial bones, and produces severe headaches. It is distinguished by the appearance of a tumor of the jaw, while in akromegaly the enlargement is uniform in all parts of the bone. It has caused blindness by pressure upon the optic nerve. No satisfactory treatment is known, although Horsley claims that he has relieved the symptoms by removing portions of the bone to take away the effects of pressure.

Actinomycosis.—In microscopic structure this disease bears a close resemblance to round-celled sarcoma, with which it was until recent years confounded. It is now known to be due to a specific germ—the actinomyces, or ray fungus. When it attacks bone, the lower jaw is the most frequently affected. The progress of the disease resembles that of tuberculosis, or, perhaps more closely, periosteal sarcoma. See Actinomycosis.

Atrophy of bone may occur in old age in the natural process of wasting. The medullary cavity gradually enlarges, while the compact tissue becomes thinner and thinner. The same thing occurs from disuse: as, for example, in old dislocations; hence, it is necessary in the aged, and in reducing dislocations of long standing, to manipulate the bones with care, lest a fracture should complicate the existing condition. Atrophy is also an accompaniment of chronic osteitis. The only treatment that offers any prospect of success is the production of hyperemia by the frequent use for a limited time of an Esmarch bandage.

Hypertrophy of bone may be the result of: (1) Increased blood supply, as when the epiphysis is the seat of chronic inflammation, and the whole shaft of the bone grows much larger than its fellow; (2) increased functional activity, as seen in the increased size of the fibula when there is congenital absence of the tibia.

Inflammation of Bone.—The study of inflammatory affections of bone is greatly simplified by keeping two points strictly in view:

1. Bone is a tissue in which inflammation follows the same course as it does in any other tissue, the only difference being that the deposit of lime salts in bone gives such density and firmness that swelling cannot take place; hence there is intense pain, and also a more ready cutting off of blood supply, resulting in death of tissue (necrosis).

2. No matter what the infection may be—whether the tubercle bacillus, the staphylococcus, the streptococcus, the pneumococcus, the colon bacillus, the bacillus of typhoid, or the germs of la grippe—the mechanism of the infection and the lesions resulting therefrom are practically identical with those occurring in the other tissues.

Of the three structures that enter into the formation of bone—viz., periosteum, compact and cancellous substance, and medulla—any or all may be the seat of inflammation. Thus, there may be *periostitis*, the periosteum alone being affected; *ostitis*, when the bony structure is inflamed; or *myelitis*, when the medullary cavity of

the long bones is the seat of inflammation. As a rule, however, two combinations are seen—osteoperiostitis and osteomyelitis.

Osteoperiostitis.—The periosteum may be the seat of inflammation (periostitis), but, as a rule, the superficial layer of bone is also involved (osteoperiostitis). The disease may be the result of injury, or of infection by the tubercle bacillus, the staphylococcus, the streptococcus, the pneumococcus, the colon bacillus, the bacillus of typhoid, or the germs of la grippe.

Symptoms.—The bones that are the most superficial are those most likely to suffer: *e. g.*, the tibia. The constitutional symptoms are not prominent except in suppurative cases. Pain is always present; it is worse at night, and it is increased by pressure or percussion. On passing the finger over the inflamed area, swelling can be detected, giving to the bone a spindle shape. As the disease progresses, the soft parts overlying the inflamed periosteum become red and edematous. Suppuration is attended with fever, chills, and severe constitutional disturbance.

Treatment.—Rest and immobilization of the parts are of the first importance. Relief may sometimes be obtained by making numerous punctures with the needle or, better, by dividing the periosteum with a tenotome. Lead and laudanum lotion, leeches, cold and hot applications—as the patient finds one or the other the more comfortable—are favorite remedies. Keep the bowels open by salines, give morphin to relieve pain, and support the parts by a bandage. In suppurative cases make a free incision through the soft parts and periosteum, and, if necessary, into the bone; then drain.

Syphilitic osteoperiostitis is slow in its onset, comparatively free from pain, and attacks the long bones and those of the skull and face. At first it has the character of periostitis, but later flat, smooth elevations can be felt; they are tender on pressure, and measure 1 or 2 cm. in diameter. They should be treated with iodid of potassium and mercurials. Operative treatment is not required unless necrosis results.

Results of Inflammation of Bone.—1. **Abscess** occurs, as a rule, in the cancellous structure of the ends of long bones, as the head of the tibia, the malleoli, the femur, and the humerus. The symptoms are the same as those of osteoperiostitis, but more localized and persistent. The pain is deep and constant, and there is tenderness, confined to one spot, increased on motion or on assuming the dependent position. The neighboring joints suffer from repeated attacks of synovitis.

Treatment.—Trephine the point of greatest tenderness, and if pus is not found, explore the walls of the bone by the aid of a stout drill. When the abscess is reached, gouge out its cavity, disinfect, and pack with iodoform gauze.

2. **Caries,** or molecular death of bone.

3. **Necrosis,** or death of bone *en masse.* Unless promptly arrested by treatment, osteoperiostitis results in the periosteum being stripped from the bone, thus cutting off the blood supply to the osseous tissue. Hyperemia and the pressure of inflammatory products in the Haversian canals or in the medulla may also cut off the circulation to a considerable area of bone. This portion dies, and the process is termed necrosis. The necrosed portion is called a sequestrum which simply means that it is separated from the sound portion. Nature throws out new bone, which sometimes encircles the sequestrum, and this envelope is called an involucrum. In the involucrum openings are sometimes found leading down to the sequestrum, and to such an opening the name cloaca is applied.

Symptoms of Necrosis.—Following inflammation in bone an abscess forms, and either bursts of itself or is opened by the surgeon. The opening becomes a *sinus,* from which there is a constant discharge of pus. Through the sinus a probe may be passed, and as it strikes the sequestrum, a clear sharp note is produced. Carious bone is gritty and the probe can be passed into it.

Sequestrotomy, or the operation for the removal of dead bone, is thus performed: When the bone of one of the extremities is affected, elevate the limb for 4 or 5 minutes, and apply an Esmarch's bandage upon the proximal side. Look for a cloaca, and if the sequestrum present at the opening, it may be possible to remove it with forceps. If held by the involucrum, the latter must be chiseled away and the sequestrum removed in a mass or in pieces. Next scrape the cavity, disinfect by carbolic acid or corrosive sublimate solution, and pack with iodoform gauze or with Mosetig-Moerhoff bone wax.

Treatment.—Remove the child from its unhealthful surroundings and give it fresh air, sunshine, baths, and wholesome and easily assimilated food. Fresh milk or cream, meat-juice, hypophosphites of lime and soda, codliver oil, syrup of the iodid of iron, and tonic treatment are invaluable. Deformity must be prevented or corrected by the recumbent position or by proper splints.

Excisions of the special bones are described under the title Excision of Joints (*q. v.*).

Acute Diffuse Osteomyelitis is an infectious disease, and may be produced by any of the germs mentioned under the head of osteoperiostitis. It is a common result of injury, such as a compound fracture, a gunshot wound, or an amputation. The inflammation spreads rapidly along the medullary canal, the cancellous tissue, and the Haversian canals. Swelling cannot take place owing to the density and hardness of the bone; hence pain is intense and destruction of bone tissue (necrosis or caries) comes on rapidly.

Symptoms.—Pain is very severe, of a boring, gnawing, or aching character, and very much increased by pressure or by percussion. The temperature is high and of a septic character. The soft parts over the bone are greatly swollen. If the disease is the result of a wound, an offensive purulent discharge takes place containing fragments of bone and necrotic tissue. If the parts are exposed to view, the periosteum appears red and thickened, and from the medullary canal protrudes a fungous mass. Many cases run into pyemia, as shown by rigors, cold sweats, and the formation of multiple abscesses.

Treatment.—Prompt action is demanded. Expose the bone freely, trephine or chisel out a trough in it sufficient to remove all the purulent material, scrape out the medullary cavity, disinfect it with corrosive sublimate solution (1:1000) or strong carbolic acid, pack with iodoform gauze, and renew the packing twice a week, or more often if necessary. Necrosis is common; the sequestrum must be removed when separated. In severe cases amputation may be necessary.

Diagnosis of Inflammation of Bone.—Acute osteoperiostitis or acute osteomyelitis must be distinguished from—(1) *Rheumatism:* Acute rheumatism attacks the joints and not the shafts of long bones, and is seldom confined to a single joint. (2) *Typhoid fever:* The morning remission and evening rise of temperature characteristic of typhoid, the serum test, and the abdominal complications should be sufficient to settle the question. (3) *Erysipelas:* The redness of the skin and inflammation of the overlying soft parts come on after the bone inflammation has lasted several hours or days. There are always pain and tenderness over the bone before the skin becomes inflamed.

Tubercular Ostitis.—The bones most liable to tubercular infection are those adjacent to the hip-, knee-, and elbow-joints, and also the wrist and ankle. See HIP-JOINT, SPINE, etc. Children are especially liable to this form of infection, and the progress of the disease is slow. In some cases pain is very slight, and is often spoken of as "starting" in character. The earliest indications of tuberculosis of bone may be seen in the muscles. The parts above and below the seat of the disease become atrophied to such a degree that simple disuse is not sufficient to account for the wasting. Spasm of muscles is observed when the patient is dropping off to sleep. Rigidity of muscles is noticeable in the earliest stages of spinal caries and of hip-joint disease. Flexion of joints is common as the disease advances, the flexors overcoming the extensors until the joints become seriously deformed.

Treatment.—Rest and immobilization of the affected part greatly retard the growth of the bacteria. Plaster casts, splints, injections of iodoform, of chlorid of zinc, or of acid phosphate of lime have given good results. The constitutional treatment proper for tuberculosis should be carefully carried out. If these methods are not applicable or have failed, the diseased areas should be removed by operation. Scraping and removal of the infected tissues must be very thoroughly done. The walls of every sinus, the medulla of infected bones, and every suspected deposit of tubercle in the soft parts, such as the tendon sheaths, the synovial cavities, or the skin should be carefully curetted.

When tubercular ostitis extends into a joint, resection or amputation must be considered. See EXCISION OF JOINTS.

Tumors of Bone.—Chondromata, enchondromata or cartilaginous tumors grow from cartilage; at least it would seem best to limit the term chondroma to the tumors which grow from cartilage. Other tumors which contain a cartilage-like material are now recognized to be degenerating sarcomas, or to belong to the class of tumors of variable composite structure described under *Endothelioma.* A chondroma consists of hyalin cartilage, having a hard, nodular outline, is encapsuled, and shows a translucent bluish-gray section. Chondromata ossify and become exostoses (see below), or may undergo myxomatous degeneration.

A **pure chondroma** not ossifying is of rare occurrence. It is met with on the hands, affecting the phalanges and metacarpal bones, more rarely in the feet and other bones. The hands become deformed by a number of tumors which grow from within the shaft of the phalanges and metacarpals, or from the surface, presumably from remnants of cartilage, from the ossification of the shaft in cartilage or at the epiphysis. The result is an increasing deformity of the hand, with pain, paralysis, and ulceration of the skin from involvement of nerves.

Treatment.—As the tumors are generally multiple, they are usually left alone, unless one presses on a nerve, when it may be removed. Amputation of a finger, of part or the whole of the hand, may be indicated for persistent pain and threatened ascending neuritis, for ulceration of the skin and degeneration of the tumors. A single growth may readily be shelled out from the interior of the phalanx in which it is situated.

Callus tumor is a slow growth of an irregular cartilaginous mass developing in the position of a fracture, usually in a rickety child, for which amputation may be necessary.

Osteomata or osseous tumors grow from bone, being formed in cartilage or in membrane. Bony masses occur in tumors of the soft parts by calcification and ossification in degenerating tissues.

Exostoses are tumors growing from the surface of bone, being either pedunculated or sessile and circumscribed. Others termed *enostoses* grow from within bone, and are more diffuse.

1. **Exostosis Developing from Cartilage.**—This is the most common type, and develops from a remnant of epiphyseal cartilage attached to the diaphysis. The origin of the tumor is therefore in the neighborhood of the epiphyseal line, although if the diaphysis grows in length, the exostosis is found attached to the shaft some distance away. In this position as it grows the tumor becomes pedunculated, consists of cancellous bone covered by a thin layer of compact bone, and at the growing surface by a cap of hyalin cartilage. A narrow pedicle may undergo quiet necrosis or be actually fractured, and a tumor so detached has been discharged through an ulcerated aperture; or a bursal cavity may form over the exostosis containing fibrinous masses and serum, and be a cause of much pain.

(a) **The single pedunculated exostosis** occurs most often to the inner side of the lower end of the femur, either near or some distance above the epiphyseal line, according to the subsequent growth of the bone; it is rarer behind the femur, where it may involve the popliteal artery, and in other bones, the upper end of the tibia, or humerus, etc.

Treatment.—The exostosis is easily removed,

being cut off by a chisel level with the shaft, while taking care to remove all the cartilage, and in operating near the knee to flex the joint so as to draw down the synovial membrane lest it be injured.

A small exostosis, generally covered with periosteum, grows from the ungual phalanx nearly always of the great toe, it is presumed from a remnant of cartilage. See SUBUNGUAL EXOSTOSIS.

(b) **Multiple exostoses** grow from the epiphyseal ends of bone like the above, but tend to be more sessile, are generally symmetrical, affecting many bones, and cause deformities resembling rickets. Some have considered them to be a rickety complication; against this is the fact that they are sometimes hereditary. Multiple sarcomata have supervened. They are generally left alone unless any one tumor is especially painful. Care must be taken that the skin-wound heals, or a troublesome necrosis may result.

2. **Exostosis Arising in Tendon.**—An exostosis in some cases arises by ossification of a tendon, as if by an extension of the ridge into which the tendon is inserted, the insertion of the abductor magnus into the tubercle just above the inner condyle of the femur, the insertion of the pectoralis major into the external bicipital ridge of the humerus, the insertion of the deltoid. This may follow injury or strain.

3. **Exostosis in Membrane.**—(a) **The single exostosis** growing from the *surface of the skull* is usually seen on the frontal bone. These tumors are generally sessile and lenticular in shape, of densely-compact bone, usually without Haversian systems. They are firmly attached to the skull, and the scalp moves freely over them; they grow slowly, and sometimes extend inward as well as outward and irritate the dura mater; otherwise there is an absence of pain and no history of injury.

Treatment.—Removal if growing or any signs of pressing on the dura. Rapidly revolving drills and saws are required; the skull has been fractured in attempts to remove them by hammering a chisel.

(b) **An exostosis** grows from the *orbital plate* of the frontal bone or in the *frontal sinus*, and displaces the eye forward and outward. As it grows the exostosis becomes more and more lobulated. By retaining discharges a frontal sinus empyema and necrosis may occur; by pressure on the eye, corneal ulceration and panophthalmitis or optic atrophy may be produced.

Treatment.—Exploration and removal as early as possible.

(c) **Diffuse exostosis and enostosis** connected with *bones of the face.* They are composed of finely cancellated bone, more compact than the cancellous exostoses, less compact than the ivory ones. Some are more vascular than bone, others less so. A symmetrical mass growing on either side of the nasal bones is common in West African negroes, and is called *Henpuye.* A mass may grow in the antrum and occlude the nose on one or both sides, or push up the orbit and displace the eye, or form nodular masses deforming the upper or lower jaw. (See LEONTIASIS OSSEA.) These masses are distinguished from sarcoma by their slow growth, by their hard, nodular surface, and by not involving the soft parts. Pain may be caused, however, by pressure on the fifth nerve ends.

Treatment.—The superior maxillary bone may be removed in part or wholly.

Fibromata or fibrous tumors grow from the outer layer of the periosteum, but are very rare, except as an epulis from the periosteum of the jaw underneath the gum, or as a nasopharyngeal polypus. Fibrous masses grow in joints from the synovial membrane.

Lipomata or fatty tumors grow from the outer layer of the periosteum, but are very rare. *Lipoma arborescens* is a lobulated fibro-fatty mass growing from the ends of the bone in cases of arthritis deformans.

Malignant Disease of Bone.—Malignant disease of bone may occur either primarily, or secondarily by metastasis or by invasion. Primary growths are usually single, but exceptionally multiple from the beginning; secondary growths are generally multiple, but exceptionally a single metastatic growth may be observed. The primary growths are always sarcomatous; the secondary growths may be either sarcomatous or carcinomatous. Besides actual tumors, malignant disease promotes changes in the osseous system of a widespread nature, having resemblances to osteomalacia and osteitis deformans.

Primary Sarcoma of Bone.—This may be periosteal or endosteal in origin. The periosteal sarcoma is usually a round-, spindle- or mixed-celled sarcoma, the endosteal, especially a myeloid sarcoma, less often a round- or spindle-celled. Rarer endosteal tumors are the small-celled myeloma or lympho-sarcoma of bone, and endothelioma. See also TUMORS.

(*a*) **Periosteal sarcomata** spring from the deeper layers of the periosteum; a rare growth from the outer layers has been termed a *parosteal* sarcoma. They rapidly invade the bone beneath and the soft parts around, spread out into muscles and along intermuscular planes, enter the veins and grow along their lumen, invade the lymphatic glands corresponding to the part, and by means of both the venous and lymphatic stream reach the blood. Then metastases appear, especially small, scattered nodules on the surface of the lungs, with a blood-stained exudation into the pleura. Meanwhile, if superficial, the primary growth may fungate, or some calcification and ossification takes place, spicules forming at right angles to the axis of the bone; spontaneous fracture occurs. They may develop anywhere, the lower third of the femur being the commonest seat.

Symptoms.—In a typical case of periosteal sarcoma, a rapidly-growing tumor is observed connected with the bone, not usually painful nor attended with signs of local inflammation or general fever. The swelling is soft, semifluctuating, or doughy in consistence, or hard in some parts and soft in others. Over the surface may appear tortuous veins, and the lymphatic glands connected

with the part may be enlarged. The patient is commonly a young adult, often gives a history of an injury to the part, and may lose weight and strength before definite signs of cachexia set in. The history is not of long duration, not more than three months.

Diagnosis.—A periosteal sarcoma has to be distinguished from gummatous periostitis, but even when the history is negative and syphilitic remedies fail, yet an exploration may reveal a gumma, either to the naked eye or on microscopic examination. It must also be distinguished from inflammatory periostitis set up by an injury. This is difficult when the sarcoma grows rapidly or is attended by local inflammation and a rise of temperature. Indeed, suppuration with necrosis may occur in connection with sarcoma.

Prognosis.—This is the worst possible in all true cases of periosteal sarcoma. No case ever appears to be cured.

Treatment.—Amputation as far as possible above the growth with excision of lymphatic glands, for periosteal sarcoma of the lower end of the femur an amputation through the upper third or hip-joint with excision of the glands in the groins, may possibly prolong life to a year or a year and a half, after which the first sign of metastases may be a blood-stained pleural effusion. It follows that as an amputation does not cure nor materially prolong life, amputation may be delayed in any case where gumma or chronic periostitis is still a possible diagnosis. Indeed, if the growth is found to be a spindle-celled sarcoma, more or less encapsuled, a local excision including the superficial layer of the bone, should be tried.

(*b*) **Endosteal sarcomata** are of much slower growth, and a very much more favorable kind for treatment.

(i) **Myeloid sarcoma,** or giant-celled myeloma, is the most frequent endosteal tumor. Its growth is slow, and it may be a year or more before it extends beyond the limits of the bone. A boring pain may be caused, then a more or less uniform swelling, generally of the articular end of a long bone, the swelling at first having the resistance of bone, later yielding and softening occur in places, and the thinned-out shell of bone occasionally gives rise to a peculiar sensation when the tumor is palpated, called egg-shell crackling, a sign much more often talked of than met with. Having perforated the shell of bone, the tumor increases rapidly, softens, and often pulsates.

Myeloid sarcoma occurs most frequently in the lower end of the femur and in the upper end of the tibia, but also in the cancellous ends of other long bones. It is also met with in the lower and upper jaws, clavicle, pelvis, and in other short bones.

The **diagnosis** has chiefly to be made from chronic central osteomyelitis in the early stages, and from aneurysm when the tumor pulsates. From central osteomyelitis it must be distinguished by exploration when the characteristic appearance of myeloid sarcoma is met with. It is likely to be confused with aneurysm when growing in the line of the iliac and femoral arteries from the pelvis, and from the upper or lower end of the femur. In the upper end of the tibia extending out into the calf, vascular tumors have been met with, called aneurysms of bone, but on examination some tumor substance has usually been found.

The **prognosis** is very good if the growth be removed completely. Metastasis is much delayed, taking place only after two years or more.

Treatment.—The tumor must be scooped out, the wall thoroughly scraped, or the cautery applied; then the shell is crushed inward, and the remainder of the cavity filled with gauze. When the growth has extended and destroyed the shell of bone a suitable excision is performed, according to the position of the growth. When the disease has spread beyond the bone to the soft parts or threatens to fungate, then an amputation is necessary through the limb just above the growth. The result is very favorable, no recurrence taking place if the primary growth is freely removed.

(ii) **Chondro-, osteo- and cystic sarcomata,** not myeloid, are usually endosteal, round- and spindle-celled sarcomata. They are more malignant than myeloids, but more favorable for operation than true periosteal growths.

(iii) **Small Round-celled Sarcoma, or Myeloma.**—Lymphosarcoma of bone is an endosteal growth which has appeared in one of two forms:

(*a*) A single local tumor grows in the marrow and enlarges the bone slowly until a spontaneous fracture occurs. On exploration, a grayish-white tumor, solid or with cysts, is found, having under the microscope the structure of a small round-celled sarcoma.

(*b*) A multiple or diffuse tumor formation occurs in the skeleton, with new growths in the spleen and in lymphatic glands not specially connected with the tumor, while the urine is milky from the albumose of Bence Jones. According to Dr. Bradshaw, the bones most affected are those of the thorax, vertebræ, sternum, and ribs. As compared with osteomalacia, the disease is commonest in men; the skeleton is brittle, but does not bend; the composition of the bones is not altered by absorption of calcareous matter, but fractures occur simply on account of the absorption by the tumors, the bone becoming so thin that it can be cut through with a knife. The tumors consist of small round-celled masses, which may become cystic, but there is not a formation of fibrous tissue as in osteomalacia. The new growth fills the medullary canal and absorbs bone, and the same growth is found in the spleen and lymphatic glands. The patient gradually becomes exhausted with dyspnea and marked vomiting. The milky urine, containing albumose, is of diagnostic importance at an early stage. The disease has lasted as long as six years after the first albumosuria.

(iv) **Endothelioma** has been suggested as an explanation of some rare endosteal tumors of bone, which have been called from their arrangement alveolar sarcoma; or from their large epitheloid cells, primary carcinoma of bone; or from containing hyalin material, chondromata; or from becoming cystic, cysts of bone. When such tumors are vascular and pulsating, a possible explanation is afforded of the so-called aneurysms of bone in

which myeloid sarcoma material has not been found in the walls; also of thyroid gland-like tumors. The tumors thus referred to have occurred in the bones above and below the knee.

Secondary Malignant Disease of Bone.—Both carcinoma and sarcoma cause metastatic growths in bone. Carcinoma is never a primary growth, but is always secondary. *Squamous-celled carcinoma* may spread by extension in the case of an epitheliomatous ulcer of the leg, or to the jaw from the lip. It is rarely a cause of metastatic growths which may then be single. One on the scapula was secondary to epithelioma of the esophagus. It is mostly *spheroidal-celled carcinoma* which infects bone by metastatic growths, especially from the breast, less often from the thyroid gland, and rarer still from the prostate. The bones especially affected by metastases from cancer of the breast, are the vertebræ, femur, humerus, ribs, pelvis, sternum. The skull is especially affected by thyroid metastases. *Columnar-celled carcinoma* of the rectum or intestine may occasionally give rise to a metastatic growth in a bone. Sarcoma appears also secondarily, whether primary in the soft parts or in bone itself. *Melanotic sarcoma* starting in the skin or orbit may develop metastases in the skull, spine or pelvis. *Hypernephroma*, or tumor of the kidney having a structure resembling the suprarenal or adrenal body, is also liable to cause bone metastases, even although the primary tumor is too small to be perceptible. At first the cancer cells may tend to new periosteal bone formation, probably by setting up some venous obstruction, but the later result is softening of bone or *cancerous osteomalacia*, bending, and fractures. A short bone like the sternum may show no external tumor, yet be soft and easily cut with a knife. Then its interior will, on microscopic examination, show the structure of the primary growth, *e. g.*, of the breast.

Treatment.—When epithelioma has spread to bone a wide removal is necessary, seeing that on reaching the medullary cavity the growth quickly extends along it. This may call for removal of all the bone, amputation of the leg, excision of the lower jaw. If only the surface is involved a free gouging away until healthy bone is reached may suffice. Rarely in other cases is any surgical measure indicated, the patient being treated medically in bed. Fractures are treated as if they were traumatic, and partial or even firm bony union sometimes occurs, although nonunion is the rule. Metastases in the liver or lungs being absent, the removal of a single metastasis in a bone may prolong life; indeed, this has been done before the primary tumor was discovered.

Cysts in Bone.—Some of those described as such would be now recognized as due to quiet central osteomyelitis. The blood cysts are probably in all cases degenerating sarcomata. Dermoid cysts are occasionally found in the line of sutures of the skull.

Hydatid cysts affect the diaphyses of the long bones, converting the shaft into a spindle-shaped thin-walled tube, which undergoes spontaneous fracture. The periosteum is not involved. The fractures do not unite. The epiphyseal ends are excavated, and the hydatids may burst into joints, but do not seem to grow primarily there. The hydatid cysts have no adventitious sac, but occur in grape-like masses of daughter cysts without a mother cyst. Suppuration may complicate the disease, by which the hydatids are killed and then discharged from the abscess, but the patient suffers from septic absorption and may die from pyemia.

The skull, vertebræ, pelvis, humerus, femur and bones of the leg and forearm are most commonly affected. It is difficult to understand how, but hydatids have many times developed after injury to a bone, after an ordinary traumatic fracture which united well, after a well-marked blow on the bone, and in one case after a charge of shot had entered the arm.

Treatment.—An early free incision is made, the cavity cleared out and stuffed with gauze. Amputation should be reserved for extensive suppuration (Spencer and Gask).

Osteomalacia (Mollities Ossium; Malacosteon).—This is a progressive softening of the skeleton with resulting deformity. It is a disease of adult life, being rare in children and old people. Pregnant women or those who have borne many children are most commonly the subjects of this grave disease.

The causes of osteomalacia are not well understood. The pregnant condition possibly predisposes to it by depriving the mother's bones of the mineral matter necessary for the growth of the fetus; starvation is supposed to produce it, and it has been observed in women who have nursed their children for long periods.

The pathologic changes consist in the disappearance of the calcium salts, which are absorbed by the fluid surrounding the bone elements. These salts are found in abnormal proportions in the blood and excretions. The bone becomes soft, and deformity may result from muscular contraction or from pressure. The pelvic bones are liable to suffer, resulting in deformity and narrowing, which necessitates operative delivery or cesarean section. As if to compensate for the softening of the bone, the periosteum becomes thickened and hyperemic. The medulla is congested, and may be the seat of hemorrhage.

Symptoms.—The earliest symptoms are nervous, painful points, supposed to be due to rheumatism. The urine is loaded with calcium salts. The bones sooner or later become twisted or bent. Fractures occur from slight causes, and, refusing to unite, false joints may result.

Treatment.—Pregnancy and lactation must be avoided. Lime salts, cod-liver oil, iron, phosphorus, and bone-marrow are the medicines to be employed. Fresh air and good hygiene are requisite. Splints or braces should be applied to bones that show special weakness. Ovariotomy has checked the process in some cases.

Rickets, or rachitis, is a constitutional disease, principally manifested by changes in the bones. It is a disease of infancy, appearing during the first three years of life, in the ill-fed, unwashed, and badly cared for children of crowded and un-

healthy localities. Its pathologic character is chiefly the formation of an embryonic tissue that, instead of being converted into bone as in healthy conditions, stops short of ossification.

Symptoms.—A rachitic child is sickly and ill-nourished, small for its age, or dwarfed. Teething is delayed and the fontanels are late in closing. Diarrhea is common, the appetite is capricious, and the abdomen is enlarged. The child is subject to night-sweats, and often screams in its sleep. Changes in the bones become marked: Those of the skull are thickened; the forehead is prominent; the sternum is projected and gives the angular or "pigeon-breast" shape to the chest; the lower limbs are curved laterally, producing bow-legs, or they may bend anteroposteriorly; the long bones are increased in size throughout, but the enlargement is most marked at their extremities; the sternal ends of the ribs are enlarged, forming "rachitic beads;" the spine is curved, but it is a long, sweeping curve, not the sharp angularity of Pott's disease. See RICKETS.

BONE-MARROW.—Extract of bone-marrow is derived from the red bone-marrow—one of the sources of the red blood-corpuscles. It has been used successfully in cases of pernicious anemia. Glycerin extracts have been used in hemophilia, chlorosis, profuse hematemesis, pernicious anemia, and other anemic affections. The raw marrow, free from spicules of bone, may be given in amounts of about 3 ounces daily, in divided doses, or made into a paste with wine, glycerin, and gelatin. Tablets of from 1 1/2 to 5 grains each of the dried marrow are on the market.

BONES, TABLE OF

NAME.	PRINCIPAL FEATURES.	ARTICULATIONS AND VARIETY.	MUSCULAR AND LIGAMENTOUS ATTACHMENTS.
Astragalus...	Irregularly cubical; forms the keystone of arch of foot; head, neck, six articular surfaces.	Tibia, Fibula, } *ginglymus.* Os calcis, Scaphoid, } *arthrodia.*	Internal and external lateral ligaments.
Atlas.....	First cervical vertebra; ring-like; anterior and posterior arches and tubercles; articular surfaces.	Occipital bone—*double arthrodia.* Axis, four joints—*diarthrodia rotatoria and double arthrodia.*	Longus colli (*tubercle*), rectus capitis posticus minor (*spinous process*).
Axis.....	Second cervical vertebra; body, odontoid process, pedicles, laminæ, spinous process, transverse processes, articular surfaces.	First cervical vertebra—*diarthrodia rotatoria and double arthrodia* Third cervical vertebra—*double arthrodia.*	Longus coli, check ligaments.
Calcaneum...	The heel bone; irregularly cuboidal; lesser process [sustentaculum tali], greater process, peroneal ridge or spine, superior groove, articular surfaces.	Astragalus, Cuboid, Scaphoid, } *arthrodia.*	Tibialis posticus, tendo Achillis, plantaris, abductor pollicis, abductor minimi digiti, flexor brevis digitorum, flexor accessorius, extensor brevis digitorum.
Carpal.....	Consists of scaphoid, semilunar, cuneiform, pisiform, trapezium, trapezoid, os magnum, unciform. See *Individual Bones.*		
Clavicle.....	Collar bone, resembles the italic "*f*:" conoid tubercle, deltoid tubercle, oblique line.	Sternum Scapula, Cartilage of first rib, } *arthrodia.*	Sternocleidomastoid, trapezius, pectoralis major, deltoid, subclavius, sternohyoid, platysma.
Coccyx.....	The last bone of the vertebral column; resembles a cuckoo's beak; usually composed of four small segments; base, apex, cornua.	Sacrum—*amphiarthrodia.*	Coccygeus, gluteus maximus, extensor coccygis, sphincter ani, levator ani.
Cranial.....	Occipital, parietal (two), frontal, temporal (two), sphenoid, ethmoid. See *Individual Bones.*		
Cuboid.....	Somewhat pyramidal; tuberosity.	Os calcis, External cuneiform, 4th and 5th metatarsal bones. } *arthrodia.*	Flexor brevis pollicis.
Cuneiform (of carpus).	Pyramidal.....	Semilunar, Pisiform, Unciform, Interarticular fibrocartilage. } *arthrodia.*	
Cuneiform (of tarsus).			
Internal.....	Irregularly wedge-shaped; the largest of the three.	Scaphoid, Middle cuneiform, First and second metatarsal bones. } *arthrodia.*	Tibialis anticus and posticus.
Middle.....	Wedge-shaped; smallest of the three.	Scaphoid, Internal cuneiform, External cuneiform, Second metatarsal, } *arthrodia.*	Tibialis posticus.
External.....	Wedge-shaped.....	Scaphoid, Middle cuneiform, Cuboid, Second, third, and fourth metatarsal bones. } *arthrodia.*	Tibialis posticus, flexor brevis pollicis.

BONES, TABLE OF

Name.	Principal Features.	Articulations and Variety.	Muscular and Ligamentous Attachments.
Ethmoid.....	Irregularly cubical situated at anterior part of base of skull; horizontal or cribriform plate, perpendicular plate, two lateral masses, crista galli.	Sphenoid, Two sphenoidal turbinated, Frontal, Two nasal, Two superior maxillary, Two lacrimal, Two palate, Two inferior turbinated, Vomer. } *synarthrodia.*	None.
Femur.....	Cylindrical; longest, largest, and strongest bone in the body; shaft and two extremities, head, neck, greater and lesser trochanters, linea aspera, condyles; a long bone.	Os innominatum—*enarthrodia.* Tibia—*ginglymus.* Patella—*arthrodia.*	Gluteus medius, gluteus minimus, pyriformis, obturator internus, obturator externus, gemellus superior, gemellus inferior, quadra tusfemoris, psoas magnus, iliacus, vastus externus, gluteus maximus, short head of the biceps, vastus internus, adductor magnus, pectineus, adductor brevis, adductor longus, crureus, subcrureus, gastrocnemius, plantaris, popliteus.
Fibula.....	Long bone; shaft, upper extremity or head, lower extremity or external malleolus.	Tibia—*arthrodia.* Astragalus, with the tibia and fibula—*ginglymus.*	Biceps, soleus, peroneus longus, extensor longus digitorum, peroneus tertius, extensor proprius pollicis tibialis posticus, flexor longus pollicis, peroneus brevis.
Foot.....	Composed of tarsus, metatarsus and phalanges, *q. v.*		
Frontal.....	The forehead bone; a flat bone; a frontal portion and an orbito-nasal portion; frontal eminences, superciliary ridges, supraorbital arches, supraorbital notches or foramina, internal and external angular processes, temporal ridges, nasal notch, nasal spine, nasal eminence or glabella.	Two parietal Sphenoid, Ethmoid, Two nasal, Two superior maxillary, Two lacrimal, Two malar, } *synarthrodia.*	Corrugator supercilii, orbicularis palpebrarum, and temporal on each side.
Hand.....	Composed of carpus, metacarpus and phalanges. *q. v.*		
Humerus....	Largest bone of upper extremity; long bone; a shaft and two extremities. Upper extremity presents a head, neck and greater and lesser tuberosities. Lower extremity, trochlea, olecranon fossa, coronoid fossa, external and internal condyles, supratrochlear foramen, supracondyloid ridges.	Scapula (glenoid cavity)—*enarthrodia.* Ulna, Radius, } *ginglymus.*	Supraspinatus, infraspinatus, teres minor, subscapularis, pectoralis major, latissimus dorsi, deltoid, coracobrachialis, brachialis anticus, triceps, subanconeus, pronator radii teres, flexor carpi radialis, palmaris longus, flexor digitorum sublimis, flexor carpi ulnaris, supinator longus, extensor carpi radialis longior, extensor carpi radialis brevior, extensor communis digitorum, extensor minimi digiti, extensor carpi ulnaris, supinator brevis and anconeus.
Hyoid.....	A bony arch; irregular bone; a body, two greater and two lesser cornua.	None.	Sternohyoid, thyrohyoid, omohyoid, digastric, stylohyoid, mylohyoid, geniohyoid, geniohyoglossus, hyoglossus, middle constrictor of the pharynx.
Ilium.....	See *Innominate.*		
Incus.....	Resembles a bicuspid tooth with two roots, body, and two processes.	Malleus—*arthrodia* (*trigger-joint*). Stapes—*arthrodia.*	None.
Inferior maxillary.	Body and two rami; contains the teeth of the lower jaw; symphysis, mental process, mental foramen, coronoid and condyloid process, head, neck, sigmoid notch, irregular bone.	The two temporal bones—*bilateral condyloid—diarthrodia.*	Levator menti, depressor labii inferioris, depressor anguli oris, platysma myoides, buccinator, masseter, orbicularis oris, geniohyoglossus, geniohyoid, mylohyoid digastric, superior constrictor, temporal, internal pterygoid, externa pterygoid.
Inferior turbinated.	Situated on the outer wall of the nasal fossa: irregular bone.	Ethmoid, Superior maxillary, Lacrimal, Palate, } *synarthrodia.*	None.

BONES, TABLE OF

Name	Principal Features.	Articulations and Variety.	Muscular and Ligamentous Attachments.
Innominate..	Large, 3 parts; flat bone; with its fellow and sacrum and coccyx forms pelvis. *Ilium*—superior broad expanded portion, crest, superior, middle and inferior curved lines, iliopectineal line, venter, auricular surface, anterior and posterior, superior and inferior spinous processes, 2/5 (about) of acetabulum. *Ischium*—lower and back portion, body, tuberosity and ramus, spine, greater and lesser sacrosciatic notches, external and internal lips of tuberosity, lower boundary of obturator foramen, 2/5 (about) of acetabulum. *Pubis*—body, horizontal ramus, descending ramus, spine, iliopectineal line, angle, symphysis, obturator foramen (upper boundary), 1/5 of acetabulum.	With its fellow of opposite side, Sacrum, } *synarthrodia.* Femur—*enarthrodia.*	*Ilium*—tensor vaginæ femoris, external oblique, latissimus dorsi, iliacus, transversalis, quadratus lumborum, erector spinæ, internal oblique, gluteus maximus, medius and minimus, rectus, pyriformis, multifidus spinæ, sartorius. *Ischium*—obturator externus and internus, gracilis, levator ani, gemellus superior and inferior, coccygeus biceps, semitendinosus, semimembranosus, quadratus femoris, adductor magnus, transversus perinei erector penis. *Pubis*—internal and external oblique, transversalis, rectus, pyramidalis, psoas parvus, pectineus, adductor magnus, longus and brevis, gracilis, external and internal obturator, levator ani, compressor urethræ, accelerator urinæ.
Ischium.	See *Innominate.*		
Lacrimal.....	Small; situated at front part of inner wall of orbit; resembles finger-nail; crest, lacrimal groove; flat bone.	Frontal, Ethmoid, Superior maxillary), Inferior turbinated, } *synarthrodia.*	Tensor tarsi.
Magnum (os).	Largest bone of carpus; occupies center of wrist; head, neck, body; short bone.	Scaphoid, Semilunar, } *anarthrodia.* Second, Third, Fourth, } Metacarpal—*arthrodia.* Trapezoid, Unciform, } *arthrodia.*	Flexor brevis pollicis (part).
Malar.....	Small; quadrangular; at upper and outer part of face; forms prominence of cheek, part of outer wall and floor of orbit, part of temporal and zygomatic fossæ; frontal, orbital, maxillary and zygomatic processes, malar foramen, four borders; irregular bone.	Frontal Sphenoid, Temporal, Superior maxillary, } *synarthrodia.*	Levator labii superioris proprius, zygomaticus major and minor, masseter, temporal.
Malleus.....	Resembles a hammer; head, neck, handle or manubrium, processus gracilis, processus brevis; irregular.	Incus—*arthrodia (trigger-joint).....*	Tensor tympani.
Maxillary, inferior.	See *Inferior maxillary.*		
Maxillary superior.	See *Superior maxillary.*		
Metacarpal..	Five in number; shaft, base, and head; long bones.	Second row of carpus—*arthrodia.* Phalanges—*condyloid.*	To the *thumb*—flexor and extensor ossis metacarpi pollicis, first dorsal interosseous. *Second metacarpal bone*—flexor carpi radialis, extensor carpi radialis longior, first and second dorsal interosseous, first palmar interosseous, flexor brevis pollicis (frequenlty). *Third metacarpal*—extensor carpi radialis brevior, flexor brevis pollicis, adductor pollicis, second and third dorsal interosseous.

BONES, TABLE OF

Name.	Principal Features.	Articulations and Variety.	Muscular and Ligamentous Attachments.
Metacarpal. *Continued.*			*Fourth metacarpal*—third and fourth dorsal and second palmar interosseous. *Fifth metacarpal*—extensor carpi ulnaris, flexor carpi ulnaris, flexor ossis metacarpi minimi digiti, fourth dorsal, and third palmar interosseous.
Metatarsal...	Five in number; shaft, base, and head; long bones.	Tarsus—*arthrodia.* Phalanges—*condyloid.*	*First*—tibialis anticus (part), peroneus longus, first dorsal interosseous. *Second*—adductor pollicis, first and second dorsal interosseous, tibialis posticus (part). *Third*—adductor pollicis, second and third dorsal, and first plantar interosseous, tibialis posticus (part). *Fourth*—adductor pollicis, third and fourth dorsal and second plantar interosseous, tibialis posticus (part). *Fifth*—peroneus brevis, peroneus tertius, flexor brevis minimi digiti, transversus pedis, fourth dorsal and third plantar interosseous.
Nasal.....	Oblong; forms with its fellow the bridge of the nose; nasal foramen, spine, crest; flat bone.	Frontal, Ethmoid, Nasal (opposite), Superior maxillary, } *synarthrodia.*	
Occipital....	Back part and base of cranium; trapezoid in shape; outer and inner tables; external protuberance, external occipital crest, superior and inferior curved lines, foramen magnum, condyles, jugular process, anterior and posterior condyloid foramina, basilar process, pharyngeal spine, 4 fossæ on internal surface, internal occipital protuberance and crest, grooves for the cerebral sinuses, torcular Herophili, jugular foramen; flat bone.	Parietal (two), Temporal (two), Sphenoid, } *synarthrodia.* Atlas—*doubte arthrodia.*	Twelve pairs—occipitofrontalis, trapezius, strenocleidomastoid, complexus, biventer cervicis, splenius capitis superior oblique, rectus capitis posticus major and minor, rectus lateralis, rectus capitis anticus, major and minor, superior constrictor of the pharynx.
Palate.....	Back part of nasal fossa; helps to form floor and outer wall of nose, the roof of mouth and floor of orbit, also spheno-maxillary and pterygoid fossæ and the spheno-maxillary fissure; L-shaped: inferior or horizontal plate, superior or vertical plate, posterior palatine canal, posterior nasal spine, inferior and superior turbinated crests, maxillary process, pterygoid process, accessory descending palatine canals, orbital process, sphenoidal process, sphenopalatine foramen.	Sphenoid, Ethmoid, Superior maxillary, Inferior turbinated, Vomer, } *synarthrodia.* Opposite palate.	Tensor palati, azygos uvulæ, internal and external pterygoid, superior constrictor of pharynx.
Parietal.....	Form sides and roof of skull; irregular, quadrilateral; two surfaces, four borders, four angles, parietal eminence, temporal ridge, parietal foramen, furrows for cerebral sinuses, depressions for Pacchionian bodies; flat bone.	Opposite parietal, Occipital, Frontal, Temporal, Sphenoid, } *synarthrodia.*	Temporal.
Patella.....	Flat; triangular; sesamoid; anterior part of knee-joint; two surfaces, three borders, apex; flat bone.	Condyles of femur—*partly arthrodial.*	Rectus, crureus, vastus internus, vastus externus.

BONES, TABLE OF

NAME.	PRINCIPAL FEATURES.	ARTICULATIONS AND VARIETY.	MUSCULAR AND LIGAMENTOUS ATTACHMENTS.
Pelvis.....	Composed of two ossa innominata, sacrum and coccyx, *q. v.*		
Phalanges of foot.	14 in number, two of great toe, three of each of the others; shaft, base, head; long bones.	First row with metatarsal and second phalanges—*condyloid.* Second of great toe with first phalanx; of other toes, with first and third phalanges, } *ginglymus.* Third row with second row,	*First—great toe*—inner tendon extensor brevis digitorum, abductor pollicis, adductor pollicis, flexor brevis pollicis, transversus pedis. *Second toe*—first and second dorsal interosseous, first lumbrical. *Third toe*—third dorsal and first plantar interosseous, second lumbrical. *Fourth toe*—fourth dorsal and second plantar interosseous, third lumbrical. *Fifth toe*—flexor brevis minimi digiti, abductor minimi digiti, third plantar interosseous, fourth lumbrical. *Second—great toe*—extensor longus pollicis, flexor longus pollicis. *Other toes*—flexor brevis digitorum, one slip of common tendon of extensor longus and brevis digitorum, *Third*—two slips from the common tendon of the extensor longus and extensor brevis digitorum, and flexor longus digitorum.
Phalanges of hand.	14 in number, three for each finger and two for thumb; shaft head, base; long bones.	First row with metacarpal bones and second row of phalanges—*condyloid.* Second row with first and third rows, } *ginglymus.* Third row with second row,	*Thumb*—extensor primi internodii pollicis, flexor brevis pollicis, abductor pollicis, adductor pollicis, flexor longus pollicis, extensor secundi internodii. *First—index finger*—first dorsal and first palmar interosseous. *Middle finger*—second and third dorsal interosseous. *Ring finger*—fourth dorsal and second palmar interosseous. *Little finger*—third palmar interosseous, flexor brevis minimi digiti, abductor minimi digiti. *Second—to all*—flexor sublimis digitorum and extensor communis digitorum: in addition. *To index finger*—extensor indicis. *To little finger*—extensor minimi digiti. *Third*—flexor profundus digitorum, extensor communis digitorum.
Pisiform.....	Anterior and inner side of carpus: small; spherical; one articular facet; short bone.	Cuneiform—*arthrodia*.....	Flexor carpi ulnaris, abductor minimi digiti, anterior annular ligament.
Pubis.....	See *Innominate.*		
Radius.....	Outer side of forearm; shaft, head, neck, tuberosity, lower extremity, oblique line, sigmoid cavity, styloid process.	Humerus—*ginglymus.* Ulna,... { superior—*diarthrodia rotatoria.* / middle—*membranous.* / Inferior—*diarthrodia rotatoria.* Semilunar—*condyloid.*	Biceps, supinator brevis, flexor sublimis digitorum, flexor longus pollicis, pronator quadratus, extensor ossis metacarpi pollicis, extensor primi internodii pollicis, pronator radii teres, supinator longus.
Ribs.....	Twelve in number on each side; shaft, head, neck, tuberosity, angle (anterior and posterior), anterior or sternal extremity: first, second, tenth, eleventh and twelfth are peculiar; flat bones.	Vertebræ—*arthrodia.* Sternum { First rib—*synarthrodia.* / Others—*arthrodia.*	Internal and external intercostals, scalenus, anticus, medius, and posticus, pectoralis minor, serratus magnus, obliquus externus, transversalis, quadratus lumborum, diaphragm, latissimus dorsi, serratus posticus superior and inferior, sacrolumbalis, musculus accessorius ad sacrolumbalem, longissimus dorsi, cervicalis ascendens, levatores costarum, infracostales.

BONES, TABLE OF

Name.	Principal Features.	Articulations and Variety.	Muscular and Ligamentous Attachments.
Sacrum.....	Large triangular bone at lower part of vertebral column, and upper and back part of pelvic cavity; composed of five vertebræ; base, promontory, four surfaces, apex, central canal, anterior and posterior sacral foraminæ, lateral masses, laminæ, articular processes, sacral cornua, transverse processes, sacral groove, ala; irregular bone.	Last lumbar vertebra, Coccyx, Ossa innominata (two), } *amphiarthrodia.*	Pyriformis, coccygeus, iliacus, gluteus maximus, latissimus dorsi, multifidus spinæ, erector spinæ, extensor coccygis.
Scaphoid, of carpus.	Largest bone of first row; boat-shaped; upper and outer part of carpus, four surfaces; tubercle; short bone.	Radius—*condyloid.* Trapezium, Trapezoid, Os magnum, Semilunar } *arthrodia.*	External lateral ligament of wrist.
Scaphoid, of tarsus.	Or navicular bone; boat-shaped; inner side of tarsus, four surfaces, tuberosity: short bone.	Astragalus, Cuneiform (three), Cuboid (occasionally), } *arthrodia.*	Tibialis posticus (part).
Scapula.....	Back part of shoulder; triangular; posterior aspect and side of thorax, two surfaces, three borders, three angles, subscapular fossa, subscapular angle, dorsum, spine, supraspinous and infraspinous fossæ, acromion process, glenoid cavity, neck, head, coracoid process; flat bone.	Humerus—*enarthrodia.* Clavicle—*arthrodia.*	Subscapularis, supraspinatus, infraspinatus, trapezius, deltoid, omohyoid, serratus magnus, levator anguli scapulæ, rhomboideus major and minor, triceps, teres major and minor, biceps, coracobrachialis, pectoralis minor, platysma, latissimus dorsi.
Semilunar...	Upper rows of carpus; four surfaces, crescentic outline.	Radius—*condyloid.* Os magnum, Unciform, Cuneiform, Scaphoid, } *arthrodia.*	
Sesamoid....	Small, rounded masses, cartilaginous in early life, osseous in the adult; developed in tendons; inconstant, except patellæ.		
Sphenoid....	Anterior part of base of skull; bat-shaped, with wings extended; body, two greater and two lesser wings, two peterygoid processes, ethmoidal spine, optic groove, optic foramen, olivary process, pituitary fossa, anterior, middle and posterior clinoid processes, sella turcica, carotid or cavernous groove, lingula, ethmoidal crest, sphenoidal cells or sinuses, sphenoidal turbinated bones, rostrum, vaginal processes, pterygopalatine canal, spinous processes, round foramen, oval foramen, foramen Vesalii, foramen spinosum pterygoid ridge, external orbital foramina, vidian canal, pterygoid fossa, internal and external pterygoid plates, hamular process, scaphoid fossa.	All the bones of cranium, Molar (two), Palate (two), Vomer, } *synarthrodia.*	Temporal, external and internal pterygoid, superior constrictor, tensor palati, levator tympani, levator palpebræ, obliquus superior, superior, inferior, internal and external recti.
Sphenoidal turbinated or sphenoidal spongy bones.	Situated at anterior and inferior part of body of sphenoid; exist as separate pieces until puberty and occasionally are not joined in the adult.	Ethmoid, Palate, } *synarthrodia.*	None.

BONES, TABLE OF

Name.	Principal Features.	Articulations and Variety.	Muscular and Ligamentous Attachments.
Stapes.....	Resembles a stirrup; one of the ossicles of the tympanum; head, neck, two branches (crura), base; irregular bone.	Incus—*arthrodia.*	Stapedius.
Sternum.....	The breast bone; manubrium, gladiolus, ensiform cartilage, or first, second and third pieces, anterior and posterior surface, borders.	Clavicles (two)—*arthrodia.* Costal cartilages (seven on each side) first—*synarthrodia;* others, *arthrodia.*	Pectoralis major, sternocleidomastoid, sternohyoid, sternothyroid, triangularis sterni, aponeuroses of the obliquus externus and internus, and transversalis muscles, rectus, diaphragm.
Superior maxillary.	Forms with its fellow the whole of the upper jaw; somewhat cuboidal; body and malar, nasal, alveolar and palatine processes; hollow (the antrum of Highmore or maxillary sinus), incisive or myrtiform fossa, canine fossa, canine eminence, infraorbital foramen, posterior dental canals, maxillary tuberosity, posterior palatine canal, infraorbital groove; irregular bone.	Frontal, Ethmoid, Nasal, Malar, Lacrimal, Inferior turbinated, Palate, Vomer, Fellow of opposite side. } *synarthrodia.*	Orbicularis palpebrarum, obliquus inferior oculi, levator labii superioris alæque nasi, levator labii superioris proprius, levator anguli oris, compressor nasi, depressor alæ nasi, dilator naris posterior, masseter, buccinator, internal pterygoid, orbicularis oris.
Tarsal.....	Consist of calcaneum, or os calcis, astragalus, cuboid, scaphoid, internal, middle and external cuneiform. See *Individual bones.*		
Temporal...	Situated at side and base of skull: squamous, mastoid and petrous portions, temporal ridge, zygoma or zygomatic process, eminentia articularis, Glaserian fissure, tubercle, glenoid fossa, post-glenoid process, tympanic plate, mastoid foramen, digastric fossa, occipital groove, sigmoid fossa, mastoid cells, meatus auditorius externus, hiatus Fallopii, meatus auditorius internus, lamina cribrosa, aquæductus vestibuli, styloid process, stylomastoid foramen, auricular fissure; irregular bone.	Occipital, Parietal, Sphenoid, Inferior maxillary, Malar, } *synarthrodia.*	Temporal, masseter, occipitofrontalis, sternomastoid, splenius capitis, trachelomastoid, digastric, retrahens aurem, stylopharyngeus, stylohyoid, styloglossus, levator-palati, tensor tympani, tensor palati, stapedius.
Tibia.....	At front and inner side of leg; next to femur in length and size; prismoid in form; upper extremity or head, tuberosities, spinous process, tubercle, popliteal notch, shaft, crest (the shin), oblique line, internal malleolus; long bone.	Femur—*ginglymus.* Fibula { superior—*arthrodia.* middle—*membranous.* inferior—*arthrodia.* Astragalus with fibula—*ginglymus.*	Semimembranosus, tibialis anticus, extensor longus digitorum, biceps, sartorius, gracilis, semitendinosus, tibialis posticus, popliteus, soleus, flexor longus digitorum, ligamentum patellæ.
Trapezium...	In lower row of carpus; very irregular; six surfaces, groove; short bone.	Scaphoid, Trapezoid, First and second metacarpal, } *arthrodia.*	Adductor pollicis, flexor ossis metacarpi pollicis, flexor brevis pollicis (part).
Trapezoid...	Smallest bone in second row of carpus; wedge-shaped; six surfaces; short bone.	Scaphoid, Second metacarpal, Trapezium, Os magnum, } *arthrodia.*	Flexor brevis pollicis (part).
Turbinate, inferior.	One on each side of outer wall of nasal fossæ; curled like a scroll; two surfaces, two borders, two extremities, lacrimal process, ethmoidal process, maxillary process.	Ethmoid, Superior maxillary, Lacrimal, Palate, } *synarthrodia.*	
Turbinate, middle.	The free convoluted margin of the thin lamella, that descends from the under surface of the cribriform plate of the ethmoid bone.		

BONES, TABLE OF

Name.	Principal Features.	Articulations and Variety.	Muscular and Ligamentous Attachments.
Turbinate, superior.	The thin curved plate of the ethmoid, that bounds the superior meatus of the nose above.		
Ulna.....	Inner side of forearm, parallel with radius; prismatic; shaft and two extremities, olecranon process, coronoid process, greater and lesser sigmoid cavities, oblique ridge, perpendicular line, head or lower extremity, styloid process; long bone.	Humerus—*ginglymus.* Radius, { superior—*diarthrodia rotatoria.* middle—*membranous.* inferior—*diarthrodia rotatoria.*	Triceps, anconeus, flexor carpi ulnaris, brachialis, anticus, pronator radii teres, flexor sublimis digitorum, flexor profundus digitorum, flexor longus pollicis (occasionally), pronator quadratus, supinator brevis, extensor ossis metacarpi pollicis, extensor secundi internodii pollicis, extensor indicis, extensor carpi ulnaris.
Unciform....	Wedge-shaped; hook-like process; in lower row of carpus; short bone.	Semilunar, Fourth and fifth metacarpal, Cuneiform, Os magnum, } *arthrodia.*	Flexor brevis minimi digiti, flexor ossis metacarpi minimi digiti, anterior annular ligament.
Vertebræ....	Twenty-six; cervical seven, dorsal twelve, lumbar five, sacrum (composed of five), coccyx (composed of four), each has a body and an arch; latter has two pedicles, two laminæ and seven processes, viz.: four articular, two transverse, one spinous. Peculiar vertebræ, first, second and seventh cervical; first, ninth, tenth, eleventh, and twelfth dorsal; sacrum, coccyx; irregular bones.	Articulate with each other, and with occipital and innominate bones and ribs (*q. v.*). Intervertebral articulations, between the bodies—*amphiarthrodia.* Between articular processes—*arthrodia*	Attachment of muscles.—*To the Atlas* are attached nine pairs; the longus colli, rectus anticus minor, rectus lateralis, rectus posticus minor, obliquus superior and inferior, splenius colli, levator anguli scapulæ and first intertransverse. *To the axis* are attached eleven pairs; the longus colli, obliquus inferior, rectus posticus major, semispinalis colli, multifidus spinæ, levator anguli scapulæ, splenius colli, scalenus medius, transversalis colli, intertransversales, interspinales. *To the remaining vertebræ* generally are attached thirty-five pairs and a single muscle; anteriorly, the rectus anticus major, longus colli, scalenus anticus, medius, and posticus, psoas magnus, psoas parvus, quadratus lumborum, diaphragm, obliquus internus and transversalis: posteriorly, the trapezius, latissimus dorsi, levator anguli scapulæ-rhomboideus major and minor, serratus posticus superior and inferior, splenius, erector spinæ, sacrolumbalis, longissimus dorsi, spinalis dorsi, cervicalis ascendens, transversalis colli, trachelo-mastoid, complexus, biventer cervicis, semispinalis dorsi and colli, multifidus spinæ, rotatores spinæ, interspinales, supraspinales, intertransversales, levatores costarum.
Vomer.....	Situated vertically at back part of nasal fossæ; forms part of septum of nose; somewhat like a plow-share; two surfaces and four borders.	Sphenoid, Ethmoid, Superior maxillary (two), Palate (two), Cartilage of the septum. } *synarthrodia.*	
Wormian....	Supernumerary bones; irregular, inconstant, isolated, interposed between the cranial bones, most frequently in the lambdoid suture.		

BORAX.—$Na_2B_4O_7,10H_2O$. Sodium borate. Occurs in lacustrine deposits as white, transparent crystals, soluble in water, alcohol, and glycerin. It is used as an antiseptic wash for ulcers and indolent lesions, and is valuable also as an emmenagog, and in leukorrhea. Borax may be used as a wash in bromidrosis or fetid sweating of the feet, in the treatment of pruritus ani and vulvæ, in diphtheria, and in aphthous and gangrenous stomatitis. Dose, 5 to 30 grains.

For freckles, tan, etc.

℞.	Borax,	ʒ ss
	Buchu water,	ʒ xjss
	Spirit of rosemary,	ʒ ss.

For ringworm of the scalp:

℞.	Borax,	gr. xx
	Distilled acetic acid,	ʒ ij.

For sore nipples:

℞.	Borax,	ʒ ij
	Prepared chalk,	ʒ j
	Rose water,	ʒ iij
	Spirit of wine,	ʒ iij.

BORBORYGMUS.—The rumbling sounds produced in the abdomen by the movements of gas within the bowels or stomach. See FLATULENCE.

BORIC (Boracic) ACID.—H_3BO_3. A crystalline substance found native in the volcanic lagoons of Tuscany. It occurs in white, transparent crystals, soluble in water and alcohol. Dose, 5 to 15 grains. **Unguent. Acidi Borici** contains boric acid 10, paraffin 10, white petrolatum 80. It is used as an antiseptic and in dermatology.

Boric acid is an efficient antiseptic, disinfectant, and deodorant, arresting fermentation and putrefaction, and very destructive to all low organisms. A solution of 1:133 arrests the activity of bacteria. It is feebly acid and but slightly irritant, and is used in the form of a dusting-powder as a surgical dressing because of its antiseptic and unirritating qualities. Its lotion and ointment have been successfully employed in ulcers, eczema, and parasitic diseases of the skin. It is one of the most commonly used substances in eye-washes. It is of particular value to inflamed mucous surfaces. As an irrigating solution for the bladder, it is invaluable; it renders the urine acid when given ernally. Its dose is 5 to 15 grains.

Application to the skin of the face and hands:

℞.	Boric acid,	ʒ j
	White wax,	ʒ j
	Paraffin,	ʒ ij
	Oil of bitter orange,	ʒ ij.

Shake well and apply night and morning.

An eye lotion:

℞.	Boric acid,		gr. xl
	Camphor water, Distilled water,	each,	ʒ ij.

Bathe the eyes freely several times a day.

BOROGLYCERID.—See BOROGLYCERIN.

BOROGLYCERIN.—A mixture of boric acid, 62 parts, with glycerin, 92 parts; it is called also *boroglycerid* and *glyceryl borate*. It is an active antiseptic in a solution of 1:40. It is readily soluble without precipitation in glycerin or water, and hence affords a convenient means of presenting any desired proportion of boric acid. A 50 percent solution of boroglycerin in glycerin is of syrupy consistence. In this form it is kept on hand by druggists and dispensed under the name of **"Glyceritum Boroglycerini."**

For the treatment of open wounds it is a non-irritating and powerful antiseptic. Barwell employs it in a watery solution for washing out abscess cavities. Sir Henry Thompson speaks highly of boroglycerin used in a watery solution as an injection for cystitis. It may be used in the proportion of 1 to 50 of water.

The indications for the use of boroglycerin are not distinct from those of boric acid. It is a favorite nasal application with some physicians. It appears to be especially adapted to aphthous or hemorrhagic ulcerated surfaces in the nasal chamber. It is an admirable application to the lines of incision in the after-treatment of operations on the nasal septum.

Boroglycerin (50 percent) is a useful application in all forms of conjunctivitis, and is almost indispensable in trachoma, painted on the everted lid with a camel's-hair brush or a small pledget of absorbent cotton.

For granular conjunctivitis:

℞. Boroglycerin (50 percent), ʒ ij.

In a compressible tube, one drop in the eye morning and night.

BOTHRIOCEPHALUS LATUS.—See WORMS (Tape).

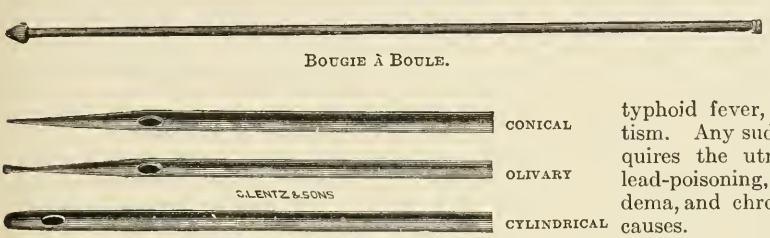
BOUGIE.—A slender, cylindric instrument, made of waxed silk, catgut, etc., for introduction into the urethra or other passage for the purpose of dilatation, exploration, etc. Sometimes bougies are covered with preparations, which are thus conveyed to the inner mucous surfaces. An *armed bougie* has a piece of nitrate of silver or other caustic attached to its extremity. A *filiform bougie* is a whalebone or other bougie of very small size. Bougies for the esophagus are about 2 feet long, those for the rectum 8 or 9 inches, and those for the urethra 13 inches.

The French scale of thickness or size of urethral bougies, generally adopted in America, has each size 1 mm. larger in circumference than the preceding one. The range is from 1 to 50 mm. in circumference. The English or gum-elastic bougie is a seamless tube of woven silk, of tawny brown color, overlaid with copal varnish, and smoothly polished. The French bougie is also of woven silk, but more flexible than the English one. Whalebone is troublesome, from its rigidity, which can be lessened by steeping in boiling water. Catgut becomes too supple after soaking in the mucus of the urethra, and is likely to get rough. Silkworm gut is strong, not affected by urine, mucus, or water. Celluloid bougies are nonabsorbent, smooth, pliant when warmed, but resume their rigidity too quickly, and sometimes, when cold,

are too brittle. They are best fitted for catheters for tying in the urethra, because they are unirritating, and, at the body temperature, yield to the curves of the passages wherein they lie.

The most commonly used bougies are the English gum-elastic and the French bougies. The former are cylindric and of the same thickness throughout. The French bougies are tapering in their lower one-third, and are better adapted to pass along the urethra.

A French bougie is called "olivary" when the tip is rounded or bulbous. The "swell" of an olivary bougie is such as to remove all sharpness, and the tapering end is so supple that it bends easily and passes an obstruction, which the gum-elastic bougie does not readily do; but they are not so durable as the English catheter. The imported French bougies are not so well varnished nor are they so smooth or so tough as those of the English manufacture. The flexibility of the tapering bougie has been modified by the introduction of leaden stilets which penetrate to the tip of the bougie. Fine shot may be used instead of the wire stilet.



Bougie à Boule.

A table based upon measurements of the circumference of the flaccid penis at the middle of the spongy portion, and showing the direct relation to the normal size of the urethra, and corresponding size of bougie, is as follows:

Circumference of Penis.	Size of Bougie.
3 inches,	26 to 28 French scale.
3 1/4 inches,	28 to 30 French scale.
3 1/2 inches,	30 to 32 French scale.
3 3/4 inches,	32 to 34 French scale.
4 inches,	34 to 36 French scale.

This table must not be regarded strictly.

Medicated bougies will be found of service in the treatment of certain inflammatory conditions of the mucous membranes, especially those of the genitourinary tract and of the rectum. They will often succeed when other methods fail. The object of the use of bougies is to keep the mucous surfaces apart, and at the same time to apply the selected medicament to advantage. As a base, gelatin is preferable to cacao-butter, for it does not become rancid, and, owing to its animal nature, is more readily absorbed. Urethral bougies are manufactured for use in the treatment of gonorrhea, gleet, etc., in two sizes, 6 1/2 inches and 3 inches.

BOUILLON.—An alimentary broth, made by boiling meat—usually beef—in water. Also a liquid nutritive medium, made by boiling meat, for the culture of microorganisms. Peptonized bouillons and solutions of powdered meats have also been used. See Bacteriology.

BOW-LEGS.—See Genu Varum.

BRADYCARDIA (Brachycardia).—A paroxysmal or permanent slowness in the cardiac action. It is often associated with organic nervous diseases. It is a symptom of such cardiac diseases as fibroid and fatty heart, atheroma of the coronary arteries, and the Stokes-Adams syndrome, "heart-block" (*q. v.*). It frequently occurs during convalescence from infectious diseases, such as diphtheria, pneumonia, typhoid fever, erysipelas, and rheumatism. Any sudden fall below normal requires the utmost vigilance. Uremia, lead-poisoning, anemia, jaundice, myxedema, and chronic alcoholism are often causes.

The pulse is quite variable, and is weak, small, and slow. As results of the slow cardiac action are vertigo, noises in the ears, syncopal attacks, and, rarely, convulsions. The onset may be either sudden or follow "warnings."

The first sound is soft and feeble, and often the second sound is not heard. As a rule, with reduction in the number of contractions there is an increase in their force; as this is not so in bradycardia, its central origin is shown. Sudden death is a very frequent termination. The cause controls the prognosis.

Treatment.—Rest in the recumbent position, heat to the precordia, and the use of such remedies as atropin, caffein, and strychnin is indicated. Often the emergency is so great as to call for the hypodermic use of the selected drug. Digitalis is contraindicated. Between the paroxysms such remedies as improve the general health and prevent the progress of the central or exciting cause should be given. See Heart-disease (Functional), Pulse.

BRAIN, ABSCESS.—See Brain (Inflammation).

BRAIN, ANEMIA.—An abnormal decrease in the amount of blood in the cerebral vessels: *general*, when the diminished supply includes all the vessels; *partial*, when the diminished supply is limited in area; characterized by pallor, headache, vertigo, some loss of power, and, rarely, convulsions.

Etiology.—Partial cerebral anemia results from obstruction of a vessel— from embolism or thrombosis. General cerebral anemia results from hemorrhages, wasting diseases, during convalescence from severe attacks of fevers, sudden shock, feeble cardiac action, and general anemia.

Symptoms.—In general anemia there is headache, relieved by the recumbent position; vertigo, aggravated by exertion; general pallor, with attacks of fainting. When the general cerebral anemia is sudden and decided, convulsions occur.

Partial anemia is manifested by sudden loss of power, of limited muscular area, generally returning to the normal condition.

Prognosis is favorable in all cases save those that are the result of severe and repeated hemorrhages.

Treatment consists in regulated nourishment, with stimulants. A certain number of hours daily in the recumbent position is of advantage. When a tendency to attacks of fainting exists, stimulants, or even the cautious inhalation of amyl nitrite, are indicated. To improve the quantity or quality of the blood give:

℞. Tincture of iron chlorid, ℥ ss
Dilute phosphoric acid, ℥ j
Solution of potassium arsenite, ℥ ss
Syrup of ginger, q. s. ad ℥ iij.

A teaspoonful, well diluted, every 6 hours.

Or—

℞. Strychnin sulphate, gr. j
Quinin sulphate, ℥ j
Dilute hydrochloric acid, ℥ ij
Compound tincture of gentian, q. s. ad ℥ vj.

Teaspoonful in water after meals.

BRAIN, COMPRESSION.—See BRAIN (Injuries.)

BRAIN, CONCUSSION.—See BRAIN (Injuries).

BRAIN, DECOMPRESSION.—See CRANIECTOMY.

BRAIN EXTRACT (Cerebrinin).—Obtained from the gray matter of the sheep's brain by digestion in 5 times its weight of pure glycerin and then adding an equal quantity of a 12 percent solution of common salt. Its effects are almost identical with those of orchitic extract, the most noticeable being increased strength and a feeling of well-being, regulation of the organic functions, and increase of the cardiac force. It has been employed with alleged benefit in locomotor ataxia, neurasthenia and allied affections, nymphomania, perverted sexual habits of cerebral origin, hysteria, melancholia, insomnia, the general debility of malaria, chlorosis, and even more profound anemias; also in cases of defective development of the spinal apparatus, as Friedreich's ataxia. The dose is 16 minims (1 c.c.), once daily or every other day, administered subcutaneously.

Cerebrin is an extract of the entire brain of the ox. The dose is 5 minims, diluted with an equal quantity of distilled water at the time of administration, by hypodermic injection.

BRAIN, FUNGUS.—See BRAIN (Hernia).

BRAIN, HEMORRHAGE (Apoplexy).—Apoplexy is a term usually applied to coma coming on rapidly as a result of cerebral hemorrhage. The word, by its etymology, means a striking off.

Seat.—The location of predilection is in the internal capsule, caused by rupture of the lenticulostriate artery. If the hemorrhage is into the meninges, it is called meningeal hemorrhage.

Etiology.—Apoplexy is the result of hemorrhage. Uricacidemia, gout, rheumatism, syphilis, alcoholism, and all other causes leading to excessive arterial tension and sclerosis are predisposing causes. Apoplexy is more common in the old than in the young, owing to a degenerative and atheromatous condition of the blood-vessels set up by predisposing causes of long standing.

Pathology.—In adults the most common seat is in the internal capsule, but in children it is cortical. The hemorrhage is usually found in the gray matter of the brain—internal capsule, lenticular nucleus—and is generally circumscribed. Its size varies—often being a miliary particle—but it may be so extensive as to burst into the lateral ventricle, or, if cerebellar, into the fourth ventricle. Osler records 2 deaths from hemorrhage into the cerebellum. The clot at first is soft and dark, and the cut edges of the area may show only punctate spots. At times the cerebral tissues may be lacerated. Should the case terminate favorably, the clot gradually loses its color, becomes cystic, and is finally absorbed, leaving only a small cicatrix, the cells and tissues being tinged brownish from the blood-pigment hematoidin.

Symptoms and Course.—As a rule, the onset is sudden; but prodromal symptoms, such as headache, vertigo, mumbness, or tingling pains in the limbs, may precede the attack.

The symptoms may be divided into (1) primary and (2) secondary.

Primary Symptoms.—If the ruptured blood-vessel is in the central ganglia, the patient may fall unconscious, and in convulsions. Hemiplegia is usually present. The face is flushed, the temporal arteries throb violently, the eyelids are half open, the lips are blue, the pulse is full and slow. Often there is a twitching of the extremities, the head being rotated toward one side; the respirations are snoring in character, and there is often sputtering of the lips on expiration. The pupils may be either dilated or contracted.

There is generally a lowering of the body-temperature (which may be different in the two axillæ), followed by a rise—the first day, if the patient survives, to 100° or 102° F., and the second day to 101° F. If there is a very rapid rise in the temperature, the prognosis is more grave. Hemorrhage into the pons or medulla causes an initial rise of temperature.

The affected parts are rigid, and if raised and allowed to drop, fall heavily. The urine and feces may be passed involuntarily.

The chief causal element in the production of the symptoms of apoplexy is probably intracranial pressure.

Secondary Symptoms.—If the hemorrhage is not of sufficient size to produce grave pressure-symptoms, consciousness is gradually restored, and the paralysis is only partial, involving one extremity, one side of face or tongue. The tongue, if protruded, deviates toward the affected side. In most cases of apoplexy there is paralysis of motion only, the sensation remaining good, except occasional paresthesia. The paralysis produces in the affected parts much rigidity, and they move as a whole, with a swinging or rotatory movement given by the trunk. The muscles of the face and those of the thorax usually escape. Should the clot not be absorbed, there may be great damage to the higher brain-functions, with consequent loss of memory, and the different forms of aphasia.

Diagnosis.—In **cardiac syncope** the heart is weak, the face is pale, the respirations are sighing, and the reflexes are not abolished.

In **uremia** the onset of coma is slow; the urine is scanty and contains albumin, especially if the patient is young. Paralysis may occur. If there is an odor it is urinous. There may be a history of general convulsions or convulsive movements preceding the attack. Edema of ankles is generally present, and control of the sphincters is not lost. The pulse at first strong becomes weak and rapid; tension is strong. The heart is hypertrophied, the second aortic sound is accentuated; there is arteriosclerosis. Breathing is stertorous, often of the Cheyne-Stokes type.

In **opium-poisoning** the patient can be aroused by loud calls; the pupils are contracted; the respirations are very slow and stertorous. There is no paralysis, and no loss of control of sphincters.

Alcoholism.—There is an odor of alcohol on the breath; the temperature is normal; the pupils are normal; the coma is less profound; and there is no paralysis nor involuntary action of bowels or bladder. The urine is usually negative but the possibility of concurrent Bright's disease should be kept in mind. The pulse is feeble and frequent.

Embolism is generally the result of valvular disease of the heart, and usually occurs earlier in life. The unconsciousness, as a rule, comes on later, and is not so complete. The left common carotid comes direct from the aorta, and the embolus has a more direct course to the cerebrum; hence the paralysis is more often on the right side.

Thrombosis comes on more gradually, on account of the thrombus usually affecting a vein.

Abscess.—There is generally a history of injury, and the symptoms often appear gradually.

Hysteric hemiplegia usually occurs in women. There is commonly a history of hysteric outbreak. Hemianesthesia is often present with paralysis of motion. Should the patient fall at the time of the attack, it will generally be where she would not be likely to suffer from bodily injury, probably on the bed or couch. This differentiates it also from an epileptic seizure, in which the patient loses consciousness completely, and may suffer severe injury by the fall.

For further diagnosis see Coma.

Prognosis depends upon the site of the lesion. A cortical hemorrhage, if in a young person, may subside without leaving serious sequels behind. The hemiplegia that develops from rupture of the lenticulostriate artery into the internal capsule is usually permanent, and gives rise to subsequent contracture and aphasia. If there is a persistent rise of temperature—103° F. or 104° F.—and persistent coma after the second day, the prognosis becomes more grave. If there is no improvement in the paralyzed member before the first month, contracture is almost sure to arise.

Treatment of the Attack.—The proper treatment of an attack of apoplexy is to put the patient immediately to bed, with head elevated. If away from home, he should not be moved, as the disturbance may lead to further damage of the brain-structure. The head should be slightly turned to one side to prevent the tongue from falling back into the throat and closing the glottis. An ice-bag to the head may prevent further hemorrhage. If the person is a full-blooded individual and the pulse is full and bounding, from 4 to 6 ounces of blood may be taken from the veins of the forearm. Venesection is indicated only when the diagnosis of hemorrhage is positive; in thrombosis it may do harm by slowing the blood current in the veins and favoring the clotting. A weak pulse contraindicates venesection. No attempts should be made to arouse the patient by loud shouting or shaking, but absolute quiet and rest are to be enjoined. If ability to swallow is present, 1 drop of croton oil with 4 or 5 grains of calomel, mixed with glycerin, should be placed upon the tongue, and a small amount of water afterwards given. Stimulants are to be avoided. Should the person not be able to swallow, no food of any kind should be placed in the mouth for a number of hours. As soon as the power of deglutition returns, a small amount of milk, beef-broth, or light soups may be given every 3 or 4 hours. Rectal alimentation may have to be resorted to. Peptonized milk is probably the most nutritious, and 6 or 8 ounces may be injected high up the bowel 2 or 3 times daily. Bed-sores are to be avoided by sponging the bony prominences with diluted alcohol once daily. They may often be prevented by keeping the body free from urine. The amount of urine passed should always be ascertained, and catheterization may be necessary after the first few days. To prevent congestion of the lungs the patient may be turned gently first on one side and then on the other every few hours after the second day. Nitroglycerin or nitrites may be given to soften the pulse and decrease blood-pressure. Restlessness may be combated with bromids.

Subsequent Treatment.—At the end of 6 weeks or 2 months, or after signs of irritation have disappeared, the contracture may be improved by applying the galvanic current over the muscles for 15 or 20 minutes every 2 days. Massage and passive motion also aid in the improvement of the parts. Never use a current so strong as to be painful to the patient. Should syphilis be suspected as the cause of sclerosis of arteries, potassium iodid should be given in 10-grain doses, and gradually increased to 40 or 50 grains, after each meal. Strychnin is valuable after the second month, to give proper tone to the muscles; 1/30 of a grain may be given after meals for periods of 10 days or 2 weeks.

BRAIN, HERNIA.—This is a protrusion of the brain tissue beneath the scalp, through a traumatic defect in the skull, as the result of increased intracranial pressure, *e. g.*, after an operation for an irremovable tumor. When there is a defect in the scalp the condition is called *prolapse of the brain.*

Symptoms.—It pulsates, has an impulse on coughing, and may be partly reducible, causing symptoms of compression of the brain. According to the cause of increased intracranial pressure, it increases or decreases in size. If uncovered by scalp, septic meningitis is likely to occur; and if of large size, gangrene frequently results. *Prolapse*

of the brain should not be confused with *fungus cerebri*, which is simply exuberant and edematous granulations from the neuroglia, as the result of wounds of the brain. Since the latter occurs only when there is an opening leading down to the brain, care should be taken after operation to suture the dura whenever possible; when a portion of the dura has been destroyed, the defect may be closed with a flap of pericranium, sutured in place with the osteogenetic surface outwards, or with a piece of the fascia lata, fatty side in.

Treatment of Hernia Cerebri.—If possible, the cause of the increased intracranial pressure must be removed. The protruding brain should be protected; and, if uncovered, dressed with sterile gauze to prevent septic contamination. Pressure may be dangerous, and amputation should be employed only when sloughing has occurred. The **prognosis** is unfavorable.

Fungus cerebri is treated by slicing off the granulations, or by cauterizing them with silver nitrate. The condition is not serious (Stewart).

BRAIN, HYPEREMIA.—Abnormal fulness of the small vessels of the brain; active, when arterial, passive, when venous. It is characterized by headache, vertigo, disorders of the special senses, and, if the hyperemia is decided, by convulsions.

Causes, Active.—Increased cardiac action, the result of hypertrophy of the left ventricle; general plethora; excesses in eating and drinking; acute alcoholism; sunstroke; prolonged mental labor; diminished amount of arterial blood in other parts, the result of the compression of the abdominal aorta; ligation of a large artery; and the suppression of a habitual bleeding hemorrhoid are active causes.

Passive.—Dilatation of the right heart; pressure upon the veins returning the cerebral blood.

Symptoms.—Fulness in the head may be gradual or sudden in its onset, the symptoms aggravated by the recumbent position. Headache, with paroxysmal neuralgic darts, disorders of vision and hearing, buzzing in the ears and sparks before the eyes, contracted pupils, vertigo, blunted intellect, inability to concentrate the mind, irritable temper, and curious hallucinations are all occasional symptoms. The face is red, the eyes congested, and the carotids pulsating. Sleep is disturbed by dreams, and there is twitching of the limbs. If the attack is sudden, unconsciousness with muscular relaxation occurs.

Cerebral hyperemia, in children often presents alarming symptoms, such as great restlessness, insomnia, night-terrors, gnashing of the teeth during sleep, vomiting, and contraction of pupils followed by general convulsions. Any or all of these symptoms may continue more or less marked from an hour or two to a day, the child enjoying its usual health after a sound sleep, save some fatigue.

Prognosis.—Mild cases terminate favorably in a few hours or a day or two, but may recur. Severe cases (apoplectiform) may recover, but usually indicate subsequent cerebral hemorrhage. The passive form is controlled through the lesions giving rise to it.

Treatment. Active Form.—Remove the cause, if possible. Elevate the head and apply cold—either cold cloths or the ice-cap; at the same time, warmth to the feet. Leeches to the mastoid or cups to the neck, or, in the apoplectiform variety, venesection, to diminish the intracranial blood-pressure; compression of the carotids or ligatures about the thighs have been recommended.

An active purgation is indicated, either by croton oil or magnesium sulphate, by the mouth. Mercury in a full initial dose (5 grains of blue mass), followed by 1/4 to 1/2 grain of calomel three times a day, is recommended. Continued purging is controlled by the addition of opium. The following enema is often valuable:

℞.	Magnesium suphate,	℥ j
	Glycerin,	℥ j
	Warm water,	℥ iv.

In mild cases the application of an ice-cap to the head, a blister to the back of the neck, and 30 to 40 grains of potassium bromid, repeated, and the foregoing enema, control the symptoms.

In severe cases, with forcible, overacting heart, to the measures mentioned must be added tincture of veratrum viride, tincture of aconite, nitroglycerin, or the nitrites.

In the **passive form** the treatment is directed to the cause. See Brain (Hemorrhage).

BRAIN, INFLAMMATION (Encephalitis; Cerebritis; Abscess of the Brain). Definition.—By encephalitis is meant inflammation of the brain substance as contrasted with that of its membranes. What is popularly known as inflammation of the brain is really inflammation of the membranes of the brain, or meningitis. When, on the one hand, inflammation of the surface of the brain accompanying meningitis is eliminated, and, on the other, softening of the brain (formerly thought to be the result in inflammation, but now known to be due to the arrest of blood supply), it leaves a very small number of cases of possible encephalitis without abscess; this both Gowers and Strümpell admit as possible.

Etiology.—The causes of cerebritis are: (1) Traumatism; (2) extension from an adjacent focus of inflammation; and (3) pyemia.

Under traumatic causes are included falls or blows upon the head, more commonly attended by fracture or punctured wound, although no visible injury, not even a scratch upon the skin, may be present.

Under adjacent disease, whence extension of inflammation is especially frequent, is to be included caries of the petrous portion of the temporal bone, due to disease of the middle ear or labyrinth, the most common of all causes of abscess of the brain. Disease of the orbit is another similar cause. The route of such a communication may be either through the sinuses of the brain or the lymph channels.

Pyemic abscess of the brain is rare. Causal foci are malignant endocarditis, gangrene of the lung, chronic bronchitis with bronchiectasis, bone-disease, suppuration of the liver, and the specific fevers, among which may be included influenza.

Encephalitis occurs most frequently between the ages of 10 and 40, and about three times as often in men as in women.

Symptoms.—In acute cases the symptoms develop rapidly, and may run their course in a few days; while in the forms known as chronic, the symptoms are scarcely less rapid after they once set in, which may be weeks, months, or even longer, after the primary causal lesion. These symptoms are the result of pressure—direct or indirect—of destruction of the brain substance, or of poisoning due to absorption of putrid matter. They are much the same as those of meningitis, with which, indeed, abscess is often associated, especially if there is injury. The most striking are headache, often severe and persistent; vomiting; vertigo; mental dulness, succeeded sometimes by delirium and sometimes by coma. Convulsions are often present, and are epileptoid in character. Optic neuritis is also one of the symptoms. There is usually fever, as shown by elevation of temperature. At times the temperature is normal or subnormal. The pulse is usually slow—60 to 70. The symptoms may set in with a chill after the latent period. The toxic symptoms are those usual to toxic states: viz., chill, irregular fever, prostration, emaciation, exhaustion. Paralysis, in the form of hemiplegia, sometimes occurs. The paralysis, however, is not always hemiplegic, and may be limited to the arm and face, especially in abscess of the temporosphenoidal lobe, which may compress the lower motor centers. If on the left side, there may be aphasia. Other cranial nerves besides the optic are sometimes involved.

When the abscess is in the parietooccipital region, there may be hemianopsia. It is especially in abscess of the cerebellum that vomiting occurs, and staggering, if the middle lobe is affected.

Phlebitis of the superior petrosal and lateral sinues is common, especially when the abscess is caused by disease of the ear, for the former receives a vein from the internal ear, and the latter the mastoid veins. Edema about the ear and neçk and hardness of the jugular veins should suggest phlebitis, while rigidity of the neck and cranial nerve paralysis even more unerringly point to meningitis.

Acute cases last from 8 to 14 days, rarely 30 days; the delayed cases may not show their first symptoms for months.

Diagnosis.—This is readily determined in acute cases, being substantiated by the history of injury, rigor, and fever, followed by the brain-symptoms described. Almost as certain is the diagnosis when such symptoms follow chronic ear-disease or localized putrid lung-disease. It is to be remembered, however, that simple ear-disease may produce some general cerebral symptoms, in which is included optic neuritis. In such cases it is impossible to make the diagnosis until the course and termination of the disease have excluded one or the other. In like manner meningitis and abscess may be confounded, and with reason, because, in the first place, meningitis may be produced by the same causes as produce abscess; and, second, meningitis may be caused by abscess. Meningitis, however, affects the cranial nerves more than abscess, unless the abscess is seated in the pons, and usually meningitis follows more promptly upon its cause. It is to be remembered that tumor of the brain may produce symptoms identical with those described. The chief distinctive symptom is the presence of fever in abscess.

Prognosis.—Unless we admit a curable form, described by Strümpell, it is always ultimately fatal, unless we have the rare good fortune to reach the abscess with the trephine.

Treatment.—A certain prophylaxis may be exercised in the proper treatment of disease of the ear, for it is often neglect of this that leads to the abscess. Such prophylaxis includes measures that secure free discharge and antisepsis. Beyond this, the only treatment for abscess that promises anything toward a favorable result is the operation of trephining.

Aconite and opium are useful in the stage of excitement, and bromid of potassium or sodium may restrain convulsions. The wound must be made aseptic. The bowels should be loosened, the head shaved, and the patient placed in a cool, quiet room. The catheter should be used if unconsciousness exists, and not forgotten later. Cold to the head by Leiter's tubes or rubber ice-caps is beneficial. Among the useful hypnotics are hydrobromid of hyoscin, chloral, and paraldehyd. Mustard plasters to the neck and forehead for short periods may be employed, especially if pressure-symptoms are observed. If depression is great, aromatic spirit of ammonia or wine (sherry or champagne) should be used. A milk diet is best. If coma develops and constipation exists, croton oil and glycerin should be administered.

BRAIN, INJURIES.—In general terms brain injuries may be classified as injuries causing intracranial lesions with or without concomitant fracture of the skull. These may act directly or indirectly, and may be caused by falls, by blows, or by wounds with blunt, pointed, or sharp-edged weapons or missiles, and by all varieties of firearms. As a result of these injuries, traumatisms of the skull that give rise to endocranial manifestations may be classified as simple contusions, direct or indirect (*e. g.*, the latter from falls on the buttocks, knees, or feet, or from blows on the chin), without fracture; and into fractures proper, which may be simple or compound, comminuted or complicated, complete or incomplete, direct or indirect—these terms being applied in the sense in which they are understood when dealing with fractures in other parts of the body. Secondarily and topographically, they are again subdivided into (*a*) fractures of the vault, and (*b*) fractures of the base; and in accordance with the nature of the injuring force, into (*a*) linear or fissured, (*b*) punctured, or (*c*) depressed. See Skull (Fractures).

The endocranial lesions that may result from the preceding direct or indirect injuries, as they are transmitted from the cranial case to its contents, may be classified, irrespective of cause, into the following categories: viz., (1) *primary* lesions, contusions, lacerations, hemorrhages, thromboses of sinuses, and, more rarely, effusions of air and cere-

brospinal fluid; (2) *secondary* lesions; these are the sequels of infectious meningitis in all its anatomic varieties, and of parenchymatous inflammations, which are usually, if not invariably, of a septic character, leading to various types of intracranial suppuration, abscess, and meningoencephalitis; finally, as (3) *tertiary* or remote lesions, we would mention the degenerative results of trauma and of those lesions that coincide with cicatrization. These sometimes occasion serious permanent disorders, such as obstinate cephalalgia, epilepsy, insanity, etc.

In addition to all these, as the almost constant attendant of cranial traumatism, is surgical shock, which is perhaps more manifest in injuries of the head than in other parts of the body, and is so important that it is usually referred to by a specific term—"concussion."

At the very threshold of the study of endocranial traumatisms a difficult question arises that relates to the definition and differentiation of certain general conditions that up to the present have perplexed the practitioner as well as the pathologist. The first of these refers to the meaning and limitations of the word "concussion." The ancients applied this term "concussion" (commotio cerebri) to every symptom and manifestation of brain injury, and it was not until 1677 that the modern concept of this term was reached, when Borel limited the application of the word "concussion" to the brain symptoms that follow injuries of the head when these are not associated with appreciable anatomic or structural lesions of its contents. The observations of Littré (1705) and J. L. Pettit (1761), followed by those of Serres, Gama, Desault, Dupuytren, Malgaigne, and others, separated two other conditions—contusion and compression—from concussion, and thus established a clinical triology, which has since remained inseparably linked with the study of cerebral traumatism. With increasing knowledge and accumulating anatomic and experimental data, this simple clinical classification of brain injuries was soon complicated by the recognition of new pathologic conditions, and it became evident that the words "concussion" and "compression" stood only for complex symptom-groups of a generic character, which embraced a variety of anatomic lesions.

The old classification was very simple and easy of comprehension. If the intracranial space was diminished by the intrusion of a fractured bone, serum, or extravasated blood or pus, it was *compression;* otherwise all symptoms were referred to a hypothetic vibration of the brain within the skull—a merely functional disorder produced by violence. But this distinction was too finely drawn, and between simple concussion and real compression there are several intermediary states or clinical conditions that result from a variety of lesions that are often very disastrous in their consequences, and that frequently may be distinguished from one another. It is in view of the almost constant presence of structural alterations in the brain-substance in the traumatic conditions that were formerly classed as pure concussion that clinicians are growing more and more reluctant to accept the existence of a purely functional disorder, such as concussion was supposed to be in former years, and are inclined to adopt a much more restricted and better defined application of this term. Hence what was formerly broadly described as "concussion," now embraces a variety of conditions, in which *contusion, laceration,* and *hemorrhage* are recognized as the dominant lesions.

As the sharp lines that at one time were artificially drawn between concussion and compression have been gradually obliterated in accordance with a better knowledge of the pathologic facts, so have the intermediary conditions of contusion, laceration, and hemorrhage assumed their true clinical value and importance.

Cerebral Shock or Concussion.—In accordance with present knowledge and with the views that prevail among the best authorities on the subject, the application of the word "concussion" is restricted to conditions of pure traumatic shock following head injuries in which the brain symptoms are of a purely dynamic character, indicative solely of vascular disturbances in the endocranial circulation, and so transitory in duration that they preclude the possibility of permanent organic lesions. As the mechanism of its production is probably different from that of ordinary surgical shock, as this is brought about by traumatisms in other parts of the body, it must be recognized as a clinical entity that has the right to separate existence by the side of the graver states known as general contusion, laceration, and hemorrhage. It must be recognized, however, that while concussion may exist as a form of shock, its presence is so intimately linked with grave organic lesions that it is practically impossible to separate it from such conditions when they coexist in complicated cases. It is, therefore, only by the careful observation of individual cases, and often only after a sufficient length of time has elapsed after the injury, that one can eliminate shock or concussion ("stunning," as it is called by the laity) and establish the existence of the graver states that are recognized as contusion or "bruising" of the brain.

It is especially those frequent cases of head injury in which there is no recognizable fracture of the skull, or when this occurs without depression, and in which partial or complete unconsciousness exists without definite localizing symptoms, that are likely to trouble the practitioner for an exact diagnosis or a satisfactory interpretation of the underlying conditions. Take, for instance, the following case: A man is struck a blow on the head, or he falls; he is temporarily stunned—that is to say, the brain is so shaken up that its functions have been temporarily arrested; at least, something has happened to it of sufficient importance to suspend the intelligence. With this temporary unconsciousness there is pallor; the pulse quickens and flickers for a few moments; phenomena like syncope ensue; the respirations are rapid, shallow, irregular; in a few minutes more he arouses; is dizzy; he gets up; slowly regains possession of himself; has a certain amount of nausea, and then for the rest of the day, or for a short time afterwards has headache, and the disturbance is over. This

is the simplest form of brain shock or concussion. It is followed by no appreciable consequences or evidences of permanent lesion.

Contusion.—The differences between concussion or shock and contusion are, as previously indicated, due to differences in the degree of violence with which the injury is inflicted. The mechanism of their production is the same; at least, when the generalized forms of contusion are considered. In contusions there are positive anatomic lesions, which may be limited to a circumscribed area, or, more frequently, disseminated throughout the brain and its membranes. The meninges, cortex, subcortical brain-substance, and the ventricles may be separately involved, but more often all these are affected simultaneously by the same process. The contusion may be so violent that a part of the brain and its membranes will be transformed into a thick magma of mushy consistency, in which the various anatomic elements are indistinguishable. This is frequently the case in compound comminuted fractures, gunshot injuries, and crushing blows with blunt instruments; in other cases the evidences of contusion are scarcely appreciable, and only the experienced pathologist will be able to recognize the minute lesions that characterize it. This is particularly true of those fatal cases in which, apart from general hyperemia and edema, only a few punctiform hemorrhages are observed in the floor of the fourth ventricle or in the substance of the medulla. The essential lesions in the general forms of contusion are:

1. General hyperemia of variable intensity.

2. General parenchymatous edema of the brain-substance. This edema is variable in amount, sometimes appreciable only after some delay and after close inspection upon section, and at other times so profuse that the fluid can be squeezed from the brain by the hand, as from a sponge. In marked cases of contusion considerable exudation follows soon after the accident, causing the ecchymosed and thrombosed brain-substance to swell and become edematous; this may speedily subside in the less severe cases, but in the more serious contusions spreading edema often follows in the wake of the capillary and venous stasis induced by vasomotor pareses, multiple thromboses, and disseminated extravasations. The pressure caused by this primary swelling of the tissues also interferes with the circulation in the superficial veins of the pia mater; this, in turn, intensifies the tendency to serous transudation and edema, and in this way a general interstitial compression of the brain elements results, which is expressed clinically in the signs of compression and coma. This spreading edema is a very important lesion; it establishes a distinct link between severe contusion and compression from extensive traumatism, and explains the mechanism by which cases of brain injury in which signs of contusion or laceration alone exist pass rapidly into a state of profound coma, with the typical sign of compression from extrinsic causes. It should be remembered that degenerative changes will follow in the brain-substance from a prolonged interference with its circulation and nutrition; yellow softening occurs, which is indicated by the presence of a pulpy, yellowish mass containing fat-granules and disintegrated nerve-elements, soft enough to be washed away by a stream of water.

3. Punctiform or miliary hemorrhages, never exceeding the size of a buckshot (anything larger than this is due to laceration and not to contusion).

4. Capillary thrombi, which are disseminated throughout the cortex or cerebral substance.

Laceration.—Intimately associated with the lesions of contusion are lacerations of the brain-substance, which vary exceedingly in extent and importance. These lacerations may be cortical or subcortical, single or multiple, trivial or important. Lacerations may be so extensive that not only an entire lobe, but a greater part of a whole hemisphere may be involved. In other cases they are scarcely larger or more important than the most inconsiderable limited contusions, from which they are distinguishable only by the great amount of hemorrhage involved. Between these extremes they present every gradation of destructive injury. Lacerations, like limited contusions and indirect fractures, almost invariably occur at points directly opposite those at which force has been applied. They occur usually at the base of the brain, and by far the largest proportion is observed in the inferior surface of the frontal or temporal lobes. When lacerations are extensive, death ensues, in the majority of cases, long before sufficient time has elapsed for cicatrization. The process of repair is very slow. After the lapse of several months lacerations have been found to be still distinctly limited, uncontracted, softened, rusty in color, and without regenerative changes. The fatalities that immediately follow intracranial injury with laceration are probably to be ascribed to concomitant hemorrhage or to general contusion; those in which the laceration is the essential cause of death occur during a period which may extend from the end of the first 48 hours to 6 weeks (Phelps).

Symptomatology.—At the bedside it is practically impossible to distinguish between the effects of pure shock, general contusion, multiple minute lacerations, or capillary hemorrhages; at least in the beginning or immediately after the infliction of the injury. It is only when the stupor is very profound from the beginning, and irritative (convulsive) signs or paralytic manifestations that point to injury done to special areas of the cortex; or, again, when the visible external injury of the skull is such (depressed comminuted fracture) that it must unavoidably implicate the brain, that a positive knowledge is had that contusion exists. General contusion of the brain, it must be remembered, is one of the most frequent of brain traumatisms; few injuries of the head sufficiently severe to produce unconsciousness are free from it, either as a dominant condition or as a complication. On the other hand, an injury that is serious enough to cause contusion or laceration of the brain must have sufficed to produce shock or concussion. The essential signs are partial or complete unconsciousness; a rapid, feeble pulse; quick, shallow respiration; pallor of skin; copious perspiration; muscle

incoordination, with frequent lack of sphincter control; occasional vomiting; and variable pupils, which usually react to light. This state, when uncomplicated, usually passes away with reasonable promptness, especially when aided by proper treatment. "When stupor or unconsciousness persists for several hours, and new symptoms are superadded to those of shock, there is every reason to believe that the intracranial condition is one of contusion, and not of shock. When, for instance, mental agitation changes into delirium, when the rapid, feeble pulse becomes stronger and slower, the respirations deeper, the limbs move in incoordinate ways, the speech is disturbed from muscle incoordination, the patient selects wrong words; or when the mental condition becomes more serious, and stupor or coma takes the place of delirium, while external irritants have gradually diminishing effects, and when the pupils gradually enlarge, while failing to respond to light, it may be said that the condition of contusion is making itself apparent. If along with muscle uncertainty there is also much spasm and rigidity in particular peripheral groups, the evidence to this effect is certain" (Park).

From the preceding statements it is evident that the clinical picture of contusion, with its frequently associated lacerations and small hemorrhages, is extremely variable, and presents no absolutely fixed or unchangeable traits. The symptomatic manifestations of this condition must, in fact, vary with the extent, the character, and the intensity of the anatomic lesions upon which it is dependent. Just as with the lesions themselves, there is no distinct line of demarcation that separates pure concussion on the one hand, from the graver lesions that constitute general compression; they imperceptibly blend or merge into one another, and it is only when the extremes are contrasted that the distinctions can be readily made.

The course, duration, and termination of contusion must, for the same reasons, be as variable as the individual cases themselves. In the most favorable and simple cases vascular equilibrium is promptly restored; the hyperemia and edema due to vasomotor paresis disappear, and capillary hemorrhages and ecchymoses are absorbed; a complete psychic and physical restoration takes place in a few hours or days. In other less favorable cases the patient remains in a doubtful condition for days, weeks and months; the primary total unconsciousness is changed to stupor, lethargy, or somnolence, from which the patient gradually recovers. In others the stupor of shock changes into mental agitation and delirium, with great irritability, in which violent paroxysms or explosions of irritation (anger, violent language) alternate with long intervals of sleep, during which urine and feces may be voided involuntarily; the patient usually lies curled upon his side, and can only be moved by loud yelling into his ears or by other means of stimulation. This latter is the condition especially described by British authors as "cerebral irritation." It is usually associated with laceration and other injuries of the frontal lobes. From this state the patient may recover completely or partially; some of the physical or psychic functions may remain impaired; focal epilepsy or insanity may also remain as relics of the damage done to the brain. In still other cases the state of contusion slowly or rapidly passes into that of acute leptomeningitis or cerebritis (meningoencephalitis); localized abscess of the brain may form; or, more often, if the meningeal infection dominates, delirium, photophobia, rising temperature, rapid pulse, and other inflammatory signs, soon followed by coma, produced by seropurulent effusions and exudates, closes the picture, indicating that septic infection has fatally invaded the bruised area of the brain. In a last group of cases the effects of contusion are immediately fatal. These were the fulminating or "foudroyant" cases of concussion of the older clinicians; they are now recognized as fatal cases of contusion in which the initial violence has involved the medulla or the floor of the fourth ventricle, when localized lacerations or extravasations mark its occurrence.

Diagnosis.—In summing up the diagnostic features of general contusions the following considerations are important:

1. **The time that has elapsed since the injury** is of diagnostic value (unconsciousness that lasts for hours means more than shock; it means structural lesions).

2. The first conclusion is accentuated and made positive by the occurrence of new **physical and focal** (sensory or paretic) **disturbances** after reaction has set in.

3. There is **abnormal rise in the temperature** after reaction has set in; the temperature is subnormal in shock. It may rise from 100° to 105° F. or more in general contusion, but any temperature of 103° F. or more that persists after reaction means that, in addition to contusion, marked lacerations coexist. The diagnostic value of the primary and persistent rise of temperature in head injuries as an almost constant accompaniment of brain laceration has been brought to light by Phelps' researches, and should be remembered—it is almost pathognomonic in its significance. The use of the thermometer is also of great prognostic value. In over 500 case of head injuries carefully studied by Phelps none recovered in which the temperature rose to 105° F. and persisted at this figure. This rise is not due, necessarily, to injury of hypothetic thermogenetic centers but is an indication of a generalized nutritive disturbance; it is significant of the extent rather than of the localization of the injury. It is interesting to observe that in the cases of general contusion in which the highest temperatures were obtained—105° to 109°—the fornix, the optic thalami, and the corpora striata were coincidently involved. This primary rise of temperature must be carefully distinguished from the secondary elevations occurring sometimes days or weeks after reaction has taken place, and which usually indicate, if persistent and progressive, that pyogenic infection has penetrated the cranium.

In localized contusion and laceration bilateral variation in the axillary temperature has been observed. "It may be said, with some reserve, that when a difference exists, the temperature is

rather more frequently 0.2° higher upon the side opposite than upon that which corresponds to the seat of cerebral injury" (Phelps).

4. **Pulse and Respiration.**—After the effect of the initial shock is over the pulse becomes slower and fuller. The respirations, on the contrary, when disturbed, are usually hastened, even though the pulse may be retarded. The want of symmetry in the radial pulse is not rare in head injuries. It is most frequently a primary aberration. The variations in the radial pulse affect its strength and fulness, not its frequency, and it is in all other respects symmetric. The pulse is sometimes stronger and fuller upon the side opposite the site of injury, but this is not constant. If localized hemorrhages sufficiently extensive to produce general compression occur coincidently with contusion, especially if the medulla is involved, respiration may be immediately and fatally retarded. Cheyne-Stokes breathing is associated most often with fatal general contusion and laceration and edema, when these implicate the medulla; it is usually the forerunner of dissolution and death.

5. **Special Peripheral Signs.**—Limited paralyses or convulsive movements, rigidity of the extremities, disturbances in sight, hearing, smell, and tactile sense, indicate that special centers in the cortex or in other well-differentiated areas have been involved in the general contusion and laceration, and their topographic significance in the brain is to be considered in the light of the knowledge furnished by experimental physiology.

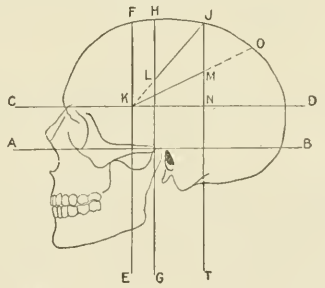
6. **Loss of bladder or rectal control** may occur in all forms of general contusion, and even in simple shock, from the loss of cortical inhibitory impulses. Any lesions of the cerebral parenchyma may give rise to these symptoms, though it is possible that in future it may be recognized as a disturbance of a special cerebral center.

7. **The condition of the pupils** is so variable in general contusion that no special importance can be attached to their appearance, except that marked permanent asymmetry is valuable as a sign of compression from epidural hemorrhage, and that fixed, immovable, dilated pupils usually indicate localized compression of the hemisphere or motor oculi nerve (Hutchinson's sign) on the side corresponding to the pupillary dilatation; and that bilateral dilatation, with fixation of the pupils, indicates general compression of the brain, and is of grave prognosis.

Cerebral Localization.—"If a patient receives a blow upon the head, and it is found that localized paralysis is present, we conclude that there exists in the cortical center a laceration of some severity corresponding to the muscles implicated. If almost immediately after the injury there is a distinct spasm affecting a localized group of muscles—a monospasm— it may be concluded that hemorrhage is going on from the lacerated brain-substance, or that there is a breaking down of the tissue of the center corresponding to the affected muscles. If the monospasm extends, first affecting one side of the body and finally both sides, so that the attacks assume the form of true epileptic fits, it is probable that the extravasated blood is extending over the surface of the brain and irritating more or less widely the whole motor area" (Erichsen). Should there be motor aphasia, a lesion of the posterior extremity of the third left frontal convolution is indicated. Should there be facial spasm or paralysis, a lesion of the lower third of the ascending frontal and of the contiguous part of the posterior end of the second frontal convolutions is probably present. Should there be paralysis of the arm—a brachial monoplegia—the middle portion of the ascending frontal lobe is probably affected. Should there be paralysis of the lower limb, the lesion probably involves the upper end of the ascending parietal, and the superior parietal lobule lying behind it, as far as the margin of the longitudinal fissure.

Briefly, therefore, a cortical lesion may be distinguished from a central lesion as follows: In the *cortical lesion* the paralysis, although it may occur immediately after the accident, often does not appear for some time. It is incomplete and localized, and probably affects only one limb or a single group of muscles. In the *central lesion*, on the other hand, the paralysis occurs immediately after the injury; it is more complete and extensive, and the whole of one side, at least, will probably be paralyzed (Walsham).

Kronlein's method of craniocerebral topography is as follows: A horizontal line, A B, is drawn through the lower margin of the orbit and upper margin of the external auditory meatus. Above and parallel with this is a second line, C D, on a level with the upper margin of the orbit. Three vertical lines are now drawn, the first passing through the middle of the zygoma, E F, the second, G H, through condyle of the lower jaw, and the



Kronlein's Method of Craniocerebral Topography.

third, T J, through the posterior margin of the mastoid process. A line drawn from K to J corresponds between L and J to the fissure of Rolando. The line K M, which bisects the angle J K N, corresponds to the horizontal limb of the fissure of Sylvius. If this line is continued backward to the middle line of the head it indicates approximately the location of the parietooccipital fissure. K and N are the points to trephine for the anterior and posterior branches of the middle meningeal artery.

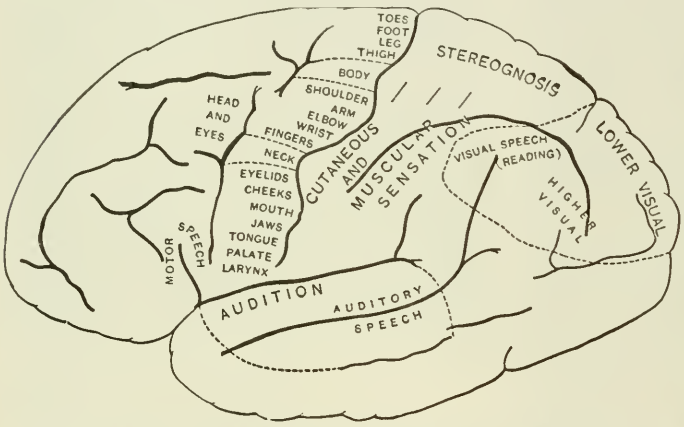
Treatment.—"No injury to the head is too slight to be despised or too severe to be despaired of" is an aphorism in surgery that must always be borne in mind when dealing with these cases. This assertion is particularly true of those cranial

injuries in which the external skull lesions are of very slight extent. All such cases should be regarded as serious and dangerous until distinctly proved to be the contrary. Inasmuch as time is the main element by which to ascertain this fact, all such patients should, if not actually put to bed, at least be kept quiet and under observation for no less than 24 hours. The usual primary indications are to combat shock, to arrest hemorrhage, to secure asepsis, and to meet any localized lesions by such surgical measures as may be indicated. When reaction has set in, the work of the surgeon is limited to counteracting excessive endocranial hyperemia and secondary inflammations, and, lastly, to promoting the absorption of effusions and exudates. If the patient is seen in the primary collapse of shock, when he is algid, pale, and in a syncopal condition, begin by putting him in the recumbent position with the head low. Apply ammonia by inhalation to the nostrils. Cover the patient with blankets and warm the feet, legs, trunk, and precordia with hot-water bags and fomentations. Dashing hot water over the head repeatedly, as recommended by Horsley, is a valuable restorative. If the pulse is weak and deglutition difficult, counterirritants (mustard plasters) to the extremities, and an enema of warm black coffee or of hot saline solution containing a teaspoonful of beef-juice, to be repeated every 3 or 4 hours, are indicated. Aromatic spirit of ammonia, Hoffmann's anodyne by mouth, and hypodermic injections of strychnin (1/40 to 1/15 of a grain), atropin (1/150 to 1/175 of a grain), digitalin (1/100 of a grain), nitroglycerin (1/100 of a grain), will materially aid in stimulating the circulatory, respiratory, and vasomotor centers.

If the degree of collapse is very great, alcoholic stimulants may be cautiously administered by mouth (champagne, brandy, whisky, etc.), hypodermically, or in the coffee enema. The objections to alcohol in cerebral shock and contusion are (1) that the blood pressure is raised and ruptured vessels may commence to bleed, and (2) that it tends to cause hyperemia of the brain and to favor the occurrence of spreading edema.

As a last resource, intravenous saline infusion may be resorted to. The infusion must be as hot as the hand can comfortably bear it, and should be of the decinormal strength sodium chlorid, 0.7 per cent.; or, approximately, 40 grains to 1 pint of water). This is the most powerful circulatory restorative at our command, but it should be used cautiously, not to its maximum effect, for the same reasons given against the too liberal use of alcohol. If saline infusion fails to improve the circulation, the prognosis is very gloomy indeed, and there is scarcely any prospect of recovery.

If respiratory failure is marked, as in some cases of bulbar contusions, artificial respiration may be resorted to with the greatest advantage, and for an indefinite period of time, by means of the Fell-O'Dwyer apparatus; in this way respiration may be kept up, as in opium narcosis, until the nutritive equilibrium of the brain is restored. With the advent of reaction and the reestablishment of a comparatively normal pulse and temperature, the earliest possible attention should be given to the cranial and intracranial lesions.



Localization of Function on the Cerebral Cortex; External Surface.—(*Starr.*)—(*From Woolsey's Surgical Anatomy.*)

The head should be shaved, shampooed, and brushed with green-soap lather, and prepared with as much care as if a primary intracranial operation were contemplated. The ears, nose, and pharynx should be carefully examined for blood, cerebro-spinal fluid, or brain matter, and cleansed with the greatest thoroughness in order to diminish the risk of infection. The auditory canal demands especial attention, as it is one of the most frequent avenues of secondary encephalic infection. The auditory canal should be plugged, after cleansing, with an antiseptic (sublimate) absorbent cotton tampon or with iodoform gauze. Unfortunately, asepsis of the nose and mouth and pharynx is always imperfect, and, therefore, of comparatively little value.

If fracture of the skull exists, the indications will vary in accordance with their simple or compound character. In compound fractures the indications are clear and positive; the external wound should be thoroughly disinfected by antiseptic irrigation with a mild germicide (lysol, 2 percent; formol, 5 percent; carbolic acid, 2 percent; acid sublimate, 1:4000) and should be enlarged as freely as may be necessary in order to remove any visible foreign bodies or loose fragments of bone. If there are any depressed fragments, they should be elevated and replaced if still adherent to the pericranium, or removed entirely if completely detached. In simple or closed fracture the attitude of the surgeon should be most guarded and conservative, as it is easy to convert a simple condition into a grave and fatal state

by hasty interference, which may be followed by infection. The rules that govern the surgeon in dealing with the various kinds of fractures are separately detailed elsewhere, and will not be repeated here. It is very important, however, that no operation be undertaken so long as profound shock exists. This rule is as imperative here as in operation for injury elsewhere in the body. The only exception is in a case of localized hemorrhage, when the lesion itself is the chief cause of the systemic depression. All such operations should be performed, whenever practicable, under the influence of cocain or eucain anesthesia, with weak (Schleich's) solutions; hemostasis and anesthesia being maintained during the operation by a tight rubber tube or band encircling the head on a level with the glabella in front and with the external occipital protuberance behind.

After disinfecting, draining, and dressing any wounds that may exist in the scalp or skull a complete antiseptic head-dressing should be applied to permanently protect the wounded area from infection. After all these preliminaries have been attended to, the patient should be kept under constant observation, with special reference to the secondary development of new symptoms that might indicate the distinct localization of lesions, with a view to further operative procedures. If pressure-symptoms, monoplegias, hemiplegias, a symmetrically dilated pupil, and mental condition should point to localized intracranial (especially epidural) hemorrhage, operative interference is immediately indicated to expose and ligate the injured vessel and remove the clot.

If the symptoms simply continue to point to a general contusion or laceration, the operative indications cease, and the rôle of the practitioner is limited to combating secondary intracranial hyperemia and edema, with its attendant symptoms—fever, headache, delirium, convulsions, scattered and irregular compression symptoms (from exudates and effusions), and, lastly, the comatose state itself. The treatment then resembles that used for a subacute form of meningocerebritis; thus, in the hyperemic state with delirium or simple cerebral irritation, an ice-helmet, Leiter's coils, or ice-bags should be applied to the head; leeches to the mastoid or temples; wet cups to the back of head, to the extent of drawing 10 to 12 ounces of blood, especially if the pulse is growing slower, more tense, and fuller.

It is also important to secure intestinal asepsis and to diminish the dangers of autointoxication. For this purpose give calomel, followed by salines, until the intestinal contents are thoroughly evacuated; give water in abundance, to favor renal elimination and to dilute toxins in the blood. Give only milk and moderate quantities of predigested food and fruit-juices, with the same object in view. If there is hyperthermia, with evidences of headache, insomnia, and great retinal and auditory sensitiveness, the bromids, with or without chloral hydrate, will be indicated, given alone or combined with the usual analgesic antipyretics, phenacetin, antipyrin, lactophenin, and such hypnotics as trional, sulphonal, etc. After the acute congestive symptoms are over, but the patient lingers for days and weeks in a doubtful state of torpor, somnolence, or lethargy, with persistent evidences of localized exudations, potassium iodid may be given, with the hope of favoring absorption.

In long, lasting cases special care should be observed in maintaining the best hygeinic surroundings about the patient. Bed-sores are easily developed, and cystitis frequently follows the careless use of unclean catheters. Consequently the patient should be bathed frequently, and if catheters are required to evacuate the bladder, they should be subjected to the most scrupulous sterilization. See Skull (Fractures, Surgery), Brain (Inflammation).

Compression.—Like concussion, this is a generic term applied to a distinct group of symptoms that may be produced by a variety of causes, all of which lead to the same effect: viz., to a notable increase in the intracranial tension and abnormal pressure upon the brain as a whole. "The brain, blood, lymph, and cerebrospinal fluid completely fill the cranial cavity, and there is normally no room for anything in the shape of a foreign body without seriously affecting the equilibrium between the brain and the contents of the spinal canal. When, however, a foreign substance exerts pressure upon the brain, the results are invariably the same—be this substance what it may—and compression signs will follow no matter what the compressing cause" (Park).

It is only the *sudden* increase of pressure that causes the characteristic symptoms of compression, and not the chronic, very gradually developing diminution of space, due, for example, to intracranial tumors, increase in the amount of cerebrospinal fluid (hydrocephalus), enlargement of the brain and diminution in size or form of the skull. In all such chronic conditions there is some compensation made by absorption of cerebrospinal fluid, by atrophy of the skull, by yielding of the cranial walls, etc. In sudden encroachments into the cranial capacity by depressed fractures, clots, foreign bodies, etc., there is a certain amount of compensation and accommodation by the passage of some of the cerebrospinal fluid from the skull into the vertebral canal; the latter, owing to the ligamentous connections between the different vertebræ, being capable of some expansion; whereas the other, on account of its rigid, unyielding, bony case, cannot expand. If, however, the intracranial pressure oversteps a certain limit, the tension of the cerebrospinal fluid becomes so great that the circulation in the brain and its membranes becomes impeded.

In dealing with this subject a clear distinction must be made between *pressure* and *compression* of the brain. A certain area of the brain may be pressed upon by a depressed bone, a clot, an abscess, a small tumor, or a foreign body, and yet not give rise to the symptoms of compression. The multiple and small hemorrhages and ecchymoses of contusion and laceration do not, in themselves, give rise to compression; but the associated edema and capillary stasis from vasomotor paresis

give rise to anemia and a vitiated (toxic) circulation, which simulate the phenomena of compression if the lesions are extensive enough. Compression means a general mechanic encroachment upon the endocranial capacity, and not localized pressure over a definite, limited area; when such pressure exists, the mere mechanic displacement caused by it is easily compensated by the dislodgement of the cerebrospinal fluid and by vascular adaptation.

Symptomatology.—The clinical picture of compression will vary in its incipiency according to the nature, seat, and extent of the compressing cause. In the fully developed state the signs and symptoms are identical, no matter what the cause may be. The signs of compression may come on gradually and very slowly, as in abscesses and tumors of the brain; they may be instantaneous, as in depressed fractures with violent contusion, laceration, and hemorrhage. There are, therefore, acute and chronic forms of compression.

When compression is general and fully developed, the symptoms are those of coma, and as such they are unmistakable. A man is struck a blow on the head; his skull is crushed in; one or more fragments of broken bone are driven in; the brain and its membranes are torn, bruised, and lacerated; the brain is not only bruised, but compressed. Under such circumstances the patient is felled to the ground senseless. No amount of shouting or shaking will arouse him. Such a patient has dilated pupils, which are wide open and will not respond to light. He snores in respiration, and his cheeks puff just as a patient does under the profound anesthesia of ether. He sweats profusely. His pulse is extremely full and labored, sometimes sinking as low as 50, 40, or even 30 beats a minute. It is regular, full and bounding, but extremely slow. He is practically dead to consciousness. As Bergmann has aptly said, "in the night of the senses" produced by pressure upon the cortex, only the medulla and spinal ganglia are awake. Everything is dead above the bulb, and even the vigilance of this sleepless sentinel is partially lessened (in the more extensive injuries) by the impairment of some of its most important functions, as shown by the diminution of the glossopharyngeal reflex and by difficult deglutition. Not only is there a general and absolute relaxation, but the muscular system of the patient is paralyzed, and he lies an inert, motionless mass. In this purely automatic condition, in which life is maintained solely by the persistence of the respiratory and circulatory functions, the immediate borderline that separates life from death is reached, and unless prompt relief is obtained, dissolution is inevitable. The final extinction of the bulbar centers need not take place immediately, but this state may continue for hours or a few days, when the patient gradually sinks, and dies as a result of the cessation, first, of the respiration, and, lastly, of the circulation. But between this comatose state, in which the patient is practically lifeless, and the condition of the patient temporarily stunned—who is quickly roused, with flickering pulse, irregular pupils, nausea, etc.—the contrast is marked and unmistakable.

Cases of simple shock and of the milder degrees of contusion and laceration, with their localized peripheral manifestations in the organs of special sense and in individual groups of muscles, are usually easily distinguished from those of pure compression; but in the more general and violent forms of contusion, laceration, and hemorrhage, the symptoms begin to run together, and culminate in a comatose condition in which it is impossible to establish any difference between them and those of compression as produced by more direct mechanic agencies. When the comatose state is fully established, it is only by a knowledge of the antecedent history, of the nature of the injury itself, and of the earlier symptoms that it is possible to differentiate between the various primary conditions that have led to the compression.

Compression is simply a *result*—a condition that, in itself, is not significant or indicative of any particular cause. It is, therefore, far more profitable to study the clinical phenomena of compression etiologically and analytically than synthetically —that is, they should be studied from the point of view of the individual causes that give rise to them. Nevertheless, the phenomena that merely indicate a general encroachment upon the cranial capacity, regardless of cause, are worthy of separate consideration.

The phenomena of compression, as studied experimentally and clinically, are the same, and may be conveniently divided into 3 stages:

1. *The stage of cortical and bulbar irritation:* irritability, erethism, restlessness, visceral disturbances (nausea, vomiting, etc.), cephalgia, delirium, congestion of the face, narrow pupils, convulsive movements; pulse begins to be hard and slow, indicating increased arterial tension; irritation of vasomotor and pneumogastric centers.

2. *The paralytic stage,* indicating general cephalic compression: the irritability and excitement of the previous stage change to torpor, lethargy, somnolence, from which the patient never rouses, or is awakened with great difficulty. Ophthalmoscopic examination of the fundus oculi clearly reveals the condition of the endocranial circulation. There is marked venous turgescence of the central retinal veins, followed by edema of the retina and optic disc, with concomitant arterial anemia of the retina. "Choked disc" is then typical. The pupils are symmetrically dilated, though bilateral dilatation is preceded by asymmetry and mydriasis on the side corresponding to the primary lesion. Monoplegias and hemiplegias occur, according as the pressure is made upon a limited area or upon an entire hemisphere. As the compression increases and becomes general throughout the encephalon, the limited or localized paralyses and convulsive movements disappear, as the focal symptoms are lost in the comatose state that follows. Then, as the vasomotor centers and pneumogastric centers are stimulated to overcome the increasing endocranial resistance, the pulse becomes progressively slower and harder; the arterial tension is greatly increased; the carotids pulsate visibly; the respirations are deep and

slow; there is stertor (snoring) from paralysis of the palatine and pharyngeal muscles, which usually flap with the air-current; there is retention of urine, involuntary discharge of feces, and the entire voluntary muscular apparatus becomes paralyzed through compression of both Rolandic areas. Temperature rises above normal, the rise varying according to the nature of the compressing cause.

3. *Stage of Dissolution.*—This coincides with the final exhaustion and surrender of the basal and bulbar centers; the hard and slow pulse of the previous stage becomes soft, rapid, irregular, and compressible; the respiration is superficial, and the Cheyne-Stokes type of breathing is established. The face is livid and cyanotic from defective respiration; the pupils are widely dilated, fixed, and immovable; deglutition is impossible and total anesthesia and paralyses are followed by failure of the respiration and death.

General Causes of Compression.—The reduction in size of the cranial cavity that is required to produce compression may be obtained, according to Park (1) by lessening of its cavity as a result of alterations in the configuration of its surroundings, whether this is diffused or local; (2) by increase in the quantity of the cerebrospinal fluid or in the size of the brain itself, which latter condition may be produced by edema, by exudation of serum, or by hypertrophy of the brain; (3) by foreign bodies that may enter the skull from without; (4) by pathologic conditions—such as hemorrhages, collections of pus, and tumors—that may be produced either from the brain-substance, its membranes, or its vessels, or that may arise from without and produce other disturbances indirectly and in a secondary way—*i. e.*, depressed bone.

The causes of compression that arise from traumatism or injury are summed up in the following conditions: (1) Compression by extravasated blood; (2) by fractures of the skull with depression, or by foreign bodies penetrating from without; (3) by products of acute infectious inflammation due to septic infection from without.

Diagnosis.—The differential diagnosis of compression, as regards the endocranial lesions that give rise to it, and of other nontraumatic conditions of which the comatose stage is a final and dominant manifestation, is of the greatest practical importance. As Phelps says: "The case of an unknown man found unconscious in the street, taken to a hospital, retained in a medical ward, and first discovered in the dead-house to have been the victim of accident or violence is not exceptional."

The primary symptom that overshadows all others, in all forms of intracranial injury, and that at the same time is the most striking of various other morbid conditions, is coma or some degree of unconsciousness. It is natural that the identity should be, as it is, the most fruitful source of error in diagnosis. The number of idiopathic diseases in which coma is characteristic is large; possibly 20 or more. The vast majority of these need not claim the attention, as their differentiation is not difficult. The greatest interest centers in the differential diagnosis of apoplexy, uremia, alcoholism, and opium narcosis, in which difficulties are sometimes so great, and erroneous conclusions so often reached, as to demand special consideration.

When the practitioner is called upon to attend to some unknown person who has been accidentally discovered in an unconscious or comatose condition, he should bear in mind the medicolegal, the diagnostic, and the therapeutic relations of the case. For the sake of possible judicial proceedings, as well as for diagnostic purposes, he should take a rapid survey of the situation, of the surroundings of the patient, and note the presence or absence of blood, vomitus, excreta, etc. He should note the position and attitude of the patient, the nature of the ground, etc. He should try to rouse the patient, in order to elicit information and to determine the degree or depth of the unconsciousness. A most thorough and critical examination of the head and body should be made; the skull should be examined for contusions, lacerations, fractures, or other evidences of local violence; the tongue should be examined for bites—so often self-inflicted by epileptics; the reflexes, the muscular resistance, and the sensibility should be tested for general or partial paralyses and anesthesias; the state of the pupils, of the pulse, and of the respiration should be noted; the urine drawn and tested for albumin or sugar; if in doubt, the stomach contents should be siphoned or pumped out to determine the character of the gastric contents, and to test later on for alcohol or poisons. Lastly, if, after a thorough examination, there is still doubt, the patient should be put to bed and kept under the observation of a trained nurse or of an intelligent person who will keep account of further developments.

In investigating for traumatic conditions the possible existence of other nontraumatic states should never be lost sight of.

In *apoplexy*, which is due to a spontaneous intracerebral or intraventricular hemorrhage—from atheromatous lesions of the lenticulostriate artery—the picture of coma is complete; but the absence of external marks of violence, the age, the atheromatous condition of the arterial system, and the temperature will usually help to distinguish it. In apoplexy the temperature is at first subnormal, and scarcely rises above the normal standard, except when death ensues. In traumatic hemorrhagic lesions there is subnormal temperature while shock lasts, but an abnormal rise follows immediately with reaction, whether recovery or death impends, and is practically continuous while the result remains in abeyance (Phelps).

In *opium-poisoning* the pupils are strongly and symmetrically contracted, the respiration is markedly and progressively diminished in frequency, and there is a pause between inspiration and expiration; the patient can frequently be roused by powerful cutaneous irritation with electric brush and faradic current; and the intelligence is only torpid, not lost; there is no incoherence, and articulation is unaffected. The breath may have the odor of opium.

In *uremic coma* the face is pale, white, edematous; the breath sweetish or ammoniacal; the pupils

dilated, sluggish, and irresponsive to light; the patient can rarely be roused; the pulse is hard, but rapid and irregular; as a rule, the respirations are frequent and irregular; the urine is albuminous. If there is diabetic coma, the presence of sugar in the urine will clear the diagnosis.

In *alcoholic coma* the breath is alcoholic, the pupils normal, the face flushed, the surface cold, and the patient can usually be roused unless very deeply comatose; his speech is then incoherent, he is irritable, and the articulation is indistinct. Respirations are regular and without stertor; the pulse frequent, weak, but it becomes slow as coma increases; the temperature, when the coma is profound, is markedly subnormal, often not over 96° F., the fall in the temperature being directly proportional to the degree of intoxication (Phelps). The urine may contain alcohol. The importance of the correct diagnosis of alcoholic coma cannot be overestimated, because it is the condition which is most frequently confounded with intracranial traumatism. It is also essential in approaching the diagnosis of a case of alcoholic coma "to divest the mind of all preoccupations and to realize that an unconscious man with a scalp wound is not necessarily drunk, and that even a drunken man may be so seriously injured as to require surgical treatment." The low temperature of pure alcoholic coma is almost a pathognomonic sign, and should not be forgotten (Phelps). See Coma.

In the differential diagnosis of the several primary traumatic lesions that give rise to general compression and the comatose state, the history of the case, the character of the injury, the cause, the duration, and the manifestations presented before the total unconsciousness has occurred are of prime importance. When these data are available, the greatest interest is centered in the recognition of *hemorrhage*, and especially in its localized meningeal forms. The diagnostic importance of hemorrhage cannot be overestimated. It is the cause of the brain symptoms in 50 to 60 percent of all cases of brain injury, and in one-third of this percentage it is the direct, if not the sole, cause of a fatal termination (Phelps). Of the intracranial hemorrhages, those furnished by the middle meningeal artery are by far the most important, as they constitute no less than 85 percent of the operable cases. When intracranial hemorrhage exists, its occurrence, at least in the epidural forms, is almost invariably preceded by a period of lucidity, which may last a few minutes, hours, or days. This lucid period intervenes between the reaction from shock and the development of sufficient extravasation to excite compression. In the extradural and most frequent forms this interval of consciousness after injury is longest, because of the adhesion of the dura, which resists the spread of the blood. If, however, primary unconsciousness persists or is greatly prolonged, its continuance may be due either to the severity of the lesion or to a complicating hemorrhage; whether the one has persisted from the beginning, or has at any time been replaced by the other, or whether both exist together, can be determined, if at all, only by the study of all the symptoms presented. In those obscure cases in which the practitioner has no previous history to guide him—nothing except the knowledge that the patient who lies comatose before him has been hurt in the head—the value of the thermometer as a differential diagnostic agent, as taught us by Phelps' painstaking observations, is inestimable.*

Prognosis.—The existence of the typical, fully developed symptoms of compression is in itself, in all traumatisms of the brain, of the gravest prognostic significance. And when signs of bulbar lesions, with failure of the circulatory and respiratory centers, are apparent, the fatal issue of the case is practically certain. The prognosis becomes darker as the symptoms become general; more hopeful when they indicate localization and areas of limited pressure. The greatest fallacy lies in waiting for the general compression symptoms to develop. In traumatic cases all is centered in the probability of removing the compressing cause and relieving the intracranial tension. Under these circumstances a great deal will depend upon the judgment of the surgeon who is quick to see the opportunity for the intervention, and who will not operate too soon, while the patient is still suffering from profound shock, or wait too long, until the prolonged action of the compressing agent has led to irreparable degeneration and atrophic changes in the damaged brain. Another of the fallacies against which the inexperienced must guard themselves is the expectation of great immediate results after the apparent removal of the gross objective cause of the compression. This erroneous expectation is usually greatest in the operative treatment of markedly depressed fractures. The tyro often forgets in his enthusiasm that the fracture of the bone is not directly a source of danger, but that this resides in the lesions of the brain and membranes that are invariably associated with it. It is upon the manifestations produced by these that the practitioner must depend in formulating his prognosis. "The traditional cases in which, by the elevation of a depressed fragment of bone and the relief of compression, the patient, in the twinkling of an eye, springs from coma into consciousness and mental activity seem to be extinct." Instances will occur in which, by the opening of the cranial cavity and incidental elevation of en-

* "The primary temperature is above the normal standard in all forms of intracranial lesion, when it has not been depressed by general shock or by the effect of alcoholic excess. In cases of comparatively uncomplicated hemorrhage it will range from 98.5° to 99.5°, and will not subsequently exceed 100°, unless general cerebral contusion is well pronounced, when it may reach 101° or 101°+. If the essential lesion is cerebral contusion, the primary temperature is but slightly higher, but will rise progressively, and, in a certain proportion of cases, will be marked by remissions, which do not attend hemorrhages. If, then, after the lapse of an hour consciousness still remains in abeyance, a *stationary* temperature, but 1 or 2 degrees above normal, will indicate a hemorrhage of some profusion without serious cerebral injury; but a higher elevation, which constantly increases, with possible remissions, will point to a visceral lesion. If this increasing temperature does not exceed moderate limits, and its advance is slow, it will suggest a contusion alone, or with lacerations of small extent a still higher, early temperature (103° to 105° +), advancing rapidly and uninterruptedly, or without important remissions, is an almost pathognomonic indication of extensive and usually fatal lacerations."

croaching bone, cerebral function is presently restored; but, as a rule, the improvement that follows the removal of the primary compressing agent is gradual, and the probabilities of recovery will ultimately depend upon the extent and degree of the general and invisible lesions that have coincided with it. On the other hand, the extreme pessimism that is entertained by some ultraconservative surgeons is not always justified by the course of even the most sombre cases, in which the removal of gross objective causes of compression—bone, clot, or pus—will be followed by surprisingly favorable results.

Treatment.—In dealing with compression from primary traumatic lesions the practitioner is called upon to remedy the evil caused by the presence of four pathologic elements, which may appear singly or combined; fractured bone, extravasated blood, a foreign body, and a purulent collection. This last must be considered as a secondary complication, and should not be regarded in the light of a primary indication for which immediate action is demanded after injury. Each one of the first three primary conditions, or all together, may, and frequently do, coexist with contusion or laceration—the extent of gravity of which can be easily estimated. The treatment in each instance demands special consideration, but in its essence resolves itself into the removal of the dominant compressing cause, whenever this is practicable. The preliminary rules that have been laid down for the treatment of shock in the section on concussion and contusion, as well as those that refer to the immediate sterilization of the head, the injured areas, and all the available avenues of infection, have been sufficiently insisted upon not to require repetition.

When it is clear that the hemorrhage is from the middle meningeal artery, and it appears probable that no other serious injury of the brain has been received, the trephine should be applied, for the purpose of removing the clot and securing the bleeding vessel. The situation of the artery is about 1 1/2 inches behind the external angular process of the orbit, and over this spot a crown of bone should be removed. The dark clot that now protrudes at the opening should be turned out by some form of scoop, and if the bleeding artery is then seen, an attempt should be made to tie or twist it, or to compress it by plugging the groove in the bone in which it lies with a piece of aseptic wax or wood. If the bleeding-point cannot be reached, more bone may be cut away.

After the depressed bone or fragments have been elevated, the extradural clot removed, and the bullet or other foreign body extracted—if this is feasible—the efforts of the surgeon should be chiefly directed toward the maintenance of the asepsis and drainage already initiated in the preliminary treatment and during the operation itself. The postoperative treatment must then aim at the relief of the general contusion and laceration, which are generally improved by the diminished tension and the drainage afforded by the operation. Nature's efforts at repair must then be aided by judicious supportive treatment, and by such measures as have been previously recommended to combat the secondary inflammatory reaction and septic complications that are likely to follow. In the cases in which the operative treatment of the chief compressing lesion is impracticable, owing to the extent of the lesion or to the condition of the patient, the only course left the surgeon is to await developments, and, while waiting, to maintain the activity of the vital centers of the medulla and of the eliminating organs, with the lingering hope that the reparative process may be initiated and spontaneous recovery still take place.

See Skull (Fractures, Surgery), Brain (Inflammation), Gunshot Wounds.

BRAIN, SCLEROSIS.—See Insular Sclerosis.

BRAIN, THROMBOSIS AND EMBOLISM.—**Thrombosis,** or the formation of a clot in a vessel—an antemortem coagulation—is as a rule the result of chronic endarteritis, as seen in the aged, together with a slowing and weakening of the blood-current. Chronic alcoholism and syphilis are the usual causes when occurring in young adults.

Emboli, in the great majority of instances, result from endocarditis—cardiac emboli; small particles of the exudation being carried into the circulation and deposited in the brain. Emboli may also be derived from aortic aneurysm or from syphiloma of the great vessels.

The cerebral arteries may be obstructed by emboli or thrombi; the cerebral veins and sinuses by thrombi alone. The changes in the cerebral tissue are those of anemia of the part or parts supplied by the occluded vessels. The subsequent changes depend upon the anatomy of the vessels.

The vessel most commonly occluded is the left middle cerebral artery, which sends branches to the second and third frontal convolutions, the anterior and superior portions of the three temporal convolutions, the island of Reil, the parietal convolutions, part of the external and all of the internal capsule, the lenticular nucleus, and most of the corpus striatum—the motor centers.

Symptoms.—There are two distinct modes of onset: gradual, when the result of thrombosis; sudden or apoplectic, when due to embolism.

Cerebral thrombosis is most common in the aged. Persistent headache and vertigo, at one time severe and at another mild, are early symptoms. Next are alterations in the patient's character. He becomes irritable, morose, and despondent, with periods of absent-mindedness, disorders of vision, and impairment of memory. Speech may be hesitating and mumbling. There is impaired locomotion, the result of the vertigo, and of muscular weakness and trembling, followed sooner or later by hemiplegia, which may be preceded by sudden insensibility or occur gradually, the symptoms slowly proceeding to senile dementia and death from exhaustion; or, rarely, the symptoms are not so grave, and partial or complete recovery occurs after the hemiplegia, from establishment of the collateral circulation.

Cerebral Embolism.—The symptoms are sudden, but mild or grave in character.

Mild Variety.—There are sudden and severe vertigo, confusion of mind, muscular twitchings, usually one-sided, and vomiting, followed by hemi-

plegia, most frequently of the right side. The intellect is clear, but hesitating. After some weeks or months the paralysis usually disappears and recovery is complete.

Grave or Apoplectic Variety.—There are sudden headache, vertigo, flushing or pallor of the face; the patient may utter a sharp cry, suddenly fall to the ground unconscious and with complete muscular relaxation, followed by death; or there may be a gradual return of consciousness with hemiplegia, which is generally right-sided, with aphasia, remaining for several weeks or months, or persistent, the mind remaining normal or enfeebled and the emotional nature highly excitable and the reason and judgment clouded; this may continue for years, or gradually develop into dementia, exhaustion, and death.

The following are some of the symptoms, according to the particular vessels occluded:

Embolism of the *vertebral artery*, the left most frequently, results in acute bulbar paralysis from involvement of the nuclei in the medulla, associated or not with hemiplegia.

Embolism of the *basilar artery* causes diplegia with bulbar symptoms. There is rapid rise of temperature. Death follows within a day or two, or suddenly, if the respiratory centers are involved.

The middle cerebral artery is the most frequent seat of embolic or thrombotic occlusions. The symptoms depend upon the exact branch involved: if plugged before the central arteries are given off, the internal capsule is deprived of its blood supply and permanent hemiplegia may follow; if the occlusion is in the central branches, the hemiplegia involves the arm and face; and if on the left side, aphasia occurs. The individual branches passing to the third frontal may be plugged, producing aphasia; the ascending parietal, producing hemiplegia, particularly of the hand; supramarginal and angular gyri, with word-blindness; and the temporal gyri, with word-deafness.

Course.—*Thrombosis*, essentially an affection of the elderly, has a chronic course. Months or years may be occupied with the various symptoms until the phenomena of senile dementia develop.

Embolism is of sudden onset, and may be followed by a rapid recovery.

Diagnosis.—*Thrombosis* is associated with changes in the vessels, with arcus senilis, and with other evidences of senile degeneration.

Embolism may be mistaken for cerebral apoplexy, and while a positive differentiation cannot always be made, the chief point to be considered is the presence of cardiac murmurs.

Prognosis.—*Thrombosis* is a permanent and progressive condition in the majority of instances. Recovery is a rare termination.

Embolism may be followed by a perfect recovery. Usually, however, some evidences of the plugging remain permanently. Death may be the result within a day or two from the plugging of a large vessel, the patient never emerging from the coma. In other cases the coma disappears, the hemiplegia with aphasia persisting, and the case pursues the usual course of localized cerebral softening.

Treatment.—The indication in the early stage of embolism and thrombosis is the reestablishment of the circulation within the district deprived of blood supply, in order to prevent the changes incident to defective nutrition. This is accomplished by means to strengthen the heart's action, tonics, perfect rest for some time after the attack, a plain but nutritious diet, and attention to the various excreta.

Bartholow recommends 10 grains of ammonium carbonate, with 5 grains of ammonium iodid, 3 times a day, continued for several months, the object being dual—to increase the action of the heart and arteries and to effect a solution of forming thrombi by maintaining the alkalinity of the blood.

In the aged presenting indications of degeneration, much benefit results from the use of:

℞. Solution of potassium arsenite, ♏ iij to v
Syrup of calcium lactophosphate, ʒ j to ij.
After meals.

It may be combined with cod-liver oil with decided advantage.

For embolism, the immediate and persistent use of the following may dissolve the plug:

℞. Ammonium carbonate, gr. v.
Solution of ammonium acetate, ʒ j.
Three or four times daily.

In a month or two a very light galvanic current may be passed through the brain in both directions.

See Brain (Anemia).

BRAIN, TUMORS.—A brain tumor is either a growth in the cerebral tissue, on the meninges, or in the vessels, characterized by symptoms of pressure upon the brain-structure. The sizes of tumors vary, and they may become as large as an orange before they will give rise to symptoms.

Tumors of the brain are of various kinds: namely, vascular tumors, as aneurysms; parasitic tumors, as cysticercus; diathetic tumors, as tubercle or syphilis; accidental tumors, as glioma, fibroma, or fibrosarcoma.

Whatever the character of the growth, it produces irritation of the surrounding parts, and, by pressure, destruction of the tissues; or it interferes with the arterial or venous flow.

Symptoms.—Those common to tumors in general are: Headache, persistent and increasing in intensity; defects of vision, even blindness, due to optic neuritis, a very constant symptom; defects of hearing, of taste, and of speech, the result of paresis of the vocal cords; vertigo, associated with nausea and vomiting; convulsions, epileptiform in character, usually limited to one side of the body, occurring at regular intervals, or confined to the eyeballs (nystagmus) or one limb, with no loss of consciousness; palsies, beginning first as strabismus, ptosis, and dilatation of the pupil, of the facial muscles, paraplegia, and general hemiplegia; defects of sensibility: namely, sensations of numbness and coldness in the limbs and body. Occasionally

disturbances of equilibrium, manifested by a tendency to go backward or to turn to the right or left; intellectual faculties well preserved until late in the affection, when the memory becomes impaired or lost for certain articles, and finally a gradually advancing imbecility.

Diagnosis.—The following points will aid in a positive diagnosis: Long-continued, persistent headache, without appreciable cause; epileptiform convulsions, unilateral, without loss of consciousness; difficulty of vision, hearing, and speech, associated with nausea and vomiting; and local and general palsies. Spiller has recently called attention to the importance of gradually developing hemiplegia as a sign of cerebral tumor.

The location of the tumor may be determined by the more or less pronounced character of certain symptoms. The diagnosis of the character of the growth can only be determined by a close study of the history.

Syphilis.—According to Herter, the indications that suggest that the tumor is syphilitic are as follows: Syphilitic history; symptoms of irritative disease of cortex rather than destructive evidences of rapid growth at the onset, followed by a period of slow progress or stationary symptoms; gradual improvement under antisyphilitic treatment; development between 20 and 45 years of age. The Wassermann reaction has become an important aid in diagnosis, but, as Spiller has well said, it must not be forgotten that a syphilitic person may have a nonsyphilitic tumor.

Indications suggesting **tubercular growth** are: Family history of tuberculosis or tuberculosis in some other organ; rapid development of symptoms; indications of the growth in the cerebellum or in the pons; early appearance of the symptoms, especially before the tenth year, and history of injury to head.

Indications suggesting **sarcoma** or **carcinoma** are: The presence of a sarcoma elsewhere and rapidly failing health, with symptoms of cerebral tumor in patients over 50 years.

Indications suggesting **glioma**: Sudden loss of consciousness, with exacerbation of all symptoms in the clinical history of cerebral tumor; cortex irritative symptoms, as in syphiloma, developing after 50 years of age, and the absence of all evidences of tubercle, syphilis, sarcoma, and cancer.

The focal symptoms of intracranial tumors are so important in diagnosis that the following summary is given of symptoms caused by brain tumors:

Prefrontal Region.—Mental impairment; pressure in central region, causing aphasia; Jacksonian epilepsy, and disturbances of smell.

Central Region.—Motor aphasia; monoplegia; partial anesthesia; Jacksonian epilepsy.

Posterior Parietal Region.—Word-blindness; homonymous hemianopsia; disturbed muscular sense.

Corpus Callosum.—Progressive hemiplegia.

Crus Cerebri.—Crossed paralyses of oculomotor nerve and limbs.

Corpora Quadrigemina.—Oculomotor paralyses; reeling gait; possibly blindness and deafness.

Pons and Medulla.—Crossed paralyses of face and limbs, or tongue and limbs; other lesions in cranial nerves.

Cerebellum.—Marked cerebellar ataxia; vomiting; convulsions; coma.

Base, Anterior Fossa.—Mental enfeeblement; disturbances of smell and vision; exophthalmos.

Base, Middle Fossa.—Impairment of vision; hemiplegia; oculomotor disturbances.

Base, Posterior Fossa.—Trigeminal neuralgia; neuroparalytic ophthalmia; paralyses of the face and tongue; impaired hearing; crossed paralyses.

Diagnosis between Cerebral Tumor and Abscess.—In both there may be any or all of the following symptoms: Headache, vomiting, double optic neuritis, monoplegia, hemiplegia, paralysis of cranial nerves, and mental failure. Tumor has, in addition, marked focal symptoms and optic neuritis; the absence of these favors the diagnosis of abscess; or, if there is hemiplegia, the ankle-clonus and knee-jerk are exaggerated. Fever and rigors point to abscess. The causes of abscess are very clear; those of tumor often uncertain.

Prognosis.—Unless of syphilitic origin, unfavorable; but it is to be remembered that all syphilitic tumors of the brain do not have a favorable termination.

Treatment is unsatisfactory and mostly symptomatic. Potassium iodid, 20 grains, 3 times a day, increased gradually and continued until the physiologic effects are produced, should be used in all cases, and discontinued only if no benefit follows. Mercurial inunctions, or the bichlorid, 1/12 of a grain, or the biniodid, 1/24 to 1/12 of a grain, may be given as required, though the biniodid is less valuable than the separate use of the iodid of potassium and the bichlorid of mercury.

In tuberculous tumors the usual constitutional treatment of tuberculosis by cod-liver oil, iron, and other tonics, with nourishing food and healthful indoor and outdoor life, is to be carried out. The usual remedies indicated to relieve pain are to be used: bromids, if necessary, in large doses, phenacetin, antifebrin, and antipyrin, and, if necessary, morphin. The ice-cap may be used, and, above all, leeching tried. The most beneficial effect is sometimes produced by free leeching, though it is, unfortunately, of but temporary duration. Other symptoms should be treated by appropriate remedies.

The hygienic treatment is of the greatest importance. Excesses of every kind should be avoided; alcohol should be rigidly excluded, as well as all sexual excitement and mental excitement of any kind, for the slightest increment of blood in the brain may bring on a convulsion and cause death.

Exploratory operation, being comparatively harmless with the aseptic precautions of the present day, should be made whenever the tumor can be localized with any approach to accuracy. Although cerebral localization has been developed to a very high degree, we frequently fail to accurately locate a tumor.

BRAN.—The ground husk of the wheat-grain, usually mixed with a very small proportion of starch. Barton's bran dressing was formerly much used in compound fractures of the leg. It has been entirely supplanted by the modern antiseptic dressings.

In the treatment of simple fractures of the femur, long, thin bags filled with bran may replace sand bags as padding for the long splint of the Liston apparatus. It has been found that good support may be given to the limb by the use of a bran bag, with this splint running from below the ankle to the axilla, and the short splint passing from the ankle to the perineum and retained by means of a splint cloth. In the absence of the air-pillow, small, circular pads may be made and filled with bran and placed under the back to relieve pressure, for the prevention of bed-sores.

In obstetric practice a shallow bag made of cheese-cloth and filled with bran will be found a satisfactory means of absorbing discharges. It may be placed over the rubber sheet. At the termination of the labor it is readily slipped from under the patient, leaving the bed clean and dry. It is superior to old blankets and comfortables, such as are ordinarily used for this purpose. A flat bag filled with bran and heated in an oven is a satisfactory means of applying dry external heat, and a good substitute for the rubber hot-water bag. It is light and easily borne, and adapts itself to all parts of the surface of the body where it may be placed. Dry external heat may be applied to the trunk in this way in the treatment of shock; it assists in hastening reaction, and adds to the comfort of the patient.

BRANCHIAL CYSTS.—Branchial cysts are developed in connection with the branchial clefts. They occur as smooth-walled unilocular cysts lined with columnar-celled epithelium, which secretes a glairy or mucoid fluid. They are sometimes associated with branchial fistulæ, which are also due to imperfect closure of the branchial clefts and usually open externally along the anterior border of the sternomastoid muscle, and internally into the pharynx. Treatment consists either in incision and drainage, or in excision.

BRAND'S TREATMENT.—A cold bath for treating fever—especially that of enteric form—consisting of immersion in a bath, at the temperature of 68° F., every 3 hours, or when the bodily temperature reaches 102° F. Friction of the surface is essential, while the temperature of the water is gradually reduced, and cold is applied to the head. Stimulants are administered after the bath, when the patient is put back to bed and dried between sheets—preferably flannel. The duration of the bath is usually from 5 to 15 minutes, the condition of the patient being the index, as shown by chattering of the teeth or cyanosis of the lips or face. Hot-water bottles are put at the feet after the bath. See Typhoid Fever, Bath.

BRASS POISONING.—In the casting of brass—an alloy of copper and zinc—workmen are subject to acute poisoning through inhalation of the fumes. Chronic brass poisoning is due to inhalation of minute particles of triturated brass.

Acute brass poisoning, *brass-founder's ague,* is usually ushered in (after a holiday) with fatigue, malaise, and also frequently a sense of oppression in the chest, nausea, and muscular pains. Then follow chills and more severe pains in the muscles and head. Finally, after copious perspiration, the patient, completely exhausted, falls asleep.

Chronic brass poisoning may attack workmen at once or after years. Some may never be affected. The initial symptoms are those of anemia. There is a metallic taste in the mouth, a metallic odor to the breath, a green line on the teeth, laryngeal or pharyngeal catarrh, gastrointestinal derangements, a sense of oppression, itchings with or without eruptions of the skin, greenish sweats, sensations of coldness.

Prophylaxis.—A susceptible person should change his occupation. Cleanliness of the workmen is imperative. Food should never be touched in the workroom, and never without washing the hands.

Treatment of the acute attack consists in the administration of milk, lobelia, and tobacco; the latter should be abstained from during intervals between attacks. In the chronic form, phosphorus or dilute phosphoric acid and potassium iodid are indicated.

BRAYERA.—See Cusso.

BREAD.—A mixture of flour and water made porous by carbon dioxid and then baked. The flour may be of wheat, corn, oats, or rye. The carbon dioxid may be introduced by decomposing an alkaline carbonate (sodium or potassium) by an acid (cream of tartar), or by fermenting the starch with yeast.

Almond Bread for Diabetics.—Beat 1/4 pound of blanched sweet almonds in a stone mortar, put in a linen bag, and steep for 15 minutes in boiling water containing vinegar, and mix into this paste 3 ounces of butter and 2 eggs. Add a little salt and the yolks of 3 eggs, stirring well for a time. Whip up the whites of 3 eggs and stir in. Place the resulting dough in greased molds, and dry over a slow fire.

Bran Bread for Diabetics.—Boil 1 quart of wheat bran in two successive waters for 15 minutes each time, and strain through a sieve. Wash well with cold water (on the sieve) until it runs off perfectly clear. Squeeze the bran as dry as possible in a cloth; spread thinly on a dish, and dry in a slow oven. This prepared bran is ground fine, until it is very soft.

Mix 3 newly laid eggs with 1/2 pint of milk. Warm 1 1/2 or 2 ounces of butter. Stir all together, adding a little nutmeg and ginger or other agreeable spice. The resulting dough should be baked in small pans, well-buttered, for half an hour in a quick oven. The bread should be but little thicker than a ship's biscuit when baked, and may be eaten at breakfast, dinner, and supper, with a little cheese or meat. At tea, butter may be freely allowed, or they may be eaten with curd or any of the soft cheeses.

In its common state the bran is soft and not easily reduced to a fine powder, hence care must be used to have it finely broken up. If moisture changes it, the cake may be put before the fire for from 5 to 10 minutes every day.

Brown Bread.—A kind of bread made from a mixture of corn, rye, and wheat flour.

Graham bread is made from unbolted wheat

flour; it contains more gluten, diastase, and mineral phosphates than white bread.

Bread-jelly is a serviceable food as an occasional change from mushes, but with a tendency to constipate if given freely. It is prepared by pouring boiling water upon stale bread and allowing it to soak for an hour. The water is then removed, fresh water added, and the whole boiled until a thick mass forms. On pouring off the excess of water and cooling, a jelly-like mass remains, which may be eaten with milk or sugar.

Bread-paste is a culture medium for bacteria. Stale, coarse bread is dried, ground to powder, and made into a paste with water. It is well suited for the growth of molds.

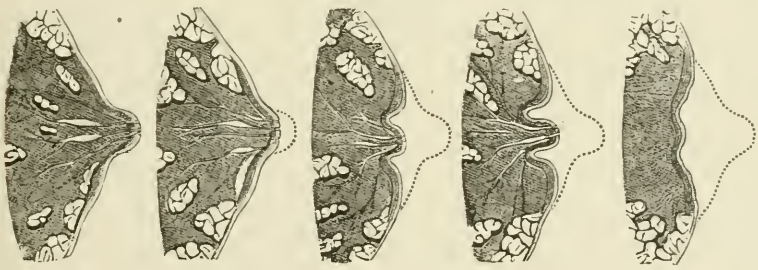
White bread is made from bolted wheat flour, and is therefore deficient in diastase, gluten, and mineral phosphates.

Other kinds, such as rye (or black), corn, barley, etc., indicate their composition by their name.

BREAK-BONE FEVER.—See DENGUE.

BREAST, DISEASES.—The more important disorders of the breasts after childbirth are: (1) Diseases of the nipple; (2) defective secretion (agalactia); (3) galactorrhea; (4) congestion and engorgement; and (5) inflammation.

Care of the Nipple.—During the last weeks of pregnancy the nipple should receive some special attention, so that it may properly perform its function during lactation. This consists in anointing it twice daily with equal parts of glycerol of tannin and water. By this treatment it is rendered firm and tough, and thus cracks and fissures are prevented later on. During lactation the nipple should be carefully washed with soap and water, or boric acid solution, after each nursing, and a little sweet oil applied.



A B C D E

SAGITTAL DIAMETER OF VARIOUS DEFORMITIES OF THE NIPPLE.

A. Normal nipple. B. Short nipple. C. Inverted nipple. D. Umbilicated nipple. E. Retraction of nipple in cancer.—(*Beck.*)

Inversion of the nipple is a not uncommon affection, and is usually due to pressure from corsets. The child is unable to take a firm hold of the nipple, and therefore nursing is interfered with. If this condition is discovered during pregnancy, the patient should be instructed to grasp the nipple firmly between the thumb and forefinger and draw it gently outward. This procedure should be practised several times daily during the last month of pregnancy.

Soon after labor effects should be made to draw the nipple out with the fingers or a breast-pump, or a shield may be used. Failing in this, artificial feeding must be resorted to.

Excoriation and Fissure of the Nipple.—This is caused by the maceration and irritation of nursing. This condition should be prevented by proper care during pregnancy and lactation, as described. The treatment consists in the application of an ointment composed of 1 dram each of subnitrate of bismuth and castor oil, or compound tincture of benzoin. Fissures may be touched with a 10-grain solution of the nitrate of silver. Sterile water and alcohol may be used to bathe the nipples. A mild or soothing ointment, such as almond oil, may be applied, and a shield should be used. Washing, drying, and dusting with dried talc powder during lactation is advisable. The following may be used as a wash:

℞. Mercuric iodid,		gr. ij
Alcohol,		ʒ jss
Glycerin, Distilled water,	each,	O j.

When a small abrasion is found, a nipple shield may be worn, the part being washed with sterile water, dried, and dusted with borated talc after each nursing. The fissure itself causes the mother intense pain during nursing, and this pain causes her to prolong the intervals between nursing, during which the breasts become swollen with milk. An area of acute inflammation surrounds the ulcer, and abscess of the breast may result. In severe cases the child must be weaned.

Defective Secretion of the Breasts.—The secretion of milk may be defective in quantity or in quality. This may be due to certain diseases—as the acute infectious diseases, syphilis, or phthisis—to severe hemorrhage, to profound emotion, or to diet. If the defective secretion is due to any acute disease, the child should be fed artificially until the disease subsides, when, on the return of the milk, it should be put back to the breast. A syphilitic or phthisical mother should not nurse her child, for fear of infecting it. Drugs are of little value in stimulating the flow of milk. If a generous diet, supplemented by 1/2 of a pint of milk twice daily, with perhaps a glass of malt liquor at dinner, fails, artificial feeding is required.

Galactorrhea.—An excessive secretion of milk, or a dribbling of milk from the breast.

The cause of this condition is not definitely known. It has been atrributed to anemia, plethora, and paralysis of the openings of the lactiferous ducts.

Treatment is usually unsatisfactory. A firm mammary binder, supplemented by the administration of ergot and potassium iodid, will sometimes prove effectual. Belladonna is an anti-

galactagog, acting when either given internally or applied locally. Camphor has been used locally and generally in hot olive oil. Antipyrin and potassium iodid have been given internally.

℞. Belladonna ointment, Lanolin, } each, ℥ ss.

Apply locally twice daily.

Congestion and Engorgement of the Breasts.—This occurs on about the third or fourth day after labor. The breast is tense, swollen and painful.

Treatment should be prompt, or inflammation may develop. A brisk saline purge should be given. The breasts should be emptied at regular intervals by the infant, the breast pump or massage. The most effective means of relieving pain and reducing congestion is the continuous application of cloths wrung out in hot water, as hot as the patient will tolerate. To have the cloths sufficiently hot, they must be placed in a thick towel to be wrung out. Massage is too painful at first; the movements must be gentle and from the nipple outward, in the direction of the venous current. A firm mammary binder should be applied as soon as the breasts begin to fill, and should be worn during the first two weeks of the puerperium.

Inflammation of the Breasts (Mastitis).—This is a not infrequent complication of the puerperium. It is usually septic in origin, the infection taking place through a crack or fissure in the nipple. Occasionally it originates in overactivity of the gland, with retained secretion (**caked breast**).

This condition is attended by more or less constitutional disturbance: fever, which may be ushered in by a distinct chill, and rapid pulse. The breast is swollen and painful; the skin is red and brawny. If suppuration supervenes, the temperature will become irregular, and fluctuation may be detected. The most distinctive **signs of suppuration** are a dusky hue of the skin and edema.

Attention to the condition of the nipples, with absolute cleanliness, will usually prevent inflammation. If it occurs, suppuration should be prevented, if possible, by free purgation, regular evacuation of the breasts, lead-water and laudanum, hot compresses as described, and a mammary binder. On the first appearance of positive signs of suppuration the patient should be anesthetized, an incision made through the skin, the pocket of pus located, evacuated, irrigated, and drained. Incisions into the breast should always be made in a line radiating from the nipple, and either wholly inside or beyond the areola. One should not hesitate to make incisions enough to thoroughly evacuate all collections of pus. Subsequently they should be irrigated several times daily and drained, or they may be packed with gauze. The child should be deprived of the breast as soon as symptoms of suppuration appear.

Mammary Abscess.—It is usual to divide mammary abscesses into 3 classes, according to their situation—superficial, intraglandular, and submammary.

Superficial Abscesses.—These require no special description; they should be opened and drained as soon as the diagnosis is made, to prevent the skin becoming undermined.

Intraglandular abscesses are more serious. The earlier symptoms—those due to the inflammation—have already been described; suppuration may begin acutely, with a definite chill; more frequently, the pain and swelling merely grow worse. After a few days, when the tough fibrous tissue that surrounds the suppurating lobule—if it commences in one—has given way, there is often a certain degree of improvement the pain is less severe, and the temperature falls a little; then, by degrees, the skin at one spot becomes thickened, edematous, and tied down, giving some indication as to the direction in which the suppuration is progressing, and at length one spot softer than the rest can be made out in the center of the swelling.

The earlier the pus is evacuated the better, but it is necessary to wait until a clear conception is had as to its position and the direction it is following; exploratory operations in a breast in a state of full physiologic activity are not advisable. As the interior of the abscess is always irregular in shape, it should be thoroughly explored with the finger, a drainage-tube introduced into every pocket, and the whole circumference packed with soft absorbent dressings, so that the fluid that exudes may be driven toward the opening. More than one incision may be required if the abscess is allowed to burrow in all directions through the gland before it is opened. Such cases, and still more those in which the pus is left to work its way out, often leave irregular sinuses that persist for years, draining the person's strength, and ultimately leading to the destruction of the gland as a secreting organ.

Submammary abscesses are fortunately rare. The breast itself is but little affected; it is thrust out from the chest-wall and floats as on a water-bed. Sometimes the abscesses develop insidiously; more often they are attended with very severe symptoms. If allowed to remain, the skin usually gives way below the gland; but frequently large tracts slough, leaving great cavities fringed with blue, congested, overhanging flaps. Great care must be taken in opening these to secure efficient drainage, and to bring the opposing surfaces into accurate contact, so that no decomposing pus may be retained in outlying pockets.

Chronic interstitial mastitis, affecting one or more of the lobules, is of very great importance, from the pain and anxiety it occasions, and from the difficulty of distinguishing it from the early stage of scirrhus.

No cause can be found in the majority of cases. It is most common about the menopause; is often associated with disorders of menstruation, and at each period it usually becomes painful and tender; but, on the other hand, it may occur at any age, and in those who are to all appearance perfectly healthy. Pain, often of a neuralgic character, and sometimes very severe, and made worse by handling, is usually the first symptom; and the induration is only found on examination.

The diagnosis, so long as the patient is under 30 years of age, is not very difficult (although the

possibility of carcinoma must not be overlooked); in older patients it rests chiefly upon the physical sign. The hardness is not of that stony description characteristic of contracting scirrhus; the surface is usually more nodular, from the presence of cysts; it may vary in size at each menstrual period.

The treatment of chronic interstitial mastitis is very unsatisfactory. Sometimes it slowly undergoes resolution, or disappears so far that the patient takes no more notice of it, but it is rarely possible to connect this with any particular remedy. Paget recommends small doses of potassium iodid with liquor potassæ, well diluted; and, of course, any menstrual irregularity must receive careful attention. Tonics, especially iron, often succeed better than anything else; but the chief thing is to protect the breast against every source of irritation, and to withdraw it as far as possible from notice by covering it with a well-shaped belladonna plaster.

Neuralgia of the breast is common among young married women, and is often associated with ovarian disease. The pain is sharp, severe, and lancinating in character, and often extends to the axilla and runs down the arm. The mammary gland and the skin over it are very tender, even to the slightest touch, and there is no tumor.

Treatment.—Since many of these patients have a great dread of carcinoma, the fear of carcinoma is to be first driven out of the mind. Ovarian or uterine disease, when present, should be appropriately treated; tonics, healthful occupation of body and mind, change of air, and the best hygienic surroundings obtained. The ordinary antineuralgic remedies and soothing applications should be tried.

Paget's Disease.—This disease, beginning upon the nipple, spreads to the areola, and often involves the skin of the entire gland. It is usually limited to one side—generally the right. It begins upon the summit of the nipple, with the formation of small corneous crusts, firmly adherent to the parts beneath. On removing the crusts a reddened surface is disclosed, which later becomes superficially ulcerated and fissured.

The areola, at first red and scaling, becomes excoriated, and discharges a yellowish, transparent, sticky fluid. There is ulceration and crusting. When the disease is fully developed, the area involved is bright red and finely granular, oozing, circular or oval in shape, with the nipple for a center, and having a sharply defined, in some cases slightly elevated, border. Scattered over the surface are small, smooth, pearly-looking islets of epidermis, round or irregular in shape, characteristic of the disease.

Early in the disease there is parchment-like induration of the superficial tissues, with itching and burning sensations. Retraction of the nipple is a prominent and early symptom of this malady, leading in some cases to its complete disappearance.

After a varying period cancerous degeneration develops, beginning upon the ulcerated superficial surface as nodules of proliferating epithelium, or in the deeper parts. Then symptoms of ordinary mammary cancer arise, with deep-seated, lancinating pain, extensive ulceration, and involvement of the axillary glands. Schambacher's recent studies tend to confirm the views of Thin, Duhring and others that the morbid process is malignant from the very beginning. He believes it to be an intra-epidermoid carcinoma which invades both milk ducts and skin. The eczematous character of the skin lesions he has found to be due to inflammatory infiltration.

The disease is usually unilateral, 75 percent of the cases occurring in the right breast.

Treatment.—If soothing and antiseptic lotions do not avail, the breast should be excised.

BREAST, EXCISION.—See Breast (Tumors, Carcinoma).

BREAST, TUMORS.—Familiarity with the normal and varied conditions of the mammary glands is most important for the examiner. A healthy gland may be mistaken for a tumor or new formation. With the gland grasped between the thumb and finger, the density, the presence of irregularities in contour and of nodules, etc., are to be noted. A greater sense of induration than normal may be set down to chronic induration. Hyperesthesia and neuralgic pain indicate a neurosis. If a tumor is found, the following questions are suggested: Is it in the center or near the periphery? Is it smooth, nodular, or lobulated? Are its edges sharply defined or rounded, or do they shade off into surrounding tissue? Is it hard, soft, elastic, or fluctuating? Is there ulceration, and what is the nature of the discharge? A mucous discharge would indicate a glandular cyst, while a bloody or thin serous discharge indicates carcinoma. Milk found in connection with a tumor indicates a glandular tumor. The condition of the axilla and the subclavicular space should be observed. Associate enlargement of the contained glands is diagnostic of malignant disease. Benign tumors are recognized by their glandular shape, painlessness, slow growth, and fluctuation.

Cysts.—The cysts met with most frequently in the breast are the serous cysts and certain of the retention cysts.

Symptoms.—Cysts in the breast form painless, tense, or semifluctuating, smooth, rounded tumors, evidently connected with the breast tissue. *Serous cysts* may occur in any part of the breast. They are often very tense and hard, and breasts containing cysts have been mistaken and removed for cancer. Hence the valuable rule of making a preliminary incision if in doubt as to the nature of the tumor. The *galactoceles* occur during lactation; they are situated near the nipple, from which a milk-like fluid may sometimes be squeezed out on pressing the cyst. They are soft and fluctuating, and usually single, form quickly, and may attain a large size. *Glandular cysts* occur chiefly in women of from 35 to 50. They are tense and painless, form slowly, may occur singly, but are often multiple. A sanguineous fluid sometimes escapes from the nipple if the cyst contains a papillary growth.

Treatment.—*Simple serous cysts* may be laid open freely and allowed to granulate from the bottom, or, better, may be dissected out. *Galactoceles*, with semisolid contents, may also be laid open freely and their contents squeezed out. *Glandular*

cysts, when numerous, call for the excision of the affected lobule, or if the whole breast is affected and they contain proliferating growths, for excision of the entire gland. The possibility of malignant change must always be borne in mind, and when operating in doubtful cases, a microscopic examination of frozen sections of tissue should be made before the operation is completed. If carcinoma cells are demonstrable the radical operation should, of course, be performed. *Involution cysts* require no treatment.

Classification.—The mammary gland, like the parotid and thyroid glands, is the seat of tumors peculiar to itself.

The following classification is based upon the investigations of Warren, Halsted, Rodman, and Wieder.

A. Benign Tumors.

Fibroepithelial tumors:

(1) Fibrous type:

1. Periductal fibroma { Intracanalicular. Pericanalicular.
2. Periductal myxoma.
3. Periductal sarcoma (slightly malignant).

(2) Epithelial type:

1. Fibrocystadenoma.
2. Papillary cystadenoma.
3. Simple adenoma.

Lipoma.
Enchondroma.
Myxoma.
Angioma.
Endothelioma.

B. Malignant Tumors.

Sarcoma:

1. Round cell.
2. Spindle cell.
3. Mixed cell.
4. Giant cell.
5. Alveolar.
6. Melanotic.

Carcinoma:

1. Adenocarcinoma.
2. Medullary carcinoma.
3. Carcinoma simplex.
4. Scirrhus carcinoma.
5. Carcinomatous cyst.

Of the benign tumors the **fibroepithelial** are the most common. They were formerly grouped under the general terms of fibroadenoma and adenofibroma, but the recent studies of Warren and Greenough and Simmons have resulted in the adoption of a much more rational classification. The fibrous type of this group is especially characterized by free movability. As it increases in size it often becomes lobulated. Although usually found in the upper, outer quadrant of the breast, it may occur in any part of the gland. As a rule, only one breast is affected. Subjective symptoms are slight or wanting. The fibrocystadenoma is the same as the periductal fibroma except that a secondary proliferation of the epithelial elements has taken place. The papillary cystadenoma is described by Warren as follows: "The histologic picture is that of a connective-tissue pedicle surmounted by an epithelial covering. Papillary structures of this character are the distinguishing feature of the tumors of this group and serve to differentiate them absolutely from other benign tumors of the breast. Their consistency is hard, although fluctuation may occasionally be detected. The situation of the tumor is generally beneath or in close relation to the nipple. The fluid content of the cyst is generally hemorrhagic." Simple adenoma is the rarest of the fibroepithelial tumors, and by some its existence is even denied. Apparently authentic cases have been observed by Gross, McFarland, Geo. P. Müller, and others.

The treatment of the fibroepithelial tumors is purely surgical and consists in extirpation of the growth. Small growths superficially situated may be excised under local anesthesia, and larger ones removed by Warren's method of plastic resection.

In this operation the preliminary incision is begun at the lower border of the breast, opposite the middle of the outer arc of the lower quadrant, and runs along the lower fold and outer margin to the inner border of the axilla, thus severing the lymphatic connections of the breast with the axillary lymph nodes. The incision is carried down to the lower border of the pectoralis major muscle, which should be freely exposed. The dissection is then carried along through the loose connective tissue which lies between the pectoral fascia and the posterior layer of the fascia in which the mammary gland is contained. The posterior surface of the gland is exposed by turning the breast upward and inward. The neoplasms are then removed by a V-shaped incision, the apex of which lies directly under the nipple. Radiating from this point incisions can be carried into the gland tissue in all directions. After arresting hemorrhage the V-incision is closed with two rows of catgut sutures, one along the anterior border and one bringing the posterior edges together. The gland is then dropped back onto the pectoral muscle and anchored there at its outer edge. Another row of sutures is advisable to hold together the deep layers of the superficial fascia before the outer edges of the wound are closed with silkworm gut.

Mammary lipomata are rare. They may be either subcutaneous, intraglandular or retromammary. They are well defined unless they become so large as to obliterate the breast.

The remaining benign tumors of the breast are extremely rare. Some pathologists deny the existence of pure myxoma.

Sarcoma is one of the rarest of mammary neoplasms. The older surgeons believed it to constitute from 5 to 9 percent of all tumors of the breast, but recent investigations have shown that this estimate is too high. Thus, Finsterer and Rodman and Bonney find that it constitutes about 3 percent of all mammary tumors, and Sick of Hamburg finds the percentage to be somewhat smaller. It has generally been taught that sarcoma is a disease which affects young women, but Rodman and Bonney's investigations show that it is, unquestionably, a disease of middle life.

Cystic or adenosarcoma, described by older writers, is the periductal sarcoma of more recent classifications. It is much less malignant than pure sarcoma. Tumors of this group are round or ovoid in shape, circumscribed, and freely movable beneath the skin. They are usually firm and indurated, although when large cysts are present fluctuation may be detected. They vary in size, although they are usually large when first seen by the surgeon. Not uncommonly they ulcerate and may extend to neighboring structures after the capsule has been broken through. Pure sarcomata are smaller, harder, and more regular in shape than the periductal tumors and do not contain cysts. Encapsulated at first, they eventually break through the capsule and become diffuse.

Sarcomata are not painful at first, and may not increase much in size for some time after they are first detected, but a time always comes when they grow very rapidly, break through the skin and form large fungating excrescences. Round cell sarcoma is the most malignant variety, mixed cell the most common. Treatment consists in removing the breast and clearing out the axilla.

Carcinoma.—When a patient with a mammary tumor presents herself for examination, our first effort should be to obtain a careful history of the case. Heredity, age, sex, race, its possible relation to traumatism and the menopause, functional activity, previous breast abscess, discharge from the nipple, rapidity of growth, and the presence or absence of pain, are all of the greatest importance.

Heredity no longer bears the significance that was credited to it in the past, when carcinoma was considered a constitutional disease; but it is still of some importance. Statistics indicate that about one-third of all cases of mammary carcinoma occur in those whose ancestors and relatives have suffered with the same trouble. Delbet states that heredity is unquestionable in 5 to 10 percent of all patients.

Of greater importance is the *age*. Carcinoma is a disease more prevalent after 40, but many cases are met with between 30 and 40, and not a few prior to 30. Statistics compiled by Gross, Williams, and Mahler give the average age incidence as 48 years. Rodman's statistics show that of 5000 cases carefully analyzed 11 percent occur in the decennium between 20 and 30; 12 1/2 percent between 30 and 40; 27 percent between 40 and 50; 28 1/2 percent between 50 and 60; and 21 percent beyond 60. More than one-tenth of the entire number occurred in women between the ages of 20 and 30. Rodman operated on several cases of cancer of the breast in young patients, five in all, ranging from 23 to 28 years. Others—McCosh, Richardson, Park and Warren—have operated upon even younger patients, the youngest being 19 years of age.

Not more than 1 percent of all cases occur in men. Keyser collected only ten instances affecting the male breast out of 1460 cases. Warfield, reporting the statistics of Johns Hopkins Hospital, found 3 out of 307 cases; Fantino, 1 case in 228; and Sick, 2 out of 216 cases.

The American Negroes and Indians have become as susceptible to carcinoma as the Whites, since they have lived under identical conditions. It would seem that both of these races were originally more or less exempt, as nearly all writers testified to their relative immunity. Many cases are encountered in negroes, and it is apparent that while they still enjoy a comparative immunity to cancer in general, they are even more prone to carcinoma of the breast and uterus than the white race. This fact is amply attested by the United States Census Reports.

Roger Williams states that carcinoma of the breast is common in China. It has been said that Hebrews are less subject to carcinoma than other white races. This belief is without foundation, as they are equally, if not more, susceptible.

A history of *traumatism* is of some importance, but distinctly less so in carcinoma than in sarcoma. The latter is frequently secondary to trauma. Rodman encountered two cases of cancer of the male breast where it seemed reasonably clear that trauma produced the disease. One was a shoemaker who habitually held his last against the affected part. The other, a laborer, was of the habit of resting the handle of his shovel against the breast.

With the return to the theory of the local origin of cancer, it would seem reasonable that trauma must have greater potentialities than was believed to be the case so long as the constitutional origin of the disease was taught. Very recent statistics of Coley indicate that trauma frequently precedes, and may cause, cancer of the breast.

Functional activity of the gland may have some influence, as carcinoma is undoubtedly more often found in married women who have borne and nursed children than in single or infertile married women. Ninety percent of 982 patients treated in Von Bergman's clinic, and 316 out of 416 women affected with mammary cancer, reported by the late S. W. Gross were found to have nursed children. It may be the result of the mammary epithelium assuming an activity to compensate for the deprivation of the normal function, as it is also logical to infer that the epithelial proliferation may overstep the physiological limits in the functionally active gland.

The climacteric seems to have some influence, as the majority of cases, as has been mentioned, occur at that time of life.

Statistics relative to the influence of mastitis are misleading. It would seem reasonable to suppose that inflammation prepared a better field for the future development of carcinoma.

A bloody discharge from the nipple leads us at once to think of a papillary cystadenoma, of which it is almost a pathognomonic sign, yet Rodman has known it to occur in two cases of abnormal involution, but does not recall ever having seen a bloody discharge in connection with carcinoma of the breast; he thinks that it should not be encountered unless the carcinoma is secondary to papillary cystadenoma, duct cancer, or abnormal involution.

The duration of the tumor may be helpful, but on the other hand may be misleading. Rodman

reports cases of scirrhous carcinoma of very long duration, and, per contra, four cases of acute cancer where the disease had made remarkable progress in a few months. One case belonging to this group of acute cancer, so aptly called carcinomatous mastitis by Volkmann, was operated upon September 21, 1908. Her left breast was very much larger than the opposite one, was tender, the skin inflamed, the axillary glands enlarged, and the whole clinical picture was not unlike that of subacute mastitis. As a matter of fact, her breast had twice been lanced at one of the very best hospitals in Philadelphia, a diagnosis of acute mastitis having been made. The condition had lasted 8 months. An operation was performed only at the urgent request of the patient's husband, after both the diagnosis and prognosis had been carefully explained. The breast was removed and a very extensive operation performed; the axillary glands were found enlarged, hard and matted together, but could be removed.

She remained well for 2 months, then developed a marked edema of the arm, also mediastinal metastases and died 6 months after the operation. The pathological report in this case was "carcinoma simplex of the left mammary gland, involving the axillary glands."

The second case was operated upon at the Presbyterian Hospital on May 18, 1910. She presented an even more typical picture of carcinomatous mastitis than did the former case, her breast being enlarged, inflamed, tender, and the axillary glands enlarged, with a history of growth extending over 3 months. The characteristic orange-peel skin was perfectly shown in this case. Acute cancer was diagnosticated and immediate operation practised. The patient was thoroughly examined 1 year after the operation, and was without sign or evidence of either local recurrence or internal metastases; her health was perfect. This case is the only one out of the four where operation has apparently been followed by great benefit, the remaining three all dying within eight months after operation.

When simple tumors take on rapid growth, the possibility of sarcomatous degeneration of either a periductal myxoma or fibroma should be considered. Rodman very recently reported a most interesting case of this kind.

Unfortunately, pain is usually a late symptom of carcinoma and is evidence of either adhesions or ulceration. This is much to be regretted, since the absence of pain gives victims of carcinoma a false sense of security which encourages them to abstain from seeking medical advice.

Of greater importance than the history is a thorough and systematic *examination of the breast itself.* It is best to have the entire chest bared when seeing such patients in office consultation. In hospital practice a still more thorough physical examination is accomplished by having the patient in bed with all clothing removed. Having the entire chest bared is insisted upon so that the affected breast may be compared with the other one, and enlarged glands of the supraclavicular and axillary spaces if present may be palpated. The size of the affected breast is of importance, as there is usually a difference in the two, the affected one being somewhat larger, particularly in those acute, rapidly growing tumors, instances of which have been cited. As a rule, however, the lesion is not strikingly apparent, and when there is a large tumor of irregular outline the probabilities are that the condition is one other than carcinoma, possibly a myxoma which has undergone sarcomatous change. The condition of the skin over the mamma should be carefully noted. It is quite characteristic in cancer for adhesions to the skin to occur early, and later to the underlying structures. Such adhesions to the skin result in dimpling or other irregularity, and more rarely the typical orange-peel appearance will be encountered. There is usually no evidence of inflammatory reaction except in the rare cases of carcinoma to which reference has already been made.

The most important point to ascertain is the *mobility of the diseased breast* compared with the healthy one. This physical sign is of the greatest importance, as restricted motion sooner or later occurs indicating that adhesions have formed which bind the breast to the underlying structures and skin. Restricted mobility is made apparent by the examiner who stands behind the patient taking the breast in both hands and moving it in the half arc of a circle. Dimpling of the skin and retraction of the nipple, later to be referred to, are also accentuated by this procedure.

Having determined these general facts regarding the diseased breast, attention will now be drawn to the tumor itself. Should there be multiple tumors, the probability of malignancy is lessened, since carcinoma is usually single; whereas benign tumors, such as adenofibromata and cysts, particularly those occurring during the stage of cystic formation is abnormal involution, are on the other hand, characteristically multiple.

The *position of the tumor* is of importance and should be considered. Carcinomata are more frequently situated in the upper and outer quadrant of the gland. They are hard, firm in consistency, can readily be palpated, and, as a rule, may not be definitely isolated since they are a part of the glandular parenchyma. The patient does not generally complain of pain on manipulation of such a tumor, and, as has been mentioned, carcinoma does not give rise to subjective pain or objective tenderness, save in advanced cases where ulceration has taken place. Benign tumors, such as the adenofibromata, are sometimes very painful.

Retraction of the nipple was formerly thought to be pathognomonic of carcinoma, but this has not been confirmed by clinical experience. While a considerable number of cases (51 percent) have shown this phenomenon, nearly as many others, unmistakably malignant, have not; furthermore others, unquestionably benign, have, in rare instances, manifested this sign. Only those tumors which are *centrally* located will give rise to *retraction.* Carcinoma is very much more prone to do so than benign tumors, since, as we have stated, adhesions to the skin are almost characteristic of this form of growth. But it must be repeated that

retraction of the nipple sometimes occurs in abnormal involution, centrally located cysts, sarcomata and, more rarely, in perfectly benign tumors. In benign conditions the nipple, if depressed, is mobile, whereas in cancer it is not only depressed but fixed.

A word should be said regarding a *discharge from the nipple.* Should there be no history of such discharge, but, upon examination, a bloody drop should appear after the manipulation of the breast, the evidence is in favor of a papillary cystadenoma situated behind the nipple. Should epithelial plugs appear after squeezing the breast, duct cancer or comedo carcinoma is to be thought of.

Having finished the examination of the breast itself, the *axillary spaces* on both sides, but especially the affected side, should be most carefully palpated to detect the presence of any enlarged lymph glands. Fortunately, there are fewer patients presenting such enlargement than formerly, as general practitioners are beginning to realize the importance of early operation. Should enlarged glands be found in both the axillary space and the supraclavicular triangle, the propitious time for surgery has passed; nevertheless, cases with axillary involvement are frequently operated on and, with a thorough procedure 25 percent of them are permanently cured.

The local examination being completed, one should now make a *careful general physical examination* to detect, if possible, any internal metastases in the liver, lungs, mediastinum and bones. It may be advisable, of course, to treat medicinally coexisting complications such as bronchitis, endocarditis, and the various forms of nephritis before attempting such a radical operation as removal of the mammary gland. The short time lost in waiting may be justified, but the desirability of operating, at the earliest practicable moment should never be lost sight of. Furthermore, it should be distinctly understood that nothing short of the complete method introduced by Halsted and Meyer is to be considered as sufficiently radical; that is to say, a large wound, free removal of skin, removal of both pectoral muscles, and an accurate and painstaking dissection of the axilla always, and sometimes in addition a clearing out of the subclavian triangle of the neck are absolutely necessary for success. The several flap operations exploited are alluring and seductive to the operator, facilitating as they ofttimes do, the closure of a large wound. But that all of them are open to objections (anatomic, pathologic, and surgical) is unfortunately true. Cancer is so protean and variant in its manifestations that it is unsafe to fashion skin flaps similarly for all cases. The growth will be in the upper and outer quadrant more often than elsewhere and yet a popular operation retains this infected skin in every case as a means of closing the wound. The end results, where flap operations are practised, are so disappointing and disheartening that they should definitely be put to one side. While convenient and time-saving to the surgeon, they are a menace to the patient and not in harmony with either modern pathology or recent discoveries concerning the lymphatic supply of the mammary gland. Moreover, they are wholly unnecessary as the largest wound can be closed without them.

It now remains to describe briefly a modern operation (that of Rodman) for attacking cancer of the mammary gland. After a thorough trial it has given uniformly satisfactory results. Its advantages are as follows:

First; the incision does not extend on to the arm. thereby avoiding secondary cicatricial contraction with limitation of its movements.

Second; it offers adequate axillary exposure. This important part of the operation is completed first for the following reasons: It enables the operator to attack vessels at their roots, thus lessening hemorrhage otherwise necessarily great from cutting and recutting the same vessel during the operative procedure. By attacking the glands and completing the axillary dissection primarily, the possibility of expressing carcinoma cells by manipulating the breast is greatly lessened. The muscles are attacked and cut at their origin. thus enabling the assistant to use the divided ends as tractors, thereby facilitating such free exposure of vessels and nerves as is compatible with safety.

Third; the axillary involvement may be so extensive that complete eradication of the growth is impossible and further surgical interference therefore futile. These are the best reasons for not working from sternum to axilla as all formerly did, and many still do.

At the time of operation, closure of the wound should not be considered, the surgeon being prepared to graft should it become necessary, but if the technic which is now being described is employed it will rarely if ever be found necessary, notwithstanding the fact that the wound is very large and the skin over the entire breast is always sacrificed. If the tumor is a peripheral one, then a still greater amount is embraced between the incisions, for it is our conviction that to insure success a free removal of skin is absolutely indispensable.

The upper portion of the sheath of the rectus muscle is removed, Handley having demonstrated that cancer of the breast metastasizes more frequently to the liver than elsewhere, and that by removing that portion of the fascia covering the rectus in the epigastric triangle, such metastases are rendered far less likely. The carcinoma cells drift along the lymphatics toward the deeper fascial planes and ultimately reach the peritoneum and then, by selection, the liver.

A straight incision is made beginning 1 inch below the clavicle, an inch and a half from and parallel with the sulcus between the deltoid and the clavicular portion of the pectoralis major. It extends well below the free edge of the pectoralis major muscle and is usually from 4 to 6 inches, in extent or possibly more, according to the stature of the patient. The great pectoral muscle is soon reached and the index-finger of the left hand inserted under the lower border of the tendon of the muscle and made to emerge above its upper border, or, if only the costal origin of the muscle is to

be removed, in the interval between the costal and clavicular portions. The tendon is divided at or near its insertion into the humerus. This may be facilitated by slightly dissecting up the external flap and using retractors. If the growth is peripheral and in the upper hemisphere, the entire muscle should unquestionably be sacrificed, but in the average case there is no reason for removing the clavicular portion.

The lower edge of the tendon of the pectoralis minor will be easily discovered after opening the costocoracoid membrane. It should be carefully separated from the fascia which covers it to avoid wounding the long thoracic artery which runs in the fascia parallel with and just below the tendon. By lifting up the muscle with the index-finger, which has been inserted under it, the tendon is made tense and prominent and one can easily ascertain whether or not other tissues are included with it. Care must be taken not to cut the acromiothoracic artery which runs just above and

Primary skin incision.—(*Rodman.*)

parallel with this tendon, which is divided at its insertion into the coracoid process. Rodman has never wounded either the acromiothoracic artery on its upper border, or the long thoracic just below its lower border, and believes that both can be avoided if care is taken. Each muscle retracts inward as soon as its tendon is severed. As this uncovers the axilla, its subsequent thorough dissection is greatly facilitated. The costocoracoid membrane is largely sacrificed, thus giving ready access to the subclavicular fat at the apex of the axilla. In removing a part of this membrane the cephalic vein at the upper and outer aspect of the wound must not be wounded. A branch of the acromiothoracic and its accompanying vein, which are to be found in the fascia, should be clamped and tied. A nerve which supplies the pectoral muscle should be sacrificed now, as would necessarily be done later when the muscles are removed.

The dissection is from the apex of the axilla downward, and must be most carefully carried out. The finger, covered with several thicknesses of gauze, is all that is necessary or desirable in the

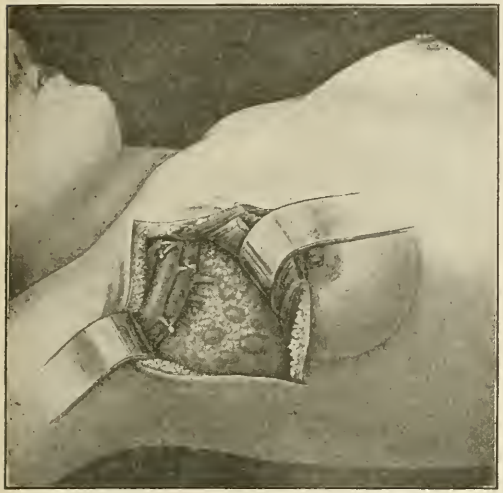
Division of pectoralis major near its insertion.—(*Rodman.*)

removal of the fat and fascia from the upper third of the axilla. An incision is now carefully made through the fascia to the outer side of the axillary vessels simply to start the dissection from without inward. This is made to the extent of the lower two-thirds of the axilla but not in the upper third where it is dangerous to cut.

Division of pectoralis minor near its insertion.—(*Rodman.*)

As the sheath and fat are removed from the vessels we come down upon the acromial, long and alar thoracic branches, and the subscapular branch of the axillary artery, in the order named, which with their accompanying veins are to be carefully

clamped in two places and then divided between the clamps. By ligating both ends the subsequent hemorrhage is greatly lessened and very little blood will be lost.

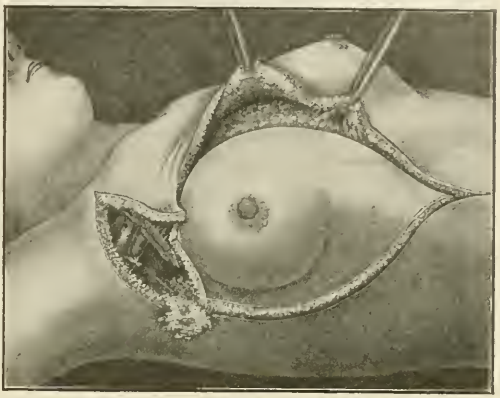


Axilla freely exposed and vessels divided at their origin —(*Rodman.*)

The enlarged lymphatic glands will usually be found at the base of the axilla between the latissimus dorsi, teres major, and subscapularis muscles posteriorly, the serratus magnus internally, and inferior to a line formerly indicated by the

Axillary dissection completed. Fascia, fat and enlarged glands *en masse* shown at base of axilla. External respiratory, or nerve of Bell, shown on the inner wall of the axilla. Subscapular nerve on the posterior wall. Sheath covering all muscles removed.—(*Rodman.*)

situation of the lower border of the pectoralis minor. The midaxillary and subclavian glands may, however, be infected. All such enlarged glands and surrounding fat should be carefully dissected from the several muscles, and to do this best the fascia covering the muscles must also be sacrificed. The axillary dissection should be so thorough that nothing is left on its inner aspect save the posterior thoracic or nerve of Bell, on the posterior aspect the subscapular nerve, and superiorly, possibly the superior thoracic artery, if it



Second skin incision. Observe the extensive undermining anteriorly.—(*Rodman.*)

arises as an independent branch high up on the first portion of the axillary.

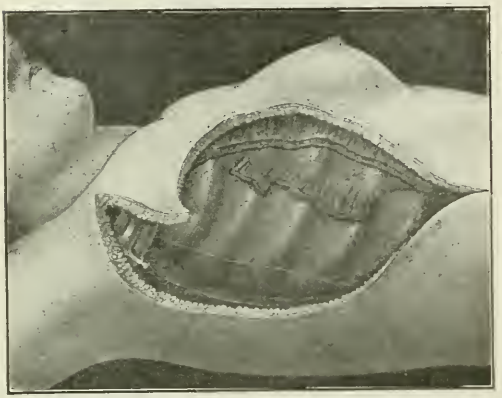
Dissection of the axilla should invariably be from above downward, without inward, and *en masse*—a piecemeal extirpation must not be considered. Though sharp instruments are not to be used at the apex of the axilla they may greatly

Undermining inferiorly. Muscles, breast and axillary mass being reflected prior to removal.—(*Rodman.*)

facilitate dissection at its base. Should there be an accidental injury to the vein, which is not common, it may be treated by suture or lateral ligature. The entire dissection is carried out through the single straight incision, and by working with blunt dissectors in a good light, can usually be completed in about twenty minutes.

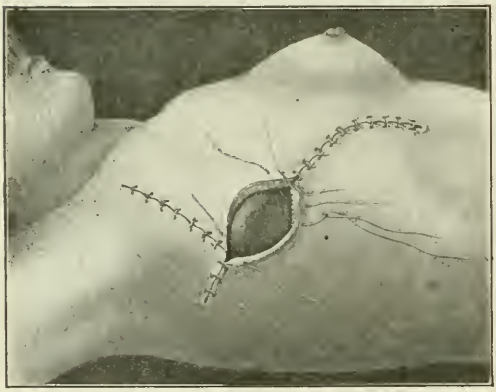
It now remains to complete the skin incision by

beginning at the middle of the initial incision and circumscribing the entire breast with an oval, broadly elliptical or egg-shaped incision. The oval is at least 5 inches in its greater diameter or over 6 inches if the breast is large or the cancer situated peripherally, for under no circumstances



Appearance of the wound after removal of the breast muscles and axillary mass A .small part of the origin of pectoral muscles left as a covering for the ribs. This very much facilitates grafting, when necessary, which is rarely the case. In fourteen operations during one winter it was necessary in only two cases.—(*Rodman.*)

must the skin incision come nearer than 2 inches to the edge of the growth. The knife should be slanted so as to divide the subcutaneous tissue or the paramammary fat at least two inches further out than the skin has been cut, which will take it nearly to the clavicle superiorly, quite beyond the



Wound being sutured. Middle third of horizontal incision may be, if necessary, covered by skin-grafting. It is rarely necessary. Latterly the drainage tube at either end of horizontal wound is omitted.—(*Rodman.*)

sternum internally, below the border of the great pectoral inferiorly, or well on to the external oblique and rectus.

Undermining insures approximation of a very large wound. The breast with its axillary tail still attached, the pectoral muscles, paramammary fat, and deep fasciæ are all lifted up on the costal wall preliminary to cutting the costal attachments of both pectoralis minor and major. In cutting the attachments of the great pectoral muscle the perforating branches of the internal mammary will be severed and should promptly be seized with forceps. The perforating branches of the opposite side may also be cut when the flap is undermined internally and should immediately be clamped and ligated. The wound is now very large; over the chest the intercostal muscles are exposed, inferiorly the external oblique and rectus, posteriorly the latissimus dorsi, teres major and subscapularis muscles and the subscapular nerve, on the inner aspect of the axilla, the digitations of the serratus magnus and the nerve of Bell are seen.

Should the tumor be situated in the upper hemisphere an incision should be made above the clavicle and the posterior triangle of the neck carefully explored. This incision should be preceded by pulling the skin downward so as to prevent injury to the external jugular vein and should extend from the posterior border of the sternomastoid to the anterior border of the trapezius. This second incision is greatly to be preferred to the extension of the original wound, as an unsightly and possibly disadvantageous scar is thereby eliminated. Cutting through the skin, superficial fascia, platysma and deep fascia, the omohyoid is exposed, held upward by a retractor, and the triangular space which it bounds carefully freed of fat and enlarged glands if any be present. The external jugular vein is usually resected. This step of the operation cannot safely be dispensed with, though supraclavicular involvement is rarely encountered, for in malignant growths situated in the upper and peripheral portions of the breast a chain of lymphatic vessels passes from the breast over the clavicle to empty into glands in the posterior cervical triangle.

Oozing may be quickly stanched by the application of hot water at a temperature of 120°. This is the best hemostatic and the part should be freely douched whether it is bleeding or not as it is advantageous in the event that cancer cells have been expressed on any part of the wound during the operation. Any vessel of sufficient size to require a ligature is tied, others are twisted. Very few ligatures will be necessary if the large branches already mentioned have been ligated at their origin; complete hemostasis is necessary. Hemorrhage must be thoroughly arrested before the suturing is begun, for a certain amount of serum must be expected in so large a wound. Closure of the wound is begun near the clavicle and is best accomplished by interrupted sutures. The first incision having been closed, the suturing of the oval part of the wound is begun at the sternal end. Approximation without tension is, as a rule, easily accomplished; hence it is unnecessary to graft.

An abundant dressing of aseptic gauze is now applied, obliterating the axillary space; and the arm is firmly bound to the side by broad adhesive straps, for at least twenty-four hours. Tension upon the flaps is increased by applying the dress-

ings so that the arm is held at a right angle to the body; moreover, there is no advantage in such a position for hemostasis certainly is not favored by it and the axillary space is made to gap, thereby inviting a subsequent collection of serum which may be troublesome. At the end of twenty-four hours the arm is released and is not included in the subsequent dressing. If it is painful it may be rubbed with alcohol. Drainage is unnecessary, though a vast majority of surgeons still employ it.

Patients, after so formidable an operation, are usually sitting up in forty-eight hours, and are able to leave the hospital when the sutures are removed on the tenth day. Primary union nearly always takes place and the functional use of the arm is as good after as before operation.

The mortality following such a radical procedure is almost negligible, being less than after incomplete operations, simply because the wound is large, the dissection carefully made, and injuries to the blood-vessels avoided. Less than 1 percent are fatal. The ultimate result is much better than was thought possible 10 years ago. If the axillary glands are not enlarged 80 percent are well and free from recurrence at the end of 3 years. If the glands of the axilla are palpably enlarged only 25 percent will be saved by operation. Taking early and late cases as they come at least 50 percent should be permanently cured. Could a stronger argument for early and radical operation be given?

Local applications, X-rays, radium, etc., are impotent and should never be employed save as adjuvants to operation. There is no reason to employ them after operation unless it is to be assumed that infected tissue may have been left behind.

BREATH, FOUL.—The *chief causes* of this condition are: pyorrhea alveolaris; adenoids; tonsillitis; diphtheria; indigestion; diseases of mouth, pharynx, or stomach; decayed teeth, and neglect of proper hygiene of mouth and teeth; diseases of nose, bronchi or lungs; chronic constipation; mineral poisons.

The *treatment* consists in discovering and, if possible, removing the cause. The teeth and gums should receive the first attention; the former should be cleansed, and the latter sponged with a solution of myrrh and water. A mouth-wash of thymol gr. vijss, borax gr. xv, and distilled water 1 pint may be used; or 1 grain of potassium permanganate to 1 ounce of rose water. The following, to be used as wafers, have also been recommended:

℞. Powdered caraway seed,
Powdered coriander seed,
Powdered cinnamon, āā ʒ ss
Sugar, ʒ j
Mucilage of acacia, q. s.
Make fifty pills. Dissolve one in the mouth when necessary.

℞. Powdered cinnamon,
Allspice,
Cardamom, āā ʒ ss
Sugar, ʒ j
Mucilage of acacia, q. s.
Make fifty pills. Dissolve one in the mouth when necessary.

BREATHING.—See Chest (Examination).

BREECH PRESENTATION.—See Fetus (Positions and Presentations).

BRIGHT'S DISEASE.—A name formerly incorrectly used as a synonym of albuminuria, and at present covering several forms of disease of the kidney associated with albumin in the urine. It may be acute (*acute parenchymatous nephritis*) or chronic (which includes *chronic parenchymatous nephritis*, *chronic interstitial nephritis*, *granular contraction of the kidneys*, and *albuminoid degeneration of the kidneys*). Bright's disease is considered by Fothergill as a secondary condition arising from a tendency toward the reversion to that preanthropic type in which the liver performed the additional office of excreting uric acid. See Nephritis.

BRILL'S DISEASE.—See Typhus Fever.

BROMETONE.—A product of the interaction of bromoform and acetone, containing 77 percent of bromin. It is said to have the properties of the bromids without producing bromism and gastric disorders. Dose, 5 grains.

BROMIDROSIS (Osmidrosis).—An affection of the sweat-glands in which the sweat has an offensive odor. It is usually associated with chronic local hyperhidrosis, especially of the feet. The odor is due to a specific decomposition of the sweat, from the presence of the bacterium fœtidum.

It is a frequent accompaniment of systemic diseases, such as small-pox, typhus, rheumatism, and pyemia. The local varieties of bromidrosis are of the axillæ, groins, perineum, genitalia, and soles of the feet. The confinement of sweat by waterproof or other clothing, dress-shields, etc., tends to make matters worse. Bromidrosis of the feet is the most common. Soaking the stockings every night in a saturated solution of boric acid, and the use of cork soles, is a very efficacious treatment. From 10 to 40 grains of chloral in solution is also recommended externally. Activity of the kidneys should be brought about by free administration of diuretics, in order to lessen the excessive sweating. Astringent lotions, dusting-powders, especially those containing boric acid and salicylic acid, and the continued application of diachylon ointment are all recommended.

℞. Powdered salicylic acid, gr. xx to xl
Powdered boric acid, ʒ ij
Powdered starch, ʒ vj.
Mix well into a dusting-powder and apply night and morning.

BROMIN.—Br = 80; quantivalence 1. A reddish-brown liquid that, at ordinary temperatures, gives off a heavy, irritant, suffocating vapor. In its elementary form it is a very active escharotic, and internally a violent poison. It is used by inhalation and as an escharotic. The salts of bromin are cerebral and cardiac depressants, and are highly valuable as hypnotics. The salts of the alkaline metals are those most commonly used. They are cerebral and spinal depressants, also alterative, antispasmodic, and hypnotic.

The bromids of calcium, ammonium, potassium, and sodium are those mainly used in medicine. They allay nervous excitement, promote tranquil-

lity, and are largely employed as sedatives. Bromids have a saline taste, are very diffusible, but are slowly eliminated. Continued administration produces gastric catarrh. They reduce the heart's action and force, the number of respirations, the activity of the brain-cells, and diminish peripheral sensibility, impair motility, and depress the sexual function. Poisoning by long-continued use of the bromids is known as Bromism (*q. v.*). They are not to be used in anemic conditions, and are more effective when given with opium. The potassium bromid and chloral mixture is unsafe when a weak or fatty heart exists. Occasional purgation prevents accumulation of the salts, and arsenic combats the acne resulting from overadministration.

Differences in Action Between the Ordinary Bromids.—**Potassium bromid** is the most toxic to the heart and the muscular system, and is the least hypnotic. It contains 66 percent of bromin.

Sodium bromid is the least toxic, but the most hypnotic, and acts most energetically on the circulation. It contains 78 percent of bromin.

Ammonium bromid resembles the potassium salt in action, except that it exerts less influence on the heart and muscular system, and is somewhat more stimulating.

Lithium bromid contains the most bromin (92 percent), and resembles the sodium salt in action. It has proved better than the other bromids in some cases of epilepsy, and by several authorities is considered the best hypnotic of the series.

Calcium bromid is an efficient hypnotic, but otherwise much less active than the other bromids.

Strontium bromid is said to be less likely than the other bromids to produce bromic acne and other results of bromism.

Zinc bromid, in large doses, is violently irritant. It is supposed to combine the tonic effects of zinc with the sedative action of the bromids.

Antagonists and Incompatibles.—Vasomotor stimulants, such as digitalis, ergot, belladonna, antagonize many of the effects of the bromids, but morphin is the most efficient antagonist, especially for the mental symptoms.

Incompatible with *Bromin* are: Alkali hydrates, arsenites, ferrous salts, hypophosphites, hydriodic acid, mercurous salts; with *Bromoform* are: Caustic alkalies, aqueous liquids; with the *Bromids* are: Acids, alkaloids, antimony salts, bismuth salts, chlorin water, chlorates and chromates in acid solutions; salts of copper, lead, and silver; mercurous salts, nitric acid, spirit of nitrous ether if acid.

Therapeutics.—The bromids are used as sedatives to the nervous system, to lower reflex activity, to produce sleep, to subdue sexual excitement, and to relieve cerebral congestion. They are used in epilepsy, diabetes, acute rheumatism, myalgia, uric acid toxemia, gout, tetanus, insomnia, all kinds of cerebral irritation, delirium, reflex coughs, colic, cholera infantum, and sexual disorders.

Preparations.—**Acidum Hydrobromicum Dilutum,** *diluted hydrobromic acid,* is composed of absolute hydrobromic acid, HBr, 10 percent, and water, 90 percent, and occurs as a clear, colorless and odorless liquid, of pungent and acid taste. It is produced by decomposing potassium bromid with sulphuric acid and distilling. Dose, 20 minims to 2 drams, well diluted. **Potassii Bromidum,** *potassium bromid,* KBr—colorless, cubical crystals, soluble in 1.6 of water and in 200 of alcohol. Dose, 2 to 60 grains, well diluted. **Sodii Bromidum,** *sodium bromid,* NaBr—colorless, monoclinic crystals, soluble in 1.2 of water and in 13 of alcohol. Dose, 2 to 60 grains, well diluted. **Lithii Bromidum,** *lithium bromid,* LiBr—a white, granular, deliquescent salt, very soluble in water and in alcohol. Dose, 2 to 40 grains, well diluted. **Ammonii Bromidum,** *ammonium bromid,* NH_4Br—colorless, prismatic crystals, soluble in 1.5 of water and in 30 of alcohol. Dose, 2 to 40 grains, well diluted. This bromid is well borne by children in comparatively large doses if epileptic from reflex causes. A child one year old can tolerate 5 grains every 4 hours (Barton). **Calcii Bromidum,** *calcium bromid,* $CaBr_2$—a white, granular, deliquescent salt, very soluble in water and in alcohol. Dose, 2 to 60 grains, well diluted. **Strontii Bromidum,** *strontium bromid,* $SrBr_2+6H_2O$—colorless, hexagonal crystals, very deliquescent, very soluble in water and in alcohol; insoluble in ether. Dose, 2 to 30 grains, well diluted. **Zinci Bromidum,** *zinc bromid,* $ZnBr_2$—a white, granular deliquescent powder, very soluble in water and in alcohol. Dose, 1/2 to 3 grains, well diluted.

BROMIPIN.—Brominized Sesame Oil. It is marketed in two forms, one containing 10 percent, the other 33 1/3 percent, of bromin. It is said to be as active as the bromids without producing untoward effects even if used for a long period, and is claimed to be more lasting in its action. Dose, 1 to 4 drams in capsules, warm milk or emulsion.

BROMISM.—Certain peculiar phenomena produced by the excessive administration of the bromids. The most marked symptoms are headache, coldness of the extremities, feebleness of the heart's action, somnolence, apathy, anesthesia of the soft palate and pharynx, pallor of the skin, and a peculiar eruption of acne that, with lowered faucial sensibility, is one of the earliest and most constant symptoms. There is also anorexia, with loss of sexual power and atrophy of the testes or mammæ. The patient may become almost imbecile.

The most efficient antagonist, especially for the mental symptoms, is morphin. Digitalis, ergot, and belladonna antagonize many of the effects of the bromids, as do most vasomotor stimulants. In the administration of bromids arsenic, in the form of Fowler's solution, may prevent bromism. Prolonged previous use of opium or morphin renders the organism extremely susceptible to the action of the bromids.

BROMOFORM.—$CHBr_3$. A bromid having a structure like that of chloroform, $CHCl_3$; it is an active anesthetic. Its use is not followed by vomiting. It causes irritation of the conjunctiva and respiratory organs. It is used in whooping-cough in daily doses of 5 to 20 minims.

BROMURAL.—A condensation product of urea

and brom-isovaleryl bromid. It is a nerve sedative and soporific recommended in functional nervous diseases. It has no cumulative or side effects. Dose, as sedative, 5 grains; as soporific, 10 grains.

BRONCHIECTASIS.—A term denoting the dilatation or relaxation of the walls of the bronchi, arising from inflammation and other causes.

Etiology.—(1) Secondary to chronic bronchitis, phthisis, asthma; (2) pleurisy with adhesions; (3) congenital defect. It is very rare as a primary condition, but is frequently associated with some chronic pulmonary disease. It occurs most frequently in pulmonary tuberculosis at the apex of the lung, but is also frequently seen in the bronchi at the base of the lung. It may involve a tube uniformly for some distance, producing the *cylindric* form; or it may occur irregularly in sacs or pockets—the *sacculated* form. If the whole lung is involved in the change, we have the so-called *turtle lung.*

Pathology.—Occasionally there is a *hypertrophic* condition of the bronchial tubes, while some cases show an *atrophic* condition. Atrophy occurs when there is diminished elasticity, giving rise to dilatation, usually circumscribed. In the hypertrophic form cellular infiltration takes place in the peribronchial tissue, lessening the lumen of the tubes in certain areas, and the increased pressure causes a localized dilatation (cylindric or saccular).

The mucous membrane shares in the process in each variety, while the epithelial cells, as a rule, remain unaffected.

Symptoms and Clinical Course.—There are severe cough, especially at night, dyspnea, and the expectoration of large quantities of a mucopurulent grayish or brownish material, occurring generally after a paroxysm of coughing. The sputum is offensive, and if discharged into a glass vessel, is seen to separate into two layers, the upper stratum being frothy and brownish in color, while the bottom layer is composed for the most part of pus-cells, fatty acids, and crystals of hematoidin.

Physical signs are the same as in chronic bronchitis. If due to phthisis, the characteristic physical signs of that disease will be present. The signs of a cavity (bronchiectatic) may be present.

Diagnosis is not always possible. If due to phthisis, the presence of tubercle bacilli will confirm the diagnosis. See BRONCHITIS (Chronic).

Prognosis depends on the disease to which bronchiectasis is secondary. It is usually unfavorable.

Treatment must be directed to the underlying cause. See BRONCHITIS (Chronic), TUBERCULOSIS.

BRONCHITIS, ACUTE (Acute Catarrhal Bronchitis, or Bronchial Catarrh).—An acute inflammation of the bronchial mucous membrane, accompanied by cough, a mucopurulent expectoration, and the presence of dry and moist râles in the bronchial tubes.

Etiology.—(1) Exposure to cold and wet; (2) changeable weather; (3) inhalation of irritating substances; (4) it is often associated with such diseases as influenza, measles, typhoid fever, nephritis, and heart-disease.

Pathology.—The mucous membrane of the bronchial tubes is reddened and swollen; the epithelial cells undergo a mucoid degeneration, forming a coating of mucus. In the acute stages there may be an infiltration of the blood in the epithelial cells. Besides this mucoid degeneration the bronchial glands pour out large quantities of mucus, thus increasing the amount of fluid in the bronchial tubes.

Symptoms and Clinical Course.—The onset is usually within the first 24 hours, marked by chilliness, hoarseness (laryngitis), distressing cough, sense of pain and constriction over the region of the sternum, slight fever (100° to 101° F.), and the expectoration of a viscid, whitish secretion.

Physical Signs.—The respirations are normal, although slight dyspnea may be present. As a rule, the objective symptoms, determined by inspection, palpation, and percussion, are negative. Auscultation in first stages yields dry râles (sonorous and sibilant) both during inspiration and expiration; later, when the mucus is more fluid, moist râles (mucous râles, small gurgling râles) may be heard during the respiratory murmur.

The dry and moist râles may be modified by coughing.

Diagnosis.—

ACUTE BRONCHITIS.	INFLUENZA.	BRONCHOPNEUMONIA.
Subjective Symptoms.	*Subjective Symptoms.*	*Subjective Symptoms.*
1. May occur at any age.	1. May occur at any age.	1. Most frequent in young or very old.
2. Pain in region of sternum.	2. Pain in forehead or back of neck; general bodyache.	2. Pain in region of chest.
Objective Symptoms.	*Objective Symptoms.*	*Objective Symptoms.*
1. Respirations normal or only slightly increased	1. Respirations slightly increased.	1. Respirations exaggerated; dyspnea may be present; livid color of lips.
2. Fever slight or entirely absent; pulse in proportion.	2. Pulse small, rapid, irregular; moderate and often high fever (103° to 104° F.).	2. High fever; pulse rapid and feeble.
3. In early stages sonorous and sibilant râles; later, mucous râles are heard.	3. Same as acute bronchitis.	3. Subcrepitant râles over base of lungs posteriorly.

Prognosis is favorable.

Treatment.—If the bowels are constipated or the tongue is coated, a purgative should be given at once. Free diaphoresis may be established by the use of hot foot-baths on going to bed, and repeated again during the night if necessary. Subsequent to the foot-bath hot lemonade will aid in aborting the disease.

The atmosphere of the room should be maintained at an even temperature—never below 65° F. or 70° F.—and the chest should be enveloped in flannel; mustard plasters may be applied to the

chest. Quinin (4 grains) with Dover's powder (5 grains) every 3 or 4 hours are indicated. The diet should be principally liquid. The majority of so-called expectorants are disappointing. The drug that most quickly relieves the distressing cough and pain is opium, or one of its alkaloids. Codein is reliable, and does not disturb the stomach so much as morphin.

In early stages:

℞.	Codein sulphate,	gr. iv
	Elixir of orange,	ʒ iij
	Solution of potassium citrate, enough to make	ʒ iij.

Two teaspoonfuls every 3 hours.

℞.	Codein sulphate,	gr. iv
	Chloroform,	♏ xl
	Acacia,	ʒ ss
	Sugar,	ʒ ss
	Glycerin,	ʒ ij
	Water, enough to make	ʒ iij.

Two teaspoonfuls every 3 hours.

The following may be substituted:

℞.	Antimony and potassium tartrate,	gr. j
	Elixir of curacao,	ʒ iij
	Solution of potassium citrate, enough to make	ʒ iij.

Two teaspoonfuls every 3 hours.

If cough is oppressive, with constriction, the chest may be thoroughly rubbed with—

℞.	Oil of mustard,	♏ x
	Olive oil,	ʒ j.

Or the following inhalation may be used:

℞.	Menthol,	gr. ij
	Chloroform,	♏ xvj
	Compound tincture of benzoin,	ʒ j.

Teaspoonful to a pint of boiling water and inhale twice daily.

In later stages of the disease, or after first 4 or 5 days:

℞.	Ammonium chlorid,	ʒ j
	Compound syrup of squill,	ʒ iv
	Camphorated tincture of opium,	ʒ iv
	Water, enough to make	ʒ iij.

Two teaspoonfuls every 3 hours.

BRONCHITIS, CAPILLARY.—See BRONCHOPNEUMONIA.

BRONCHITIS, CHRONIC (Chronic Bronchial Catarrh).—A chronic catarrhal inflammation of the mucous membrane of the bronchial tubes.

Etiology.—It may result from an acute attack, but is most frequently due to the presistent action of improper hygiene—especially damp atmosphere—or to diseases of the heart, liver, or kidney.

Differential Diagnosis

Chronic Bronchitis.	Bronchiectasis.	Emphysema.	Asthma.	Phthisis.
Subjective Symptoms.	*Subjective Symptoms.*	*Subjective Symptoms.*	*Subjective Symptoms.*	*Subjective Symptoms.*
1. May result from acute attack.	1. Generally results from chronic bronchitis of long standing or from phthisis.	1. Same as bronchiectasis.	1. Hereditary tendency; frequently associated with gouty diathesis; neurotic tendency, heart- and kidney-disease, or phthisis.	1. Hereditary tendency.
2. Localized pain generally absent.	2. Localized pain uncommon.	2. Localized pain uncommon.	2. Localized pain uncommon.	2. Localized pain frequently present.
3. Bodily health remains good.	3. Great emaciation.	3. Slow loss of flesh and strength.	3. Slow loss of flesh and strength.	3. Rapid emaciation.

4. Sonorous and sibilant râles most frequently heard.	4. Dry and moist râles.	4. Sibilant râles most frequently.	4. Dry and moist râles, most frequently sonorous and sibilant.	4. Moist râles most frequently.
5. Expectoration scanty and whitish in color.	5. Expectoration whitish or grayish and abundant, containing fatty crystals and hematoidin.	5. Expectoration whitish and scanty.	5. Expectoration copious, whitish, containing Curschmann's spirals and Charcot-Leyden crystals.	5. Expectoration copious, whitish, yellowish or greenish, containing nummular plugs and tubercle bacilli.

Pathology.—In chronic bronchitis the continued irritation may give rise to cellular infiltration or hyperplasia in certain areas, causing a narrowing of the lumen of the bronchial tubes. Other areas occur, however, in which there is atrophy, and the epithelial surface may be roughened considerably. When the tubes become dilated, *bronchiectasis* or emphysema may result. If the secretion is abundant and mostly serous, it is termed *bronchorrhea;* and if offensive or putrid, *putrid bronchitis,* or *bronchoblennorrhea.*

Symptoms and Clinical Course.—Distressing, violent attacks of coughing, especially at night; expectoration of a scanty, tenacious, mucopurulent character, and dyspnea are generally present. The health appears to remain in good condition, and fever is generally absent, but may be present as a septic symptom, accompanied by increase of cough, pain in the side, chill, loss of appetite, indigestion, and general failure of health.

Physical Signs.—There is usually emphysema of the chest, with diminished expansion on inspiration and diminished tactile fremitus. On percussion, the note is hyperresonant, and on auscultation the expiratory breath-sound is prolonged and wheezy in quality. Sonorous, sibilant, or mucous râles may be present.

Varieties of Chronic Bronchitis.—(1) Bronchorrhea; (2) putrid bronchitis; (3) dry catarrh.

Bronchorrhea.—Characterized by cough and expectoration of large quantities of serous material.

Putrid Bronchitis.—Secretion abundant, grayish or whitish in color, often containing yellowish masses, and generally associated with empyema or phthisis during the existence of cavities.

Dry catarrh generally occurs in the very old, characterized by severe cough and scanty or entire absence of secretion from the bronchial tubes.

Sequels.—Emphysema, bronchiectasis, bronchopneumonia, dilatation of right ventricle.

Prognosis.—For absolute recovery, unfavorable; chronic bronchitis, *per se,* rarely, if ever, causes death, the patient usually dying of some intercurrent disease.

Treatment.—Avoid contracting cold, wear flannel underclothing, and guard against wet feet. The skin may be kept in a healthy condition by use of baths and massage. If the disease is due to constant inhalation of irritating particles, the patient should select another occupation. If due to organic disease, treatment must first be directed to the diseased part. A change of residence will generally be of great benefit. If the health is not good, tonics are indicated, such as the syrup of hypophosphites (2 drams) or the elixir of phosphates of iron, quinin, and strychnin (2 drams), taken after meals. Cod-liver oil is of especial advantage, and should be given in the form of an emulsion. See Tuberculosis (Treatment). Beechwood creosote (2 to 4 minims) is valuable in lessening the amount of secretion, and may be combined with cod-liver oil or given in sherry wine. The carbonate of ammonium may be given for a day or two, but should not be continuously administered lest the digestion become impaired.

℞. Aromatic spirit of ammonia, ℥ ijss
Compound syrup of squill, ℥ iv
Camphorated tincture of opium, ℥ iv
Water, enough to make ℥ iij.

Two teaspoonfuls every 3 hours.

℞. Potassium iodid, ℥ j
Syrup of senega, ℥ j
Glycerin, ℥ iij
Water, enough to make ℥ iij.

Two teaspoonfuls one hour after meals.

Local Treatment.—Stimulating inhalants are indicated:

℞. Creosote (beechwood), ℥ j
Eucalyptol, ℥ j
Compound tincture of benzoin, ℥ ij.

Teaspoonful to a pint of boiling water, and inhale morning and at bedtime.

Subsequent to the use of inhalants, it is essential that the patient should remain indoors at least one hour.

Troches may be given:

℞. Oil of cubebs, ℥ ss
Oil of lemon, ♏ xv
Oil of cloves, ♏ x
Guaiac, ℥ ij
Althea, ℥ j
Acacia, ℥ iv
Sugar, ℥ jss
Confection of rose, enough to make 30 lozenges.

Allow 1 to dissolve in mouth every 4 hours.

BRONCHITIS, FIBRINOUS (Plastic Bronchitis).—A rare form of chronic bronchitis, characterized by the formation and expulsion of a cast formed in the bronchial tubes.

Etiology.—It is frequently associated with tuberculosis; spring season, adult life, male sex, specially predispose.

Pathology.—The disease is generally circumscribed, certain tubes being affected. The changes in the mucous surface are slight, but the submucous tissue may be infiltrated with serum. The casts are whitish or grayish in color, and composed of fibrin. They have a branched appearance, and may be several inches in length. Microscopic examination detects degenerated epithelial cells, leukocytes, and Charcot-Leyden crystals.

Symptoms and Clinical Course.—The disease may be acute or chronic. In the acute form the manifestations resemble those of acute bronchitis, except that the symptoms are more grave and a pseudomembrane is expelled.

The chronic form resembles chronic bronchitis, but symptoms are more severe. The disease may recur periodically.

Prognosis is unfavorable.

Treatment is the same as for Bronchopneumonia.

BRONCHITIS, INFANTILE.—Bronchial catarrh is a very common disease in early life, children under 3 years of age being those most often affected by it. In them, owing to the want of elasticity of the chest walls, the ease with which the bronchial tubes collapse, the tendency for the lungs to join in the inflammation, and from the diseases which are liable to follow, bronchitis is an important affection.

Etiology.—Improper feeding, unhygienic surroundings, teething, gastrointestinal disturbances, malnutrition, and rickets are common predisposing causes. The disease may be caused by exposure to cold or wet, sudden changes in the temperature, extension of inflammation from the upper air-passages, or contact with another case.

Bronchitis is present in children suffering from the acute infectious diseases, especially measles, pertussis, influenza, and typhoid fever.

Pathology.—The bronchial mucous membrane is congested, with at first a diminished and later an increased mucous secretion. In mild cases the large bronchi only are affected, but when severe, the medium and the small tubes may also be involved. Bronchitis is usually bilateral—both sides being equally affected.

Symptoms.—The attack may be primary or may begin with coryza, pharyngitis, or laryngitis. Tracheitis is usually present. As the inflammation extends to the bronchi it will be indicated by increased temperature (100° to 102° F.), cough, which may be slight or severe, and accelerated respiration accompanied by a wheezing or rattling in the chest, and soon by expectoration of mucus or mucopurulent secretions. Infants do not expectorate, but the secretions, when coughed up into the mouth or pharynx, are swallowed, and may excite vomiting or diarrhea. The appetite is diminished, the gastrointestinal tract sluggish or irritable, and the child is restless and fretful.

On physical examination the percussion resonance will be found normal, but a bronchial fremitus will be felt on palpation. Auscultation will reveal roughened breathing over all the affected area, and sibilant, sonorous, and mucous râles may be heard all over the chest, but especially between the scapulæ. In mild cases the symptoms mentioned will not be sufficiently severe to cause alarm, and recovery will gradually be effected in the course of a week. Relapses, however, are frequent, and in weak children or in those predisposed one attack may follow another during the entire winter and spring.

When the smaller tubes are involved, a more serious condition exists than that just described. The temperature is higher; prostration more marked; and dyspnea more severe, as shown by rapid breathing, laboring of the alæ nasi and of all the accessory muscles of respiration. In severe cases cyanosis is present, and in young infants there are sometimes sudden attacks of suffocation that may prove fatal.

Diagnosis.—In influenza the onset is more severe, with pains in the limbs and back, headache, and gastrointestinal disturbances; the temperature is higher and there is great prostration.

Bronchopneumonia.—Higher temperature, remittent in character; physical signs of consolidated areas, with greater severity of all symptoms.

Prognosis.—Recovery may be expected in the milder, uncomplicated cases. When the smaller tubes are affected, the prognosis is less favorable, but in infants not suffering from malnutrition or rickets a fatal termination is not common.

Treatment.—The hygienic treatment of acute bronchitis is very important. The patient should be confined to a sunny, well-ventilated room, kept at a temperature of about 70° F., and the air of which is moistened by steam. When any fever is present, the child should be kept in bed. Hot camphor liniment should be well rubbed over the chest, front and back, twice a day, and a woolen cloth or shirt or, better, an oiled silk jacket kept over this part of the child's body. The oiled silk jacket is made by enclosing cotton batting about 1/2 of an inch thick in a covering, on the outside of oiled silk and on the inside of cheese-cloth or thin muslin. In severe cases counterirritation with a mild mustard plaster is very valuable. A suitable plaster is made as follows: To 1 part of powdered mustard and 6 parts of wheat flour add lukewarm water to make a paste, and spread between 2 layers of muslin large enough to envelop the chest. This, when applied, should be allowed to remain from 5 to 10 minutes, or until the skin becomes well reddened, and it may be repeated 2 or 3 times a day, or every 2 or 3 hours, according to the indications; the jacket being kept on in the intervals and worn throughout the attack.

Inhalations of steam, using the croup-kettle and a tent—as recommended in the treatment of croup—are very useful. Either lime-water, compound tincture of benzoin, creosote, turpentine, or eucalyptus, or a combination such as the following, may be used in the water:

℞. Carbolic acid,
Benzoic acid, } each, ʒ ss
Oil of eucalyptus,
Oil of turpentine, ʒ ijss.

Add a tablespoonful to the quart of water.

At the first visit a laxative should be given—magnesia, 15 to 60 grains; castor oil, 1/2 of a teaspoonful to a tablespoonful, according to the child's age; or, better, for a young child, small doses of calomel, as follows:

℞. Calomel, gr. j
Powdered ipecacuanha, gr. ij
Sugar of milk, gr. xij.

Mix and make 12 powders, giving 1 every 2 hours until the bowels are acted upon, and repeat daily, or when necessary to keep the bowels freely open, in order that the mucus that is coughed up and swallowed may be cleared out of the system.

In children under 2 years of age cough syrups and expectorant cough mixtures are not indicated, but an occasional dose of syrup of ipecacuanha (2 to 5 drops every 3 or 4 hours) may be given. For older children one of the following recipes will be found

useful, given every 2 or 3 hours in 1/2 to 1 teaspoonful doses:

℞. Solution of potassium citrate, ℥ ss
Tincture of aconite, ♏xv
Camphorated tincture of opium, } each, ℥ ij
Syrup of squill,
Syrup of tolu, q. s. ℥ iij.

℞. Aromatic spirit of ammonia, ℥ vj
Tincture of hyoscyamus, } each, ℥ j
Tincture of belladonna, }
Syrup of ipecacuanha, ℥ ij
Glycerin, ℥ ss
Syrup of wild cherry, q. s., ℥ iij.

℞. Ammonium carbonate, ℥ j
Ammonium chlorid, ℥ ij
Spirit of chloroform, ℥ ij
Wine of ipecacuanha, ℥ iv
Compound licorice mixture, q. s., ℥ iij.

℞. Wine of ipecacuanha, } each, ℥ ij
Paregoric, }
Solution of potassium citrate, ℥ j
Syrup of acacia, ℥ jss

℞. Codein, gr. iij
Syrup of ipecacuanha, ℥ j
Solution of ammonium acetate, ℥ ss
Mucilage of acacia, ℥ j
Water, ℥ ss.

When the pulse is weak and there is general prostration, stimulants should be given, as brandy or whisky, 10 to 30 drops well diluted every 2 or 3 hours to a child 6 months old. Five- to ten-drop doses of aromatic spirit of ammonia act as an excellent stimulant, and may be alternated with the alcohol every 2 hours. Strychnin is also a valuable cardiac and respiratory tonic, and may be given to a child 6 months old in doses of 1/200 to 1/100 grain hypodermically every 3 or 4 hours.

When there are symptoms of suffocation, as sometimes occurs in severe cases in infants, it is necessary to stimulate the cutaneous circulation and compel the child to take deep inspirations. This is best accomplished by slapping the child's bare body with a wet towel or handkerchief until it cries lustily. For the same object, alternate hot and cold douching of the chest, the mustard bath, or the mustard pack will be effective.

The diet in older children during the febrile stage should be liquid (milk and broths), and they should be given mucilaginous drinks, such as linseed tea, elm-bark tea, or barley-water. Proper regulation of the diet is especially important in infants. In bottle-fed infants the milk should be carefully modified and prepared, the proteids being reduced to a lower percentage than in health, and the rule for feeding should be strictly observed. See Infant Feeding.

Nursing infants should not be allowed to take the breast more frequently than usual, unless their appetite is so poor that they take but a small quantity at each feeding; all children should be given cool boiled water to drink.

During convalescence, and to prevent the attack in infants who are predisposed to bronchitis, they should have a daily salt bath, followed by inunction of cod-liver oil or sweet oil; they should not be exposed to damp or extreme cold; should sleep in flannel night-clothes, in a warm room, well ventilated but free from draft; and, if possible, reside in a dry, temperate climate.

In other children tonics, such as iron, quinin, cod-liver oil, or creosote, should be given—the last in emulsion or in capsules, as:

℞. Carbonate of creosote, ℥ j
Magnesia, sufficient to make a mass.
Mix and make 30 capsules, giving 1 three times a day.

See Bronchopneumonia.

BRONCHOCELE.—See Thyroid gland (goiter.

BRONCHOPNEUMONIA (Capillary Bronchitis; Suffocative Catarrh).—A term applied to inflammation of the lungs caused by microbic infection that, beginning in the bronchi, finally involves the parenchyma of the lungs. This disease is most frequently encountered in children, but may occur in old age. Three varieties are described: (1) A simple acute form following a severe bronchial catarrh; (2) a secondary form, occurring after whooping-cough or some general febrile infective disease; (3) a rare suppurative form, with the formation of abscesses throughout the lung.

Etiology.—It may be primary in the very young or old; it is usually secondary to measles, diphtheria, whooping-cough, tuberculosis, scarlet fever, nephritis, and heart-disease. Emphysema is a common predisposing cause (Pepper). It may result from lodgment of food in the bronchial tubes (*aspiration pneumonia*). It is usually due to mixed infection, the organisms most frequently found being the staphylococcus albus and aureus, the streptococcus pyogenes, the pneumobacillus and the micrococcus lanceolatus.

Pathology.—The mucous membrane of the terminal bronchioles is red, congested, and swollen, and covered by a thick, very tenacious mucus. The lungs are larger than normal, and externally are lighter in color. On the pleural surfaces are dark spots over areas where collapse has taken place. On section, the cut surface is dark red in color, containing reddish-gray spots. Pressure causes the exudation of large quantities of mucopus from the cut end of the bronchioles. Certain areas are red and hepatized, and surrounded by airless tissue (collapse of lung, or atelectasis).

Symptoms and Clinical Course.—In children the onset is marked by convulsions, high fever (104° F.), violent cough, rapid respiration (60 a minute) or intense dyspnea, pulse rapid and feeble, blueness of the lips, and cold extremities.

Physical Signs.—There are symptoms of intense dyspnea, the lips are blue, the nose pointed, the alæ expand and retract, the suprasternal notch is retracted, the sternomastoid muscle is rigid. Localized areas of dulness may be present, but usually these are never detected. Fine subcrepitant râles are heard posteriorly at base of lungs; sibilant râles may also be present, but the presence

of subcrepitant râles on both sides of the chest is specially diagnostic of the disease.

Diagnosis.—The disease may be mistaken for lobar pneumonia, but the physical signs, if systematically elicited, should prevent this error.

Prognosis.—In children under 5 the mortality is from 30 to 50 percent. In the aged the prognosis is unfavorable. In adults or middle age prognosis is better.

Treatment.—Absolute rest in bed and a nutritious diet; the chest should be enveloped in a thick cotton jacket; the temperature of the room should be equable, about 65° or 70° F. The windows should be kept open so that the patient may breathe pure air while at the same time he should be protected from drafts. If the bowels are inclined to be constipated, fractional doses (1/6 grain) of calomel are advisable every hour until 6 or 7 doses have been taken.

In the earliest stages the tincture of aconite is of service. Its action should be *cautiously* watched, and as soon as the pulse become soft the drug may be omitted. Usually 6 or 7 doses are sufficient.

For a child over 2 years old:

℞. Tincture of aconite, ♏ xxx
Simple elixir, ʒ ij
Solution of potassium citrate, enough to make ʒ j

One teaspoonful every 3 or 4 hours.

After the second or third day its action is too depressing, and is not recommended. Stimulating applications to the chest and massage appear to give comfort:

℞. Oil of mustard, ♏ xv
Olive oil, ʒ ij.

Apply a small quantity to chest twice daily and rub thoroughly.

Both the hot and the cold baths are of great value. If the temperature rises above 102.4° F., it should be reduced by means of a cold bath. The cold bath stimulates the circulation, respiration, kidneys, and the skin—which is beneficial.

Phenacetin may be given in appropriate doses to relieve persistent hyperpyrexia, but as a routine practice its use is harmful. Ammonium carbonate is valuable if given in sufficient doses.

Mustard applications, packs or baths (at 85° F.) of mustard are highly recommended. After the third or fourth day, or when the secretion becomes more abundant, with increased respiration, heat may be applied to chest in the form of a flaxseed poultice containing mustard (1 1/2 drams), and removed every hour if necessary. After the poultice has remained on the chest about 2 hours, give syrup of ipecacuanha (15 minims for children) every 10 minutes, until emesis is produced. In adults larger doses (1/2 to 1 dram) must be given. The poultice may be applied on the following day, and syrup of ipecacuanha repeated in a similar manner. The poultice should never be bound too closely around the chest, otherwise the respirations may become embarrassed from its weight. When the poultice is removed, the cotton jacket should be immediately replaced to prevent undue exposure. If the heart is weak, tincture of digitalis combined with the aromatic spirit of ammonia is of great benefit. Strychnin is of especial value if respirations are embarrassed. See Bronchitis (Infantile.)

BRONCHOSCOPY.—See Larynx (Foreign Bodies).

BROOM.—See Scoparius.

BROVALOL.—The brom-isovaleric ester of borneol, containing 25.2 percent of bromin. A restorative, sedative and antispasmodic. It is claimed to be well tolerated even in large doses, and to be more potent as a sedative than other valeric acid derivatives. Dose, 1 to 3 capsules each of which contains 4 grains.

BROW-PRESENTATION.—See Fetus (Positions and Presentations).

BRUCIN.—A poisonous alkaloid found in *Strychnos nux-vomica* and in *Strychnos ignatia.* It crystallizes in prisms containing $4H_2O$, and melts at 178° F. Its taste is exceedingly bitter and acrid. Its action on the animal economy is similar to, but much less powerful than, that of strychnin. It is seldom used; dose, 1/10 to 1/3 grain. See Nux Vomica.

BRUISE.—A slight contusion or subcutaneous injury, occasioned by a blow, crush, or tear of the tissues, combined with extravasation of blood from ruptured capillaries and smaller vessels of the part, the overlying skin being seldom broken.

An *ecchymosis* is diffused hemorrhage over a large area; a *hematoma* is a blood tumor or circumscribed hemorrhage. When the damage is sufficiently great, sloughing and gangrene may result. More commonly, the superficial vessels only are ruptured, leading to extravasation of blood. Swelling soon follows the injury, and occasionally large bullæ form containing blood-stained serum. Inflammation may ensue, leading to suppuration. In persons with thin, delicate skins and a tendency to the hemorrhagic diathesis, the tissues will be bruised and discolored from the most trifling injuries. The tendency to the formation of bruises varies widely in different persons, and the extent of the discoloration is no indication of the violence employed.

If seen early, before discoloration has resulted, ice or an evaporating spirit lotion may be most beneficial. A cold, saturated, recently prepared solution of ammonium chlorid is of value in the contusion when a "black eye" is dreaded. The fresh root of convallaria is useful for the same purpose, while arnica should be used with caution, as it is of little or no value.

If ecchymosis has taken place, a warm spirit lotion, covered with oiled silk and thick layers of cotton-wool, and bandaged moderately tight, will cause absorption of the effused blood. Capsicum, camphor, mild counterirritants, and moderate pressure may be used to hasten the process. A solution of lead-water and laudanum, or aconite, belladonna, opium, or lead acetate, may be used. Leeches occasionally prevent discoloration if used

very early, but they are of doubtful value. Incisions into the skin in extensive extravasations are very seldom necessary, although the aspirator may be used.

BRUIT.—See CHEST (Examination).

BRUSH-BURN.—The complex injury caused by rapid and forcible friction of a body surface—a rapidly revolving body, as a strap connected with machinery striking the skin, or by a sliding or gliding along a tree trunk or pole with much velocity, slipping of rope through the hands, etc. The skin is usually abraded, severely bruised, and sometimes actually burned away. The subcutaneous tissue, fasciæ, and muscles are usually greatly contused. The skin may become gangrenous, and a slough result.

The treatment consists in applying lead-water and laudanum lotion, or similar anodyne solutions; and, if necessary, removal of the slough, and then dressing with a stimulating lotion or ointment. The ulcer is to be treated on general principles.

BRYONIA.—Bryony. The root of *B. alba* and *B. dioica;* indigenous to Europe, with properties due to an intensely bitter glucosid, *bryonin*, a strong irritant when applied to the skin or mucous membrane, often producing vesication. It is a remedy of value in pleurisy, pleuropneumonia, and rheumatic fever, and an excellent remedy in colds. It is soluble in water and in alcohol but not in ether. Dose of the powdered root, 10 to 30 grains. Bryonin is a violent poison in 3- to 4-grain doses. Dose as a drastic purgative, 1/6 to 1/3 grain.

BUBO.—See LYMPHATICS (DISEASES, LYMPHADENITIS), GONORRHEA, SYPHILIS.

BUBONIC PLAGUE.—See PLAGUE.

BUCHU.—The dried leaves of *Barosma betulina*, containing a volatile oil as its active principle, giving them an odor resembling peppermint. The dose of the leaves is 15 to 45 grains. The preparations are the fluidextract of buchu—the dose of which is 15 to 40 minims—and the infusion of buchu (1 ounce to the pint)—the dose being 1/2 to 2 ounces. Buchu increases the flow of the urine, and is of especial use in chronic affections of the genitourinary mucous membrane. It is very useful in bronchitis, pyelitis, cystitis, urethritis, lithiasis, and affections of the prostate gland. The infusion makes an excellent vehicle for saline diuretics. When the urine is highly acid, muddy, and laden with salts, and produces incontinence from its vesical irritation, the fluidextract of buchu in teaspoonful doses, with sweet spirit of niter, will be beneficial.

The following is serviceable:

℞. Potassium citrate,	ʒ iv
Spirit of chloroform,	ʒ iij
Tincture of digitalis,	ʒ j
Infusion of buchu,	℥ viij.

Give 2 tablespoonfuls 3 times a day.

BULIMIA—An insatiable and inordinate craving for food. Found in certain cases of true diabetes, and normally in convalescence from fevers such as typhoid and the exanthemata. It is met with as a *nervous or hysterical* manifestation as well as in cerebral disease, epilepsy, exophthalmic goiter, etc. In the hysteric and neurasthenic cases it may be associated with an absence of the sense of satiety (achoria) or there may be a craving for unusual, seemingly or actually injurious, or, possibly, disgusting articles, as is observed in hysteria, pregnancy, chlorosis and to a less degree in childhood, where it no doubt oftentimes represents in normal children a genuine structural need in so far as it relates to special types of ordinary food, the craving for sweets and fruits or the preference shown for an exclusive starchy or proteid diet being too often combated by parents.

BULLET WOUNDS.—See GUNSHOT WOUNDS.

BUNION.—The enlarged and thickened bursa resulting from distortion over the inner side of the metatarsophalangeal joint of the great toe. The constant wearing of short and narrow-pointed shoes (especially in women) crowds the toes together, and the pressure on the inner side has the effect of dislocating outward the two phalanges of the great toe. The head of the metatarsal bone forms an increasing projection, and the bursa met with there enlarges. At the same time the head of the metatarsal bone itself enlarges, and presents small bony outgrowths similar to those in osteoarthritis.

The chief sequels of a bunion are recurrent inflammatory attacks, suppuration leaving an ulcer most tedious to heal. On account of the feeble circulation after middle life, the ulcer is liable to lead to cellulitis, erysipelas, or even senile gangrene. Perforating ulcer may lead to disorganization of the joint and caries of the bones.

The treatment includes insistence upon the wearing of proper shoes, with straight inside border and rounded toes, giving sufficient room and play for the foot. The phalanges may be drawn inward by passing a strap between the first and second toes, around the phalanges of the first, and then carrying it along the inner border of the foot and around the heel as far as the center of the outer side. Bandages from side to side around the foot will help to retain this strip. Cotton-wool pledgets or "elephant plaster" should be worn between the first 2 toes. A glove of buckskin or linen may be fitted over the phalanges, with a few inches of elastic webbing attached, and this fastened to a strip that goes around the heel, and is kept in place as described.

If simple treatment is insufficient, mechanic contrivances must be devised, such as metal soleplates and bunion-springs, which draw the phalanges inward.

The internal lateral ligament and tendons may be cut, followed by forcible and steady replacement of the phalanges. Osteotomy of the first phalanx may be performed or amputation by the oval method. C. H. Mayo resects the head of the metatarsal bone and also cuts away two-thirds of the hypertrophy on the inner side. He then sutures the bursa into the joint area in front of the bone. The latter procedure is said to give a fairly movable joint.

When simple thickening and effusion exist, the bunion may be treated with flying blisters, ichthyol, iodin, silver nitrate (1 dram to 1 ounce),

strapping with mercurial ointment, etc. If inflammation exists, lead-water and laudanum, dilute lead acetate, or conium are indicated. Frequent hot foot-baths are beneficial. If suppuration intervenes, incision and drainage are indicated. If ulceration has developed, the undermined skin must be snipped away, the bursal cavity laid freely open, and obliteration by granulation obtained by cleanliness and stimulating applications.

A stimulating ointment:

℞.	Iodoform,	gr. xx
	Oil of eucalyptus,	♏. xx
	Vaselin,	ʒ j.

More stimulating is compound tincture of benzoin.

℞.	Mercury biniodid,	gr. x
	Vaselin,	ʒ j.

Warmth, elevation of the foot, and weak solutions of silver nitrate will stimulate the circulation and healing. Skin-grafting may be resorted to. In advanced life warmth (obtained by cotton-wool applications), avoiding exposure, and the raised position are of much importance.

BUPHTHALMOS.—See Keratoglobus.

BURDOCK.—See Lappa.

BURNS.—Injuries caused by fire or dry heat. Scalds are caused by heated fluids or steam, but there is no distinction as to the nature of the changes produced in the tissues or as to their results and treatment.

The classifications of burns are many, but they are herein regarded as of 3 degrees, viz.: (1) that of congestion; (2) that of vesication; and (3) that of more or less disorganization of the soft parts.

The lesion of the **first degree** is that of simple scorching; that of the second degree is marked by one or several patches of erythema and studded with bullæ containing clear and serous fluid. In the mildest form of the third degree a part of the cuticle, in addition to the epiderm, is destroyed. In the most severe form the burn extends to the muscular and other deep-seated parts. In the majority of burns of the first degree the injury is mild, and needs scarcely any treatment save the application of cold; yet if it involves two-thirds of the body surface, it is said, it will inevitably prove fatal.

In burns of the **second degree** there is always pain, at first very severe, and in favorable cases the heat and redness subside speedily, the vesicle bursts, the dry and shriveled epidermis is thrown off, and recovery ensues in a few days. The lesions of this degree are most common after scalds and applications of heated metals, and are, in the primary stage, more painful than those of any other degree. They are very serious when the chest and abdomen are involved, and sometimes fatal. In favorable cases of burns of the **third degree** the sloughs gradually separate in a few weeks, leaving the well-known pale-gray surface thickly studded with granulations, resulting in a scar that can never be effaced, but that is movable over the subjacent parts. The depth to which a burn has extended cannot be determined easily until disorganization has ensued. Burning clothes and the prolonged application of heated metals and other solid bodies are the most frequent causes of the third degree of burns. The danger of the detachment of the eschar or slough in this degree is the profuse bleeding that may ensue. The deep ulcer resulting heals very slowly, and after prolonged and exhausting suppuration.

The stages of prostration, reaction, and suppuration follow the course of most severe burns.

The first stage lasts from 18 to 24 hours, and pain is the most prominent symptom. Careless removal of the sufferer's clothing ruptures the vesicles and detaches the epidermis, leaving the raw cutis exposed. Profound collapse or extreme restlessness and excitement ensue. Death from shock or from gradually increasing prostration, or, in children, after convulsions and coma, may ensue. Obstinate thirst is often a symptom, and the desire to evacuate the bladder although it is empty is troublesome.

The second stage, or that of reaction, lasts for 2 or 3 days in mild injuries of the first and second degrees; but in severe burns of the third degree does not ensue until the sloughs are cast off. Two weeks are usually regarded as the period of inflammatory reaction. Complications, such as cough, pleurisy, or bronchopneumonia, vomiting, and diarrhea, must be closely guarded against.

The third stage, or that of suppuration, is characterized by the exhaustion due to the profuse discharge. Hectic fever, marasmus, cellulitis, erysipelas, pyemia, septicemia, with asthenic lung conditions and duodenal ulcerations, are the special complications.

The treatment of severe burns is directed to reaction from shock, relief of pain, quieting of any restlessness and agitation, and guarding against coma. Recumbency, stimulants, such as brandy and water, with blankets and hot-water bottles along the sides of the trunk and at the extremities are to be employed. Hypodermics of morphin or full doses of laudanum must be given for the pain. Potassium bromid may be given during the course of reaction, and thirst relieved by giving frequently and in small quantities hot beef-tea, soup, milk and soda-water, weak lemonade, barley-water, and dilute sulphuric or phosphoric acid.

In the stage of reaction the strength must be supported and undue stimulation avoided. The diet should consist of milk, beef-tea, and soups, and should be nourishing. Liquor ammonii citratis and small doses of antimony and potassium tartrate are indicated for pulmonary congestion or bronchopneumonia, if the patient is not very weak. Chalk and opium, small doses of laudanum and castor oil, zinc sulphate and opium should control the diarrhea.

The third stage, or that of suppuration and healing, requires stimulation, with a free and generous diet, wine and malt liquors, and, if possible, occasional change of scene and air.

Burns of the first degree should have instant application of a saturated solution of sodium bicarbonate. If this is made before the cuticle is

raised, a painful burn may be prevented. Cold, in the form of cold compresses, cold baths, iced water, lead-water, or diluted cologne water, will relieve the smarting pain in this stage. When an extensive surface is involved, prolonged immersion in a bath of slightly warmed water or the local application of some cooling and oily fluid, covered over with a thick layer of cotton-wool, is desirable.

In *burns of the second degree* the blebs should be punctured at their most dependent parts, and dusted with wheaten flour or boric acid and flour, 1 : 4, or boric acid mixed with starch or talc powder in 10 percent strength. Salol, thiol, bismuth, potassium sozoidol, and other powders may be used with talc or oxid of zinc. The principal object is to exclude the external air from the seat of the injury.

The list of dressings and applications is endless. The old-fashioned carron oil, made of equal parts of linseed oil and lime-water, or some modification of it, was good of its kind, and in the pre-antiseptic days; but it should not be used now if other (modern) methods are available. Olive oil and yolk of egg, or carbolic acid and olive oil (1 : 10), may be used. A 1 percent solution of picric acid makes an excellent application. Gauze saturated with the solution is laid over the burned surface, covered with cotton and then a bandage is applied. The dressing is left in place for two or three days. Before the gauze is taken off it is made wet with the same solution. Boric acid, or chalk and zinc ointment spread on strips of soft lint, makes a suitable application. Cotton wadding, absorbent cotton-wool, or cotton tissue treated with some antiseptic may be applied in thick layers over the mentioned lotions or ointments.

Treatment of *burns of the third degree* should be directed toward accelerating the separation and removal of eschars, of controlling putrefaction, and of advancing the cicatrization of the wound. Strong antiseptic solutions retard the separation of sloughs. Hot applications are indicated. Dilute peroxid of hydrogen may be used to cleanse the wound before dressing, or a tepid carbolic solution (1 : 30), or a weak iodin solution, or zinc chlorid (10 grains to the ounce).

Large granulating surfaces require procedures to overcome the effects of cicatricial retraction, and to favor the formation of a thin, soft, and lax scar. Burns about a large joint, as the elbow or popliteal region, call for measures to prevent a tendency to flexure. Burns of the neck need constant endeavors to prevent depression of the chin. The best means to resist this retractile action is extension of the distorted parts and compression by an elastic bandage.

Amputation is indicated (when the general condition of the patient does not forbid) if the extremity has been destroyed or if the resulting cicatrix renders the member quite useless.

The open-air treatment for extensive surface burns consists in letting nature do the work of repair, few dressings if any being used. Over the patient, who is kept perfectly quiet by morphin, is placed a cradle which is covered by blankets when the weather is cold, the head alone being exposed. In suspensions over the region of the burn glass may be substituted for the blanket so as to get the benefit of sunlight. When the weather is warm enough, blankets are discarded, a netting over the bed protecting the patient from flies. Thus the patient is exposed to air and sunlight. The temperature of the room should be kept constant. The patient may be placed on a water bed if the burn is mainly on the back. An electric heater beneath the bed is useful in warming the air when necessary.

Antemortem and Postmortem Burns.—In *burns* produced *before death:* There is usually a blister, with a bright, red base, and containing a serous fluid, which is albuminous, occasionally there will be no blister if there has been excessive shock; also, there will be a red line of demarcation between the injured and the uninjured parts, and this, being a vital process, is only developed during life. In *burns* produced *after death* there is no true blister, no red base, and gas only is present in place of the serous fluid.

See also ELECTRICITY (Injuries).

BURSITIS.—Inflammation of a bursa. Acute bursitis ensues from strain or traumatism. It is most common in the bursæ of the patella, those about the hip and over the olecranon, and in small bursæ formed beneath an old BUNION or a CORN (*q. v.*). The affected bursæ may suppurate.

The treatment consists of rest, the application of lead-water and laudanum, hot fomentations, and pressure.

The following is a valuable application:

℞. Glycerin,
Extract of belladonna, } equal parts.

Later, tincture of iodin, blue ointment, or ichthyol may be applied. If pus forms, an incision should be made, and the sac swabbed out with pure carbolic acid.

Chronic bursitis may follow acute bursitis, and presents an accumulation of serous fluid distending the sac. Its most common form is that of "housemaid's knee," and there is little or no pain unless inflammation arises.

Tincture of iodin may be painted twice daily for some weeks over the swelling, or small blisters applied. The mechanic cause of the injury must be avoided. Incision may be made, and a drainage-tube inserted for from 7 to 10 days, or aspiration may be practised. When the bursa becomes converted into a dense fibroid mass, or when so-called melon-seed bodies float in the interior of the bursa, the only treatment is removal by the knife.

BUTYL-CHLORAL HYDRATE.—Croton chloral hydrate. An analogue of chloral, having similar properties, though it is claimed to be less depressing and more analgesic than the latter drug. It is said to be especially valuable in tic douloureux. Dose, 5 to 20 grains in syrup or pill (best given in 5-grain doses) every half hour till 20 grains have been taken or until relief is afforded.

C

CACAO-BUTTER (Oleum Theobromatis).—A fixed oil expressed from the seeds of the chocolate tree (*Theobroma cacao*). It is a yellowish-white solid, of faint odor, bland taste, and neutral reaction. Its action is demulcent, and it does not become rancid on exposure to the air. Its chief use is as a basis for making suppositories.

CACHEXIA.—A term used to designate any morbid tendency, dyscrasia, depraved condition of general nutrition, or impoverishment of the blood, etc. It is applied particularly to scrofulous, syphilitic, or carcinomatous patients. It is characterized by emaciation and a peculiar sallow or muddy complexion. See CARCINOMA, TUBERCULOSIS, SYPHILIS, LYMPHADENOMA, etc.

CACODYLIC ACID.—An organic arsenic compound, which, it is claimed, may be introduced into the body in considerable doses without producing toxic symptoms. Cacodylic acid or *sodium cacodylate* has been used in the treatment of phthisis, various cutaneous disorders, anemia, and chorea. The dose is 1/2 to 1 grain hypodermically, and 3 to 6 grains by the mouth or rectum. Sodium cacodylate contains nearly 50 percent of arsenic. The cacodylate is particularly recommended in obstinate psoriasis, pseudoleukemia, diabetes, anemia, chlorosis, tuberculosis, malarial cachexia, etc. It is said to promote the growth of hair and to increase the menstrual flow. It is much less tonic than the ordinary arsenical preparations and less likely to be accompanied by untoward effects because of the slow liberation of arsenic trioxid in the body. The drug has recently been recommended in syphilis and good results are reported in late as well as early stages of the disease. Dose, 1/2 to 2 grains, hypodermically, or in pills or as an enema.

CACTUS GRANDIFLORUS (Night-blooming Cereus).—A sedative diuretic plant. Its active principle, *cactin*, has been found to have a decided stimulant action upon the heart, the arterial tension and the spinal motor centers. This drug has been employed as a cardiac stimulant in the functional disorders of the heart, also in valvular diseases and in pseudoangina pectoris. It does not prolong the diastole, as digitalis does, and on this account it has been especially recommended in complicated aortic regurgitation. A tincture is prepared, ℥iv of the fresh stems to a pint of strong alcohol, the dose of which is 5 to 10, up to 30 minims, every 4 hours. Dose of cactin, 1/100 to 1/30 of a grain.

CADE OIL (Oleum Cadinum).—A tarry oil from the wood of *Juniperus oxycedrus*. It is similar in action to tar, but has less odor, and is less injurious to the clothing. It is used externally in chronic eczema, psoriasis, pityriasis rubra, lichen, prurigo, and pruritus, also as a parasiticide in favus or tinea.

CAFFEIN.—$C_8H_{10}N_4O_2+H_2O$. The alkaloid derived from the dried seeds of *Coffea arabica*, or the dry leaves of *Thea sinensis*, occurring in colorless, flexible crystals, soluble in 80 parts of water and 33 of alcohol. The caffein of commerce is in reality thein, obtained from old tea leaves; the two are chemically identical. It occurs in long, silky needles, slightly soluble in cold water and alcohol, and having a feebly bitter taste. It contains more nitrogen than almost any other vegetable principle. Caffein is usually employed in medicine as the citrated caffein, prepared by dissolving equal quantities of caffein and citric acid in double the quantity of hot distilled water. Dose, 1 to 5 grains. It is an uncertain mixture. **C. Citrata Effervescens,** effervescent citrated caffein. Dose, 1/2 to 1 1/2 drams in water.

Caffein is a rapidly acting stimulant to the brain and spinal cord, quickens the action of the heart and raises blood pressure, increases the rate of respiration and the secretion of urine. Caffein, thein, guaranin, and theobromin are closely allied chemically and physiologically. Caffein is an ingredient of many proprietary preparations of which acetanilid is part, in which it antagonizes the depressing action of acetanilid on the heart. Its range of usefulness is very extensive. In opium-poisoning especially it is very valuable.

℞. Sodium salicylate, 30 parts
Citrated caffein, 40 parts.
Distilled water, 60 parts.

Or—

℞. Sodium benzoate, gr. xlv
Citrated caffein, gr. xxx
Distilled water, ℥ jss

Ten drops at a dose. Give heated.

In hemicrania or nervous headache:

℞. Citrated caffein, gr. vij
Distilled water, ℥ iij.

Mix and add:

Hydrochloric acid, ♏ ij
Syrup of orange, ℥ ss.

Give a tablespoonful every hour or two, as required.

Or—

℞. Acetanilid, gr. xx
Monobromated camphor, gr. v
Citrated caffein, gr. x

Make 10 pills.

One every 2 hours until relieved.

CAISSON DISEASE.—Also called "*The Bends.*" The symptoms due to increased atmospheric pressure, sometimes occurring in divers, caisson workers, etc. Paraplegia, hemiplegia, anesthesia, or apoplectic attacks are common, but paralysis of the legs is the most frequent symptom, coming

on only after return to the normal atmosphere. The nature of the lesion is obscure. The **leading symptoms,** as given by Parkes are: (1) Unpleasant sensations or severe pains in the ears, which may be materially aggravated if the person happens to be suffering from a cold in the head or sore throat, when pain in the forehead is often marked. (2) Neuralgic pains. (3) A feeling of giddiness, with a tendency to fall. (4) Loss of power in the legs, amounting at times to paralysis. (5) Slight to severe pains in legs, arms, and shoulders. (6) Epistaxis. (7) Itching of skin. (8) Hemoptysis. (9) Epigastric pain, and sometimes nausea and vomiting. (10) Occasionally unconsciousness. There is, of course, a physiological rise in the blood pressure.

The **predisposing causes** are: Too long stay in the compressed air, insufficient ventilation of the compressed air space—the amount of illness varies inversely with the extent of the provision for ventilation, too rapid decompression, fulness of habit, advancing age, overindulgence in alcohol, and organic disease. New hands suffer more than the old.

Treatment.—The affection may be prevented to some extent by avoiding sudden changes in the atmospheric pressure and long-continued work under high pressure. Slow decompression, and a careful selection of the worker will do much to prevent this disease. No worker should be accepted who is suffering from obesity, arteriosclerosis, cardiac weakness, nephritis, anemia or chlorosis, or neurasthenia.

CAJUPUT OIL.—A volatile oil distilled from the leaves of *Melaleuca leucadendron*. It resembles oil of turpentine in its general effects, being irritant externally and producing a sense of warmth internally, with accelerated pulse. It is used with benefit for flatulent colic, dropsy, hysteria, and cutaneous disorders; it also relieves toothache. Dose, 5 to 10 minims.

CALABAR BEAN.—See PHYSOSTIGMA.

CALAGE.—A method of prophylaxis or treatment of sea-sickness by fixation of the viscera by pillows placed between the abdomen and the wall of the cabin and between the back and edge of the berth, the patient lying upon the side. See SEA-SICKNESS.

CALAMUS.—Sweet-flag. The rhizome of *Acorus calamus*. It contains a volatile oil and *acorin*, a bitter nitrogenous principle. The root is an aromatic, stomachic tonic, and a common ingredient of many popular "bitters." Dose, 10 to 20 grains. **C., Fluidextractum.** Dose, 10 to 20 minims.

CALCIUM.—Ca = 40; quantivalence II. A brilliant, silver-white metal, the basis of lime and limestone, characterized by strong affinity for oxygen, and isolated with great difficulty. It is best known in the forms of the oxid, or "quicklime" or "burnt lime," and the carbonate, or chalk. The preparations of lime used in medicine are alkaline and slightly astringent.

Lime has great affinity for water. It is irritant to the skin; more severe on mucous membranes. Chalk possesses the astringent and antacid qualities of lime and is not so irritant. Calcium chlorid is an irritant poison in large quantities. It increases the amount of the urine, and probably the excretion of urea, and is used in pharmacy to abstract water from other substances.

Therapeutics.—Lime may be used as a caustic and depilatory, but is better known as an agent for hastening decomposition, which it does by its affinity for water, the resulting hydrate absorbing many of the products. The chlorinated lime is an excellent antiseptic and disinfectant, and it owes its energy entirely to its power of evolving chlorin. Lime-water is a favorite remedy for vomiting, especially in children, and is added to milk to increase its digestibility. A mixture of milk and lime-water will be retained by the stomach when no other food can be borne. Lime-water is an efficient agent in acid dyspepsia, mucous enteritis, and typhoid fever, as an astringent and antacid. Locally, it is well employed as an enema against thread-worm, as a mouth-wash for aphthæ, and as a lotion for cracked nipples, eczematous eruptions, and many mucous and purulent discharges. For these purposes it may be mixed with oil or glycerin, and if a few drops of carbolic acid are added, the efficacy of the mixture is much increased. The liniment is best known by the name carron oil, from the foundries at Carron, where it was extensively used. It is one of the best applications for burns and scalds, and makes a good dressing for the face in small-pox, and for cases of eczema affecting a large area of the skin. The vapor of slaking lime or lime-water in the form of spray has been usefully employed for inhalation in diphtheria. Lime-water is a good injection into the bladder in vesical calculus, in which its benefit is probably due to its astringent and soothing effects on the inflamed vesical mucous membrane, blunting its sensibility, and preventing the further growth of the stone by neutralizing the free acid of the urine.

As a solvent of false membrane in diphtheria:

℞.	Carbolic acid,	♏ xij
	Glycerin,	ʒ j
	Lime-water, enough to make	ʒ iv.

Apply with an atomizer every hour.

In glandular swellings:

℞.	Calcium chlorid,	ʒ j
	Powdered digitalis,	ʒ ij
	Diluted acetic acid,	♏ xl
	Lard,	ʒ j.

Apply locally.

In struma and phthisis:

℞.	Calcium chlorid,	gr. clx
	Glycerin,	ʒ ij
	Water, enough to make	ʒ viij.

Shake well. Half an ounce in a wineglassful of milk or water immediately after taking food.

An antacid and carminative:

℞.	Lime-water,	ʒ iij
	Prepared chalk,	ʒ ss
	Anise water,	ʒ iij.

Give 2 tablespoonfuls at a dose.

In poisoning by caustic lime the antidotes are: A dilute vegetable acid or lemon-juice or carbonated water freely, followed by demulcents or fixed oils to protect the mucous membranes; opium or alcohol as antagonists against the vital depression. Potassium salts and calcium salts are mutually antagonistic. Poisoning by calcium chlorid is treated with albumin, mucilaginous drinks, oils, milk, flour and water, but no acids.

Incompatible with preparations of lime and chalk are all the acids and metallic salts, especially the sulphates and tartar emetic; and borates, alkaline carbonates, and astringent vegetable infusions are also incompatible with the preparations of lime.

Preparations.—**Calx,** *lime, calcium oxid,* CaO, is lime prepared by burning white marble, oyster-shells, or the purest varieties of native calcium carbonate. Occurs in hard, white masses, gradually resolving to a white powder in the air, odorless, of sharp, caustic taste and alkaline reaction, soluble in 750 of water and 1600 of boiling water, insoluble in alcohol. Not used internally except in solution. **Calcii Carbonas Præcipitatus,** *precipitated calcium carbonate,* $CaCO_3$, a fine impalpable, white powder, odorless and tasteless, insoluble in water or alcohol, but soluble in mineral acids or acetic acid with effervescence. Creta (chalk) is native calcium carbonate. Dose, 5 to 30 grains. **Calcii Chloridum,** *calcium chlorid,* $CaCl_2$, hard, colorless masses, deliquescent, of sharp, saline taste, soluble in 1 1/2 of water and in 8 of alcohol. Dose, 3 to 10 grains in solution. This salt should not be confounded with chlorinated lime. Calcium chlorid has been employed in traumatic hemorrhage, purpura, hemophilia, small-pox and other hemorrhagic diseases. In hemoptysis its action is doubtful; but good results are reported in serous effusions and edema in general. It has long been used in furunculosis but with questionable success. The eruptions that so metimes follow injections of diphtheria antitoxin are said to yield to daily doses of calcium chlorid on the day of injection and the two following days. **Calcii Sulphas Exsiccatus,** *exsiccated calcium sulphate* (*dried gypsum*), contains about 5 percent of water. A fine, white powder, without odor or taste, insoluble in alcohol, soluble in 410 of water at 59° F., in 388 of water at 100° F., and in 451 of water at 212° F. Used in the preparation of calx sulphurata. **Calcii Sulphidum,** *calcium sulphid;* dose, 1/10 to 1/2 of a grain; **Calcii Bromidum,** *calcium bromid,* dose, 15 grains; **Calcii Hypophosphis,** *calcium hypophosphite,* dose, 7 grains. **Calcii Phosphas Præcipitatus,** *precipitated calcium phosphate,* dose, 15 grains. **Liquor Calcis;** *solution of calcium hydroxid, lime-water,* contains not less than 0.14 percent of calcium hydroxid, $Ca(HO)_2$. A clear, colorless liquid, of saline taste and alkaline reaction. Dose, 4 to 8 drams. **Syrupus Calcis,** *syrup of lime, syrup of calcium hydroxid*—contains 6 1/2 percent of lime, and 40 of sugar, the latter aiding the solvent power. Dose, 10 to 60 minims. Is an antidote to poisoning by oxalic acid and phenol. **Linimentum Calcis,** *lime liniment* (*carron oil*), contains equal volumes of lime-water and linseed oil, mixed by agitation. For local use. **Calx Chlorinata,** *chlorinated lime,* dose, 4 grains; and **Calx Sulphurata,** *sulphurated lime,* dose, 1 grain. **Creta Præparata,** *prepared chalk,* $CaCO_3$, is native calcium carbonate, freed from most of its impurities by elutriation; a white, amorphous powder, odorless and tasteless, insoluble in water or alcohol. Dose, 10 to 30 grains. It is a constituent of hydrargyrum cum creta, and also of the following: **Pulvis Cretæ Compositus,** *compound chalk powder,* has of prepared chalk 30, acacia 20, sugar 50 parts. Dose, 5 to 60 grains. **Mistura Cretæ,** *chalk mixture*—has of the preceding 20 parts, cinnamon water 40, water to 100, rubbed together and made fresh as required. Dose, 1 to 8 drams. See LIME.

CALCULUS.—See BLADDER (Stone), GALL-BLADDER (Diseases), KIDNEY (Stone), etc.

CALENDULA (Marigold.)—The flowering plant known as the garden-marigold, *C. officinalis.* **C., Tinct.,** contains 20 percent of the leaves and stems. It has been used exclusively as a local application to wounds, bruises, and ulcers, and has been vaunted as a cure for carcinoma.

CALISAYA.—See CINCHONA.

CALLOSITY.—See CORN.

CALOMEL.—See MERCURY.

CALUMBA.—One of the purest bitters known, derived from the root of a climbing plant, *Jateorrhiza palmata,* native to South Africa and parts of the East Indies. It contains the alkaloid *berberin* and a bitter principle, *calumbin.* The odor of calumba is slightly aromatic. Its action is favorable to mucous surfaces, and it has no astringent effect. Being free from tannic acid, it may be combined with iron. In gastrointestinal atony, especially following fevers, and in convalescent stages of summer complaint and serous diarrheas, it is of service. Dose, 5 to 45 grains. In the foregoing conditions, especially with flatulence, give:

℞. Powdered calumba, Powdered ginger, each, ʒ ss
Senna leaves, ʒ j
Boiling water, O j.
Make into an infusion. Take a wineglassful 3 times a day.

Calumba is an excellent tonic in the hectic fever of phthisis, and is a good vehicle for the administration of acids, alkalies, tonics, aromatics, and mild cathartics.

Preparations.—**C., Fluidextractum.** Dose, 5 to 45 minims. **C., Tinct.,** contains 20 percent of calumba. Dose, 1/2 to 2 drams.

CAMBOGIA.—See GAMBOGE.

CAMMIDGE REACTION.—See PANCREAS (Diseases).

CAMOMILE.—See CHAMOMILE.

CAMP SELECTION AND CAMP HYGIENE.—The "ratio of sickness and death" in the United States army camps of instruction and detention during the summer of 1898 was such as to make the whole nation stand aghast. The losses in battle were as nothing in comparison. Of the 5731 American soldiers who died during, or as a consequence of, the war with Spain, only 454

received death-wounds in battle. All of the remainder, or 5277, expired from disease. It is true that the armies of other nations in former times have also suffered terribly from improper hygienic conditions in camps. In the earlier half of the last century the annual mortality of the British troops in Jamaica was 13 in 100 by the medical returns, but the actual mortality amounted to about 2 percent more, a mortality of which we may give some idea by stating that a soldier by serving 1 year in Jamaica encountered as much risk of life as in 6 such actions as Waterloo. This frightful mortality, however, having been persistently pointed out by the medical officers, led finally to a searching investigation as to its causes. This was followed by greater care in the selection of sites for camps and barracks, a diminution of the evil of overcrowding, more variety in the dietary and better cooking, and a reasonable adaptation of the uniform to the climate, with the result that, at the present time, the mortality of British soldiers stationed in the West Indies is not notably greater than that of those at home stations.

There are two principal reasons for unhealthfulness of camps:

First (and most conspicuous).—The failure on the part of the military authorities to avail themselves of the superior knowledge of the medical staff in determining their location and in supervising the daily life of the soldier in all its details while in camp. The "Sanitary Report on Barracks and Hospitals," published in London just at the time of the outbreak of our Civil War, contains the following with regard to the British Army: "There being no regulations on these subjects, it naturally follows that the degree of respect shown medical opinions on matters affecting the health of the troops, whether concerning personal hygiene or the larger and more difficult subjects of barracks, hospitals, and camps, depends solely on the good sense and capacity of the officer in command, and on the tact and ability of the medical adviser."

Second.—This failure on the part of commanding officers to accord to their medical subordinates the respect to which their knowledge and acquirements entitle them naturally breeds in the latter a feeling of distrust and discouragement which leads them to neglect that careful study of military and camp hygiene that alone can qualify them properly to care for the health of their commands.

Surgeon John S. Billings, U. S. A., in a report similar to the one just alluded to, published at Washington five years later, at the close of the same war, says: "The mortality from disease (excluding epidemics) in the United States army for the last 3 years is probably 50 percent greater than it should be; in other words, it has been increased to that extent by causes that might have been obviated;" and later comments as follows: "As the subject of hygiene is not *officially* and *necessarily* a subject of daily consideration, as it should be, the surgeon does not have the motive to bestow that amount of study and labor upon it which must be given if good results are to be obtained." Surgeon Tripler, in his "Report on the Operations of the Medical Department of the Army of the Potomac," uses the following language: "To superintend the sanitary conditions of the regiment, to call upon the commanding officers to abate nuisances, to take measures for the abatement of disease, were, in many instances, considered impertinent, and the suggestions of the medical officer to these ends were too frequently disregarded and ignored." Treatment of this kind might be quoted indefinitely. It is true that in 1874 a general United States army order was issued that elevated the medical officer of a post from the position of attending surgeon to that of sanitary officer, to whom was assigned the supervision of the hygiene of his post or command. But this never seems to have been taken very seriously, and during the recent war was evidently disregarded.

The first step in reform, then, in matters pertaining to the health of the soldier must be to make the sanitary commander as absolute in his department as the combatant commander is in his—not of subordinate but of coordinate rank. It will be objected that this may lead to occasional conflict of authority. The only time when the combatant commander should be permitted to disregard the representations of the sanitary commander is on the field of battle or on a forced march in a hostile country. At such times, of course, the military exigency overrides all other considerations. The regimental surgeon should have the rank and pay of colonel, not that of major; and so of the other grades. It is necessary, therefore, to urge as strongly as possible the necessity for making hygienic regulations a part of the general routine regulations of the army, and of placing the enforcement of these regulations entirely and unreservedly in the hands of the medical staff, and at the same time to succinctly outline the character of such regulations and the responsibility of the surgeon in relation thereto.

A military surgeon should, in addition to the ordinary medical and surgical curriculum, spend a year in a laboratory of hygiene, making himself thoroughly acquainted with both the chemic and bacteriologic analysis of water, milk, meat, and other foods. He should possess a sufficient knowledge of geology to enable him to judge at a glance of the water-bearing capacities of a formation, and of the character of the water likely to be obtained from a given soil. He should know enough of botany to be able to distinguish poisonous plants, and to determine with a considerable degree of accuracy the nature of a soil from its flora. He should be able to pass such an examination in public health as is required in the English universities, and such as should be required in our own. The Army Medical School at Washington affords an opportunity to such medical officers as desire to avail themselves of its advantages, and can obtain leave of absence for the purpose, to obtain a limited amount of information on these subjects; but as the course covers only 5 months, and embraces instruction in the duties of medical officers in war and peace; military surgery; the care of the wounded in time of war; hospital administration; military hygiene; military medicine; microscopy, sanitary and clinical; pathologic histology, bacteri-

ology and urinology; hospital-corps drill; and first aid to the wounded, it can readily be understood that no very thorough knowledge of the particular branches can be obtained.

In order to refresh the memory on all points connected with the general hygiene of the camp, the medical officers of the United States army should keep constantly by them General Orders No. 117, August 10, 1898; that part of the army regulations that refers to the care of companies; circular No. 1, April 25, 1898; and circular No. 7, September 5, 1898. A man thus instructed and trained will be able to select almost by instinct.

The Proper Site for a Camp.—A camp is the station of an army, with its artillery, baggage, animals, and other accessories, when it has taken the field for purposes of war or for instruction in the art of war. The habitations of a camp are either tents or huts. It is not a fortress or fort or post, and has no permanent erections upon it It may be occupied for a single night, for a period of weeks, or for a season, but the same site is rarely suitable for both the hot and the cold seasons or the dry and the wet seasons. A camp used for a night or two may be called a *flying camp*, and one occupied for several weeks, a *fixed camp*. A permanent camp should not exist. Let it not be supposed, however, that because a camp is to be used only for a brief period it is a matter of indifference what sort of place is chosen for it. A single night in a marsh may prostrate an entire command with malaria, and one drinking of a polluted water is enough to introduce the germ of typhoid or dysentery into the system of many a soldier. "Wood, water, and grass," is the old comprehensive formula of the soldier, aiming purely at convenience. But before all these the sanitarian puts dryness of soil. Better additional labor in carrying water than sleeping on damp ground amid the emanations from fermenting vegetation. A cavalry troop of the National Guard has been known to establish its camp on an oozy flat close to a little stream that carried the entire sewage of a large summer hotel. A hillside with an abundant growth of grass, with several feet of gravel underlying the top layer of humus, and with rock below, constitutes the best location. An old orchard is the ideal site, as the apple will not flourish save on a soil of this general character, while the trees afford a refreshing shade in hot weather. A luxuriant growth of shrubs indicates water close to the surface. The apparent dryness of a sandy surface is often dangerously misleading. The sand may be, and often is, underlaid at no great depth by impermeable clay, which retains the water, thus producing great dampness of the atmosphere. In such localities every deep hollow is likely to contain a stagnant pool. This is the characteristic of the soil at Montauk point, U. S. A., which, while admirably meeting the exigencies that led to its choice as a camp of quarantine and detention for a brief time, was soon found to be unsuited for permanent occupancy as a post. Next to dryness of soil, perhaps even of equal importance, is a sufficient supply of pure, wholesome water for drinking and cooking, within reasonable distance, and, if the encampment is to continue for several days, for bathing as well. The soldier may sleep on damp ground or in an insufficiently ventilated tent, but so long as he has an abundance of pure water to drink he has a fair chance of maintaining his health; but compel him to drink water containing organic pollution, animal or vegetable, and therefore the germs of disease, and no matter how favorable are his hygienic conditions in all other respects, he will inevitably fall sick. Improper food, exposure, overwork, unhealthful emanations, loss of sleep, all combined do not entail one-fourth of the sickness, disability, and mortality in our army that are due to polluted water. Within a few years a division camp of a National Guard was visited by bloody diarrhea. The camp was located on a series of hills, the general conditions were favorable, and customary sanitary precautions were observed. Water in sufficient quantity was distributed over the greater part of the area in iron pipes, supplied by a tank on the summit of the highest elevation. Investigation, however, developed the fact that the water was pumped up to this tank from a small spring, directly above which, and at a distance of not more than 20 feet, stood a privy used by a small settlement of Italian laborers. Bacteriologic examination of the water disclosed the presence of the colon bacillus in great numbers. And yet this site had been determined upon after weeks of mature deliberation, evidently on the grounds of convenience alone. The sanitary commander should, therefore, make, or cause to be made, chemic tests of all the available waters on a proposed camping-ground, and, if time permit, bacteriologic examinations also, in addition to a careful inspection of the several sources and of possible causes of contamination. Those that are found to be fit for use should be carefully guarded before the main body of the troops arrives, in order to prevent their pollution. Such as are unfit for use should be guarded in order to prevent their use. To another detail should be assigned the duty of carrying water to various convenient points of the proposed camp, in order that the men, coming in with parched throats, may quench their thirst before the labor of pitching tents, securing fuel, and building fires is begun. Otherwise they will seek relief at the first roadside brook, regardless of its probable contamination, and dysentery, if not typhoid, will quickly make its appearance. He must not trust a spring or old well, no matter how seductively sparkling the water or how excellent its local reputation. All such water must be tested. The Nessler and permanganate tests can be made so expeditiously that there is absolutely no excuse for neglecting them and thus risking the health of the command.

On the whole, the safest source is the driven well. It would be proper for a brigade to be equipped with the necessary machinery for sinking such wells, and in many soils the operation could be accomplished in a short time and with great ease. Such wells should not be sunk within 200 yards of a privy, barnyard, camp sink, or garbage pit. In a fixed camp the water should be conveyed all over the fields in pipes, as an immense amount of labor is thus saved. For this purpose iron pipes

only should be used. In estimating the amount of water to be furnished, at least 5 gallons a day should be provided for each man.

While a camp should not be located in a forest, yet the close proximity of woods is convenient and useful. In summer their shade is not only grateful but healthful, and in winter they act as a screen from prevailing winds. They may also furnish a ready supply of fuel. When lumber cannot readily be obtained, split logs will answer many useful purposes, as for flooring tents or for building huts. Another point to be kept in view in the selection of a site is the inclination of the surface, as related to the question of drainage. One general comprehensive plan of surface drainage should be determined on in advance, if practicable, as much trouble will thus be avoided. The advice of an engineer officer should, of course, be sought in regard to this.

The final word on the selection of a site is that which has passed into an axiom with experienced campaigners: namely, never to occupy grounds previously used by another corps, as these are sure to be contaminated and to become foci of disease. If it is necessary to use a site near an old camp, select a position to the windward of it.

Camp Hygiene.—As soon as the camp is reached, a police detail should be established. It is astonishing how soon the ground becomes littered—often with scraps of food, which are trodden into the ground and gradually decompose.

The essentials for health in camp are not different from those under other conditions; they are dryness and purity—purity of soil, purity of water, purity of air, purity of food, purity of person, purity of morals.

Dryness.—Not only should a naturally dry soil and location be sought, but its dryness should be maintained and protected. This is to be accomplished by a thorough and scientific system of surface drainage. Every company street should have gutters on both sides, of sufficient depth to carry off storm-water, and into these should empty the smaller drains from the tents or huts, around each of which should be dug a trench 4 inches in depth and 8 inches in width. All hollows should be filled up. Tent flaps should be raised every day, to allow the free passage of air, to dry both the surface and the tent walls, and twice a week, if the weather permits, the tents should be struck, to allow the direct action of the sun's rays. Blankets and underclothing should be freely exposed, both to sun and air. If drenched, either with rain or perspiration, the men should be compelled to put on dry underclothing before going to bed.

Inasmuch as in the driest soils there lurks a certain amount of moisture, the men should not sleep directly on the ground. In fixed camps the tents should always be floored. In flying camps, straw, hay, or cornstalks, or the twigs of trees—especially of evergreens—may be used. The rubber poncho should be thrown over these, or placed on the ground, if nothing else can be obtained. The floors should be of loose boards, elevated a few inches on stringers. These should be taken up twice a week, when the tents are struck, and the ground underneath carefully swept. If straw must be used for a few days, it should be woven into mats, for the sake of neatness. As soon as soiled, it should be burned. With a few pieces of scantling and a strip of unbleached muslin or canvas, the soldier will readily learn to make a cot that will keep him off the ground. Hammocks also serve a good purpose.

The earth should never be excavated under a tent, nor should a burrow be dug in the side of a hill, as the earth, under such circumstances, quickly absorbs, and becomes contaminated with, the effluvia of the body. The men should not wash in or near their tents, but common lavatories should be established, warmed in winter, provided with hot as well as cold water, and carefully drained. Laundries should be established, apart from the lavatories, if possible, although the two may be combined. The mechanic facilities for these purposes should form a part of the army equipment—as much a matter of course as cook-stoves and soup-boilers.

Company streets should be kept as hard and dry as possible. Mud is both unhealthful and depressing. Gravel, ashes, furnace-slag, may be found in many localities, and may be used to face the roads. Corduroy and plank roads may also be laid. At least, there should be board-walks for two abreast to all frequented points. Wet feet are responsible for a vast amount of sickness. In camps of instruction that are used for considerable periods a few asphalted streets, which are constructed with ease and rapidity, would add greatly to comfort, ease of locomotion and transportation, and health.

Purity of the soil may be maintained by the enforcement of severe penalties for the deposit of filth of any kind or of animal or vegetable refuse on the surface. All kitchen garbage should be received in water-tight receptacles, and removed after each meal, either to pits or crematories. A fixed camp should invariably be provided with the latter. A limited amount of refuse can be destroyed in the kitchen fires, but they cannot be depended on for this purpose. Each deposit in a garbage pit should be at once covered out of sight with a layer of quicklime and fresh, dry earth. For this purpose the earth excavated in digging the pit should be protected from the rain. When within 3 feet of the surface, all the remaining earth should be thrown in and the surface covered with quicklime. One of the most powerful agents for the destruction of garbage, when fermenting or putrescent, is bromin. The men should not be allowed to take their rations to their tents, but should have their meals served in a common mess-tent or shed. Otherwise the ground under and around the tents will soon become filthy from refuse food.

Recent investigations confirm the possibility suggested by the illustrious Leidy, that the common house-fly may often be a carrier of contagium. This being admitted, the banishment of this insect from camps becomes of the utmost importance. This may be accomplished by never allowing deposits of horse manure, the acknowl-

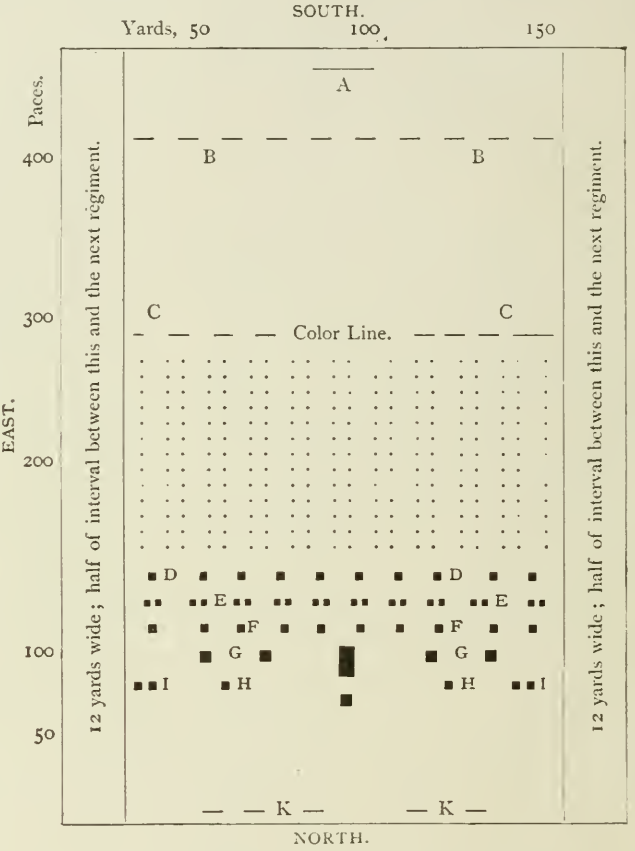
edged breeding-place of the fly, to accumulate in or near camps.

Inasmuch as the complete exclusion of these pests cannot, however, be hoped for, those which still infest the camp should be prevented from gaining access to the sinks. These insects always seek the light, and it will be necessary to build close sheds over the latrines and keep them carefully darkened. The use of mosquito-netting around kitchens and mess-tents would be an additional precaution of value. These expedients are simple, but will likely result in a considerable diminution of typhoid mortality in camps, especially if combined with the free use of clean earth and disinfectants.

Small latrines or sinks are preferable to large. In their construction the effort should be made to secure privacy for each man. This may be accomplished by means of muslin partitions. Urine troughs should be constructed at each latrine, and urination about the tents at night should merit severe punishment. Water-tight iron buckets may be placed at the foot of the company streets during the night, each containing a pint of solution of copperas. Disinfectants should be freely used in sinks and on garbage deposits. It is true that the evacuations of healthy men do not need disinfecting, but 10,000, or even 5000, men never were assembled, even with the strictest examinations, who were all in perfect health. One unhealthy stool will infect a whole latrine. The dangerous cases in a camp are those of walking typhoid and incipient dysentery, not detected by the surgeon. To wait for infection to be discovered before using disinfectants in the sinks is to invite disaster. Economy in disinfectants is not to be recommended. Fortunately, freshly burned quicklime is a cheap and efficient disinfectant. It may be crushed and strewed over the surface, or used in freshly made solution, as milk of lime. A small amount of coal oil poured on the top of this solution in a barrel, however, will at once form a protective film that will preserve its activity for many days. When this cannot be obtained in abundance, the sanitary officer should not hesitate to use any of the other disinfectants (not deodorizers) that the supply table contains—chlorid of lime, carbolic acid, and mercuric chlorid. To this list should be added formalin and bromin. Carcasses of animals should never be buried, but hauled to a distance and burned with an abundance of wood, coal oil, and rosin.

Copperas should be freely strewed on the ground around kitchens, which cannot fail to become foul, and in stables and horse-sheds, or where horses are tethered. All deposits of horse manure should be removed daily and strewed over distant fields.

Purity of water will not avail unless the greatest care is exercised, first, to prevent the supplies selected from becoming polluted, and, secondly, to prevent the men from drinking from any unauthorized source. They should be especially cautioned against drinking while bathing in streams or ponds. If water cannot be obtained that is above suspicion, they should be forbidden, under pain of severe punishment, to drink it unboiled. Boiled water, either plain or as weak tea, should be furnished by the cooks, and canteens should be filled with this in the morning, if on the march from camp to camp.



Purity of air will, of course, be greatly promoted by the foregoing measures for securing dryness and purity of soil. There are, however, two important factors in vitiating the air of a camp that require the greatest vigilance and determination on the part of the sanitary officer for their prevention. They are, first, overcrowding *of* tents; and, second, overcrowding *in* tents. Only the most urgent military necessity should lead to a greater degree of

compression than is indicated by the accompanying diagram for a camp of 600 men.

The depth is specified in paces from the color line, the pace being 28 inches, the average step of the soldier. Ten paces in rear of the color line (C) are the tents of the men, which are ranged in 2 files with a street between, the tents opening on the street. The streets should have a length of 50 paces and a width of 9 yards. The company kitchens (D) are in line parallel to the color line, and 20 paces back of the rear ends of tents. The company officers are quartered on the line (E), 20 paces in rear of the kitchens, and a depth of 15 paces is allowed for their tents, servants' quarters, and kitchens (F). Further to the rear, 20 paces, are the quarters (G) of the field and staff of the command, and behind them, 20 paces, their kitchens (H) and the tents (I) of the noncommissioned staff. Officers' sinks (K) are 100 paces beyond, with regimental wagons, if any, parallel in the interval. The sinks of the men (B) are 150 paces in front of the color line, and the advance guard (A) 50 paces in front of the sinks.

This diagram represents a regulation camp, but the plan is open to some slight criticism from a sanitary standpoint. Thus, if the wind is blowing from the south, the emanations from the men's sinks will be wafted toward the camp. If the camp faces west and east and the wind is from the north or south, this inconvenience will not be experienced; but in the latter position if the wind is from the east, the same difficulty arises. It would seem best to place the men's sinks in the rear, in a line behind the officers' sinks. Thus, a wind blowing from in front would not carry their emanations over the camp, while a rear wind would have very little effect, providing a woods formed the northern background of the camp, and if it did not, the trouble would only exist when the wind happened to be in this particular direction. This arrangement of the sinks would also be advantageous from an economic point of view, as the advance guard could be set back at least 140 paces, thus saving this much space in the extreme length of the camp. The only valid objection to this location of the men's sinks is that in going to them the men would be obliged to pass the kitchens of the officers' tents. This drawback could be avoided by a proper guard service, especially when it is remembered that this guard is necessary to keep the men away from the commissariat, even though the sinks might be in the opposite direction.

From the diagram it will be seen that a camp for a regiment of 600 men should cover a space 174 yards wide by 358 yards (460 paces) deep; giving an area of 62,292 yards, or 104 square yards for each man. The utmost extent of crowding permitted by the regulations consists in reducing the frontage to 124 yards, the depth remaining the same, which gives a superficies a man of 74 yards. The diagram provides for 20 rows of tents and 13 in a row, which would give 260 tents for each regiment, and with 2 men in each tent, accommodation would be had for 520 men, a number rarely, if ever, exceeded in any command. This is the proper proportion; not more than 2 men should occupy each of the ordinary tents, for a greater number will result in overcrowding that must prove detrimental to health. It is the overcrowding in the tents even more than the contraction of the total area of the camp that is to be avoided. There is no greater error than to suppose that because a tent is made of canvas, and not of wood or stone, air can penetrate its walls in sufficient quantity to make overcrowding a matter of little consequence and ventilation unnecessary. Typhus, essentially a disease of overcrowding, is better known by its familiar synonym of camp fever. The tents should be ventilated by holes near the ridges, guarded by flaps that can be looped up or let down at pleasure. In a battalion camp the tents should never be arranged in double line; short, single lines are best. The tents in line should be separated by a space at the very least equal to a diameter and a half of a tent, and the further the lines can be conveniently placed from one another, the better. The sinks, one for each company, should be located at least 150 paces from the tents, and in the rear, for the reasons already given. A deep and narrow trench should be dug for the purpose; and if too wide, it will require more earth to cover the excreta, and will, moreover, expose a greater surface from which the noxious effluvia will be given off than if it is narrow. Care must be had not to locate these sinks over streams of water or in the vicinity of springs or wells. In either case the water will become contaminated and serious disease may result. In cavalry camps care must be taken that the horses are not stabled near the water-supply, for horse refuse will prove almost as dangerous as that from the soldier.

Food.—Without pure, wholesome, digestible food no soldier can be maintained in fighting condition. To this end the food must be furnished pure by the commissary department, and so treated and handled by cooks, stewards, and attendants, in stoves, kitchens, and mess-tents, that it shall be kept clean and pure. Regimental surgeons should inspect all food brought into their camps, and should unhesitatingly condemn any that is found to be unfit for food. Next to the incompetent commissary and the careless cook, the great obstacle in the way of furnishing the soldier with pure food, at least in the summer season and in tropic climates, is the house-fly. Bacteriologists have detected disease germs on its feet and in its tracks. Every effort should, of course, be made to protect food from its visits. But as this is often an impossibility, the danger that it may infect food only emphasizes the importance of the free use of disinfectants in sinks and latrines, and, it may be added, in hospitals.

The necessity for purity of person cannot be too strongly urged upon the soldier by the sanitary officer. The former cannot wash too often or too carefully. Hot water and soap are essential for all surfaces that are hairy or where perspiration collects. A soap that is offensive to parasites is to be preferred. Chafing and other serious discomforts will thus be prevented, as well as the more serious systemic affections that result from

clogging the pores of the skin. Quite as important is frequent washing of clothing. The arduous labors of the soldier provoke constant and profuse perspiration, and as he is often compelled to sleep in the clothes he has worn during the day, these soon become offensive and full of animal poisons. Every opportunity should be afforded, therefore, for this important measure of prophylaxis.

Purity of morals is too often either neglected or sneered at or regarded as impossible of attainment in camp. And yet drunkenness, debauchery, private vice, and profligacy are among the greatest enemies of the soldier's health and efficiency. The soldier will often listen to advice and remonstrances on these subjects from the surgeon when he will turn a deaf ear to the warnings of the chaplain. It therefore becomes the duty of the former to allow no opportunity to pass unimproved of representing to the individual members of his command the frightful consequences that may follow forbidden indulgences.

Just as judicious parents endeavor to preserve their sons from falling into evil courses by making the home pleasant and attractive, so the surgeon, obtaining the cooperation of the general staff, can devise means to make the camp pleasant and attractive. Athletic sports and games of all kinds should be encouraged. Musical members should be sought out and organized into vocal and instrumental clubs. Amateur theatricals, lectures, and concerts, lyceums, debating clubs, and reading clubs should be formed, and in every possible way that mental occupation and excitement which the young soldier craves should be furnished.

CAMPHOR.—$C_{10}H_{16}O$. A solid volatile oil obtained from *Cinnamomum camphora*, a tree indigonous to eastern Asia. It yields *camphoric* and *camphretic acids*, also **C. Cymol** when distilled with zinc chlorid.

Camphor is antispasmodic, anodyne, antiseptic, diaphoretic, a stimulant expectorant, a cerebral excitant, a gastrointestinal irritant, and a rubefacient. It has an acrid, hot taste, and irritates the skin and mucous membranes, in quantity exciting severe gastric inflammation with all the effects of an irritant poison.

Large doses cause gastrointestinal inflammation, depress the heart and lower arterial tension, diminish the reflex function of the spinal cord, produce coldness of the surface, insensibility, coma, convulsions, and, perhaps, death.

Poisoning.—Arterial stimulants, coffee, cold, etc., antagonize its action. Water precipitates it from the alcoholic solution; alkalies and earthy salts precipitate even the small quantity that is soluble in water. Emetics to remove as much as possible. Opium and bromids for the convulsions.

Therapeutics.—Camphor has a reputation for uncertainty of therapeutic action, but is usefully administered in cholera and choleraic diarrhea, summer diarrhea and that of infants, vomiting, gastralgia, cardiac depression, nervousness and nervous headache, nymphomania, capillary bronchitis, typhoid and eruptive fevers, dysmenorrhea, after-pains, chordee, strangury, and catarrhal colds. Locally, it is effective in myalgia, lumbago, toothache, gangrene, and other conditions in which counterirritation or a local anodyne is required. A solution in ether has been found to be a beneficial application in erysipelas.

Monobromated camphor is used as a nerve sedative and hypnotic, but is not particularly efficient. It has been employed with advantage in whooping-cough, neuralgia, chorea, hysteria, delirium tremens, and epilepsy; but it is taken with difficulty, and is very liable to irritate the stomach.

Camphoric acid, in solutions of 0.5 to 6 percent strength, has been used with benefit as a topic agent in cystitis, and in coryza, acute bronchitis, and other affections of the respiratory tract. Internally administered it gives good results as an intestinal disinfectant, and has recently come into prominence as one of the most efficient agents against sweating from various causes, especially the profuse night-sweats of pulmonary tuberculosis. For this purpose it is best administered dry on the tongue, in dose of 10 to 30 grains, not more than 2 hours before the time for the expected sweating to occur—as it is quickly and abundantly eliminated by the urine.

To prevent chordee:

℞. Camphor, gr. xv
Powdered opium, gr. iij.
Make into 7 pills; 2 or 3 to be taken every night at bedtime.

An anaphrodisiac:

℞. Camphor, Extract of lettuce, each, gr. l.
Make into 20 pills; from 4 to 6 to be taken daily.

In spasmodic asthma, vomiting, etc.:

℞. Camphor, gr iij to vij.
Tincture of calumba, Spirit of cinnamon, each, ʒ jss.
Dissolve and add:
Peppermint water, Spice water, each, ʒ v.
Make into a drink. To be taken when the vomiting is troublesome.

In lumbago:

℞. Camphor liniment, ʒ xij
Oil of turpentine, ʒ ij
Pure soft soap, ʒ iv.
Rub the parts well.

Preparations.—**C., Aqua**, consists of camphor 8, alcohol 8, talc 15, distilled water q. s. ad 1000 parts. Dose, 1 to 4 drams. **C., Ceratum**, consists of camphor liniment 1, white wax 3.5, and lard 7 1/2. Used for itching skin-affections. **C., Linimentum**, contains camphor 20, cottonseed oil 80 parts. **C., Monobromated**, $C_{10}H_{15}BrO$, camphor in which 1 atom of hydrogen has been replaced by an atom of bromin. Dose, 1 to 5 grains, in emulsion. **C., Spt.**, contains camphor 10, alcohol 90. Dose, 5 to 20 minims.

Incompatible with *Camphor* preparations are: Butyl-chloral hydrate, chloral hydrate, chromic trioxid, dichloracetic acid, euphorin, hydrochloric acid, menthol, monochloracetic acid, napthol,

phenol, potassium permanganate, pyrocatechin, pyrogallol, resorcin, salol, salicylic acid, thymol, urethane, water; with *Camphora Monobromata* are: Chloral hydrate, euphorin, phenol, pyrocatechin, salol, thymol. With *Spirit of Camphor* are acacia, aqueous fluids, gelatin.

CANALICULUS.—See Lacrimal Disease.

CANCER.—See Carcinoma; Tumors; Breast (Tumors).

CANCRUM ORIS.—See Stomatitis (Gangrenous).

CANITIES.—Poliosis; hoariness; hair-blanching. A premature or senile, partial or universal, decolorization of the hair, the change varying from black or brown through every gradation to the whiteness of wool. This change may be physiologic or pathologic, gradual or rapid, general or confined to localized patches.

CANNABIS INDICA.—Hemp; Indian hemp. The flowering tops of *C. sativa*, of which there are two varieties, *C. indica* and *C. americana*, the former being the more potent and also official. They contain a resin, *cannabin*, and a volatile oil, from which are obtained *cannabene*, $C_{18}H_{20}$, a light hydrocarbon, and *hydrid of cannabene*, a crystalline body. It is an antispasmodic, anesthetic, narcotic, and a powerful aphrodisiac. In large doses it produces mental exaltation, intoxication, and a sensation of double-consciousness. It is a valuable hypnotic in delirium tremens, and is useful for painful affections of the bladder and for functional impotence. It is efficacious in uterine disorders as dysmenorrhea, menorrhagia, chronic metritis, subinvolution. It is also used for nervous headaches. It is highly recommended in whooping-cough and chorea minor. In large doses it diminishes reflex activity in traumatic tetanus and paralysis agitans. In gonorrhea it may lessen the discharge, allay the pain and restlessness, and relieve the chordee. *Bhang*, *siddhi*, *ganjah*, *churrus*, and *hashish* are the various Indian names by which the drug is known.

In sleeplessness:

℞. Chloral, Sodium bromid, each, gr. xx
Fluidextract of belladonna, Fluidextract of cannabis indica, each, ʒ j
Syrup of acacia, ʒ vj.
Give a tablespoonful at a dose.

Habit.—The drug is used extensively by the natives of Egypt and India and is the cause of much crime and insanity. The intoxication it produces is agreeable—mental activity is stimulated, time and space seem markedly extended, sight and hearing are keener, sexual desire and uterine activity are stimulated. Gradually follow anesthesia, diminished reflex activity, sleep or coma. The habitual use of the drug causes mental impairment, sexual impotence, indigestion, anemia.

Poisoning.—Strychnin and faradism are antagonistic, and caustic alkalies are incompatible. The stomach should be evacuated, stimulants given cautiously, and respiration maintained in poisoning by cannabis indica. Lemon-juice is said to be antagonistic in its effects; these effects, even of a large dose, seldom last over 24 hours.

Preparations.—**C. Indica, Ext.** Dose, 1/8 to 3/4 of a grain. **C. Ind., Fluidextract**, an alcoholic preparation. Dose, 1 to 5 minims. **C. Ind., Tinct.**, contains 10 percent of the drug. Dose, 5 to 30 minims.

CANTHARIS (Cantharides).—Spanish fly. The dried body of a species of beetle, *C. vesicatoria* (natural order *Coleoptera*). It contains a powerful poisonous principle, *cantharidin*, $C_{10}H_{12}O_4$. Locally applied, cantharis is a rubefacient and vesicant; internally it is an irritant, causing gastralgia and vomiting. In toxic doses it produces severe gastroenteritis, strangury, and priapism. It is used chiefly as an external counterirritant in the form of blisters. It is used as a uterine stimulant to relieve amenorrhea, and is valuable in small doses in the second stage of desquamative nephritis; in albuminuria, when the kidneys are torpid or relaxed; the tincture is useful in chronic nephritis, particularly from alcoholism; in impotence from sexual excess; in chronic gleet and chronic prostatorrhea; incontinence of urine; and in pyelitis and chronic cystitis. It is serviceable in small doses in psoriasis, eczema, prurigo, and lichen. In alopecia and seborrhea, with other remedies, it is a good agent. Blisters must be very cautiously used in the young, old, and debilitated, and cantharis should never be employed, either externally or internally, in acute nephritis.

The cantharidal blisters require from 6 to 10 hours to draw a blister. When the part is bright red, however, at about the end of 4 or 5 hours, it is best to remove the plaster and apply a flaxseed poultice. See Counterirritation.

Cantharidal pitch is an active rubefacient.

A plaster may thus be prescribed:

℞. Cerate of cantharides, q. s.
Make into a plaster 2 by 3 inches. Apply as directed.

Poisoning by cantharides is generally discovered by finding some of the glistening, iridescent wings and coats in the vomitus, and by the great thirst. The stomach must be washed out, if an instrument is at hand, or an emetic given, as of zinc sulphate, 30 grains in water, or a tablespoonful of mustard in water. Barley-water, white of egg and water, linseed tea, opium or morphin, but no oil, should be given. Stimulants may be necessary.

Preparations.—**C., Ceratum**, cantharides 32, yellow wax 18, resin 18, lard 17, liquid petrolatum 15. **Collodium Cantharidatum**, cantharides 60, flexible collodion 85, chloroform, q. s. **C., Picis, Emplast.**, *warming plaster*, Burgundy pitch 92, cerate of cantharides 8 parts. **C. Tincture**, 10 percent; dose, 1 to 10 minims.

CANTHOPLASTY.—See Eyelids (Deformities).

CAPSICUM (Cayenne Pepper). The fruit of *C. fastigiatum*, native to tropic Africa and America. Its odor and hot taste are due to a volatile oil, *capsicin*, which is irritant to the skin and mucous

membranes. Internally, it is a stomachic tonic, diuretic, and aphrodisiac. It is useful in atonic dyspepsia, flatulent colic, and in intermittent fever; also as a "pick-me-up" for alcoholics.

For alopecia:

℞. Tincture of cantharides, ʒ jss
Tincture of capsicum, ♏ xx
Glycerin, ʒ ss
Odorated spirit, enough to make ʒ vj.

Apply to the head 2 or 3 times daily.

As a stomachic:

℞. Pepsin, gr. viij
Extract of nux vomica, gr. x
Capsicum, gr. v.
Ipecacuanha (powdered), gr. v.

Make into 30 pills. One pill 3 times a day.

Incompatibles are: Alum, ammonia, alkaline carbonates, copper sulphate, ferrous sulphate, galls infusion, lead acetate, mercuric chlorid, silver nitrate, zinc sulphate.

Preparations.—**C., Emplastrum,** prepared from the oleoresin and adhesive plaster. **C., Fluidextractum.** Dose, 1/2 to 2 minims. **C., Oleoresin,** Dose, 1/4 to 1 grain. **C., Tinct.,** contains 5 percent of capsicum. Dose, 5 to 20 minims.

CAPUT SUCCEDANEUM.—An edematous swelling of the skin and subcutaneous tissue, caused by uneven pressure upon the presenting parts during labor. It is so common an accident of all tedious labors that it may almost be considered all physiologic in such cases. Its usual location is over the upper and posterior portion of a parietal bone, less frequently over the occipital bone, still less frequently over the frontal bone, and in breech presentations over the buttocks. These swellings are purely mechanic, being due to an inequality of pressure upon the presenting parts, hence at the point of least resistance a localized edema is produced. It consists in a round, oval, or sometimes elongated swelling, usually 1 to 3 inches in its longest diameter, but at times large enough to greatly disfigure the head. It pits, but does not fluctuate on pressure; it is often purplish, and may even become dotted with gangrenous spots, but usually disappears spontaneously in from 24 to 36 hours.

Diagnosis may be made by the disappearance of the caput succedaneum in from 24 to 36 hours; other tumors found upon the head are persistent: *e. g.*, cephalhematoma.

Hernia Cerebri, or Encephalocele.—In line of the sutures, and pulsates.

Hydromeningocele.—Grows tense with respiration or crying.

Cephalhematocele.—Communicates with the sutures, and is diminished by cutting off blood therefrom.

Angiomata or Erectile Tumors.—Change color on pressure.

Hydrocephalus.—The entire shape of the head is altered.

Wens, or Enlarged Sebaceous Cysts.—Solid, and do not pit.

Hydatid and Simple Cysts.—Like all cysts, fluctuate. Hydatids may be diagnosed by microscope.

Treatment.—The prognosis is always favorable. The tumor usually disappears in a few hours, even the largest persisting for only 2 or 3 days. In rare cases of breech presentation sloughing has been known to follow. In the majority of cases no treatment is needed other than a little vaselin or cold cream. If the skin is broken, dust with subnitrate of bismuth or impalpable boric acid. If the swelling is very great, the child may require feeding with a spoon for several days while the reduction of the swelling may be hastened by the application of cloths dipped in alcohol and water or in a solution of ammonium chlorid.

CARAWAY (Carum).—The seeds of *C. carvi*, indigenous to Europe. Its odor and taste are due to a volatile oil. It is valuable in infantile colic, but is used chiefly as a flavor. **C., Oleum.** Dose, 1 to 5 minims. **C., Infusum.** Dose, 1/2 to 2 ounces.

CARBOLIC ACID.—See PHENOL.

CARBON.—See CHARCOAL.

CARBON DIOXID.—The acid, gaseous product, having the composition of CO_2, commonly known as "carbonic acid gas," or carbonic acid. It is a colorless gas having a specific gravity of 1.52, soluble in cold water, and possessing a pungent smell and an acid taste. Inhaled, it destroys animal life by asphyxiation. In solution it is an excellent refrigerant and stomachic. Its inhalation is fatal in a short time, even when diluted with 95 parts of air. It is a product of respiration. It accumulates in brewers' vats, in old wells, caves, grottoes, and deep valleys, and forms the "chokedamp" of miners. Soda-water is distilled water, carbonated under pressure, the gas escaping when the pressure is removed. Of the natural carbonated mineral waters, Apollinaris water is the best known, and contains 47 cubic inches of carbonic acid to the pint.

Carbonic acid gas is highly antiseptic and preservative. Beef surrounded by this gas will remain fresh and its taste unchanged for 8 days.

Therapeutics.—Carbonic acid has been locally employed as a stimulant in ulcers and as an anesthetic in carcinomata, either by directing a stream of the gas upon the part or by the application of a yeast poultice. The gas has been applied in streams to the eyes, ears, nose, vagina, and rectum, in catarrhal inflammation of these parts, also to the bladder, for irritability of that viscus and its application is beneficial when there is no acute inflammation present. It is injected into the vagina with good results in dysmenorrhea and in many other painful affections of the pelvic viscera, whether neuralgic in character or arising from organic disease. Diluted with 90 to 95 percent of air, its inhalation is serviceable in chronic laryngitis and pharyngitis, also in asthma, chronic bronchitis, and chronic cough.

Carbonated water, or "soda-water," as it is popularly known, is a grateful beverage in warm weather, especially when flavored with certain syrups and fruit-juices. It is a serviceable drink in febrile affections, as it relieves thirst, allays nausea and gastric irritability, and is both diaphor-

etic and diuretic in slight degree. It is an efficient remedy for vomiting, and in the form of iced champagne is one of the numerous agents which have proved efficacious in the vomiting of pregnancy. It forms an excellent vehicle for the administration of saline cathartics, the various carbonates, and piperazin. The free use of carbonated mineral waters is of service in gout, especially when they contain the salts of lithium in solution. At many European spas the course of treatment is largely based on the use of carbonic acid, administered in the forms of baths and inhalations as well as by the ingestion of the waters containing it. Bathing in the natural carbonated waters is sometimes beneficial in catarrh, gout, rheumatism, anemia, amenorrhea, and leukorrhea, the gas acting as a general stimulant of the cutaneous cirulation and promotin g slight diaphoresis.

Treatment of Carbonic Acid Poisoning.—The antagonists are oxygen and stimulants of the peripheral circulation. The prime object of treatment is to oxygenate the blood as quickly as possible. The patient should be brought at once into the open air, and if the respiratory movements have ceased, cold water should be dashed on the face and chest, in order to awaken them by reflex action. If no effect is thereby produced, recourse must be had to artificial respiration, which should be maintained for at least an hour. If the heart does not begin to beat shortly after artificial respiration has been begun, the jugular vein should be opened, with care to prevent the entrance of air, in order to relieve the distention of the right ventricle and prevent the consequent paralysis of the heart. This vein is selected because there are no valves of any importance between it and the heart. A series of sharp, quick blows upon the chest in the cardiac region will sometimes start the heart into action after it has stopped. See Asphyxia, Artificial Respiration, Mineral Waters, Water.

CARBONIC ACID SNOW.—Crystals or snow of carbonic acid are obtained by the evaporation of liquid carbonic acid within a perforated receptacle. This snow, formed at 110° below zero (F.), is then compressed and molded into the desired shape and applied to the diseased area by means of contact under a light pressure. It has been used with success in lupus erythematosus, epithelioma, nævi, warts, and has proved efficient as a local anesthetic.

The compression ice mold used by LeFevre consists of a triple-barreled screw syringe, the two inner tubes are of brass, perforated with fine holes and between the two is a layer of chamois skin. The other tube is of fiber; being a nonconductor it does not become very cold. The syringe is screwed directly to the valve of the tank and the plunger is set so as to hold as much snow as is desired. The rapid evaporation of the liquid carbon dioxid produces such an intense cold that the cylinder is soon filled with snow. This is then compressed into ice, taken out of the mold and applied directly to the part. In the compression the temperature is reduced and the ice becomes hard and dry so it can be fashioned into any shape with a penknife. A cone of the ice about 1/2 inch long will last about 15 minutes in the open air and for about 60 minutes if wrapped in chamois skin.

CARBUNCLE.—Carbuncle is an acute phlegmonous inflammation of the skin and subcutaneous tissue, characterized by multiple foci of necrosis and sloughing of the superimposed integument.

Symptoms.—There is, as a rule, but one lesion present, having for its seat of predilection the neck or back. It begins as a flat, painful infiltration, varying in size from that of a chestnut to that of an orange. The skin is of a violaceous hue, and board-like. At the end of a week or 10 days the overlying integument sloughs at numerous points, exposing to view grayish-yellow necrotic masses, from which a sanious pus exudes. This cribriform appearance is characteristic of carbuncle. Later, the entire superjacent skin becomes gangrenous, and, being thrown off with the necrotic masses, leaves a gaping ulceration, which heals up by granulation, with the production of a permanent scar. The process is usually accompanied by chill, fever, and prostration. In the old and debilitated, fatal septicemia may develop.

Carbuncle occurs usually after the fortieth year. The same predisposing causes are operative as in furuncle: namely, diabetes, general debility, etc. The exciting cause is the introduction into the skin of a pyogenic microorganism. The pathologic process begins in the sebaceous or hair follicles. Suppuration occurs simultaneously in numerous adjacent foci. The skin and subcutaneous tissue are enormously swollen, and have embedded in them the yellowish-white necrotic plugs. The process extends laterally and vertically, and ends in a gangrene of the entire area.

Diagnosis.—In the beginning, only, may furuncle and carbuncle be confounded.

Carbuncle.	Furuncle.
1. Occurs usually in late adult life.	1. Occurs at any age.
2. Favorite situation, neck or back.	2. Indefinite localization.
3. Chestnut- to orange-sized.	3. Pea- to cherry-sized.
4. Surface flat.	4. Surface round or conic.
5. Skin board-like or brawny.	5. Ordinary inflammatory induration.
6. Multiple suppurating openings.	6. Single opening.
7. Terminates in gangrene.	7. Heals after extrusion of "core."
8. Marked constitutional disturbance.	8. As a rule, absent.

The prognosis is always guarded. Carbuncle upon the head or face is more serious than in other localities. In the aged and debilitated and in diabetics and alcoholics the prognosis is grave.

Treatment of carbuncle consists in free crucial incisions under an anesthetic and removing the necrosed tissue by the forceps and scissors, cureting the sinuses or pockets, checking hemorrhage by hot water and pressure, and cauterizing with pure carbolic acid and dressing antiseptically. The sore should be dressed every day by washing with

hydrogen peroxid followed by a solution of bichlorid, and dusting with an antiseptic powder. Tonic treatment, such as quinin, strychnin, milk-punches, nourishing diet, and attention to bowels and kidneys, should be given, and sleep procured by morphin.

If free incisions at right angles are made through the slough into the tissues underneath, hemorrhage is very great, although pain is relieved and the discharge of the slough is hastened. Only the young and robust can withstand this.

By thrusting a stick of fused potassa, caustic potash, or potassa cum calce through the various openings into the slough beneath, the gangrenous mass is converted into a blackish gelatinous material, easily discharged. The use of a cloth wet with vinegar will prevent injury to the adjacent skin. A mixture of olive oil and phenol (40 : 1) or boric acid ointment are good applications after the crucial incisions or the use of a caustic.

Pressure by means of strapping over the swelling to the sound parts around, with an opening at the top for the escape of pus, has been advocated. It hastens the discharge of the slough.

A conservative and efficient treatment consists in the application of Bier's vacuum cups once or twice daily, for from 10 to 15 minutes. Small incisions are made, if necessary, to facilitate aspiration of the pus, and the carbuncle protected with a simple or bichlorid gauze dressing. Not only is the application painless, but the hyperemia promptly relieves pain.

Phenol may be injected into the slough without crucial incisions. Or the following, in dram doses, is injected in different parts of the tumor:

℞. Pure phenol, 1 part
Glycerin and water, each, 5 parts.

Pain may be relieved by extract of belladonna, rubbed up with glycerin and smeared over the part, or applied on the surface of a poultice. A 2 percent solution of cocain may be applied under oiled silk, or ether may be sprayed over the slough.

Fetor may be overcome by the use of corrosive sublimate solution (1:5000), turpentine, terebene, or a solution of chlorinated soda (1 dram to 1 ounce), or Condy's fluid and water. Iodin liniment may be applied around the base, as it gives relief and subdues pain from congestion, particularly after incision of the carbuncle. Five grains of chloral to the ounce of water makes a good lotion at a late stage, and relieves pain. Iron, in 15-minim doses of the tincture, with 2 to 3 grains of quinin, 4 times daily, with saline purges every morning, should be given from the beginning. Calcium sulphid, 1/8 of a grain every 2 hours, influences the process. Arsenic is useful in chronic cases. If great prostration exists give:

℞. Aromatic spirit of ammonia, } each, ʒ ij
Tincture of cinchona, }
Brandy, ʒ iv
Water, ʒ ij.

Two teaspoonfuls every 2 hours.

Staphylococcus vaccines have been used, and in some cases with good results. See Staphylococcus Infections.

CARCINOMA.—A malignant tumor, characterized by a network of connective tissue the areolas of which are filled with cell-masses resembling epithelial cells. Observations have seemed to point to its microorganismal origin and infectious nature, but the negative results of experiments have reduced this view to a mere supposition thus far.

Following is the differential diagnosis between Sarcoma and Carcinoma (Woodhead, modified by Coplin):

	Sarcoma.	Carcinoma.
1. Origin...	Entirely mesoblastic. (Connective-tissue type.)	Epiblastic and hypoblastic. (Epithelial-tissue type.)
2. Stroma..	Intercellular. Rarely forms alveoli.	Vascular connective tissue, which surrounds and forms the walls of the alveoli; these communicate with one another, and contain masses of epithelial cells.
3. Cells.....	Granulation tissue or embryonic connective-tissue cells; shape and size vary.	Epithelial cells contained within alveoli; shape and size vary.
4. Intercellular substance.	May be present.....	Absent, or merely fluid.
5. Vessels..	Embryonic in character. They are in direct contact with, or may be formed by, the special cells, slightly modified, of which the tumor is composed.	Well developed; entirely contained within the connective-tissue stroma, and supported by the walls of the alveoli. Seldom in contact with the cells.
6. Spreads..	*Primarily* and *secondarily* by blood-vessels, rarely by the lymphatics.	*Primarily* by lymphatics, except in the later stages, when it may also spread by blood-vessels, in which case it spreads with very great rapidity. *Secondarily* by blood-vessels.
7. Secondary changes.	Chondroid, osseous, calcific, and pigmentary changes frequent.	Very rare
8. Growth..	Not invariably continuous. Likely to be interrupted.	Rapid. Continuous.
9. Site....	Primarily in deep structures; always from connective tissue.	Primarily in superficial structures or glands; always from epithelium
10. Heredity	Seldom hereditary...	May be hereditary.
11. Capsule .	Primarily, pseudoencapsulated; later, infiltrates the surrounding tissue.	Never encapsulated.
12. Fat	Rarely, if ever, contains fat.	Nearly always contains fat.
13. Age.....	Occurs most frequently before middle life.	Most frequent after middle life.
14. Injury...	Not uncommonly follows injury, such as trauma.	Rarely, a history of trauma, but may follow prolonged irritation. Especially is this true of the superficial forms.

Diagnosis during Operation.—A rapid method requiring only 7 minutes is that of Leitch. A thin piece of the excised tissue is thrown into acetone, then immersed in hot water, surrounded by gum, frozen, cut, and stained with an acetone solution of krystall-violet.

Prophylaxis.—All tumors should, as soon as recognized, receive careful medical examination and generally surgical consultation. Early excision of them in their precancerous condition will prevent the subsequent development of cancer.

Treatment.—Early operation should be insisted upon. After the operation, X-ray treatment combined with open-air treatment has been found valuable to prevent recurrence. In inoperable cases the open-air treatment and the X-rays are markedly beneficial as palliative treatment. Radium may be of value in some cases. Recently it has been claimed that serum of a horse afflicted with the disease is beneficial. Reicher advocates the use of adrenalin injections around the growth.

Local carcinoma is described under the special headings, as Breast, Epithelioma, etc. See Tumors (Classification, Etiology).

CARDAMOM.—The fruit of *Elettaria repens*, cultivated in Malabar. Its properties are due to a volatile oil, $C_{10}H_{16}$. It is an aromatic, carminative stomachic, used as an ingredient of several "bitters." It is useful when combined with purgatives to prevent griping. **C., Tinct.**, 20 percent strength. Dose, 1/2 to 1 1/2 drams. **C., Tinct., Comp.**, cardamon 25, cinnamon 25, caraway 12, cochineal 5, glycerin 50, dilute alcohol, q. s. ad 1000 parts. Dose, 1/2 to 1 1/2 drams.

In atony of the stomach and small intestines:

℞. Dilute nitric acid, ʒ j
Compound tincture of cardamom, enough to make ʒ vj.
A dessertspoonful after each meal.

CARDIALGIA.—A term loosely used as synonym of gastrodynia in general, heartburn, and stomachic pains on the left side. See Gastralgia, Gastric Neuroses, etc.

CARDIANTS.—Remedies affecting the heart. They are either sedatives, stimulants or tonics.

Cardiac Sedatives.—These lessen the force and frequency of the heart's action; the chief are: Aconite, antimony, chloral, cold, digitalis, emetin, hydrocyanic acid, muscarin, ouabain, pilocarpin, potassium salts, senega, saponin, vératrum, and quinin in full doses.

Cardiac Stimulants.—These rapidly increase the force and frequency of the pulse in depressed conditions of the cardiac apparatus; the chief are: Adrenalin, alcohol, ammonia, atropin, aromatic oils, camphor, chloroform, cocain, counterirritation, continuous galvanic current, ether, heat, hydrastin, nitroglycerin, opium and morphin in small doses, orchitic extract, spartein, spermin, turpentine.

Cardiac Tonics.—These, when given in moderate doses, stimulate the cardiac muscle, slowing and strengthening its contractions; the chief are: caffein, cimicifuga, convallaria, digitalis, helleborein, saponin, spartein, squill, strophanthus, strychnin.

Physiologic Action.—Cardiac stimulants increase the force and frequency of the pulse. Alcohol acts largely reflexly, and should be given in small doses, frequently repeated. Ether is next in value, and more rapid, and heat most powerful and available. Ammonia is energetic upon all organs except the heart. Cardiac tonics stimulate the cardiac muscle, slowing and making stronger its contractions.

Digitalis stimulates the vagus end-organs in the heart, and also the cardiac center in the medulla, and has a direct influence on the heart-muscle itself. Strophanthus does not effect the vessels nor raise blood-pressure. Convallaria, erythrophlein, squill, and cimicifuga are safer than digitalis, and acts less powerfully.

Of the cardiac sedatives or depressants, muscarin and pilocarpin stimulate the inhibitory ganglia; aconite relaxes inhibition or stimulates the vagus center; and aconite, hydrocyanic acid, muscarin, pilocarpin, saponin, and veratrum are direct cardiac poisons, depressing the heart-muscle and cardiac motor ganglia. See under the separate headings, Caffein, Digitalis, Strychnin, etc.

CARDIOLYSIS.—An operation for breaking up adhesions between the pericardium and the heart. Through an opening in the pericardium the adhesions are broken with the fingers; or a resection is made of the portions of the ribs and sternum to which the pericardium adheres. The latter method is the less dangerous.

CARDITIS.—See Heart-disease (Organic).

CARGILE MEMBRANE.—Sterilized animal membrane used chiefly in abdominal surgery for the purpose of preventing the reunion of previously adherent peritoneal surfaces. It is also employed to envelop tendons and nerves which have been sutured, and occasionally to protect wounds.

CARIES.—A chronic inflammation of bone with rarefaction or absorption of bony tissue, followed usually by pus formation; molecular death of bone, with the accompanying process, as ulceration. See Bone (Diseases).

CARMINATIVES.—Drugs that aid the expulsion of gas from the stomach and intestines by increasing peristalsis, stimulating the circulation, and relaxing the cardiac and pyloric orifices of the stomach. They also act as diffusible stimulants both of bodily and mental faculties.

They are extensively used in flatulent dyspepsia, especially when associated with heart-disorder or a nervous state. A combination is more successful. With antacids they correct acidity as well, and they are frequently prescribed with purgatives to prevent pain.

The principal carminatives are asafetida, camphor, capsicum, cardamon, chloroform, ether, fennel, ginger, horseradish, mace, mustard, pepper, serpentaria, spirits; oils of anise, of cajuput, of caraway, of cinnamon, of cloves, of coriander, of eucalyptus, of fennel, of peppermint, of spearmint, of nutmeg, of pimento; valerian.

A carminative mixture:

℞. Aromatic spirit of ammonia, ʒ ij
Spirit of ether, ʒ iij
Tincture of orange, enough to make ʒ iij.

Tablespoonful every 3 hours.

CAROTID ANEURYSM.—Aneurysm of the common trunk high in the neck presents the ordinary signs of aneurysm, and in this situation has to be differentiated from (1) simple dilatation of the artery at its bifurcation; (2) enlarged glands; (3) abscess or tumor over the artery; (4) pulsating goiter. In simple dilatation there is no bruit; in enlarged glands and tumors there is also no bruit, and the pulsation is not expansile, and ceases when they are lifted from the vessel; in abscess, in addition to the absence of the preceding signs, there is the history or presence of inflammation; in pulsating goiter the tumor moves up and down with the larynx on deglutition.

The treatment consists in pressure or ligation of the artery below the aneurysm, or if there is no room in this situation, distal ligation.

Aneurysm of the external and internal carotids requires no special mention. Pressure or ligation of the common carotid is the treatment generally indicated. See ANEURYSM.

CAROTID ARTERY.—See ARTERIES (Ligation), NECK (Injuries).

CARPAL BONES, FRACTURE.—The carpal bones are seldom broken, except in crushes in which the fracture is compound and associated with injuries to neighboring bones. Until the advent of the X-ray simple fractures of the carpal bones were usually treated as sprain, weak wrist, rheumatism, etc. Although any of the carpal bones may be involved in a simple fracture, the scaphoid is the one most frequently broken, often being associated with anterior dislocation of the semilunar bone; the proximal fragment passes forward with the semilunar. There is a "history of a fall on the extended hand; localized swelling of the radial half of the wrist joint; acute tenderness in the anatomical snuff-box when the hand is adducted; limitation of extension by muscular spasm, the overcoming of which by force causes unbearable pain. The possibility of the existence of a bipartite scaphoid should be considered in interpreting X-rays of simple fracture of the scaphoid" (Codman and Chase). Crepitus may be obtained in some instances of simple fracture of the carpus. The treatment in compound fractures is disinfection and the application of a straight palmar splint or possibly resection of bone or amputation. In simple fractures deformity, if present, should be reduced by traction and direct pressure, and the wrist immobilized for three or four weeks by a palmar or dorsal splint. If pain and stiffness persist after fracture of the scaphoid, excision of the bone through a dorsal incision may give relief (Stewart).

CARPHOLOGY.—A condition characterized by picking at the bedclothes, searching for or grasping at imaginary objects, and other movements of the hands, occurring in the delirium of the later stages of febrile affections. It is generally regarded as an unfavorable symptom. Floccillation or "floccillatio" was the term formerly used.

CARREL-DAKIN SOLUTION AND TREATMENT OF WOUNDS.—See WOUNDS.

CAR-SICKNESS.—The well-known symptoms induced by riding in railway or street cars. They are more common in women, particularly before the menopause. Riding backward aggravates the symptoms. It is an established fact that the majority of cases are directly due to astigmatism with or without some other form of ametropia or derangement of the ocular muscle-balance; therefore, in every case it is well to correct any such disorder. The proper lenses will afford great relief and in most cases effect a complete cure. It has been suggested that sufferers compelled to take extended journeys should be put under atropin-mydriasis during their trip. For other treatment see SEA-SICKNESS.

CARTILAGE, DISEASES.—Cartilage is entirely destitute of nerves, sensibility, and blood-vessels, being nourished by imbibition from neighboring vessels. All cartilages, except fibrocartilages, are covered with a fibrous membrane, the perichondrium, similar to periosteum. It is never reproduced when destroyed, being replaced by bone or fibrous tissue.

Cartilage being nonvascular, its inflammation is of a modified type. The diseases peculiar to cartilages are:

1. Ossification and necrosis of the ensiform and costal cartilages, with those of the larynx and trachea, from senile changes. Articular cartilages never ossify, but portions of them may necrose and be detached.

2. Ulceration rather than ossification of the cartilages of the epiglottis, ears, eyelids, nose, and Eustachian tube. The diseased action has generally spread by contiguity from adjacent tissue.

3. Chalk stones and deposits of urate of sodium in the cartilages of the external ear.

4. Inflammatory changes in epiphyseal cartilages. These are more general, and chiefly acute. They are important for destruction of this layer of cartilage checks further growth of the end of the bone. Syphilis is the most common cause. Injury, particularly in strumous children, is also a factor.

5. Carcinoma does not primarily attack cartilage. However, the epithelial form frequently extends from mucous or cutaneous surfaces to the subjacent cartilage.

6. Structural changes from disturbed nutrition in the articular and fibrocartilages. Syphilis, tuberculosis, and injury are the most common causes of disease of the articular ends of bone with their cartilage.

7. Cartilaginous tumors, or enchondromata, are innocent, grow slowly, and do not return on removal. Cartilage is frequently attacked by sarcoma. Cartilaginous tumors are generally encapsulated, and are found especially on the phalanges of the fingers and sometimes of the toes, the lower end of the femur, and heads of the tibia and

humerus, and in the parotid gland. When possible they should be removed.

Symptoms.—The spreading of inflammation to the cartilage of a joint cannot be recognized until ulceration has occurred and the bone has been exposed. Painful startings in the joint, greatly aggravated by movement, become prominent symptoms. This spasm occurs just at the commencement of sleep, when, the voluntary muscles relaxing, the sensitive bone-surfaces are drawn into contact, the patient awaking with a cry of pain; as, for instance, the "night-scream" of children with HIP-JOINT DISEASE (*q. v.*).

Treatment.—Rest and extension are primary essentials in treatment. Extension by weights or by splints will prevent the muscular spasm. Opium internally or subcutaneously is frequently necessary. The joint-disease must be treated as a whole.

Articular cartilages, in the aged, undergo fatty degeneration, and sometimes fibroid changes occur. In gout deposits of urate of sodium take place in the cartilage, whence ensue wasting and calcareous degeneration.

Floating cartilages, or loose bodies in the joint, may have a pedicle, or move about in the joint, sometimes blocking it, and may be single, multiple, flat, or ovoid, composed of cartilage, bone, or fibrous tissue, and are most common in adult males.

When locking results from a floating cartilage, forced flexion and sudden extension may relieve the condition. Cure can be obtained only by operation. The body, may be brought where it can be felt, transfixed with a pin or held between the fingers, and excised, under ether or a local anesthetic. See JOINTS (Diseases).

CARUM.—See CARAWAY.

CARUNCLE, LACRIMAL.—A fleshy protuberance upon the conjunctiva near the inner canthus, containing the lacrimal punctum. See LACRIMAL DISEASE.

CARUNCLE, URETHRAL.—A urethral caruncle is a small tumor, rarely larger than a filbert, situated at the external urinary meatus. It is composed of dilated capillaries set in a groundwork of dense connective tissue. It is usually bright red in color and bleeds easily when handled. Intense pain is the most prominent symptom. Contact with urine or with the clothing causes the most agonizing pain. The general health suffers and nervous symptoms develop. If the growth is pedunculated, it may be seized with forceps and twisted off. If it is sessile, its base should be excised and the wound closed by interrupted sutures.

CARYOPHYLLUS, See CLOVES.

CASCARA SAGRADA (Rhamnus Purshiana; Chittem Bark; Sacred Bark).—The bark of a California plant—*Rhamnus purshiana.* Its properties are due to a volatile oil. The fluidextract, made with diluted alcohol, is the official preparation most frequently employed; the dose of which is 10 to 30 minims. It acts as a tonic to the intestine, as well as a laxative, and it is claimed that there is no secondary constipation, such as follows the use of other purges and laxatives. Its bitter taste is its great fault. Two parts of the syrup of orange to one of the cascara will partially overcome this. The aromatic elixir furnishes another good vehicle. Cascara is best given at bedtime. The dose of the extract is 1 to 6 grains, given in pill form. Cascara cordials, or preparations of this drug, are made by manufacturers in almost tasteless form, and are really nonbitter fluidextracts.

℞.	Fluidextract of cascara sagrada,	ʒ j
	Compound syrup of orange,	ʒ ij
	Alcohol,	ʒ j
	Syrup,	ʒ iv
	Cinnamon water, enough to make	ʒ iv.

Give 1 or 2 teaspoonfuls at night.

CASSIA FISTULA (Purging Cassia).—The fruit of a tropic tree of which the pulp is the only valuable part. *Purging cassia* is laxative in doses of 1 to 2 drams, and is a purgative in larger quantities. It is rarely prescribed alone because it causes colic and flatulence. It is an ingredient of the confection of senna. *Cassia cinnamon* is the bark of the shoots of a Chinese tree. It is a constituent of the compound tinctures of cardamom, catechu, and lavender. *Cassia acutifolia* (Alexandria senna) and *Cassia angustifolia* (Indian senna), are shrubs grown in Egypt and India. See SENNA.

CASTOR OIL (Oleum Ricini).—A fixed oil, expressed from seeds of the *Ricinus communis.* It is almost colorless, transparent, viscid, of faint odor, bland or slightly acrid taste, soluble in equal weight of alcohol. Externally, it is bland. Internally, it is nonirritant until it reaches the duodenum, where it is decomposed by the pancreatic juice setting free the ricinoleic acid, which produces a mildly irritant action on the bowel. It is a simple purgative, acting with marked regularity in from 4 to 6 hours, producing liquid stools, with no pain or tenesmus, and is followed by a sedative effect on the intestine. The leaves of the plant have galactagog properties when applied to the breasts.

Castor oil is one of the best simple purgatives, and is used to unload the bowel. In children and the aged and infirm it is often employed. Infants require a proportionately larger dose than adults. In dysentery, 10 to 20 drops of laudanum may be added to counteract pain. If depression exists, 5 drops of turpentine may be added. It is much abused in the puerperal state. Given before breakfast, in 1- to 2-ounce doses, it has been of great service in severe neuralgia. Glycerin increases its purgative power.

Oil of bitter almonds best conceals its nauseous taste. Emulsions are not a success, and it may be administered in capsules. To administer pure, smear the sides of a wineglass with very thick cream, pour in the oil, and cover with more cream. Give a teaspoonful of milk, to be kept in the patient's mouth, and let the whole be taken at one gulp. It may be floated on orange-juice, strong coffee, gruel, wine, sarsaparilla, foaming beer, and soda-water.

CASTRATION.—The excision of one or both testicles. Removal of the ovaries is called oophor-

ectomy, or spaying. Castration is performed for carcinoma, sarcoma, and syphilitic or tubercular conditions of the testicle, and, in the aged, in the treatment of hypertrophied prostate gland. A retained testicle may become sarcomatous and necessitate castration.

After shaving and cleansing the pubes and examining for hernia, an incision is made over the spermatic cord from the external ring to the base of the scrotum. The cord is divided near the ring, the testicle removed, the spermatic artery tied alone, and the entire thickness of the cord is then ligated. Considerable scrotal skin should be removed.

In malignant disease or tubercular infiltration the inguinal canal should be slit up on a director and the cord pulled down as far as possible before it is secured. Silk and chromicized gut are recommended as ligature for the cord. Each vessel should be tied separately as divided. See Testicle.

CASTS.—Masses of fibrous or plastic material that have taken the form of some cavity in which they have been molded. From their source, casts may be classified as bronchial, intestinal, nasal, esophageal, renal, tracheal, urethral, vaginal, etc. Of these, the *renal* casts are the most important, by reason of their significance in diseases of the kidney. Classed according to their constitution, casts are epithelial, fatty, fibrinous, granular, hyaline, mucous, sanguineous, waxy, etc. See Urine (Examination).

CATALEPSY.—A peculiar neurosis characterized by loss of will and muscular rigidity, due to a diseased condition of the central nervous system. It occurs in those of the neurotic diathesis, and usually between the ages of 20 and 30 years. It is commonly associated with hysteria, but may be found in conjunction with tetanus and the various psychoses. It often forms a part of the hypnotic state.

Catalepsy is usually paroxysmal, the onset sudden, commonly with loss of consciousness, and the attack may last for several minutes or hours. Recovery is gradual or sudden.

The peculiar rigidity of catalepsy is characteristic and invariable. Hysteria, with tonic spasm, is distinguished by the local position of the spasm, and by the fact that it does not yield to force. Tetany is likely to be mistaken for catalepsy, but in this the rigidity is fixed and cannot be overcome, and the fingers of the hand are straightened at the middle joint, and their points and that of the thumb brought together.

During an attack, continued external stimulation is necessary. Cold douches and ammonia to the nostril often fail in true catalepsy. A pinch of snuff often succeeds in both the true and the induced catalepsy. Faradization may be effectual. Emetics are useful in arresting an attack. Apomorphin, 1/20 to 1/10 of a grain, hypodermically, may remedy the paroxysmal condition.

In the intervals between attacks iron, valerian, aperients, antispasmodics, and cold baths are most effectual. Moral treatment is indispensable, and removal from home is often necessary. See Coma, Hysteria, Somnambulism.

CATALYTIC ANESTHESIA AND ANALGESIA.—See Anesthetics, Local; Electricity, Anesthesia.

CATAMENIA.—See Menstruation.

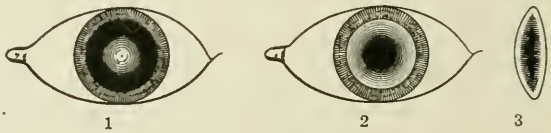
CATAPHORESIS (Ionic Medication).—The introduction of drugs into the system through the skin by means of ointments or solutions applied by the electrode of a battery. See Electricity.

The part affected may be covered with a pad soaked in the desired solution (*e. g.*, of sodium salicylate or potassium iodid in chronic rheumatism and rheumatoid arthritis, or cocain and adrenalin for local anesthesia) and connected with the negative electrode, while on another part of the body, covered with a pad wet with salt solution, is laid the positive electrode. The effects of ionic medication seem encouraging in arthritis deformans and chronic rheumatism. Favorable results are also reported in rodent ulcers, tinea and favus. See Joints, Arthritis Deformans.

CATAPLASM.—See Poultice.

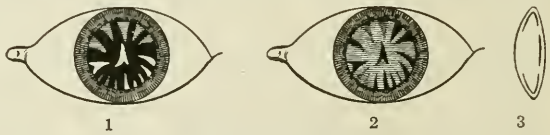
CATARACT.—A pathologic change in the lens or its capsule diminishing its transparency.

Causes.—Traumatic cataract, due to injury of the capsule or lens, needs no explanation, as it is not supposed that the subsequent cicatricial tissue will be transparent. If the lens or capsule is not directly injured by trauma, but is dislocated or its surrounding mediums disturbed, it becomes opaque through altered nutrition, due to the suspension of the exchange of fluid between the lens-structure and the surrounding mediums. Any chemic alteration in the fluid constituents of the body in general may be participated in by the aqueous and vitreous humors and the suspensory ligament, and may endanger the lens: as, for instance, cataract due to diabetes. Inflammations of the uveal tract, myopia, retinitis pigmentosa. detachment of the retina, and glaucoma are causes of cataract. Rickets is an almost constant accompaniment of lamellar cataract. The gouty diathesis is mentioned as a predisposing cause. Heredity



Nuclear Cataract.

1. Section of lens; central position of opacity. 2. Appearance by ophthalmoscope. 3. Appearance by oblique illumination.



Cortical Cataract.

1. Section of lens; opacities beneath the capsule. 2. Opacities as seen by the ophthalmoscope. 3. Opacities as seen by oblique illumination.

is sometimes an etiologic factor. Glass blowers and other workers in great heat and glare are particularly susceptible to cataract. Certain toxic agents, such as naphthalin and ergot, may cause cataract. There is no satisfactory explanation of senile cataract. Old age predisposes to cataract, but whether by weakened nutrition, sclerosis, atheroma of the arteries, or the undue strain on the accommodation in presbyopia, is not known. It has been suggested that as the lens grows by proliferation of the epithelial cells lining the anterior capsule, these cells become more compressed and harder at the nucleus, the oldest part of the lens, and when the normal increase of the nucleus at the expense of the cortical substance ceases, the first step is taken toward cataract formation. The disturbances in nutrition, directly and indirectly brought about by prolonged eye-strain due to uncorrected ametropia, are not only possible, but general causes of cataract.

Varieties and Nomenclature.—Opacities in the capsule are called **capsular** cataract; opacities in the lens-substance are called **lenticular** cataract, and may be **cortical** or **nuclear,** or, if both cortex and nucleus are involved, it is termed **complete** cataract. **Complicated** cataract is one in connection with other eye-diseases. If the diseased lens is adherent to any of the neighboring structures, the condition is known as **cataracta accreta.** A **polar** cataract is one confined to one pole of the lens. In **pyramidal** cataract the opacity is at the anterior pole, and is conoid, the apex extending forward. **Recurrent capsular** or **secondary** cataract is a cataract of the capsule appearing after extraction of the lens. **Diabetic** cataract is associated with diabetes. Probably the most convenient division of cataract is into **senile, juvenile, traumatic,** and **stationary.** An important distinction of cataracts refers to their maturity or ripeness, whence they are classed as **ripe, unripe,** and **overripe** (Morgagnian).

Symptoms and Diagnosis.—Cataract does not cause pain. The symptoms are disturbance of vision and reduction of acuity, which vary according to the kind of cataract and its stage of maturity. Opacities on the pole or on the axis between the two poles may escape the patient's notice, if they are small, dense, and sharply defined; whereas opacities including the entire pupillary area cause great disturbance of vision. Opacities at the periphery, when covered by the iris, as a rule produce no obstruction to sight; but when the pupil is sufficiently dilated, as in a dim light, these opacities become evident; hence such patients see better in a bright light with a contracted pupil. Patients with an opacity in the pupillary area with the periphery remaining clear see better with a dilated pupil: *e. g.*, under a mydriatic or in a dim light. Even a completely opaque lens does not destroy vision. If the retina and nerve are healthy, the patient should be able to tell the direction from which light is projected, and should recognize an ordinary candle-flame at 6 meters. With normal light-perception, the pupil of a cataractous eye should contract distinctly if light is suddenly thrown into it.

Objective Examination.—If the anterior polar region is opaque, the pupil appears grayish-white instead of normal black. It must not be supposed that every grayish discoloration of the pupil is caused by cataract; indeed, in old persons some diffused light is always reflected from even a transparent lens, giving the pupil a grayish color. The general plan in the diagnosis of cataract is to use both oblique illumination and the ophthalmoscopic mirror. With the first, opacities appear grayish against a black background, and with the second, black against a red background. If the cataract is almost complete, the whole pupillary area is grayish under oblique or direct illumination, and black under the transmitted light of the ophthalmoscopic mirror. When a distinct area in the lens appears *gray or white by focal illumination*, and *black* to light thrown through it *by the ophthalmoscope*, an opacity may be assumed. The entire lens can be examined only by complete dilatation of the pupil, and even then the peripheral edges may be hidden.

Cataract is most common in old persons, next in infants, and rarest in middle age.

The **test for maturity** of a cataract is known as the **iris-shadow.** By throwing a strong light obliquely into the pupil, the margin of the pupil is made to throw a shadow upon the opacity. If the lens is completely opaque, the white light reflected from it and the dark brown of the pupillary margin of the iris lie immediately against each other; if, on the contrary, the external cortical layer of the lens is still clear, there will be seen, between the white shadow of the opaque pupillary portion of the lens and the pigmented edge of the iris, a dark ring, which will be wider the less the lens is opaque. The treatment for mature senile cataract is extraction.

An **overripe** cataract becomes smaller and more dense, due either to a diminution in the aqueous constituents, or to the cortex becoming a yellowish, mushy mass of fluid, with a brown nucleus floating in it. This latter condition is known as the **Morgagnian cataract,** and causes the greatest disturbance of vision and difficulty of extraction.

Treatment of Cataract

General Remarks.—The treatment of unripe cataract must be the use of proper reading glasses, protecting the eyes from irritation of any kind, and the maintenance of the general health of the patient. In considering **what cataracts may be operated on,** it is necessary to first determine whether any retinal, choroidal, or nerve-disease coexists, which may be discovered by examining the light-sensation or field of vision.

Stationary cataract, in which the visual acuity is sufficient for the patient's occupation, or in which an artificial pupil will suffice, should not be operated on. If one eye is unaffected and healthy, it is not advisable to operate, for even under the most successful conditions perfect binocular vision cannot be expected, on account of the great optic disparity between the eyes.

Ripe and overripe cataracts are best treated by operation. Unripe cataracts should not be operated on before the completion of the ripening process, or, if operation is demanded, should be

artificially ripened by intracapsular irrigation (McKeown) or by Förster's method, which consists in performing an iridectomy or a paracentesis of the cornea, allowing the escape of aqueous, and irritating the lens by massaging the cornea against it with a strabismus hook or spatula, followed by extraction after reaction has ceased. Bettmann's method consists in "direct trituration" of the lens with a spatula introduced into the anterior chamber after iridectomy. All these operations are attended with more or less danger. In fact, many operators believe it is safer to extract an unripe cataract than to resort to artificial ripening.

The health of the patient and the condition of the eye should be considered before proceeding with any operation. General debility and any inflammatory disease of the eye or appendages are contraindications.

Preparation for Operations.—A gentle purgative should be given the day before the operation. The head should be washed with soap and hot water, and a bandage of sublimate placed over the eye to be operated on. This bandage is removed at the operation, the head enveloped in a cloth wet with sublimate solution, the vicinity of the eye thoroughly scrubbed with a strong sublimate solution, and the eye douched with a mild antiseptic solution. Anesthesia is produced by instilling several drops of a 4 percent solution of cocain in the eye 5 times, at intervals of 2 or 3 minutes. All instruments, sponges, and dressings used should be thoroughly sterilized before the operation.

Choice of Operation.—*Discission* is applicable to the soft cataracts and lamellar cataracts in childhood. The reaction and increase of tension in adult eyes after discission is so great as to be dangerous, although discission has been successfully used before extraction of the lenses of highly myopic eyes. However, in this case an early iridectomy and extraction is performed.

Extraction without iridectomy is a beautiful operation, and often gives ideal results. Many reliable operators advise it, but only an expert should perform it, and only upon selected and trained patients. The tendency to prolapse of the iris and secondary capsular cataract is greater than in the combined operation.

Extraction with iridectomy is the safest of all cataract extractions. It is absolutely demanded in complicated or difficult cases. The so-called "mutilation" of the iris is slight, and the cosmetic disadvantage is hardly noticeable, and is much more than offset by the safety and good results. Prolapse of the iris is infrequent. With careful irrigation of the anterior chamber, the dangers of secondary cataract are greatly reduced.

Discission is the operation most used in lamellar cataract and in all soft cataracts without hard nuclei. The necessary instruments are a lid-speculum, fixation forceps, and a discission knife-needle or Bowman's stop-needle. The pupil should be dilated to the utmost. The needle is entered perpendicularly to the under and outer side of the center of the cornea. The capsule is pierced near its anterior pole, and is divided up and down by a vertical sweep of the handle, taking care not to penetrate deeply into the lens. If necessary, the vertical incision in the capsule may be enlarged transversely; the needle is then withdrawn in the same direction as it was entered, avoiding, as much as possible, escape of the aqueous. While the lens is undergoing absorption, the pupil must be kept dilated with atropin. If the swelling is too intense and iritis ensues, the swollen mass should be let out by simple linear extraction. If absorption is obstructed, simple release of the aqueous by paracentesis and repeated discissions are necessary. Inflammatory symptoms are met in the usual way.

Extraction with Iridectomy.—The lids are fixed by a lid-speculum or by the fingers of an assistant, and the conjunctiva is firmly held with fixation forceps at a point centrally below the margin of the cornea. A Graefe knife is entered at the corneal margin, just above its horizontal diameter, and is passed through the anterior chamber in front of the pupil, making counterpuncture at a point exactly opposite. With the cutting-edge upward, the knife is gently sawed to and fro, until the upper two-fifths of the cornea is opened at the scleral border. The operation is then momentarily suspended, and the patient is directed to look downward and to keep the eye quiet while closed iris-forceps are introduced through the center of the incision. The iris is grasped at its pupillary border, slowly withdrawn, and the portion to be removed is excised by iris-scissors, the blades of which are held in the plane of the vertical meridian. The anterior capsule of the lens is then opened by a cystotome, which is introduced into the wound to the edge of the iris, with its cutting-point directed upward; it is then partly revolved, turning the point backward toward the capsule, over which it is drawn in a horizontal and vertical direction, or around the circumference of the pupil; another quarter revolution of the handle is made, and the instrument is withdrawn with its point downward.

The delivery of the lens is then effected by gentle pressure and massage with a lens-spoon until it is extruded through the corneal incision. Counterpressure may be made with one spoon on the inferior portion of the cornea, while another spoon presses on the sclera above the incision. The anterior chamber is freed from blood, and the remaining cortical fragments are expelled by stroking the cornea with a spoon or by the gentle injection of sterilized water or a weak antiseptic solution. Care must be taken that the iris is not engaged in the wound, and if it cannot be successfully pushed back into the anterior chamber, it should be excised.

If the vitreous presents at the corneal wound before the lens is delivered, the speculum must be withdrawn, and the lens removed by means of a wire loop, a spoon, or a special lens-extractor. In cases in which, for any reason, prolapse of the vitreous is anticipated, the **Kalt suture** is sometimes employed. A fine suture is introduced into the substance of the cornea, not penetrating it, below the line of expected section, and brought out and carried over into the tissues beyond the limbus. After extraction, this suture may be

tightened. The Kalt suture has not found general favor.

Extraction without Iridectomy is suitable for cases in which the operator is skilled by long experience, and in which a smooth and complete delivery of the lens may be anticipated in a healthy, calm, and intelligent patient. A Graefe knife is introduced near the horizontal diameter of the cornea at its junction with the sclera, and a flap made by transfixion, as before, including about five-twelfths of the corneoscleral margin. The capsule is divided as in the preceding operation, or rather more extensively if a Knapp knife, especially designed for this purpose, is used. The lens is expelled by slow, steady, continuous pressure with a spoon on the lower part of the cornea. The rest of the operation and the complications are treated as in extraction with iridectomy.

Extraction of the Lens in its Capsule.—This opeeation, proposed by Pagenstecher and especially advocated in all cases by Smith in India, consists in scooping out the lens, after the iridectomy, while making pressure on the cornea. The obvious advantages are offset by the danger of prolapse of the vitreous.

After-treatment consists in removing all shreds from the corneal wound, cleansing the eye, and after simple extraction instilling a drop of eserin, to prevent prolapse of the iris. If much cortical substance remains in the wound, it may be removed by gentle massage of the cornea, or by careful irrigation of the anterior chamber with a special syringe. Lippincott has devised a most convenient apparatus for this purpose. The eyelids are closed with adhesive strips. A light absorbent bandage, consisting of a little absorbent cotton and thin material, like tarlatan, is applied over both eyes, not to exert pressure, but to keep the eyes closed, at rest, and moderately warm. The dressings may be protected by a pasteboard shield. The patient is kept quiet in bed, and, unless there are active signs of infection, the bandage is not opened until about 48 hours after the operation. If there are no signs of inflammation then, the eye is cleansed twice daily, and at the end of a week the bandages may be omitted altogether, and dark glasses worn to protect the eye from strong light. After removing the bandage, atropin may be instilled daily, to keep the ciliary muscle and iris completely at rest. Strong convex lenses may be ordered after several weeks, and the patient allowed to begin the use of the eyes. Under ordinary circumstances the correcting lens for distance is about +S. 10, and about +S. 13 or 14 for reading. Some astigmatism is usually present, and should be corrected; this, however, gradually diminishes, and a reexamination of the refraction is soon necessary. Any inflammation secondary to cataract operations should be treated on the general principles heretofore discussed.

Secondary cataract is due to the opacity of the remaining capsule of the lense, with or without any remaining lens-substance, cataract-débris, or inflammatory exudate. The treatment of an opaque capsule in a pupillary space consists of discission by a needle or a Graefe's knife (**capsulotomy**), or, if the capsule is tough, by dilaceration with 2 needles. Care should be taken not to exert too much pressure and dragging on the ciliary body. Some operators divide the capsule with a pair of fine scissors-forceps, and others extract the capsule through an opening in the cornea near the scleral margin (**capsulectomy**). Small hooks are also used for tearing an opening in an opaque capsule, or drawing it out of the corneal wound.

CATARRH.—Inflammation of any mucous membrane, but especially that of the nose. See RHINITIS.

CATATONIA.—See KATATONIA.

CATECHU.—See GAMBIR.

CATGUT.—A full discussion of the preparation of catgut is given under LIGATURE and ABDOMINAL SECTION (*q. v.*).

CATHARTICS (Purgatives).—Agents that increase or hasten the intestinal evacuations. According to their respective degrees and direction of action they are subdivided into several groups, as follows (Potter):

Laxatives, including those that excite moderate peristalsis and produce softened stools without irritation. Sulphur is the typical laxative. The others are magnesia, cassia, manna, figs, prunes, tamarinds, honey, cascara sagrada, physostigma, ergot, belladonna, stramonium, hyoscyamus, almond oil, olive oil, soap, taraxacum, glycerin, oatmeal, bran biscuit, brown bread.

Simple purgatives, that increase peristalsis actively, and stimulate the secretions of the intestinal glands, producing one or more copious and semifluid stools with some irritation and griping. Senna is the type of this group. The others are aloes, rhubarb, castor oil, rhamnus frangula, oxgall, calomel, small doses of drastics, salines, or cholagogs.

Drastic purgatives, that act still more intensely, producing violent peristalsis and watery stools, with much griping pain, tenesmus, and borborygmi. They irritate the intestinal mucous membrane, cause exosmosis of serum from its vessels, and in large doses set up inflammation and symptoms of irritant poisoning. Jalap is a typical drastic. The others are gamboge, colocynth, elaterium, scammony, croton oil, cathartic acid (hypodermically).

Saline Purgatives.—This group comprises the neutral salts of metals of the alkalies or alkaline earths. They stimulate the intestinal glands to increased secretion, and by their low diffusibility impede reabsorption, causing an accumulation of fluid in the intestinal tract that, partly from the effect of gravity and partly by gentle stimulation of peristalsis excited by distention, reaches the rectum and produces a copious evacuation. Magnesium sulphate and sodium sulphate are the typical salines. They should be given in plenty of water and during active movement (as in walking) in order to produce their best effects. The other saline purgatives are magnesium citrate, potassium sulphate, potassium tartrate, potassium bitartrate, sodium phosphate, sodium chlorid, potassium and sodium tartrate, manganese sulphate.

Hydragog purgatives, including the most active of the drastic and saline groups, are those that re-

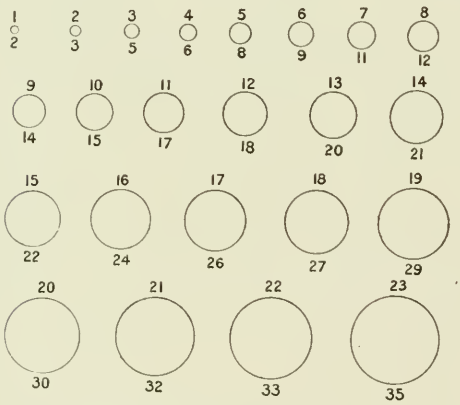
move a large quantity of water from the vessels. Elaterium is a typical hydragog. The others are gamboge, potassium bitartrate, croton oil, salines in large doses.

Cholagog Purgatives.—Those agents which stimulate the flow of bile and produce free purgation at the same time, the stools being green-colored (or "bilious"), and liquid. Podophyllin is the type of this group. The others are mercurials, aloes, rhubarb, euonymin, iridin.

CATHETER.—A tube-like instrument for evacuating the liquid contents of a cavity, usually the bladder.

Urethral catheters are generally made of soft rubber, woven silk, silver metal or celluloid. The last are usually 11 inches in length and of equal thickness throughout. Two rings are on each side of the mouth, indicating the direction of the beak to be in a plane parallel with that of their openings. The sizes are shown in the diagram.

The flexible catheters of woven silk are of the same thickness throughout, highly flexible when warm, stiffening with the cold, and they thus can be given any curve. The French flexible catheters taper for the last 3 inches, becoming very fine and pliant near the beak. The beak often ends in a small swelling or "olive," hence the term "olivary." The elbowed catheter, made of flexible material, is bent 1/2 of an inch behind the beak, to an angle of 45 degrees with the stem. See Bougie.



The Sizes of Catheters.
The upper number indicates that of the American system; the lower, that of the French.

Passing a Catheter.—General: 1. See if the instrument is clean, perfectly smooth, not defective in any part, and pervious.

2. Warm and oil the instrument—a cold catheter is unpleasant and tends to produce spasm, and an unoiled catheter does not pass easily along the urethra. Carbolized oil or vaselin may be used.

3. The patient should occupy the recumbent position, especially if passing for the first time is practised.

4. Pass the instrument with greatest gentleness and use no force.

Difficulties met with in passing an instrument are:

1. The point may catch in a lacuna or fold of mucous membrane. This is best avoided by keeping the point on the floor of the urethra, especially at first.

2. It may hitch where the urethra passes through the triangular ligament. Should it do so, withdraw it a little and direct the point against the roof of the urethra.

3. It may enter a false passage. This may be known by (*a*) the handle being deflected from the middle line, (*b*) by the catheter being felt out of the right passage by the finger in the rectum, (*c*) by free bleeding if the false passage is recent, (*d*) by no urine escaping, and (*e*) by the point not moving freely, as it does when in the bladder.

Formation of a false passage may be avoided by using no force, and entering an old one may be avoided by using a silver catheter and directing its point along the wall of the urethra opposite the false passage.

Female catheters are best in the simplest forms and when they are most effectually cleansed. They generally consist of a tube slightly curved near the beak, 6 or 7 inches in length and of the diameter of a No. 12 American male catheter, perforated with 5 or 6 small openings on either side near its extremity.

The instrument should never be introduced by touch alone; but always by sight. The labia minora should be separated, and the vestibule cleansed with absorbent cotton saturated with an antiseptic solution. The instrument, preferably of glass, should be perfectly smooth, with no rough or cutting edges. It should be boiled, kept in an antiseptic solution, and previous to use should be washed with sterile water. It is then lubricated and passed upward and backward by very gentle pressure and without using any force.

For **retention in the bladder** the best form of instrument is a short, slightly curved, vulcanite tube, terminating in a perforated olive-shaped bulb, to prevent its escape after its introduction. Rubber tubing will convey the urine into a distant vessel.

Aseptic Catheterism.—Moullin ("Lancet," September 10, 1898) says of aseptic catheterism that it is one of the problems of modern surgery. He has been called upon to deal with it especially in cases in which there has been a large amount of residual urine. The following are the essential features of Moullin's instructions: All instruments must be disinfected first by boiling. The hands, the prepuce, and the skin of the penis must be cleansed as thoroughly with soap and water as if a surgical operation were to be performed, and then sponged over with a solution of corrosive sublimate, 1 : 5000. The glands of the meatus require especial care. An irrigating catheter is then introduced into the fossa navicularis, and this part of the canal is thoroughly washed out from behind with boric acid. The catheter is then pushed on into the deep part and the process repeated. Finally, Melchior's double catheter is introduced and the urine drawn off. In this way it is possi-

ble to obtain a very high degree of asepticity. When catheters must be passed at frequent intervals, the disinfection of the hands, penis, and front part of the urethra will manifestly never be carried out each time. At the best it will only be done night and morning, and often one has to be content if it is done thoroughly once a day. But catheters can be kept clean. Those as smooth and polished on the inner surface as they are on the outer will stand boiling day after day (if they are kept straight while in the boiling water and drained afterward) and continued immersion in boric acid, without injury. Each patient is provided with 2 glass catheter cases. One of these is filled with boric acid lotion for instruments that have been used; the other, provided with a rubber cork as well as a metal cap, is dry and aseptic. These cases are so arranged that they may be hung up in the patient's wardrobe, out of sight and away from dust. No catheter is used more than once a day. As soon as a catheter is withdrawn from the urethra, it is dropped into the case filled with boric acid solution and left there. Once a day all the catheters are taken out, boiled for 5 minutes, and placed in the dry case until required. The plan works fairly well with an intelligent private patient who can be made to understand the necessity of observing strict precautions. Unfortunately, patients are not all intelligent, and in the case of a hospital out-patient so complicated a plan is out of the question. The best that can be done is to start such people as well as possible and hope that by degrees they will acquire a certain amount of immunity against the toxins they are bound to absorb. There is a little evidence to show that a certain degree of immunity may be acquired.

CATOPTRIC TEST.—By placing the source of artificial light (a candle) at an angle, and putting the surgeon's eye in the path of the equivalent or reflecting angle, by looking through a strong convex lens, if the patient's crystalline lens is transparent and in position, the 3 images of the flame are seen: One on the patient's cornea, upright; the second on the anterior surface of the lens, upright and smaller; the third on the posterior surface of the lens, very small and inverted. If the patient's lens is absent, only the first upright corneal image will be seen. In accommodation the first and second images approach, thus showing bulging of the anterior portion of the lens in this act. If only a posterior polar opacity exists, only the third inverted image will be obscured. If the opacity extends anteriorly, then both the second and third images will be invisible.

CAUL.—A child is said to be *born with a caul* when part or all of the fetal membranes remain unruptured and are carried out in advance of the head. This condition is usually due to abnormal thickness of the membranes. It occurs most frequently in premature births and when the child is undersized. In a case of this kind the membranes must be immediately removed, else the child will be asphyxiated. See Amnion.

CAUSALGIA.—Neuralgia with burning pain, often of the foot; sometimes with a local glossiness of the skin due to impairment of the normal nerve-stimulus of the part. See Neuralgia.

CAUSTICS (Escharotics).—Agents that disorganize or destroy living tissue. They are chiefly used in surgery to destroy unhealthy growths. They act usually in one of four modes: viz., (1) By abstracting the water of the tissue. Such caustics are mineral acids, glacial acetic acid, carbolic acid, arsenic trioxid, chromic trioxid, antimony chlorid, caustic potash, caustic soda, lime. (2) By combining with the albumin of the part. Such caustics are dried alum, silver nitrate, copper sulphate, mercuric chlorid, mercurie oxid, mercuric nitrate, zinc sulphate, zinc chlorid. (3) By corrosive deoxidation: examples, chromic trioxid and bromin. (4) By converting the tissues into carbon or gaseous bodies; such are the cautery, moxa, and boiling water.

CAUTERY.—Primarily, the term was applied to caustics, but more frequently now to the platinum wire heated by an electric current, or to the hot iron, for counterirritation, removal of tissue, etc.

The actual cautery is used for its counterirritant, destructive, and hemostatic action. It may be applied either in a simple or a complicated manner, as by the heating of any metallic or nondestructible substance to the required temperature by fire, or by the use of some of the more elaborate chemic or electric apparatus. The common method of its application is by irons of various shapes heated to a red or white heat in a charcoal furnace. A gas cautery has been introduced, by which a jet of burning gas may be directed to the desired spot. The galvanocautery, owing to the variety and delicacy of its means of application, offers to the surgeon a means of dealing with many conditions that could not be attempted with the more primitive instrument. The electric current may be obtained either from the chemic or the storage battery. For the general use of the surgeon Paquelin has introduced a cautery in which the heat is maintained by throwing the vapor of some hydrocarbon (as benzin) upon spongy platinum that has been previously heated. This ingenious apparatus forms a compact, convenient, and easily regulated means of cauterizing, and has almost superseded the use of the galvanic cautery in general surgery. The temperature at which a cautery should be used depends altogether upon the object in view. If used for its counterirritant and destructive effect, it is best employed at a high temperature, as from a bright red to a white heat; if for its hemostatic action, the cautery should not exceed a dull, cherry-red; otherwise the blood-vessels will be seared through so rapidly that a very imperfect clot will be formed, and bleeding will recur. Care should be exercised in the use of the cautery never to employ it when the temperature is below a dull red heat, as the tissues will adhere to the iron, and on its withdrawal a portion of the burned part will be removed, causing unnecessary pain.

CELIAC AFFECTION.—A chronic intestinal disorder most common in children between the ages of 1 and 5, characterized by the occurrence of pale, loose stools, not unlike gruel or oatmeal por-

ridge; they are bulky, not watery, yeasty, frothy, and extremely offensive, and there are anemia and debility without much emaciation. The exhaustion may be aggravated by intercurrent attacks of watery diarrhea, and death may supervene. It is also called *diarrhea alba* or *diarrhea chylosa.* It is due probably to a temporary suspension of the pancreatic function. See DIARRHEA (Infantile).

CELIOTOMY.—Surgical opening of the abdominal cavity. See ABDOMINAL SECTION.

CELLULITIS.—Inflammation of cellular or loose connective tissue, chiefly subcutaneous, but also of that between muscles and viscera, or surrounding various organs. It is characterized by the same spreading and atonic character as erysipelas, and is circumscribed or diffuse. It is most virulent from septic poison, such as that of a venomous serpent. In surgical operations upon women or after parturition it may arise in the pelvic cellular tissue. It is common after scalp-wounds. The swelling is marked early by branching lines of lymphangitis. At first it is edematous, and soon becomes brawny, the skin being mottled, with no definite limit to the redness. Pain is tensive and great, and the absorbent glands and vessels are often inflamed. Later the skin becomes dark, and unless relieved by intervention, may slough. Constitutional symptoms are grave. The diagnosis is simple unless the inflammation is deep-seated.

The disease consists in an active cell-proliferation and increase. It is often mild in degree, and the lymphatics may dispose of the poison and suppuration fail to occur. When pus forms, the condition is known as diffuse cellulitis, and is essentially the same as phlegmonous erysipelas.

Treatment.—At once antisepticize and drain any existing wound. Lead-water and laudanum, ichthyol, iodin, or blue ointment should be applied to the inflamed area. The bowels should be opened by doses of calomel or by salines, and stimulants, nourishing diet, quinin, iron, and strychnin should be given. Incisions, each 2 to 3 inches long, should be made near each other. Hydrogen peroxid may be used in spray by an atomizer, and mercuric chlorid solution as a wash. If sloughs form, employ antiseptic poultices to facilitate removal, and excise spots of gangrene as well. The dressings should be changed often, and when healing, the wound treated as an open wound. See SUPPURATION.

CENTRIFUGE.—See URINE (Examination).

CEPHAELIN.—An alkaloid derived from ipecacuanha root. The hydrochlorid is readily soluble in water. Its properties are similar to those of ipecac. As an emetic it is more energetic though slower in its action than ipecac and less depressing. Dose, 1/12 to 1/6 of a grain.

CEPHALALGIA.—See HEADACHE.

CERATES (Cerata).—Unctuous preparations similar to ointments, but of a much finer consistence. They all contain wax (cera), and do not melt at temperatures below 104° F. They are intended for external use, and are generally spread on lint before being applied. There are 6 official cerates, including ceratum itself.

TITLE.	COMPOSITION.
Ceratum (Simple Cerate).	White wax, 300 gm.; white petrolatum, 200 gm.; benzoated lard, 500 gm.
Ceratum Camphoræ...	Camphor liniment, 100 gm.; white wax, 350 gm.; white petrolatum, 150 gm.; benzoated lard, 400 gm.
Ceratum Cantharidis (Blistering Cerate).	Cantharides, 320 gm.; liquid petrolatum, 150 gm.; yellow wax, 180 gm.; rosin, 180 gm.; lard, 170 gm.
Ceratum Plumbi Subacetatis.	Solution of lead subacetate, 20 gm.; wool-fat, 20 gm.; paraffin, 20 gm.; white petrolatum, 38 gm.; camphor, 2 gm.
Ceratum Resinæ (Basilicon Ointment).	Rosin, 350 gm.; yellow wax, 150 gm.; lard, 500 gm.
Ceratum Resinæ Compositum (Deshler's Salve).	Rosin, 225 gm.; yellow wax, 225 gm.; prepared suet, 300 gm.; turpentine, 115 gm.; linseed oil, 135 gm.; to make 1000 gm.

CEREBELLUM, DISEASES.—The cerebellum lies below the cerebrum. It is liable to the same diseases as the brain, such as abscess, hemorrhages, various forms of degeneration, tumors, etc. The symptoms are vertigo, disorders of equilibrium, uncertainty of gait, pain in the head, more particularly at the back, vomiting, hemiplegia, and visual disturbances. Symptoms may be entirely latent and cause no very obvious distress, and sensation is not directly affected in cerebellar disease.

Cerebellar abscess, although very infrequent, is more common in children, and usually is a result of suppuration or inflammation of the mastoid cells. In many instances it is associated with thrombosis of the lateral sinus. Location of a cerebellar abscess is difficult. Severe occipital pain, persistent vomiting, and retraction of the head are suggestive of its presence. Examination by exploration should never be made until the existence of a temporosphenoid abscess has been excluded. No abscess being found in the anterior operation, either between the dura and the bone or in the substance of the brain, and no evidence existing of thrombosis, the lateral lobe of the cerebellum is to be explored after the periosteum and the muscular attachments have been separated from the occipital bone beneath the superior curved line. In many cases sinus thrombosis exists as well, and there is considerable danger of overlooking one if the other is found.

Tumors of the cerebellum usually cause tonic rigidity of the muscles of the back of the neck, with retraction of the head, often with flexion of the forearms and extension of the lower extremities. A cerebellar tumor may be removed without certain early fatal termination, and even after a number of cerebellar cysts have been evacuated, with immediate and permanent benefit.

Cerebellar hemorrhage is a rare accident. The most constant symptoms are vomiting, paralysis, headache, vertigo, and perhaps priapism. The headaches are usually occipital, generally preceding the onset of the more serious symptoms by a few days or several weeks, and even 2 months. Unconsciousness is an inconstant condition.

CEREBRAL DISEASE.—See BRAIN (Inflammation, Tumors, etc.).

CEREBRAL LOCALIZATION.—For topical diagnosis of cerebral lesions, see BRAIN (Injuries).

CEREBRIN.—See BRAIN EXTRACT.

CEREBRININ.—See BRAIN EXTRACT.

CEREBRITIS.—See BRAIN (Inflammation).

CEREBROSPINAL MENINGITIS. Synonyms.—Cerebrospinal fever, spotted fever, malignant purpuric fever; petechial fever.

Definition.—An infectious disease, sporadic and epidemic, due to microorganismal infection, and characterized by intense pains in the back of neck, head, and extremities, often giving rise to a position of opisthotonos, and by an irregular fever of several weeks' duration.

Varieties and Etiology.—(1) Abortive, (2) intermittent, (3) malignant or fulminant.

The term cerebrospinal meningitis is descriptive of a certain pathologic anatomy found in the central nervous system, and represents no etiologic entity. It may be caused by any of the pathogenic organisms; it may be caused by the tubercle bacillus; it may appear as a manifestation of syphilis. There is wide difference of opinion as to the relative frequency of occurrence of these various causes. There are probably marked variations according to locality. In Dunn's experience the order of frequency is as follows:

1. Tubercular Meningitis.
2. Epidemic Meningitis (Diplococcus Intracellularis).
3. Pneumococcus Meningitis.
4. Streptococcus Meningitis.
5. Influenza Meningitis.
6. Staphylococcus Meningitis.
7. Other forms.

The disease does not seem to be directly contagious, but the infectious agent appears to arise in localities where the necessary conditions for its development prevail and to be carried through the air for considerable distances. It most commonly occurs in young children in certain localities where there is overcrowding, bad food, and poorly drained soil. Fatigue, cold, moisture, and exposure are predisposing causes.

DIPLOCOCCUS INTRACELLULARIS MENINGITIDIS.—(*Weichselbaum.*)

Pathology.—The membranes of the brain and spinal cord are reddened and highly congested in the early stages. Later necrosis sets in, and the exudation of lymph becomes purulent, especially at the base of the brain. The cranial nerve-sheaths may be thus involved, giving rise to disturbance in the parts to which they are distributed. The blood-vessels of the brain and the venous sinuses are highly congested. The meninges of the spinal cord also share in the inflammatory process, and are greatly congested posteriorly. The exudate early becomes purulent, and may occupy a large portion of the spinal canal. Pressure-symptoms arise from this irritating fluid, and local palsies or convulsions ensue. The liver, kidneys, stomach, and intestines are congested. If the fever has been protracted, nephritis may arise.

Symptoms and Clinical Course.—The symptoms depend upon the area most affected. If the meninges of the brain are diseased, there are delirium, stupor, paralysis of ocular muscles, disturbed vision, deafness, and semiconsciousness. If the meninges of the cord are the seat, there will be opisthotonos, hyperesthesia, paresthesia, rigidity and tremor of the extremities, localized spasms of the muscles, which, if irritated, often cause a general convulsion.

The onset is characterized by anorexia, malaise, pain in the back of neck, head, and down the spine, slight rise of temperature, chill, or convulsion. Vomiting comes on early, and the pain in the back and head increases. The temperature is not usually high—about 102°—very irregular, and without the diurnal variation so common in typhoid fever. The pulse is full and strong. Intolerance to light and sound is a prominent feature. The skin becomes hypersensitive and a petechial rash appears, hence the synonym—spotted fever. Trophic changes may occur and herpes is common. This is generally a leukocytosis. To test for the distinctive **Kernig's sign,** the patient lies with the thighs flexed upon the abdomen and the legs flexed upon the thighs; if meningitis is present extension of the legs is impossible, being prevented by the contraction of the hamstrings. Recently, two new signs have been observed: **Mac-Ewen's sign,** in which a change in the percussion note is found over the lateral ventricles, due to increased intraventricular pressure; and **Brudzinski's sign,** in which the patient flexes and everts the arms and legs when an attempt is made to flex the head on the chest.

KERNIG'S SIGN. Proper method, *i. e.*, preliminary flexion of thighs on abdomen followed by attempted extension of leg on thigh.—(*Greene.*)

KERNIG'S SIGN. Improper method lacking the essential preliminary flexion of thighs on abdomen.—(*Greene. After Sahli-Wiener.*)

Delirium is present usually from the onset, and may be so prominent as to give rise to maniacal outbreaks. The urine is high-colored, scanty, and may contain albumin. Late in the disease it may be passed involuntarily. Occasionally, the joints may be swollen.

Abortive Variety.—The onset is rapid, and runs a course of only a few days' duration.

The intermittent variety is characterized by an

irregular fever with marked remissions, and with intermissions every day or two.

Malignant or Fulminant Variety.—The onset is more sudden, with chill, high fever, convulsions, opisthotonos. Full, slow (50 to 60) pulse, disturbed and labored respirations, delirium, coma, and death within a few days.

Complications and Sequels.—Pneumonia, pleurisy, endocarditis, facial and ocular palsies, otitis media, deafness, arthritis, aphasia, and mental impairment.

Diagnosis.—Pneumonia may be differentiated by the respiratory symptoms and the physical signs; scarlet fever by redness of the fauces and the early appearance of the rash; typhoid fever by the more gradual onset, less severe and not so continuous nervous symptoms, and the intestinal symptoms. It may also be confused with rheumatism and influenza. Lumbar puncture is a valuable aid in rapid diagnosis.

Prognosis.—The mortality is from 20 to 75 per cent. Children under 2 years of age nearly always perish.

In fatal cases death usually occurs the first week, though it may occur (generally from exhaustion or complications) after weeks of suffering. In those who recover the course is 2 to 3 or 4 weeks, with a gradual decline of the fever and a slow and protracted convalescence.

Treatment.—The treatment of cerebrospinal meningitis is divided into two classes: (1) *Specific treatment*, directed toward combating the specific cause of the disease; (2) *general symptomatic treatment*, directed toward combating the morbid changes and their symptomatic manifestations. The general symptomatic treatment of cerebrospinal meningitis contains nothing new, and will not be discussed. It is in specific treatment that the most notable advance has been made.

From time to time, various methods of specific treatment have been advocated in cerebrospinal meningitis. The most notable of these methods are: (1) Lumbar puncture, (2) diphtheria antitoxin, (3) vaccine therapy, (4) leukocyte extract, (5) urotropin, (6) serum therapy.

There have appeared in medical literature favorable reports from the use of each of these methods of treatment, but only one method, serum therapy, has given positive and unquestionable proof of efficacy, and in only one form of cerebrospinal meningitis, the so-called epidemic form, caused by the *diplococcus intracellularis* of Weichselbaum. It is possible that the other specific methods of treatment may have some value in certain etiologic forms of cerebrospinal meningitis other than the epidemic, or in certain particular conditions arising in the epidemic form. Such value remains to be proved. It is a fact that tuberculous meningitis, pneumococcus meningitis, and streptococcus meningitis are practically invariably fatal forms, as far as our present evidence shows. One or two cases of apparent recovery from tuberculous meningitis have been reported, and in these cases early lumbar puncture was performed. In all of these fatal forms, the diagnosis having been established, such methods as treatment by serum therapy, vaccine therapy, leukocyte extract, or urotropin, are at least not contraindicated, and their value has not been finally disproved. In pneumococcus and streptococcus infections, serum therapy with subcutaneous injections of the serum has not proved of notable value, but serum therapy with intradural injections, such as is used in epidemic meningitis, has been used in very few cases as yet. The known value of vaccine therapy in staphylococcus infections, would point to that method of specific treatment as the most promising in cerebrospinal meningitis due to that organism. Diphtheria antitoxin has received fair trial in epidemic meningitis, and its value has been disproved. In general, these various specific treatments may be tried in the forms of cerebrospinal meningitis which are as yet unconquered.

The Serum Treatment of Epidemic Cerebrospinal Meningitis. Evidence of its Value.—The term epidemic cerebrospinal meningitis refers to that form caused by the meningococcus or diplococcus intracellularis of Weichselbaum. The name of the disease is derived from the tendency to occur in epidemics, although the disease is not exclusively epidemic in its occurrence, but may be found practically at any time and is constantly present in many localities. It is frequently referred to as "spotted fever." The pathology of this disease has been thoroughly elucidated through the work of Councilman and others, and the recognition of its specific character has led to

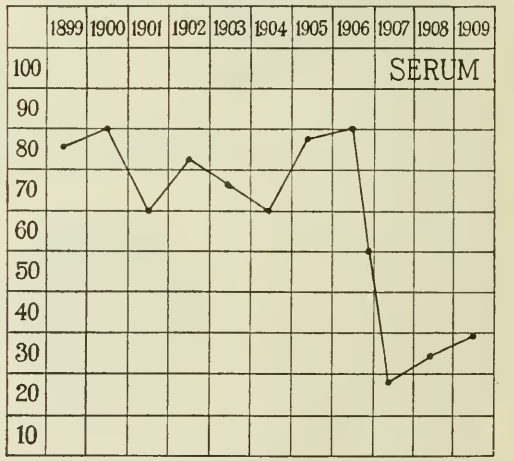


Chart Showing Death-rate from Cerebrospinal Meningitis at the Children's Hospital, Boston, from 1899 to 1909.

the successive trials of various methods of specific treatment, some of which have been retained as of possible contributing usefulness, and one of which has been almost universally adopted as of the highest efficacy.

It is possible to throw some light on the comparative value of these various methods of treatment by comparison of the mortality figures of various years at the Children's Hospital in Boston. While the average number of cases treated each year

varies, the average yearly number treated for the last ten years is twenty. Up to 1903, the treatment was symptomatic, no specific measures being employed.

In 1903, 1904, and 1905 lumbar puncture was employed as a routine therapeutic measure, and was often frequently repeated. In 1906, diphtheria antitoxin by subcutaneous injection was used as routine treatment; and in 1907, vaccine therapy. Each year is regarded as beginning on November 1 of the preceding calendar year, as serum therapy was begun as the routine treatment in November, 1907. There was no notable variation in the type of the disease from year to year. The figures are shown in the accompanying chart.

Serum therapy is now recognized by the majority of authorities as an effective specific method of treating epidemic meningitis. Thanks to the work of Flexner, the proof of the value of this treatment has been placed beyond the possibility of reasonable doubt.

Beginning in 1906, epidemic meningitis in various parts of the world began to be treated with the serum of animals inoculated with the diplococcus intracellularis. The results obtained by European observers are of value chiefly as confirmatory evidence, when considered in connection with the results obtained in this country and in England, with the antiserum prepared by Flexner at the Rockefeller Institute for Medical Research.

For proof of the value of the Flexner antiserum the reader is referred to the various publications of Dr. Flexner and his associates, and the reports of the various investigators who have been using the serum. Through a careful method of distribution, Flexner has been able to collect an overwhelming set of statistics, based on carefully studied cases properly proved to be true epidemic meningitis, which show a reduction in the average mortality of the disease under the use of the serum from 75 percent to 25 percent.

Flexner's conclusions are now based on more than 600 cases. The conclusions drawn by Flexner and Jobling from their former analysis of 400 cases are as follows: "It is our belief that the analysis of histories of cases of epidemic meningitis which have been presented in this article furnish convincing proof that the antimeningitis serum when used by the subdural method of injection, in suitable doses and at proper intervals, is capable of reducing the period of illness; of preventing, in large measure, the chronic lesions and types of the infection; of bringing about complete restoration of health, in all but a very small number of the recovered, thus lessening the serious, deforming, and permanent consequences of meningitis; and of greatly diminishing the fatalities due to the disease."

What Antimeningitis Serum Is.—Antimeningitis serum, like diphtheria antitoxin and other immune sera, is horse serum. The horses are treated with successive inoculations of preparations of the diplococcus intracellularis, until, as shown by experiment, their blood serum contains the maximum amount of immune body. The antimeningitis serum is not primarily an antitoxin, although it contains a small amount of specific antitoxin with neutralizing power. It differs from diphtheria and tetanus antitoxins, in that it is bactericidal rather than antitoxic in its nature. Although the theory of its action is not entirely clear, it is evident that its chief action is exerted upon the diplococci themselves. It appears to injure them in such a way as to cause restraint of multiplication, with rapid death and disintegration, while at the same time phagocytosis is greatly increased and within the phagocytes the toxin is broken up and rendered harmless. Concentration is a necessary factor in its good effects.

How Antimeningitis Serum is Obtained.—While in the experimental stage, the serum was made only at the Rockefeller Institute for Medical Research, Dr. Flexner having wisely elected to keep the use and distribution of the serum under his personal supervision, in order that the reports upon which the evidence of its value rests might be unquestionable. Now that the value of serum therapy is proven, the Rockefeller Institute has given up its preparation, leaving it to the manufacturing chemists and local health boards.

Technic for the Administration of Antimeningitis Serum.—The antimeningitis serum is injected directly into the spinal canal. Experimental evidence showed that concentration was one of the most important factors in its efficacy, and led Flexner and his associates to waste no time with subcutaneous injections. All the clinical evidence goes to show that the subcutaneous injection of the serum is practically of no value in comparison with subdural injection.

The technic is that of ordinary lumbar puncture. If the lumbar puncture is undertaken for the purpose of administering antimeningitis serum, or to relieve excessive intradural pressure in chronic cases, as much fluid should be allowed to escape as will run freely. It is of little use to continue the withdrawal after the fluid is running no faster than four drops to the minute. If the lumbar puncture is undertaken for diagnosis only, not more than 5 c.c. should be withdrawn.

When serum is to be administered, the sterile syringe should be filled with whatever dose of serum is to be given, which has previously been warmed to about blood temperature. The needle remains in place. After the air is expelled from the syringe, the latter is connected with the needle, and the serum is injected through the same needle by which the spinal fluid has escaped. The injection should be made slowly, so as to consume about the same amount of time as that taken by the fluid in escaping. During the injection the patient should be closely observed, particularly as to respiration, pulse and color. Signs of dangerous raising of the intradural pressure are very rare, but are occasionally seen, and should be watched for. These signs are, in order, disturbed or stertorous respiration, cyanosis, cold sweat, and failing pulse. When they appear, the serum should be allowed to run out again through the needle until the symptoms have disappeared. It is a good habit, after finishing the injection of serum, to hold the needle and syringe in place for three or four minutes

before withdrawing the needle. This does away with the necessity of making a second puncture in case pressure symptoms appear. No fatal case has yet been reported from the raising of intradural pressure in giving antimeningitis serum.

Indications for the Administration of Antimeningitis Serum.—In considering this division of the subject, a distinction must be drawn between those cases in which the diagnosis of epidemic cerebrospinal meningitis has been established by the finding of the diplococcus intracellularis in the fluid obtained by diagnostic lumbar puncture, and those cases in which the diagnosis is suspected upon clinical grounds alone. In the former class of cases, the *antimeningitis serum is positively indicated in every case*, except those cases which have advanced so far into the chronic stage, that the meningococci can no longer be found in the cerebrospinal fluid.

In the latter class of cases, the early administration of the antiserum in epidemic meningitis is so important, that no time should be lost in confirming the diagnosis by lumbar puncture. In every case in which any form of meningitis is suspected, when meningitis cannot be excluded by fully explaining the symptoms suggesting meningitis by some other diagnosis, lumbar puncture should be performed at once. If the serum is at hand, the physician should be prepared to give the serum *at the time of this first lumbar puncture*, without waiting for the result of the bacteriologic examination of the cerebrospinal fluid, under the following indications: If the fluid obtained is clear, like distilled water, no serum should be injected at the first lumbar puncture, and the serum is not indicated except in those rare cases in which meningococci are found in clear fluid. Clear fluid means either tubercular meningitis, or no meningitis. If the fluid is bloodstained, the serum should be given at the first lumbar puncture only if the case is a rapid or severe one, and strongly suggestive of meningitis. Bloodstained fluid throws no light on the diagnosis until examined bacteriologically. If the fluid is cloudy, with a cloudiness varying from a slightly opalescent to a distinctly purulent character, serum should be given at the *first* lumbar puncture without waiting for the bacteriologic examination. Cloudy fluid means that some form of cerebrospinal meningitis is actually present. It may be any etiologic form, but the chances are somewhat in favor of its being the epidemic form, and the advantages to be derived from its early use are great enough to warrant the serum being given at once. There is little or no harm in wasting one dose of serum on one of the other forms of meningitis, the dose not being repeated unless the spinal fluid shows that the meningitis is caused by the diplococcus intracellularis. It must be remembered that the serum is of no value against any of the other forms.

If the serum is not at hand, the lumbar puncture should be diagnostic only, and should be made as early as possible, in order that the diagnosis may be established before the serum is sent for, yet without undue loss of time.

Size of the Dose.—In the early days of the use of the serum, such questions as the proper size of the dose, and the frequency of its administration were entirely unsettled. The earlier work with the serum was more or less experimental. It was soon recognized that on theoretical grounds the larger the dose, the better would be the probable result, and in practice this rule has turned out to be true. On the other hand, the contraindication for large doses was the risk of producing serious disturbance by a sudden raising of the intradural pressure. So great did this risk appear, that the first rule was to give an amount of serum no larger than the quantity of cerebrospinal fluid withdrawn by lumbar puncture. This rule has since been modified, and the various observers are in agreement in the view that at least 30 c.c. is required to produce a good reaction, and that this amount may usually be given with safety, even when smaller amounts of cerebrospinal fluid are obtained. The exceptions are found in very young babies, and in a few other cases in which only a small amount of cerebrospinal fluid can be obtained, and in which, on attempting the injection of a full dose, after a certain point further injection appears to encounter an abnormal resistance. This last point of resistance can only be judged fully by practice.

In all cases it is absolutely essential to withdraw as much cerebrospinal fluid as can possibly be obtained before injecting the serum. After the withdrawal of the cerebrospinal fluid, if the quantity withdrawn is 30 c.c. or under, the routine dose should be 30 c.c. except in case of the exceptions mentioned above. If the quantity withdrawn is more than 30 c.c., the quantity of serum injected should be equal to the quantity of cerebrospinal fluid withdrawn. In very severe or fulminant cases, especially in adults, in which the quantity of fluid withdrawn is between 30 c.c. and 45 c.c., 45 c.c. should be given, provided that no sensation of abnormal resistance is encountered.

Frequency of Administration.—In connection with this point, in spite of the fact that single doses of the serum are frequently followed by a very marked favorable reaction, which fact might suggest that the most favorable times for repeating the dose were only when the limit of improvement from a previous dose had been reached, observers are now agreed that it is better to repeat the injections a number of times at the outset in all cases without reference to the reaction, and that by so doing the improvement is more likely to be permanent, the course of the disease is more likely to be short, and that the liability to relapse is greatly lessened. As a routine, in every case, the injections should be repeated daily so long as diplococci are found in the cerebrospinal fluid, no matter how many doses must be given. In cases in which diplococci disappear early from the cerebrospinal fluid, the injections should be repeated daily for four doses. This number four is an arbitrary one, but is based on the experience of a number of observers and, although undoubtedly in some cases fewer might suffice, yet, as one can never know beforehand, four may be considered the safest number to be used in this class of cases to insure

obtaining the most permanent improvement and the greatest freedom from relapse. Very severe or fulminant cases should be very closely watched and the physician should stand by ready to give a second injection the moment the period of initial improvement shows any tendency to cease; and if they cannot be so watched, or if there is no period of improvement, the injection should be repeated in 12 hours instead of 24.

The Treatment of Relapses.—In one form of relapse the patients have not become entirely free from symptoms and fever, although they have shown marked improvement before they began to get worse again. The treatment of this form of relapse will be described under prolonged cases, but if the relapse begins while one is waiting 3 or 4 days, treatment should be begun at once. In another form of relapse, a true relapse, the patient has been without fever or important symptoms, when he becomes worse, either by rise of temperature, a recurrence of symptoms, or both. Cases in which a rise of temperature is the only manifestation are not nearly so serious as those in which there is a recurrence of any affection of the mental condition. The latter is quite serious, especially if there is no fever or reappearance of diplococci, and may be the precursor of the unfavorable chronic stage.

The treatment of a true relapse is the same as that of the form described under prolonged cases—immediate lumbar puncture and injection of full doses of serum, the injections to be repeated as long as diplococci or symptoms persist; or in the absence of such persistence, until four full doses have been given; or, in the presence of continued symptoms, until the chronic stage is established.

Too much stress cannot be laid upon the necessity of giving several repeated full doses rather than a single one, or smaller ones at all times when the injection of serum is indicated. The cases in Dunn's series in which single doses were given in relapses did not do as well as those in which the relapses were combated by repeated full doses.

The Treatment of Prolonged, Chronic, and Resistant Cases.—A prolonged case is one in which recovery is delayed, with persistence of symptoms. If diplococci persist in the cerebrospinal fluid, daily injections should be continued, until they have disappeared. If diplococci have disappeared, but active symptoms persist after the initial four doses, it is best to wait 3 or 4 days, and then repeat the treatment with four injections, and continue this procedure of occasional repeated daily doses until symptoms have disappeared, or until the chronic stage has become established.

In the chronic stage the consciousness remains affected, but the temperature is normal and the patient's condition remains indefinitely stationary, while no diplococci are found in the cerebrospinal fluid. In this stage the serum has appeared to be powerless. It is as well, however, even in this stage, to perform occasional lumbar puncture, to know if by any chance diplococci have appeared in the cerebrospinal fluid, where there would be some hope of good effect from several successive doses. At these times an occasional dose of serum should be given, though little good is to be expected from its use if diplococci are absent.

It is a probability that in some chronic cases there is a condition of chronic hydrocephalus, and it is a question whether this may not be largely responsible for the patient's condition. This would be shown by the fact that at lumbar puncture a considerable amount of fluid is obtained under considerable pressure. When this is the case, it is suggested that the older treatment by repeated lumbar puncture, without the injection of serum, should be tried.

Resistant cases are distinguished from the prolonged cases described above, in that while the prolonged cases show some good effect from the serum, though later they may remain stationary, resistant cases are those in which the course of the disease appears to be entirely uninfluenced by the serum. In one class of resistant cases, there is some obstacle to proper administration, such as inability to obtain sufficient cerebrospinal fluid to permit the injecting of serum without pressure symptoms. Under such circumstances, if the first lumbar puncture has given a dry tap, and the diagnosis has failed of being established by bacteriologic examination, it is better to inject serum into the canal with great caution, watching for the manifestations of pressure symptoms. If the diagnosis has been established by a previous lumbar puncture, but later lumbar punctures obtain either a dry tap or a very small amount of fluid, the physician had better give serum, but be ready to desist at any moment if pressure symptoms intervene.

In another form of resistant case, no obstacle to the successful administration of the serum is encountered, but no improvement follows in the clinical symptoms. Here there are two classes which call for different treatment. In one class, while there is no improvement in the clinical symptoms, the organisms found in the spinal fluid show the usual effects of the serum treatment, viz., a progressive diminution, and an eventual disappearance. In this class of cases there is evidence suggesting that the failure of the treatment is due to some anatomic change, such as the closure of the foramen of Magendie, which prevents the serum reaching the diplococci developing in the ventricles. In these cases the injection of the serum directly into the cerebral ventricles has been suggested. In a resistant case, growing progressively worse, or failing to improve, in spite of the routine serum treatment, this procedure is worthy of trial.

In the other class of resistant cases the diplococci in the spinal fluid show no effect from the serum. These cases can only be explained on the ground that there may be subspecies or strains of the diplococcus intracellularis which resist the serum. In these rare cases, nothing is to be gained by giving the serum subcutaneously. Vaccine therapy should be tried with homologous vaccine, and the routine serum treatment should be continued in spite of its apparent failure, as these cases sometimes yield after a time.

Summary of the Serum Treatment of Epidemic Cerebrospinal Meningitis

1. Perform lumbar puncture, prepared to give the serum, as soon as meningitis is suspected. If the fluid is cloudy, give the first full dose of serum at once, without waiting for the bacterial examination, although further doses are only to be given in case the diplococcus intracellularis is found in the cerebrospinal fluid. The serum is of no value in other forms of meningitis.

2. At every dose give as much as possible. Always withdraw as much cerebrospinal fluid as possible. Give 30 c.c. in all cases in which the amount of fluid withdrawn is 30 c.c. or less, unless a distinctly abnormal sense of resistance is encountered after as much has been injected as has been withdrawn. In all cases in which the amount of fluid withdrawn is more than 30 c.c. give as much serum as the quantity withdrawn. In very severe or fulminating cases, in which the amount withdrawn is between 30 c.c. and 45 c.c., give 45 c.c. unless abnormal resistance is encountered.

3. In very severe or fulminating cases, repeat within 24 hours as soon as the patient begins to get worse again, or at 12-hour intervals.

4. In average cases, repeat daily, until four full doses have been given in all cases.

5. If diplococci persist after four full doses have been given, continue the injections until they have disappeared.

6. If subjective symptoms, any impairment of the mental condition or fever persist, after diplococci have disappeared, or after four full doses have been given without progressive improvement, wait four days if the condition of the patient is stationary. At the end of four days, or at any time if the patient's condition is getting worse, repeat the treatment with four daily full doses, and continue as if this were the original attack.

7. When a relapse occurs, either by reappearance of diplococci in the cerebrospinal fluid or by a reappearance of symptoms, give four daily full doses and continue treatment as if this were the original attack.

8. Treatment along these lines should be continued until the patient is symptom-free, without diplococci in the fluid, or until the chronic stage is established.

9. In the chronic stage, watch for possible reappearance of diplococci by doing occasional lumbar punctures. If diplococci reappear, resume treatment with the serum as outlined above. In chronic cases with excessive cerebrospinal fluid under marked pressure, try daily lumbar puncture without the injection of the serum.

The Effect of Serum Therapy in Epidemic Cerebrospinal Meningitis

The three principal effects of the use of the serum seem to be: First, to produce a fall of temperature; second, to produce a rapid improvement in the patient's general condition, accompanied by a more or less marked relief of certain symptoms, and, third, to cut short the course of the disease. The effect on the mortality has been mentioned above. For the details the reader is referred to the published reports of Flexner and others.

The most striking effect on the temperature is a permanent critical fall following the first dose of serum. This phenomenon was never observed in epidemic meningitis before the use of serum therapy. With serum treatment, particularly when the serum is used early in the course of the disease, such a crisis is striking in some cases, the temperature falling at once to normal, or nearly normal, and showing no further tendency to rise. Other cases show a similar critical fall of temperature, which is, however, not permanent, the temperature rising again and finally coming down by lysis. Another effect is seen in a rapid permanent lysis which is very striking in cases in which there has been a consistent high temperature up to the time when the first dose of serum was given. A similar lysis, but not permanent, the temperature going up again, occurs at times, as does a temporary sharp fall of temperature, not to the normal and not permanent; in these the temperature rises again, to come down by lysis later in the course of the disease. There is no immediate effect on the temperature noted in some cases.

The effect on the symptoms and general condition is the most striking phenomenon observed with the use of the serum. In some cases there occurs a permanent return to consciousness, a disappearance of mental dulness, a disappearance of delirium, and a disappearance of headache, hyperesthesia, tenderness of the neck or vomiting. These symptoms are often relieved completely within 24 hours after the first injection, the patient changing in the most remarkable way from a serious condition of coma to a favorable condition or normal mental activity.

At other times the improvement in this set of symptoms occurs more slowly, and at still other times, particularly in the late chronic cases, no such effect is noted. The rigidity of the neck and Kernig's sign are usually much more persistent, so that at times patients remain for some time normal in every way, even playing, while these signs persist.

As to the cutting short of the disease, the average length of time which patients remain under treatment at the Children's Hospital is but a small fraction of the time which patients who recovered remained under treatment at the hospital in previous years.

Another notable effect of the serum is seen in the successive examinations of the cerebrospinal fluid during the period of its use. This effect is most striking in early cases, in which the cerebrospinal fluid contains large numbers of diplococci. In such a case a great many intracellular diplococci are observed in the fluid withdrawn by the first lumbar puncture. Twenty-four hours after the first injection the fluid presents a strikingly different picture. The whole number of organisms seen is much smaller, but the chief change is that the majority are intracellular, only rare extracellular forms being seen. The third lumbar puncture shows still fewer diplococci, and those only intracellular. In the fourth fluid, after three

doses, there are frequently no diplococci to be found, or, at most, very rare intracellular forms.

The completeness of recovery is another noteworthy point. Permanent sequels, such as deafness, blindness, paralysis, or idiocy, are rarely observed under serum therapy.

The results of the use of the serum appear to depend chiefly on how early it is first used. The earlier it is employed the more marked are its effects. We may conclude that the prospects of aborting or rapidly cutting short epidemic cerebrospinal meningitis are better the earlier in the disease the serum is given, and that the antiserum usually has no effect in the late chronic stage. There are cases which prove exceptions to this rule, as in some cases in which the serum is used comparatively early the patients die. Most of these are cases of the very rapid, fulminant type, in which death occurs within 12 or 24 hours of the administration of the first injection. In these, death occurs before the serum has time to produce its effect. Some of these fatal cases in which the serum is used early are of one of the resistant types described above.

On the other hand some patients in the late chronic stage begin to improve immediately after one dose of serum and make a rapid convalescence. This would show that there is always some hope of a good result so long as diplococci are present. In most cases the serum causes a cessation of the active process, and the resulting course of the disease depends mainly on the extent of tissue damage which has already been done.

CEREBRUM.—See Brain.

CERIUM OXALATE.—Consists chiefly of a mixture of the oxalates of cerium, didymium and lanthanum, and other rare earths of this group. It occurs as a fine, white powder, odorless and tasteless, permanent in the air, insoluble in water, alcohol or ether. Dose, 1/2 to 5 grains in pill or powder.

It is a gastric sedative, and is considered to be particularly useful in vomiting of reflex origin, especially in the vomiting of pregnancy, but it often fails, probably because not given in sufficient doses. To be effective, at least 4 or 5 grains should be given 3 times a day, and no results promised until after it has been used several days. It is also recommended in the vomiting of phthisis and bronchitis, cough with vomiting, chorea, and diarrhea.

CERUMEN, IMPACTED.—See Ear (Diseases).

CERVICAL RIB.—Cervical rib springs from the anterior transverse process of the seventh cervical vertebra. It is bilateral in about two-thirds of the cases; rarely a second cervical rib may arise from the sixth cervical vertebra. The anterior extremity is usually free, but it may unite with the first rib or with even the sternum. The brachial plexus and subclavian artery pass over it, and with the growth of the rib or its ossification these structures are compressed, causing pain, weakness of the arm, trophic troubles, or even obliteration of the pulse and gangrene. There is no edema of the arm, because the subclavian vein lies in front of the middle scalene muscle and escapes pressure. The rib forms a prominence in the neck, which has been mistaken for aneurysm, because it pushes the subclavian artery forward and upward. The X-ray will dispel all doubt. If there are pressure symptoms, the rib may be removed through a transverse incision after separating the nerves and vessels (Stewart).

CERVIX UTERI, AFFECTIONS.

Laceration

Injury of the cervix uteri is of very frequent occurrence. A large proportion of women have the cervix more or less extensively lacerated during their first confinement.

There are several varieties of lacerated cervix: (1) Through the anterior lip; (2) through the posterior lip; (3) single lateral tear; (4) bilateral tear; (5) stellate tear; and (6) the incomplete tear. In the last condition the muscular structure and the mucous membrane lining the cervical canal are torn, but the vaginal mucous membrane remains intact. The most frequent of these varieties are the *unilateral* and *bilateral* tears.

Symptoms.—The symptoms of laceration of the cervix are by no means diagnostic. There are usually leukorrhea and menorrhagia. These symptoms are not due to the laceration itself, but to the cervical catarrh and subinvolution that accompany it. Pain in the pelvis and extending down the leg is a not unusual symptom. Various reflex nervous disturbances may be present.

The diagnosis of laceration of the cervix is made not by the symptoms, but by the physical signs. Inspection will reveal the site of the tear; the two lips of the cervix are everted; the external os is patulous; and the whole area of the tear is red and eroded. The condition is most marked in the complete bilateral tear.

By palpation is detected the angles of the laceration; plugs of indurated, cicatricial tissue may be felt here and there; and frequently small shot-like cysts, embedded in the mucous membrane, are noticed. The cervix loses its conic shape and becomes broader and flatter.

Treatment.—This consists in repair of the torn surfaces by a plastic operation. The operation is called **trachelorrhaphy,** and consists in denuding the torn edges and bringing them together with sutures. The best time for the operation is about a week after the menstrual period. The steps of the operation are as follows:

1. The patient is anesthetized and placed in the lithotomy position.

2. The physician's hands, instruments, and the field of operation are sterilized in the usual manner.

3. The anterior lip of the cervix is seized with a double tenaculum and drawn down to the vulva; the posterior lip is seized in a similar manner, and the two surfaces are separated.

4. Beginning upon the posterior lip, the areas to be denuded are marked out with the point of a sharp knife.

5. These areas are denuded with scissors, care being taken to preserve strips of mucous membrane in the center for the formation of a new cervical canal.

6. Sutures of silkworm gut are introduced, begin-

ning at the angle of the tear, entering the mucous membrane on the vaginal aspect of the cervix, and emerging at the edge of the mucous membrane that is to form the new cervical canal.

7. Three or four of these sutures are introduced on each side, the denuded edges are brought together, and the sutures are shotted.

8. A douche of sterile water is given and a light gauze tampon is introduced into the vagina.

The patient remains in bed for 2 or 3 weeks; the tampon is removed at the end of 24 hours, and the sutures are removed at the end of 2 weeks. If the laceration is of long standing, the cervix is likely to be hypertrophied, indurated, and cystic. congested. The characteristic discharge may be seen escaping from the cervical canal.

Treatment.—In every case a thorough examination is necessary in order, if possible, to detect the cause of the condition. If this is found and removed, the cervical catarrh will probably disappear spontaneously. Improvement of the general health will frequently relieve the symptoms and lessen the leukorrhea. Preparations containing iron, such as Blaud's pill, Basham's mixture, and the four chlorids, are particularly beneficial. Exercise and attention to the diet and to the condition of the bowels are also necessary. Should the condition persist after the foregoing line of

Denudation of Lacerated Cervix. Sutures Introduced. Sutures Tied.

(Repair of lacerated cervix.—(*Montgomery.*)

Under these circumstances preparatory treatment should be instituted, for the purpose of bringing the cervix to as nearly a normal condition as possible. This consists in the administration of copious douches of hot water, regulation of the bowels, scarification and puncture of the cervix, local applications, and tampons. If after 2 or 3 weeks of this treatment the induration and cystic degeneration have not disappeared, the case is not suitable for trachelorrhaphy, and in such case the cervix should be amputated.

Endocervicitis

Inflammation of the mucous membrane of the cervical canal. Cervical endometritis is a very common affection, and in greater or less degree may be found in the majority of women.

Causes.—The affection is usually a secondary one, being dependent upon some local or general condition. The various displacements of the uterus are a common cause. Laceration of the cervix is almost always accompanied by cervical catarrh. Gonorrhea causes a most intractable form of the disease. Improper hygienic conditions, impaired health, and the scrofulous and tubercular diatheses are predisposing factors.

Symptoms.—The most important symptom is leukorrhea. The character of the discharge is almost diagnostic. It is thick, opaque, and tenacious, and is discharged in the form of strings or shreds. Associated with this there may be other symptoms, such as headache, backache, and pain in the pelvis. Inspection of the cervix will reveal a patulous condition of the external os, while the mucous membrane surrounding it will be red and

treatment, local treatment will become necessary. This consists in the administration of hot vaginal douches; in the use of glycerin tampons; in the application of tincture of iodin to the cervix; and in application to the cervical canal. The vaginal douches should be given 2 or 3 times daily by means of a fountain syringe; they should consist of large quantities of hot water—a gallon or more—at a temperature of about 110° F. Glycerin tampons may be inserted against the cervix twice a week; they should remain 12 hours, their removal being followed by a vaginal douche. Applications of tincture of iodin may be made to the cervix and vaginal vaults every 5 or 6 days. Finally, applications may be made directly to the cervical mucous membrane. These may be made by means of an applicator, or, better, with a long glass pipet. The pipet is filled, its point is introduced as far as the internal os, and the solution is expressed as the pipet is slowly withdrawn. The best solutions for application to the cervical canal are chlorid of zinc or nitrate of silver (2 grains to 1 fluidounce), pure carbolic acid, and Churchill's tincture of iodin, or argyrol (20 to 40 percent solution). After the application a cotton pledget saturated with boroglycerid or a 15 to 25 percent solution of ichthyol in glycerin should be placed against the cervix.

Polypi

These are usually mucous in character, and are the result of degeneration of the cervical glands. The symptoms are not characteristic; they are usually attended by more or less menorrhagia and leukorrhea. Inspection will sometimes reveal the

growth protruding from the cervix. Pedunculated growths should be twisted or cut away; the sessile varieties should be excised.

Hypertrophic Elongation

This consists of a hypertrophy and an elongation of the infravaginal cervix. The condition is most frequently found in virgins, and it is probably congenital in origin. The hypertrophy may be so pronounced that the cervix projects from the vulva.

Treatment consists in amputation of the cervix.

Carcinoma

Cancer of the cervix uteri occurs more frequently than cancer in any other part of the body. It appears in two forms: 1. Squamous-cell (*epithelioma*) when springing from the vaginal portion of the cervix; 2. cylindric-cell (*adenocarcinoma*) when attacking the cervical canal.

Causes.—The exciting cause of cancer of the cervix is unknown. Laceration and erosion are predisposing causes, for cancer of the cervix is rarely found except in women who have borne children. It occurs most frequently between the ages of thirty-five and fifty.

Symptoms.—The classic symptoms are *hemorrhage*, *discharge*, and *pain*.

Hemorrhage is usually the first symptom. It may appear as a slight menorrhagia or there may be bleeding between the periods. This is excited or aggravated by exertion of any kind. A long walk, straining at stool, or coitus may be followed by slight hemorrhage. Ofttimes, after the patient has passed the menopause, there will occur more or less regular bleeding, so that she may suppose menstruation has returned. As the disease progresses the hemorrhage becomes more pronounced, until finally the patient bleeds almost continuously. **Leukorrheal discharge** is another important symptom. In some cases it may appear before the hemorrhage. At first it presents the characteristics of an ordinary leukorrhea, but later it becomes blood-stained and mixed with particles of the ulcerating cancerous mass. It has an extremely offensive odor. It is irritating to the skin, and frequently causes pruritus and even excoriation of the vulva and inner parts of the thighs. **Pain** is not a prominent symptom early in the disease. It may be absent throughout the entire course of the disease. It is usually felt in the back, and is referred down the legs. The disease may extend to the bladder and rectum; it may involve the pelvic nerves and ureters. This will cause such symptoms as vesical irritability and constipation, intense pelvic pain, and finally uremia. As the disease progresses the general health fails; the patient loses weight and strength; becomes anemic; and finally presents the typical picture of a cancerous cachexia.

Diagnosis.—This usually depends upon the physical signs, with perhaps a microscopic examination of a portion of the diseased cervix. In the first stage the cervix is hard and nodular; the mucous membrane seems to be immovably fixed upon the underlying tissue. In other cases a small ulcerated area may be the only evidence of the disease. As the disease progresses the nodular growths break-down; the entire cervix becomes ulcerated; or large cauliflower-like masses may fill the upper part of the vagina. The tissues are exceedingly friable, and bleeding occurs at the slightest touch. Since the successful treatment of cancer of the cervix depends upon its early recognition, unnatural bleeding in a woman past the age of 30 should be viewed with the greatest suspicion, and unless a satisfactory cause can be assigned for it, microscopic examination of the cervix and endometrium should be made without delay. In all cases in which there is the least doubt the microscope should be used.

Prognosis.—The prognosis is unfavorable unless radical operation is performed. The duration of the disease is from a few months to about 3 years.

Treatment.—This is either radical or palliative. Radical treatment, which consists in complete hysterectomy, should be attempted in all cases in which the disease has not extended to inaccessible organs. Thus, it would be contraindicated when the bladder or the rectum was involved, when the vagina was extensively infiltrated, or when the disease had extended to the broad ligaments and cellular tissue of the pelvis. Palliative treatment consists in relieving the pain, hemorrhage, and discharge. The pain is best relieved by morphin, taken internally or given hypodermically. The hemorrhage and discharge are best relieved by removing as much as possible of the cancerous tissue with scissors and a sharp curet. This is done in the following manner: The patient is anesthetized and placed in the lithotomy position. All accessible diseased tissue is removed with scissors or with a sharp curet. Hemorrhage is controlled and tissue not accessible to the knife is further destroyed by the use of the actual cautery. The vagina is douched with sterile water and packed with iodoform gauze, which is removed at the end of 48 hours. Douches of potassium permanganate or creolin are given daily. Relief afforded by the foregoing treatment is prompt and usually continues for some months. The progress of the disease is also arrested for a short time.

CERVIX UTERI, AMPUTATION.—According to the extent of disease or hypertrophy of the cervical mucous membrane, the double or the single flap (Schroeder's) method is preferred. In the former operation, after an incision is made into each angle anterior and posterior cervical and vaginal flaps are formed by the removal of a wedge-shaped piece from each lip. Chromic catgut is used for suturing. Two sutures introduced into each lip and two or more lateral sutures bring the surfaces in apposition. In the latter operation indicated in the more serious cases, instead of a cervical flap a transverse incision is made into the lip from within outward at the level of the lateral incision, extending half through the lip; then a vertical incision is made to the junction of the vaginal and cervical mucous membranes. The end of each flap is brought in apposition to the cervical mucous membrane by sutures, and lateral sutures are introduced.

CESAREAN SECTION.—Delivery of the child through an incision in the abdominal and uterine wall.

Indications.—There are certain conditions under which Cesarean section is absolutely called for. These are extreme degrees of contracted pelvis, when the true conjugate is below 7 cm.; obstruction of the pelvic canal by a tumor—large, bony growths of the pelvis, or fibroid or cystic tumors of the uterus and ovaries, respectively; extreme atresia of the vagina or cervix, and rupture of the uterus. When surgical interference becomes necessary in pelves with a conjugate between 7 cm. and 8 cm., craniotomy is ordinarily advised. The present low mortality of Cesarean section, under favorable circumstances, makes it advisable. The question should be left to the patient and her husband or friends to decide. Craniotomy is rarely ever justifiable upon a living, healthy child.

Varieties.—There are 2 varieties of Cesarean section: one is the so-called *Sänger operation,* in which, after the extraction of the child, the uterine incision is closely approximated and the uterus allowed to remain—*laparohysterotomy;* the other is the *Porro operation,* which is essentially a supravaginal amputation of the uterus—*laparohysterectomy.*

Laparohysterotomy is indicated when the condition that necessitates the interference can be removed at the time of operation. Thus, if Cesarean section is demanded on account of an ovarian cyst, the uterus should be allowed to remain, as the cyst can easily be removed and subsequent difficulty avoided.

Although still valuable as a life-saving procedure when haste and the minimal amount of shock are demanded, the Porro operation has been largely superseded by the more correct surgical method of abdominal hysterectomy proper.

Abdominal hysterectomy is indicated when the operation is performed for pelvic deformity or contraction; for extreme atresia of the cervix or vagina; for large fibroid tumors of the uterus, and for extensive rupture of the uterus. If the uterus fails to contract and hemorrhage is profuse, or if there is reason to believe that the patient is septic, the uterus should be removed. The advantages of abdominal hysterectomy are that it lessens the chances of puerperal infection; that it eliminates the possibility of postpartum hemorrhage; that it prevents the formation of adhesions between the uterus and anterior abdominal wall; that it prevents the formation of fistulæ between the uterine cavity and abdominal wall; that it prevents rupture of the uterus in a subsequent pregnancy, and that it prevents the necessity of a repeated Cesarean section.

Technic.—When an absolute indication for Cesarean section exists, it should be performed about 2 weeks before term. When the patient is not seen until labor, it should be performed as quickly as possible. The prognosis is always graver if the patient is allowed to exhaust herself by futile attempts at spontaneous delivery.

The steps of the operation are as follows:

1. The patient is thoroughly prepared for the operation, anesthetized, and placed upon the table.

2. A long median incision is made, extending from about 2 inches above the umbilicus almost to the symphysis pubis.

3. The fundus of the uterus is lifted out of the abdominal cavity, and warm sterile towels are placed about it to protect the intestines and peritoneal cavity.

4. An assistant grasps the abdominal walls and lower uterine segment, and compresses them to avoid hemorrhage when the uterus is incised.

5. An incision about 5 inches in length is made through the anterior wall of the uterus, and the child, placenta, and membranes are extracted.

If it is purposed to perform the Porro operation, the remaining steps are the same as in an ordinary hysterectomy. If the Sänger operation is decided upon:

6. The cervical canal is dilated with the fingers from above downward, and the end of a good-sized strip of gauze is passed through the cervix into the vagina; the remainder is packed firmly into the uterine cavity.

7. The uterine incision is closed by 3 sets of sutures—1 set of interrupted, medium-sized, silk sutures, which are placed about 3/4 of an inch apart and go down to, but not through, the mucous membrane; another continuous suture of catgut, which is buried in the uterine wall; and a superficial Lembert suture of fine silk, which closes the edges of the peritoneum and thus prevents leakage into the peritoneal cavity. Then, if desirable, with the consent of the patient the Fallopian tubes may be ligated and divided. The remainder of the operation consists in freeing the peritoneal cavity of blood and serum by careful sponging and in closing the abdominal wound with four planes of sutures. The after-treatment is the same as for an ordinary laparotomy.

Prognosis.—The maternal mortality from Cesarean section is yearly decreasing. Cases that are operated upon before the onset of labor, under favorable circumstances should have a mortality of not more than 5 percent. In the hands of experienced operators the Porro operation should give the best results, although statistics show that the Sänger method has a lower mortality.

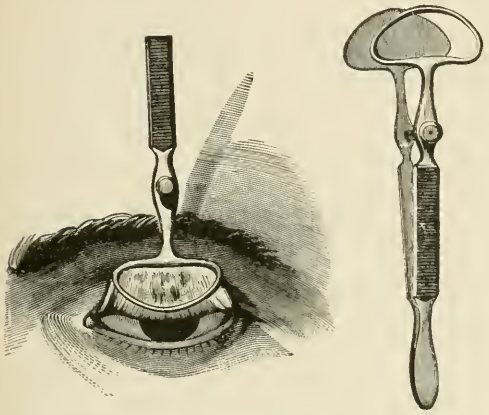
CESAREAN SECTION, VAGINAL.—Delivery of the fetus by forceps or version through an incision in the anterior cervical wall extending beyond the internal os into the lower uterine segment. Introduced in 1896, this operation is still in its experimental stage. It is contraindicated in a markedly contracted pelvis with a true conjugate of 8 cm. Its chief indication is in eclampsia when rapid dilatation is contraindicated and quick delivery is demanded. It is also indicated in cardiac disease and stenosis of the cervix.

CHAFING.—See Erythema Intertrigo.

CHALAZION.—A small tumor arising from an inflammation or closure of a duct of a Meibomian gland. It is the size and shape of a split pea, the convex side being toward the skin. It usually points toward the palpebral conjunctiva. It may be distinguished from hordeolum by its location,

chronic course, and noninflammatory symptoms. The conjunctiva is often red and spongy-looking, especially directly over the tumor. The skin over the tumor is freely movable, and is normal in appearance.

Treatment consists in excising and cureting the tumor, under cocain, using a special forceps. In excising through the conjunctiva, the scarification following an extensive excision may cause entropion, and a simple incision should be made in the direction of the gland, and curetting alone should be resorted to. In excising through the lid, an incision parallel to the edge of the lid is made over



Excision of Chalazion. Desmarres' Forceps.

the chalazion, its capsule is opened, and the whole mass excised and the cavity cureted. Suture of the wound is optional.

CHALICOSIS.—Marble-cutter's phthisis; phthisis due to the inhalation of marble-dust. See Tuberculosis.

CHALK.—Prepared chalk is native calcium carbonate, a white, amorphous powder, odorless and tasteless, insoluble in water and alcohol. Dose, 5 grains to 1 dram. It is used with mercury in compound chalk powder, in chalk-mixture, and in troches.

It is much used as an antacid, as a tooth-powder, and as a dusting-powder in erythematous eczema and intertrigo, and for chafing of the genitalia and buttocks of young children.

In simple diarrhea of children:

℞. Tincture of krameria, Camphorated tincture of opium, each. ℥ j.
Chalk-mixture, enough to make ℥ j.

A teaspoonful every 2 hours to a child of 5 years.

See Calcium.

CHAMOMILE.—There are no official preparations. The flower-heads contain a volatile oil, a camphor, and a bitter principle, but no alkaloid. An infusion (4 drams to 1 pint of water) may be given in doses of from 1 to 2 ounces. Chamomile is a bitter tonic, improving the appetite and aiding the digestion. In large doses the warm infusion is an emetic, perhaps diaphoretic. Chamomile is popular in domestic practice for infants' complaints, and externally as a fomentation to relieve pain, as in colic. The oil is useful in reflex cough, pulmonary catarrh, acute dyspepsia, diarrhea of children, spasmodic asthma, whooping-cough, colic, and in the spasmodic and pseudoneuralgic affections of hysteric women. In poisoning from strychnin it may be employed to allay reflex excitability.

The German chamomile is official in the U.S.P. as "**Matricaria,**" and is the "chamomilla" of homeopathy.

CHANCRE.—See Syphilis.

CHANCROID.—A sore (soft chancre) developed upon the genitals as a result of contagion and probably caused by the bacillus of Ducrey. It is distinguished from true or hard chancre partly by the absence of induration, but chiefly by the absence of subsequent constitutional symptoms and by the fact that the period of incubation is much shorter; the one is always less than a week, and generally less than 3 days; the other is always more than 3 weeks, and is often as much as 5.

Soft chancre never occurs except upon the genitals, and is probably due to infection from retained and decomposing purulent discharge. The intensely irritating character this possesses may be judged by the fact that soft chancre occurring on a mucous surface is almost sure to infect the opposite side, and if the secretion is pent up, as in the case of phimosis, is almost certain to become phagedenic. It can be inoculated times without number without conferring the least degree of immunity. It is never followed by any other results than those which are so common after all foul and sloughing sores on parts that are never kept at rest, and constitutional treatment is of little or no avail for it.

Symptoms and Causes.—The favorite situation is on the mucous surface of the prepuce or just behind the corona. A small red papule is the first sign; by the third or fourth day this has become a pustule with a bright areola, and in 24 hours more it breaks, leaving a sore with angry base and edges. In some few cases this heals without any further ulceration; probably the infection has never really penetrated into the submucous tissue. More frequently it continues to spread; the edges are sharply cut, perhaps undermined; round them is a bright red rim of inflammation; the base is grayish or yellow, covered with a slough; and the whole thickness of the mucous membrane is destroyed. The sore is usually circular in shape and very tender. On the glans it may be perfectly soft, without sign of induration; but when it is upon the skin, the base is often infiltrated to such an extent that it is nearly as hard as true infecting chancre. The margin, however, is different; in a soft sore the edge of the induration is ill-defined; it shades off imperceptibly into the healthy tissues around, and no limit can be made out; but, at the same time, it must be recollected that this is equally true of a

hard chancre when it is inflamed; and that, owing to the extreme mobility of the skin upon the penis, any sore with a hardened base felt in the longitudinal direction and lifted up from the tissues beneath appears exceedingly well defined. The secretion, at first, is thin and watery, with a few shreds and sloughs, detached from the surface, floating in it; later, when granulations form, it consists of ordinary pus, such as comes from any other sore.

If, owing to phimosis or balanitis, the secretion is retained under the prepuce, so that it decomposes, the ulceration is more severe, and may become phagedenic. The sore increases in all directions; the opposite surface of the prepuce is attacked; the skin on the outside is reddened; the whole of the end of the penis becomes swollen; and if relief is not speedily given, the skin sloughs, ulcerating through from beneath, and the end of the glans protrudes through a ragged opening on the dorsum. In the worst cases the destruction is even greater; the whole of the skin covering the end may perish, the glans be in great measure destroyed, and the urethra laid open.

The inguinal glands that lie parallel to Poupart's ligament are always more or less inflamed. In the milder cases they are simply enlarged, swollen, and tender; their outline is indistinct, and if several on the same side are attacked, they cannot be isolated from one another. In the more severe cases suppuration occurs, generally commencing in the loose cellular tissue around (periadenitis), so that when the bubo is opened, the glands are seen projecting into the cavity, surrounded and bathed with pus. Sometimes, however, it appears to begin in the interior of the gland, and occasionally in both places at the same time. It is said that when this happens the pus from the interior of the gland is infective, while that from the tissues around is not. Phagedenic and serpiginous buboes are met with exceptionally in very severe cases of syphilis combined with soft sores, or when the patient's health is utterly broken down. No constitutional symptoms ever follow a true soft sore, and the inflammation of the lymphatic gland is merely due to the absorption of pyogenic organisms, assisted by the retention of decomposing secretion or other injurious influences (Moullin).

Diagnosis.—Herpes præputialis presents the greatest difficulty. This very peculiar affection may occur after each attempt at coitus; it has even been known to follow nocturnal emissions; and though it may be more severe and more common in those who have suffered from syphilis, it is certainly met in those who are perfectly free from the disease. If there is only one vesicle, or two, perhaps, and the case is not seen until the epidermis is broken, there is no means of forming a diagnosis. If, owing to the enlargement and swelling of the prepuce, the existence of a sore is doubtful, circumcision must be performed; the need for this increases with the amount of redness and inflammation. The coexistence of syphilitic infection cannot be affirmed or excluded until the period of incubation (6 weeks at least) is past. See Syphilis.

Chancre	Chancroid
First lesion of a constitutional disease, viz., syphilis.	A local disease.
Due to syphilitic infection.	Due to contact with secretion from chancroid.
Generally a venereal infection.	Always a venereal infection.
May occur anywhere on the body.	Nearly always on genitals.
Period of incubation never so short as ten days.	Period of incubation always less than ten days (generally about three).
Generally single.	Generally multiple.
Not autoinoculable.	Autoinoculable.
Secretion slight.	Secretion profuse and purulent.
Slightly or not at all painful.	Generally painful.
As a rule only occurs once in any patient.	May reoccur in same patient.
Buboes are painless and seldom suppurate.	Buboes are painful and usually suppurate.

Treatment.—Local chancre spreads because of the poisonous character of its discharge. A single application of the acid nitrate of mercury leaves, as soon as the slough separates, a healthy granulating surface. So severe a measure as this, however, is rarely necessary, unless the sore is phagedenic and it is imperative to stop the progress at once. Ordinarily speaking, if the surface is well cleansed with an antiseptic wash and dried, and then dusted over with iodoform, night and morning, the character of the secretion changes immediately. Phagedena should be treated, as already mentioned, by the use of prolonged warm baths. Mercury is not required unless the healing of the chancre is unaccountably delayed or there is suggestion of syphilis.

CHANGE OF LIFE.—See Menopause.

CHARBON.—See Anthrax.

CHARCOAL.—Two forms of carbon are official: **Carbo Animalis**, *Animal Charcoal*—prepared from bone, occurring in dull black fragments or powder, odorless and nearly tasteless, insoluble in water or alcohol. **Carbo Ligni**, *Charcoal*—prepared from soft wood, and very finely powdered; is black, shining, brittle, inodorous, tasteless and insoluble. Dose, 10 to 20 grains. Charcoal is largely used as an absorbent for foul gases, as a deodorant and disinfectant. It is used in hyperacidity and flatulent distention, in chronic gastric catarrh, cancer, intestinal dyspepsia, and diarrhea. As a tooth-powder it is not so useful as chalk. It may be mixed with flaxseed for use as a disinfecting poultice to sloughing sores.

For flatulent dyspepsia:

℞. Powdered light charcoal, Heavy magnesia, } each, ʒ ij
Salicylate of bismuth, gr. lxx.

Divide into 24 powders. One before meals.

Preparation.—**Carbo animalis purificatus**, purified animal charcoal.

CHARCOT'S DISEASE.—Also called Charcot's joint, tabetic arthropathy, and neuropathic arthritis. This is a condition found in locomotor ataxia, and is anatomically identical with rheumatic gout. It is due to trophic disturbance, and is an inflammation of the bone and structures in and around a joint. The knee is the most often attacked. There is no constitutional involvement, and the disease begins acutely, often as a sudden effusion, which disappears after a time. The bones and cartilages are rapidly destroyed, the joint grates, and the softening and relaxation allow great range of movement, with ensuing deformity.

An apparatus to sustain the joint is necessary in the treatment of Charcot's disease, and resection may be necessary. Cotton-wool, covered with light and well-adjusted bandages, should be applied. Strips of buckskin covered with mercurial and ammoniacum plaster, and carefully applied, are useful for any stage. Remedies for the central nervous lesion must be employed as in ordinary locomotor ataxia, benefit being sometimes derived from silver nitrate, potassium, iodid, mercury, and codliver oil. Monobromated camphor is of value for the "lightning pains." Benign cases may altogether subside. See JOINTS (Diseases), AMYOTROPHIC LATERAL SCLEROSIS, LOCOMOTOR ATAXIA, etc.

CHARTÆ (Papers) consist of strips of paper medicated by impregnation of its fibers with medicinal substances or by being coated therewith. There is only one official paper, Charta Sinapis, which is made with sized paper, and is intended for external application as a vesicant or counterirritant.

Charta Sinapis.—black mustard, 100 gm.; rubber, 10 gm.; petroleum benzin, carbon disulphid, of each q. s. Before it is applied to the skin, mustard paper should be dipped in warm water for about fifteen seconds.

CHAUFFEUR'S FRACTURE.—This is a fracture of the forearm caused by a blow from the crank handle of a motor being suddenly thrown backward during the operation of cranking. It is practically a Colles' fracture. In favorable cases the displacement is slight, and the permanent result good; in severe cases the deformity is that of a typical Colles' fracture, and the treatment is that of the latter injury. See FOREARM (Fractures).

CHELOID.—SEE KELOID.

CHEST, DISEASES.—Diseases of the chest may be divided into certain groups, viz.:

1. Diseases of the walls or extending inward from them.
2. Diseases of the respiratory apparatus contained within the chest-walls: viz., pleuræ, trachea, main bronchi, and lungs.
3. Diseases connected with the circulatory system: viz., pericardium, heart, and great vessels within the chest, both arteries and veins.
4. Diseases originating in the mediastinal cellular tissue.
5. Diseases of the absorbent vessels or glands within the chest, of the thoracic duct, and of the thymus gland or its remains.
6. Diseases of the esophagus.
7. Diseases of any of the important nerves traversing the chest.
8. Diseases of the diaphragm.
9. Diseases encroaching upon the thoracic cavity from the abdomen or from the neck.

The particular diseases comprehended within most of the groups are very numerous, and are considered elsewhere under their separate headings. They may be mere functional disorders, to which the heart is especially prone, or organic diseases, common, and ranking high as causes of death. They may be either local or general. Physical examination constitutes an essential part of clinical investigation of the chest and its contents. It comprises inspection, palpation, percussion, auscultation, measurement, succussion, and the use of special instruments.

CHEST, EXAMINATION.—For the purpose of applying **physical methods of diagnosis** to determine the objective symptoms (physical signs) of diseases, the chest may be conveniently divided into 3 general regions—*anterior*, *posterior*, and *lateral*.

The anterior region is subdivided into the clavicular, supraclavicular, infraclavicular, mammary, inframammary, upper sternal, and lower sternal regions.

The posterior region is subdivided into the scapular, infrascapular (subscapular), and interscapular regions.

The lateral region is subdivided into the axillary and infraaxillary regions.

Boundaries of the Anterior Region

The clavicular region is that portion of chest covered by the clavicle.

The supraclavicular region is that portion of the chest situated above the clavicle. It contains the apex of each lung, with portions of the subclavian and carotid arteries and the subclavian and jugular veins.

The infraclavicular region has for its boundaries the clavicle above, the lower border of the third rib below, the edge of the sternum inside, and externally a line drawn *vertically* from the junction of the middle and outer third of the clavicle. This region contains the upper lobe of the lung and the main bronchi; on the right side, the superior vena cava and a portion of the arch of the aorta; and on the left side, a portion of the pulmonary artery. The clavicle usually corresponds with the first rib.

The mammary region is bounded above by the lower border of the third rib, below by the upper margin of the sixth rib, inside by the edge of the sternum, and externally by a vertical line drawn through the middle and outer third of the clavicle.

The contents on the right side are the right lung, the right portion of the diaphragm, a portion of the right auricle, a portion of the right ventricle; and on the left side, the lung and a small part of the right ventricle.

The nipple in the male is placed, in the majority of cases, between the fourth and fifth ribs, and in the center of the mammary region. A line drawn vertically through the nipple is termed the *mammillary line*. As this line is usually carried upward

to the center of the clavicle, it is also called the *midclavicular line.*

The inframammary region is bounded above by the sixth rib, below by the margin of the false ribs, inside by the sternum, and outside by the vertical mammillary line. It contains, on the right side, the liver, with a portion of the lung on deep inspiration; on the left side, the left lobe of the liver, the stomach, and a portion of the spleen.

The upper sternal region is that portion of the chest that extends from the suprasternal notch to the junction of the third costal cartilage with the sternum. It contains the ascending arch of the aorta, portions of the superior vena cava, the innominate veins, the subclavian arteries, the esophagus, and the trachea.

The lower sternal region is that portion of the chest that extends downward from the junction of the third costal cartilage with the sternum. It contains portions of the lung, right and left ventricles, liver, and stomach.

The *parasternal line* is a vertical line drawn midway between the edge of the sternum and the mammillary line.

Boundaries of the Posterior Region

The scapular region is that portion of the chest within the dimensions of the scapula. It contains on each side the greater portion of the lung.

The **infrascapular (subscapular) region** is bounded above by a horizontal line drawn across the inferior angles of the scapulæ; below by the twelfth rib; inside by the spinous processes of the vertebræ (*vertebral line*); and outside by the posterior border of the lower axillary region. It contains a portion of lungs on each side; on the right side a portion of liver and kidney; and on the left side a portion of intestine, spleen, kidney, and descending aorta.

The interscapular region is the space between the inner margin of the scapula and the spines of the dorsal vertebræ (*vertebral line*) from the second to the sixth. This region contains portions of lung, bronchi, esophagus, and descending aorta. The inferior angle of the scapula usually rests on the seventh rib.

The *scapular line* is a vertical line drawn through the center of the inferior angle of the scapula, while the arms hang by the side. It extends downward to a transverse line drawn through the inferior angles of the scapulæ.

The *vertebral line* is a vertical line drawn on each side of the spines of the vertebræ.

Boundaries of the Lateral Region

The axillary region is the space bounded above by a transverse line continuous with the lower border of the mammary region (sixth rib); in front by the external border of the mammary and inframammary regions; and behind by a line drawn vertically downward from the uppermost portion of the internal border of the scapula. This region corresponds to the upper lobes of the lungs and main bronchi.

The infraaxillary region is bounded above by the axillary region; anteriorly by the inframammary region; posteriorly by the infrascapular region; and below by the edges of the false ribs. This region contains the lower edge of the lung on each side. On the right is the liver and on the left the stomach and spleen.

The physical methods of diagnosis employed in obtaining the objective symptoms (physical signs) of disease of the chest are (1) inspection, (2) palpation, (3) percussion, (4) auscultation, (5) mensuration, (6) succussion.

Inspection

By inspection are recognized the changes in size, form, and symmetry of the chest, movement of muscular walls, with regard to rhythm, frequency,

1. Normal Chest. 2. Pigeon Breast. 3. Rickets. 4. Emphysema.—(*Greene after Gee.*)

and force. Special features to be noted are the apex beat, epigastric pulsation, and abnormal localized enlargements (aneurysm, gumma) and pulsations.

In applying this method of diagnosis the patient should be in a good light, either standing or in sitting posture.

Phthisical Chest.—Small in dimensions; the thorax is long and flat; the ribs oblique; the angles of the scapulæ project, giving the appearance of wings; the spaces above the clavicle are depressed; the divergence of the costal margin from the sternum forms an acute angle.

Rachitic Chest (Pigeon-breast).—The sternum is very prominent; the sides of the chest are flattened; there are often "beads" or nodules along the sternal ends of the ribs.

Emphysematous Chest.—Barrel-shaped; the thorax is short, with the anteroposterior diameter as long as the transverse; the ribs are at right angles to the sternum. The respiratory movements are diminished and the chest moves up and down as if in one solid piece.

Palpation

This method is employed by placing the hand upon and feeling the external surface of the chest. It detects tenderness, edema, *vocal or tactile fremitus,* and the amount of expansion. The back of the finger-tips is frequently more sensitive than the palmar surface, and comparisons should be made at times during examinations. Fremitus is produced by the vibration of the air below the vocal cords, beginning in the bronchi, thence to lungs, and finally communicated to the cutaneous surface of the chest.

The tactile fremitus (vocal fremitus) is greater in thin chest-walls, and is *increased* in abnormal consolidation of the lungs, such as is found in pneumonia and tuberculosis; and is *diminished* when there are thick chest-walls and when the pleura is separated from the chest by a liquid, as in pleurisy. The upper portions of the chest yield a stronger tactile fremitus than the lower, and the right apex vibrates more than the left. It is best developed when the patient produces deep intonations of the words "ninety-nine." In determining the modifications of tactile fremitus (vocal fremitus) on each side of the chest it is essential that the corresponding parts be compared. As before stated, often the dorsal surface of finger-tips detects more quickly these modifications than the palmar surface.

Percussion

This physical method of diagnosis is employed by striking the chest gently with finger-tips, or by means of a percussion hammer (plexor) with a piece of ivory (pleximeter) interposed. The patient is preferably examined in the standing position.

Immediate percussion is performed by simply striking the chest without an interposing substance.

Mediate percussion is performed when the finger or pleximeter is interposed.

The stroke is made by the middle finger or by the index- and middle fingers combined. The interposing finger or pleximeter must be pressed down firmly on the surface so as to yield a clear note. The method should be employed systematically on the two sides of the chest in corresponding locations, without moving promiscuously from one to the other position.

The percussion-note or sound possesses certain acoustic properties, as *intensity, pitch, duration*; and *quality*.

Intensity means the loudness of the sound, and depends upon the force of the blow, the thickness of the muscular walls, and the amount of air in the lung tissue. The intensity of the percussion-note is very great when there is tympany.

Pitch may be either high or low. The pitch of the percussion-note is always high over solid mediums, as over consolidation of lung tissue. Increased volume gives a low pitched note, while a diminished volume gives a high pitch. The pitch is normally higher over the apex of the right lung than over the left apex. A forcible expiration lessens resonance and lowers the pitch over the lungs.

Duration depends upon the pitch. If the pitch is high, the duration is short.

Quality in sound is that element by which one sound is distinguished from another. The quality of the note elicited by percussing over healthy lung tissue is called normal vesicular resonance, or pulmonary resonance.

A *resonant* sound indicates the presence of air; *dulness* indicates a more dense medium. Normal pulmonary resonance on the right side extends from 1/2 of an inch to 1 inch above the clavicle downward to the upper boarder of the sixth rib in front, and to a line draw through the tenth spinous process posteriorly. Normally, the right apex is somewhat less resonant than the left, both posteriorly and anteriorly, just as the right apex yields a stronger tactile fremitus and, on auscultation, slightly increased vocal resonance and bronchovesicular breathing.

On the left side pulmonary resonance extends from 1/2 of an inch above the clavicle downward within the mammillary line to the third rib; outside the mammillary line to the tenth rib, and posteriorly to a line drawn through the tenth spinous process.

Hyperresonance is observed in cavities, emphysema, pneumothorax, and excessive distention of stomach or colon. Hyperresonance is also present over a portion of the lung above the line of pleural effusion, and above the line of consolidation in a lung during the initial stage of pneumonia. In these conditions it is spoken of as *Skoda's resonance.*

Tympany (or tympanitic resonance) is a hollow or drum-like sound elicited by percussion over a large cavity filled with air, as in a dilated stomach or intestine.

Cracked-pot resonance is a modified tympany detected over a cavity or in pneumothorax.

Dulness or flatness is the opposite of resonance, hyperresonance, or tympanitic resonance, and is elicited by percussion over a medium more dense than the normal lung. It is also present in congested or consolidated lungs.

Percussion over the heart gives rise to dulness. Percussion over the region of the right lobe of the liver gives rise to flatness, because the medium is very dense. The quality of a note over a medium more dense than the normal lung will therefore give rise to dulness or flatness of the percussion-note, and there will be a corresponding high pitch, of short duration. If the medium is filled with gas, as in distended stomach, the quality of the percussion-note will give rise to tympany, which is of low pitch, great intensity, and prolonged duration.

Auscultation

The act of listening to sounds, especially over regions of the chest or the abdomen. When the ear is applied directly to the bare surface, it is termed *immediate auscultation;* and when the sound is conveyed through a stethoscope, it is termed *mediate auscultation.*

This physical method of diagnosis detects: (1) *vocal resonance;* (2) *adventitious sounds* (*râles* and *pleuritic friction sounds*).

Rules to be Observed.—As in percussion, the methodic way should be employed, by comparing the sound over the corresponding positions of the chest both during inspiration and expiration, after coughing, and while the patient repeats the words "ninety-nine." It is very essential that the patient remain as motionless as possible while the examination is being made. The examiner's body should not be bent at more than a right angle, for if the head is too low, the position is uncomfortable and the sounds are not distinct.

Auscultation of the Respiration

Normal respiration (respiratory murmur) is termed vesicular breathing or bronchial breathing, according to the area of lung to which the method

of auscultation is applied. Normally, vesicular breathing is best heard under the left clavicle, while normal bronchial breathing is heard over the region of the larynx and trachea, and to a less extent at bases of the lungs posteriorly. The respiratory murmur is made up of the two breath-sounds—inspiration and expiration. It is also termed vesicular or bronchovesicular breathing. The normal respiratory murmur is produced by the movement of the air within the bronchial tubes and air vesicles. It is characterized by a soft or breezy sound during inspiration and a rather short high-pitched sound during expiration. The expiratory breath-sound normally is not more than one-third so long as the inspiratory breath-sound.

The respiratory murmur may be modified in *intensity*, *rhythm*, and *quality*.

Modifications of Normal Respiratory (Vesicular) Murmur (Loomis).—

In **intensity** the respiratory murmur may be: (1) Exaggerated or increased. (2) Diminished or feeble. (3) Absent or suppressed.

In **rhythm** the respiratory murmur may be: (1) Interrupted. (2) Interval between inspiration and expiration prolonged (3) Expiration be prolonged.

In **quality** the respiratory murmur may be: (1) Bronchovesicular. Expiration slightly prolonged and high-pitched. (2) Bronchial, termed bronchial respiration. (3) Cavernous, termed cavernous respiration. (4) Amphoric, termed amphoric respiration.

Modification of Intensity of Respiratory Murmur. Puerile Respiration.—Heard over the lungs of children. In this variety of breathing the inspiration is loud, the expiration high pitched and prolonged.

Exaggerated Respiration.—In this variety the inspiration is soft or blowing, while the expiration is louder but not harsher than normal. In *health* it may occur after forcible breathing. In *disease*

TABLE OF BREATH-SOUNDS IN HEALTH AND DISEASE

(*Altered and enlarged from J. K. Fowler*)

Variety of Breathing.	Period.	Pitch.	Quality.	Interval.	Duration.	Intensity.	Where Heard.	Condition in which Heard.
Vesicular....	1. Inspiration.	Low.....	Vesicular...	None.....	.....	Variable....	Over the lungs, in health.	In health.
	2. Expiration.	Lower.....	Blowing....	.....	Shorter than inspiration or absent.	Faint or absent.		
Bronchial....	1. Inspiration.	High.....	Tracheal....	Distinct..	.....	Variable....	In *health*, over the seventh cervical spine. In *disease* over areas of consolidation.	In health; pulmonary tuberculosis, lobar pneumonia, large pleuritic effusions, thoracic aneurysm, mediastinal tumors.
	2. Expiration.	Higher.....	Tracheal....	.....	Equal to or longer than inspiration.	Greater.....		
Bronchovesicular.	1. Inspiration.	Higher than in vesicular breathing.	More or less tracheal.	Slight....	.....	Variable....	In *health, ant.*, over sternal portion of infraclavic. region; *post.*, upper part of interscapular region. In *disease*, over slight consolidation.	In health; pneumonia, pulmonary tuberculosis.
	2. Expiration.	Higher than in vesicular breathing.	More or less tracheal.	.....	About equal to inspiration.	Greater.		
Amphoric ...	1 Inspiration.	Low.....	Hollow and metallic.	Distinct..	.....	Variable....	Over a large cavity communicating with an open bronchus.	Pulmonary tuberculosis.
	2. Expiration.	Lower.....	Both characters more marked.	.....	Longer than inspiration.	Greater.....		
Cavernous...	1. Inspiration.	Low.....	Blowing and hollow.	Distinct..	.....	Variable....	Over a cavity communicating with an open bronchus.	Pulmonary tuberculosis.
	2. Expiration.	Lower.....	Both characters more marked.	.....	Longer than inspiration.	Greater.....		
Tubular.....	1. Inspiration.	Higher than in bronchial breathing.	Laryngeal or whiffing.	Distinct..	.....	Variable....	Over consolidated areas.	Lobar pneumonia, pulmonary tuberculosis.
	2. Expiration.	Higher.....	Laryngeal or whiffing.	.....	Equal to or longer than inspiration.	Greater.		

during vicarious breathing, or over healthy lung when the opposite one is affected.

Weak or feeble Respiration.—Inspiratory and expiratory breath-sounds weak. In *health* it may occur in persons with thick chest-walls, and in *disease* during the course of exhaustive disease—pleurisy, pleurodynia, incipient phthisis, pulmonary edema.

Modification of Rhythm of Respiratory Murmur.—Asthmatic respiration, that resembles bronchial breathing, but the expiration prolonged and wheezing.

Emphysematous Respiration.—The inspiratory and expiratory sounds are very feeble, and the expiration is prolonged, almost inaudible.

Cogged-wheel or Jerky Respiration.—A series of sounds jerky in character, most marked during inspiration. It occurs in asthma, first stage of pleurisy, pleurodynia, and incipient phthisis.

Modification of Quality of Respiratory Murmur.—Bronchovesicular Breathing. Inspiration diminished, expiration prolonged and heightened in pitch. It is heard normally over the right apex, and over areas of beginning infiltration or solidification, in early pulmonary tuberculosis.

Bronchial (or Tubular) Respiration.—Both inspiration and expiration are harsh and have a high-pitched (tubular) character. Bronchial breathing is heard in lobar pneumonia, phthisis, a lung that is doing vicarious work, as in pleurisy, tumor of the lung, syphilis, and hemorrhagic infarct of lung.

Cavernous Respiration.—Inspiration is low pitched and blowing in character. Expiration is power pitched than inspiration, and has a puffing or blowing sound.

Amphoric respiration is similar to the sound proeuced by blowing gently over the mouth of an dmpty bottle. It is present in phthisical cavity, pneumothorax with patulous opening, localized consolidation near a large bronchus.

Auscultation of the Voice

The patient should say "ninety-nine" continually during the examination.

Vocal Resonance.—Transmission of the vibrations of the voice to the ear during auscultation. Normal vocal resonance varies according to the position of the lung to which the ear or stethoscope is applied.

Vocal resonance is increased in *health* over the apex of the right lung. It is increased in *disease* in phthisical or pneumonic consolidation.

Vocal resonance is diminished in thick chest-walls, pleural effusions, emphysema, pulmonary edema.

Bronchophony.—Exaggerated vocal resonance. It is a special objective symptom of phthisis. It is heard normally over the thyroid cartilage. In conditions giving rise to bronchophony a thrill or fremitus is conveyed to the ear.

Pectoriloquy.—A complete transmission of the whispered words to the ear, the sound seeming to be produced at the spot where the ear or stethoscope is applied.

Pectoriloquy is heard over phthisical cavities, and in pneumothorax when the lung is patulous.

Egophony.—A modification of the vocal resonance, in which the voice has a nasal trembling sound like the bleating of a sheep. It is heard at the upper border of dulness in pleural effusions, most marked posteriorly at the inferior angle of scapula.

Adventitious Sounds During Auscultation

Adventitious sounds include (1) râles or rhonchi, (2) metallic tinkling, (3) pleuritic friction sound.

Râles, or Rhonchi.—These sounds are called adventitious, because they do not occur in health. A râle may, then, be spoken of as a *new sound* produced in the trachea, bronchi, bronchioles, airvesicles, or in phthisical cavities, and heard during either inspiration or expiration.

- Râles
  - Dry râles
    - Sonorous râles.
    - Sibilant râles.
  - Moist râles
    - Crepitant râles.
    - Subcrepitant râles.
    - Gurgling râles
      - Large or cavernous râle.
      - Small or mucous râle.

Dry râles are probably due to the vibrations of particles of viscid mucus in the air tubes as the air is inhaled or expelled. They are abundant in bronchitis and asthma, and may often pass away temporarily after coughing.

Sonorous râles are low-pitched, snoring sounds, and may be heard during inspiration, expiration, or both. The seat is in the larger bronchial tubes.

Sibilant râles are high pitched, musical, or whistling in character. They may also be heard during inspiration, expiration, or both.

Dry râles are abundant in bronchitis and asthma. Dry râles may often pass away temporarily after coughing.

Moist Râles.—These are due to the presence of fluid, generally having a more liquid character than in the case of dry râles. They are probably produced by the passage of air through blood, mucus, serum, or pus.

Crepitant Râles.—These are the finest râles heard, and only occur at the end of inspiration. Crepitant râles, when present, usually occur in great numbers. The sound is short and has a clicking character. It may be compared to the sound produced by fine hail as it strikes against the window-pane. It also resembles the sound produced by rolling the hair between the finger-tips.

The crepitant râle is considered pathognomonic of the first stage of pneumonia, when it is heard posteriorly over the base of the lungs. It is sometimes present in pulmonary engorgement, during the course of adynamic fevers, and in edema of the lungs. The crepitant râle may pass away temporarily after coughing.

Subcrepitant Râles.—These are moist râles produced in the finer bronchioles, usually of the same size and comparatively few in number. They are very likely produced by breaking of air bubbles as they are forced through liquid in the tubes. They are found in capillary bronchitis, pulmonary edema, and hypostatic congestion of lung;

when present at the apex of the lung, they often indicate incipient phthisis. The subcrepitant râle is heard during both inspiration and expiration.

Gurgling Râles (Large or Cavernous Râles).—These are large, bubbling sounds, produced in phthisical cavities. They also occur in the trachea, and in this location just before a fatal termination are popularly known as the "death rattle." They are heard in both inspiration and expiration.

Gurgling Râles (Small or Mucous Râles).—Smaller, bubbling râles, produced in the trachea and larger bronchi. This râle may pass away temporarily after coughing, and is heard during both inspiration and expiration. The mucous râle is present in bronchitis during the stage of secretion, in bronchial hemorrhage, and in phthisis. See RÂLES (Table).

Metallic tinkling is a bell-like sound heard in cases of pneumothorax or phthisical cavities, and is caused by the dropping of a liquid through the space inclosed in tense walls.

The succussion splash is the sound produced in pneumohydrothorax when the patient is suddenly shaken.

Pleuritic Friction Sounds.—Râles are produced within the bronchi or lungs, while friction sounds occur in the pleura. In health the two surfaces of the pleura are bathed in a natural secretion and the parts glide over each other without producing any sound; but in disease of the part they become agglutinated or roughened, giving rise to pleuritic friction sounds, having a grating, rubbing, grazing, creaking, or crackling character, and are pathognomonic of pleurisy.

They are heard during both inspiration and expiration, and do not pass away after coughing. The creaking or crackling pleuritic friction is often mistaken for a crepitant râle, and Tyson gives the following distinguishing characteristics: The friction sound does not pass away after coughing, while the crepitant râle may do so; the friction sound is more superficial and localized, while the crepitant râle is deep and more diffuse; the friction sound has a to-and-fro movement during inspiration and expiration, while the crepitant râle is only heard at the end of inspiration; pleuritic friction sounds are generally heard in the axilla or side of the chest, while the crepitant râle is most frequently posterior—often at the base of the lung.

Mensuration

Mensuration is that physical method of diagnosis by which comparisons are made of the two sides of the chest. It is usually determined by making circular measurements around the chest, selecting two bony prominences, one anterior the other posterior: as, for instance, the spinous process behind and the median line in front, on a level with the sixth costosternal articulation. The estimate may be made by means of a steel measure or by bending two strips of sheet lead (one on each side) around the body and drawing the outline on a sheet of paper. Quain's stethometer may also be used. The average circular dimension of the chest at the sixth costosternal articulation is 32 1/2 inches (Loomis). In right-handed individuals the right side of the chest is 1/2 of an inch larger than the left.

The left side of the chest may be increased in dimensions from congenital heart-disease, left-sided pleurisy or emphysema, or cardiac hypertrophy.

Succussion

This method is practised by suddenly shaking the patient and auscultating the chest, when, if fluid is present, as in pneumohydrothorax, a splashing sound is heard. Amphoric respiration is usually present.

Roentgenography

The discovery of the X-ray has added one more to our methods of examining the chest and thoracic organs. Up to the present time its chief value in the chest has been found in the localization of aneurysms, suspected but not demonstrable by ordinary methods of examination. Displacements of the heart may be studied by means of a roentgenogram. On the other hand, interpretation of the shadows obtained in different pathologic conditions—solidification, serous and purulent effusion, carcinoma and sarcoma—even by an expert is too uncertain for any reliance on roentgenography as a means of differential diagnosis. See ROENTGEN RAYS.

Association of the Physical Signs (DaCosta).

As many of the signs elicited by the various methods of physical diagnosis depend on the same physical conditions, they may be studied in groups. The following will usually be found to be associated:

PERCUSSION.	AUSCULTATION OF RESPIRATION.	AUSCULTATION OF VOICE.	VOCAL FREMITUS.	PHYSICAL CONDITIONS.
Clear	Vesicular murmur or its modification.	Normal vocal resonance.	Unimpaired	Lung tissue healthy or nearly so; at any rate, no increased density from deposits, etc.
Dull	Bronchial or harsh respiration.	Bronchophony	Increased	Solidification of pulmonary structure.
	Absent respiration.	Absent voice	Diminished or absent.	Effusion into pleural sac.
Tympanitic	Cavernous or feeble, according to cause.	Uncertain; cavernous or diminished.	Uncertain; chiefly diminished.	Increased quantity of air within the chest, due to a cavity or to overdistention of the air-cells.
Amphoric or metallic	Amphoric or metallic.	Amphoric or metallic.	Mostly diminished.	Large cavity with elastic walls.
Cracked-metal sound	Cavernous respiration.	Cavernous respiration.	Uncertain	Generally a cavity communicating with a bronchial tube.

CHEST, PAIN.—Chest pains may be due to:

Intercostal neuralgia, in which there is tenderness at points only. For neuralgia, strap the chest and give arsenic, with an occasional mercurial purge. Quinin acts best after mercury.

Rheumatism of the fascia, the whole region being tender.

Neuritis, in which there is circumscribed linear tenderness—neuroma.

Acute pleurisy, with chill, fever, and friction sound. Dry pleurisy; very common; the patient is relieved so surely by adhesive straps that the relief confirms the diagnosis.

Aneurysm, which, however, may not cause pain, even if large.

Ataxia and other spinal disease.

Bronchitic pain; calls for strapping and opium.

Myalgia; relieved by straps.

Mitral Disease; rarely painful. *Aortic disease;* generally painful.

Dyspepsia; diffusible, radiating pains.

Herpes zoster; pain may precede eruption for days.

Angina pectoris.—The pain begins in the precordia and radiates down the left arm, rarely the right, or both arms. Pain is intense, agonizing, so that the patient remains immovable while it lasts, and is accompanied by fear of impending death. Amyl nitrite or nitroglycerin relieves, and may sometimes avert an attack.

Pseudoangina, occurring in women; not relieved by nitrites, but instantly by chloroform.

Phthisis. Syphilis. Gout. Carcinoma.

CHEST, WOUNDS AND INJURIES.—Injuries may be classified as those of (1) the chest-walls; (2) the lungs; (3) the pleura; (4) the heart; (5) the thoracic duct; (6) the blood-vessels; (7) any combination of these.

The character of injuries will be in accordance with the wounds, which are divided into (1) incised; (2) lacerated; (3) gunshot; (4) contused; (5) punctured—(*a*) penetrating, (*b*) nonpenetrating; (6) nail wounds; (7) infected; (8) noninfected.

Wounds of the chest-walls are not generally serious, but when the thoracic viscera are involved, grave consequences often follow. Fractures and dislocations of the ribs or sternum, contusions of the wall of the thorax, and wounds involving the nerves, muscles, or vessels, may occur with or without injury to the subjacent viscera. In some cases it may be seen at once whether they have escaped or not; in others it is a matter of the greatest difficulty; but if there is the least doubt, the case should be treated as if the graver injury were present, and no attempt must ever be made, by probing or otherwise, to prove or disprove it. The finger may be used to explore for foreign bodies, or to ascertain the depth and extent of a penetrated wound, not to find out whether it penetrates or not. The deeper structures do not always escape when the external injury is apparently slight; the pleura may be bruised and become inflamed; there may be a contusion of the lung, with hemorrhage into the substance, causing pneumonia and even traumatic gangrene; or, without the pulmonary pleura being torn, the air vesicles may be ruptured and the air forced into the cellular tissue of the lung until it appears at the root of the neck (*interstitial emphysema*); and in young patients particularly, when the ribs are still elastic and the wall of the chest can yield without breaking, the lung and pleura may be lacerated, so as to cause pneumothorax or hemothorax, without external injury of any kind; even the pericardium and the heart may be crushed and torn.

Diagnosis.—In ordinary falls or blows an examination should be made to determine the existence or nonexistence of **fracture of the ribs.** For this purpose pressure and counterpressure exerted on the sternum and the vertebral column respectively will elicit pain at the seat of the fracture, should a fracture exist. Otherwise, the pain, if complained of, would be situated at the points of contact with the fingers used by the surgeon for the examination.

The injuries to the chest calling for special attention are those accompanied by **dyspnea.** A careful count of the number of respirations each minute will enable the physician to determine to some extent the involvement of lung tissue, while percussion, auscultation, and palpation may be practised with profit.

Railroad accidents are frequently attended by injuries to the respiratory organs and to the nervous system. The **stethoscope** may be employed over the apices of the lung.

The most frequent result of traumatism of the tissue is **emphysema,** a condition arising from the failure of the bronchi and lobules of the lungs to dispose of the air inspired, so that it is disseminated into the parenchymatous structure of the lungs. The presence of the residual air is a means of keeping up the equilibrium, but when thin partitions allow of the escape of air into the surrounding tissue, emphysema ensues.

Empyema, a collection of pus in the pleural cavity, frequently results from severe contusions and incised or lacerated wounds of the chest. The most frequent cause of empyema is tuberculosis, but the cases arising from injuries are many, and should be taken into account in making a diagnosis.

Hemoptysis indicates serious traumatism to the lung tissue. Blood may become extravasated in the thoracic cavity, in which case the condition known as **hemothorax** exists. This should be carefully eliminated in making a diagnosis.

Treatment.—In cases of fractures of the ribs or other serious injury of the chest, fixation is demanded. Adhesive strips may be stretched along the side of the chest including the line of any fractured rib. The whole chest, on one side may be rendered immovable by a broad piece of moleskin plaster that extends from the sternum to the spinous processes of the vertebræ. Rest is thus secured to the injured side, and repair takes place. The respiration is confined to the sound side of the chest.

In cases of **hematemesis** a resort to the following prescription may be advantageous:

℞. Fluidextract of ergot, ℥ j
Tincture of digitalis, ℥ j.
Take a teaspoonful every half hour until relieved.

Hypodermic injections of ergotin, morphin, nitroglycerin, and atropin are beneficial.

The **shock** from many injuries necessitates the use of strychnin, 1/30 of a grain, hypodermically. Of unquestioned value are also the following drugs: Aromatic spirit of ammonia, Hoffmann's anodyne, camphor water, carbonate of ammonium.

Turpentine is an excellent styptic, antiseptic, and anodyne whether applied externally or given internally.

Operative measures may be demanded in cases of empyema, hydrothorax, hemothorax, pneumothorax, or emphysema; or simply to arrest hemorrhage from incised, lacerated, or contused wounds.

Of great import is the **exploration of the thoracic cavity** for bleeding vessels. This may be done through a so-called "*trap-door*," which may be made in the chest-walls. Observations of great consequence may be made in injuries inflicted upon the heart, lungs, and blood-vessels, in which lesions may be repaired immediately after an injury. Observation of the pericardium may be made and even the heart may be seen to beat.

Injuries to the chest from **falls upon sharp objects**—*e. g.*, picket-fences—may be associated with **hernia of the lung or pleura.**

Hernia of the diaphragm may also result from the protrusion of the stomach or other viscera of the abdominal cavity through the stab wound involving the diaphragm.

Treatment consists in the prompt resort to the thorough exploration of the opening in the diaphragm and in the reduction of the hernia, with subsequent closure of the rent or wound in the diaphragm. The aperture in the diaphragm should be enlarged when the reduction calls for this procedure. It is very probable that the stomach may pass up when empty and require the use of the stomach-pump to evacuate its contents, in order to facilitate the descent into the abdominal cavity from the thoracic cavity. The most marked symptoms calling for this evacuation would be the continued tympanites upon auscultation above the eighth rib in front, and the absence of this behind, should the stomach have gone in front of the lungs; while at the same time the reverse might occur in cases in which the stomach had been pressed into the pleural cavity posteriorly, or when the viscus was in the posterior mediastinum.

The nausea and retching would be a prominent symptom, and, later, stercoraceous vomiting and singultus, and a sufficient reason for resorting to the stomach-pump before an operation was indicated. This reduction in size might cause a spontaneous reduction of the hernia.

Injuries to the thoracic duct may occur without the adjoining blood-vessels and nerves suffering, as shown in the report of a case by H. W. Lyne, of Richmond, Va. Recovery was complete, although a knife-blade had severed the walls of the thoracic duct by a longitudinal incision; it may be inferred that spontaneous cicatrization occurred, and no operation was thought necessary to suture the walls of the duct. The chyle was not examined microscopically, but was observed during the first dressings to be flowing through the external wound, situated near the upper border of the clavicle and near the sternal articulation. The interesting feature of the case was the complete cessation of the flow of chyle after the wound was packed with gauze on the basis of a tampon. The usual surgical dressings were afterward applied, and the man was examined 2 years afterward and found to be in perfect health. W. W. Keen has reported a somewhat similar case. A neoplasm of the thorax or any compression may cause rupture of the thoracic duct, and such injuries are likely to result in death, unless the flow of chyle can be stopped. The chyle is a necessary element of nutrition, and any great amount lost will cause death.

The chyle is emptied by the thoracic duct into the left subclavian vein at its union with the internal jugular vein, but there is no history on record of the rupture of the thoracic duct at this distal connection, when pressure is from within the chest-walls.

One of the most serious consequences of violence to the walls of the thorax is **rupture of the lungs.** A fall upon some solid body or the pressure of some heavy weight while the lungs are greatly distended by closure of the glottis induces rupture of the pulmonary tissue, with all the serious results of pneumothorax and hemoptysis. This may occur even without an abrasion upon the surface of the chest, and the history of such an accident is the only explanation of the grave condition within the thorax. A forcible impression upon the walls of the chest may fracture the sternum or ribs and drive either inward so as to lacerate the lungs or the heart, leading to immediate or remote serious effects.

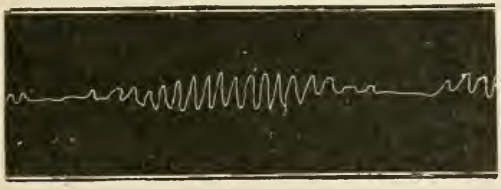
One of the grave consequences of an opening through the chest-walls is the protrusion of a portion of the lung, constituting a **pulmonary hernia.** If this should occur under the observation of a surgeon, he would find little difficulty in returning it and retaining it within by a compress. Hernia of the lung tissue through a stab wound of the intercostal spaces calls for immediate attention. The lung tissue itself may become gradually disintegrated, when it is necessary to ligate externally and to sever the mortified tissue. When the structure and vitality of the lung tissue is capable of restoration, an effort may be made to widen the aperture so as to replace the segment that appears externally.

The heart has also been sutured in case of penetrating wound.

The diagnosis, symptoms, and treatment of injuries of the special thoracic viscera are further discussed under their separate headings. See Empyema, Heart, Lungs, Pleura, Pleurisy, Ribs, etc.

CHEYNE-STOKES BREATHING OR RESPIRATION.—An undulating type of breathing. The respirations gradually become more frequent and deeper, until a certain point is reached, when they slowly become more shallow and less frequent, until the person seems to have finally stopped breathing. After a pause as long as half a minute respiration again begins very slowly, gradually increasing in depth and frequency. It ordinarily accompanies the coma of organic disease of the brain, apoplexy, tumor, uremia, opium poisoning,

myocardial degeneration and meningitis. It may also be observed in diabetes and various acute infections, such as cerebrospinal fever, septicemia, typhoid, pneumonia and the exanthemata. In normal children it may occur during sleep. It is usually a precursor of death.



Tracing of Cheyne-Stokes Breathing.

CHICKEN-POX.—See Varicella.

CHIGOE.—See Bites and Stings.

CHILBLAIN.—See Frost-bite.

CHILL.—A chill consists in a sensation of cold and of shivering, coming on within a few hours after exposure to cold or wet, but is frequently the initial symptom of grave acute disorders, such as pneumonia. It is a prominent symptom of various forms of malarial fever. Chills appear in typhoid fever sometimes with its onset, and occasionally at intervals throughout the course of the disease, and may be followed by sweats. They also occur in this disease with the advent of complications, such as pleurisy, pneumonia, otitis media, periostitis, etc.; with active antipyretic treatment by coal-tar remedies; and occasionally during defervescence, without any relation to any complication or sequel, when they are probably due to septic infection. They may even be a result of constipation (Herringham). Throughout the latter half of the attack chills may occur with marked severity.

Treatment.—Artificial warmth in all its multifarious forms—hot-water bottles and bags, blankets, hot air, hot drinks, etc.—is to be employed. In the malarial fevers quinin or some preparation of cinchona, preceded by an active cathartic, is indicated. See Rigor.

CHILL, POSTPARTUM.—A feeling of chilliness, or even a well-marked rigor, may occur shortly after the birth of the child. This is not significant of any beginning pathologic condition, and usually subsides spontaneously in a few moments.

CHILLS AND FEVER.—See Malarial Fevers.

CHIMAPHILA (Pipsissewa).—The leaves of an evergreen containing tannic acid and employed in atonic renal conditions, being probably the most active of the group including buchu, uva ursi, pareira, and scoparius. It is an agreeable tonic, excites the appetite, and promotes digestion. It is a good diuretic in dropsy, and is efficient in several forms of kidney disease with albuminuria, and in chronic catarrhal affections of the urinary passages, as hematuria, ischuria, dysuria, and gonorrhea. It is believed to check the secretion of uric acid, and externally has been applied to ulcers with benefit. The fluidextract is the official preparation, and is given in the dose of 10 minims to 1 dram.

CHINAPHENIN.—Phenetidin quinin carbolic acid ester. It combines the properties of quinin with those of phenacetin and is said to be free from any tendency to produce cinchonism. It is recommended in influenza, neuralgia, spasmodic and febrile conditions. Dose, 5 to 10 grains.

CHINOSOL.—Normal oxychinolin sulphate. A nontoxic antiseptic as powerful as mercuric chlorid and considerably stronger than phenol. As a germicide it is weaker than phenol and far weaker than mercuric chlorid. Dose, internally, 5 grains; as an antiseptic it is generally used in solution of 1 to 1000; as a nasal or vaginal douche 1 to 5000; as an eye wash 1 to 8000; with gradual increase of the strength of the solution.

CHIRATA.—The entire plant, *Swertia chirayita*. It resembles gentian in its therapeutic properties. It is a bitter tonic, possessing distinct influence over the liver, and is devoid of tannic acid, and, therefore, may be used with preparations of iron. In indigestion, with loss of appetite, when the liver is torpid and constipation present, it is useful. Dose of the powdered plant, 10 to 20 grains. C. **Fluidextractum.** Dose, 10 to 20 minims.

CHIRO-POMPHOLYX.—Dysidrosis; pompholyx; an ill-defined, inflammatory skin-disease, confined to the hands and feet, and characterized by the development of peculiar vesicles or blebs, arranged in groups. They are deeply seated and are distributed chiefly on the soles and palms and on the sides of the fingers. Itching, burning, pain, and stiffness are present. The disease is common in neurotic women in the prime of life; it is almost invariably recurrent, and is rare in winter.

CHLOASMA.—Chloasma is characterized by yellowish, brownish, or blackish pigmentation of the skin, occurring in variously sized and shaped patches or as a diffuse discoloration.

Symptoms.—The patches may be of any size, from that of a coin to that of the palm of the hand or larger. They are irregular or rounded, with fairly defined borders. They are usually fawn-colored, yellowish, brownish, or blackish (melanoderma). In the diffuse form the color merges imperceptibly into the surrounding skin.

The affection is most frequently seen upon the face.

Etiology.—There are 2 varieties: (1) idiopathic chloasma, due to external causes; (2) symptomatic chloasma, due to internal causes.

Under **idiopathic chloasma** may be included all the pigmentations that result from the use of local irritants, such as sinapisms, blisters, scratching, pressure, friction, solar rays, etc.

Symptomatic chloasma occurs in the pigmentation seen in association with visceral and general diseases, such as uterine disease and pregnancy, Addison's disease, tuberculosis, cancer, malaria, etc. In these cases the pigmentation is usually diffuse, and may involve large areas of cutaneous surface.

Chloasma Uterinum.—This is most commonly seen during pregnancy, although it is often observed in pathologic conditions of the uterus and the ovaries. The patches are yellowish or brownish in color and are usually located around the forehead and eyelids.

In **Addison's disease** the pigmentation is of a

brownish, olive-greenish, or bronze tint. The prelonged administration of silver may produce a permanent bluish-gray or slate-colored discoloration of the skin (argyria).

In rare cases a diffuse brownish pigmentation results from the long-continued use of arsenic.

Pathology.—The only change is an increased deposition of pigment in the mucous layer of the epidermis. It is not improbable that pathologic conditions of the sympathetic nervous system play an important rôle in symptomatic chloasma. Thus, in pigmentation resulting from affections of the abdominal viscera the solar plexus is probably implicated.

Diagnosis.—Chloasma may be distinguished from tinea versicolor by the presence of the former upon the face, the paucity of patches, the absence of furfuraceous scaling and of a fungous parasite.

The prognosis depends upon the removability of the cause. Local applications have, as a rule, but a temporary influence.

Treatment.—If the pigmentation is due to a systemic cause, this should, naturally, be treated.

Locally, the same measures are employed as in the treatment of Freckles. Duhring recommends:

℞. Mercuric chlorid, gr. vj
Compound tincture of benzoin, ʒ jss
Almond emulsion, ʒ iij.
Apply night and morning.

Or the following ointment may be employed:

℞. Ammoniated mercury, } each, ʒ ss
Borax, }
Oil of rosemary, ♏ x
Vaselin, ʒ j.

CHLORAL HYDRATE (Chloral).—$C_2HCl_3O + H_2O$. A crystalline solid composed of trichloraldehyd (chloral) with 1 molecule of water. It occurs in colorless, transparent, rhomboid crystals, slowly volatilizing when exposed to the air; of aromatic, penetrating, and slightly acrid odor, bitterish, caustic taste, and neutral reaction. It is freely soluble in water, alcohol, ether, chloroform, oils, etc., and liquefies when triturated with about an equal quantity of camphor, menthol, thymol, or carbolic acid. Its aqueous solution becomes acid, but the alcoholic solution remains neutral.

The dose varies much with individual susceptibility and with the presence or absence of cardiac and pulmonary disease. Death has been caused in several instances by 30 grains, in one case by 10 grains, and in another 7 1/2 grains produced alarming symptoms—all in adults. On the other hand, recovery has occurred after the ingestion of an ounce; several hundred grains have been taken at a time in more than one instance without fatal results; and when tolerance has been established by habitual use, 2 to 3 drams are frequently taken without poisonous symptoms. An average dose for a healthy adult is 15 grains; for a child, 1 grain for each year of age up to 6 grains. It is best given in syrup of tolu or in peppermint water.

Incompatible with *Hydrated Chloral* are: Acetanilid, alcohol, alkalies, ammonium salts, benzamid, borax, borneol, camphor, camphora monobromata, diuretin, euphorin, exalgin, glycerin (with heat), lead acetate, menthol, mercuric nitrate, mercuric oxid, methacetin, phenacetin, phenol, piperazin, potassium cyanid, potassium permanganate, potassium iodid, pyrocatechin, quinin sulphate, saligenin, salocoll, salol, sodium phosphate, thymol, urea, urethane. *Physiologically incompatible* are: Ammonium chlorid, atropin, brucin, caffein, cocain, codein, digitalis, phenol, physostigmin, picrotoxin, strychnin, thebain.

Caution is necessary when prescribing this drug in combination with alcoholic preparations, as the chloral is then very likely to separate as an alcoholate, especially if the bromids of potassium or sodium are used in the same mixture and if the solutions are at all concentrated. In this way great danger is incurred of giving a heavy overdose, as the alcoholate floats on the surface of the mixture, and the entire chloral contained therein may be taken at a single dose.

Chloral is a powerful hypnotic, an antispasmodic, an antiseptic, indirectly an anesthetic, and especially a depressant of the cerebral, medullary, and spinal centers and of the cardiac muscle. It is more hypnotic than chloroform, but less of an anesthetic. Applied to the skin or mucous membranes a 1 percent solution (5 grains to 1 ounce) is antiseptic, but strong solutions are irritant, and if taken internally, may excite gastritis, with nausea and vomiting.

Therapeutics.—Chloral must be used cautiously when weak or fatty heart, atheromatous vessels, or advanced pulmonary disease exists. It is very useful when combined with potassium bromid, and it is by far the best hypnotic in acute mania and delirium tremens. With potassium iodid it is of service in bronchial asthma, and in the nervous dyspepsia of neurotic persons, characterized by pain in the cardiac region of the stomach. It is very serviceable in fevers, when high temperature exists with excitement, restlessness, and a sthenic condition, as it lowers temperature and prevents the coagulation of fibrin. In the algid stage of cholera and in violent cases of cholera morbus it has been injected hypodermically in 15-grain doses, with extraordinary efficacy. In seasickness small doses (5 grains) 2 or 3 times a day are generally very efficient. In obstetrics it is used to relieve suffering, relax the os uteri, palliate convulsions, and relieve after-pains. In neuralgia it may be trituated with camphor and applied over the course of the affected nerve, and the same preparation is efficiently employed as a local application for toothache and earache.

Chloral is well borne by children, and is an excellent remedy for infantile convulsions and colic, chorea, whooping-cough, laryngismus stridulus, and the first stage of diphtheria, but it should not be used when the first sound of the heart becomes dull and weak. In these affections it may be given with paregoric, as its combination with opium enhances its value and guards the patient against its dangers. Its hypnotic power in adults is much increased by the conjoint administration of laudanum or morphin, and this combination is an excellent remedy in colic, cholera, and cholera morbus. In strychnin-poisoning chloral is the

antagonist. It is generally given by the mouth in very dilute solution, with some simple elixir, syrup of tolu, or cinnamon water, but is well absorbed by the rectum. Its hypodermic administration is liable to result in great local irritation, and even in sloughing ulcers.

Chloral may be applied to the skin as an antipruritic in the eruptive diseases, for which purpose it is well combined with carbolic acid, 10 grains of each to an ounce or two of water or oil. It is said to be the best of all local applications for boils—1 1/2 drams in 15 ounces each of glycerin and water constantly applied to the boil by a tampon of cotton. For ulcers and cancers a 25 percent solution is a good antiseptic and anodyne application.

The chief contraindication to the use of chloral is the presence of cardiac affection. Other contraindications are rosacea and hysteria of grave character.

In insomnia:

℞.	Chloral hydrate,	ʒ j to ij
	Potassium bromid,	ʒ ij
	Syrup of wild cherry,	ʒ j
	Water, enough to make	ʒ iij.

Dessertspoonful at night.

In spasmodic asthma:

℞.	Chloral hydrate,	gr. xv
	Peppermint water,	ʒ j.

To be taken every 3 or 4 hours.

For seasickness:

℞.	Chloral hydrate,	gr. xxx
	Camphor water,	ʒ j.

In poisoning by chloral give emetics in the early stage; or if later, use the stomach-pump, with external heat. Give strychnin in 1/20 to 1/10 grain dose, or atropin to stimulate respiration. Tincture of digitalis in 10-drop doses may be given hypodermically every 20 minutes. Ether and ammonia or brandy and whisky may precede these. The head should be lowered to the level of the heels to keep the blood in the brain.

CHLORAL HABIT.—Chloralism is easily acquired by those who have used the drug for insomnia, etc. The patient suffers from digestive and vasomotor disturbances, as evidenced especially by diarrhea, and erythematous eruptions; there is lowered temperature, mental and physical weakness and depression, muscular tremor, dyspnea, cardiac palpitation. Sudden withdrawal of the drug is hazardous.

Treatment consists in the gradual withdrawal of the drug and the administration of stimulants, tonics, massage, electricity, good nourishing food. For the insomnia, sulphonal, trional, or veronal may be tried.

CHLORALAMID.—A name incorrectly applied to chloral formamid. In doses of 10 to 30 grains it is a hypnotic usually efficient in simple insomnia. It seems to have no cumulative effect, or tendency to induce a habit.

CHLORALOSE.—Anhydro-gluco-chloral. It is a prompt hypnotic, producing sound sleep in which sensibility is not lost, and leaving no unpleasant after-effects. It depresses the cerebral functions, but excites the spinal cord, so that reflex activity is exalted by it. A dose of 10 grains has produced profound unconsciousness. The maximum dose is 5 grains, in capsule, and this may have to be repeated in not less than an hour.

CHLORETONE.—Chlorbutanol, acetone chloroform. A hypnotic, antispasmodic, anesthetic, and antiseptic, also narcotic in overdose. In moderate doses it promptly relieves gastric irritability, and prevents the nausea and vomiting due to ether or chloroform inhalation. As a hypnotic it is valuable in insanity and in cases of simple insomnia. In epilepsy it has been used with benefit, and it is frequently employed with cocain for the production of spinal anesthesia by subarachnoid injection, also in a 1 percent solution as a local anesthetic application in ulcers and wounds. It is considered by many authorities to be a dangerous narcotic in doses over 30 grains. Dose, 5 to 20 grains.

CHLORIN.—The gas is not official under its own name.

Preparations.—**Liquor Chlori Compositus,** *Compound solution of chlorin, chlorin water,* is an aqueous solution containing about 0.4 percent of chlorin, with some oxids of chlorin and potassium chlorid. It should be freshly made when wanted. Dose, 20 minims to 2 drams in water; as a lotion or spray 1 to 4 drams, well diluted. **Calx Chlorinata,** *chlorinated lime, chlorinated calcium oxid* (often improperly called chlorid of lime), is a compound resulting from the action of chlorin upon calcium hydroxid, containing not less than 30 percent of available chlorin. It occurs as a white or grayish-white, granular powder, of repulsive taste, partially soluble in water or alcohol, but when dissolved in diluted acetic acid gives off an abundance of chlorin gas. Dose, 3 to 6 grains in water; for external use a 1 to 3 percent solution. **Liquor Sodæ Chlorinatæ,** *solution of chlorinated soda* (*Labarraque's solution*), is an aqueous solution of several chlorin compounds of sodium, containing at least 2.4 percent by weight of available chlorin; prepared by adding together aqueous solutions of monohydrated sodium carbonate 65, and chlorinated lime 90, then adding water to 1000. Dose, 10 to 30 minims in 20 parts of water.

Incompatible with *chlorin water* are: Alkalies, ammonium salts, arsenous salts, bromids, ferrous salts, hypophosphites, iodids, lead salts, lime-water, mercurous salts, oxalic acid, silver salts; with *chlorinated lime* are fats, glycerin, iodids, oils; with *chlorids* are hydrogen peroxid, lead, mercurous and silver salts, nitric acid, sulphuric acid; with *chlorates* are ammonium picrate, arsenites or bromids in acid solution, charcoal, cyanids, ferrous salts in acid solution, gallic acid, glycerin, honey, hydrochloric acid, hypophosphites, hyposulphites, iodids in acid solution, iodin, iron (reduced), lycopodium, mercurous salts in acid solution, oxalic acid, phenol, phosphorous (amorphous) salicylic acid, shellac, starch, sugar, sulphids, sulphites, sulphuric acid.

Action and Uses.—Antiseptic; disinfectant; stimulating; intensely irritating to mucous membranes, especially those of the deeper respiratory

passages. Action mainly local, but aside from this it is thought to have a narcotic effect upon the brain. Chlorin is inferior to formaldehyd and sulphurous acid anhydrid as a disinfectant for rooms, because it is more difficult to apply in sufficient quantity, and it also has the disadvantage of injuring or bleaching fabrics. Fresh chlorinated lime is the best disinfectant for excreta, and is also excellent for drains, closets, urinals, etc. The chlorinated preparations are very useful for destroying fetor in scarlet fever, diphtheria, aphthæ and gangrene, and also in sloughing wounds and ulcers. Chlorin water is somewhat stimulating, and, well diluted, it has been used with good effect in the diarrhea of typhoid fever, especially in markedly septic patients.

CHLORODYNE.—A proprietary remedy supposed to contain chloroform, ether, morphin, cannabis indica, hydrocyanic acid, and capsicum.

A COMPARISON OF TEN FORMULÆ FOR CHLORODYNE, THE QUANTITIES BEING CALCULATED FOR EACH TO A FOUR-OUNCE MIXTURE, OR 1920 MINIMS.—(*Potter.*)

The various imitations differ widely. It is a powerful anodyne and narcotic, but very dangerous. Dose, 10 to 30 minims, *with care.* Unof.

CHLOROFORM.—Trichlormethane, $CHCl_3$. A heavy, colorless liquid obtained by the action of chlorinated lime in ethyl or methyl alcohol, or by that of an alkaline hydroxid on chloral. The commercial article, **C. venale,** contains 2 percent of impurities, and is unfit for administration. The **official form** consists of 99 to 99.4 percent by weight of absolute chloroform, and 0.6 to 1 percent of alcohol. Administered internally, chloroform produces narcosis and violent gastroenteritis. Chloroform has an agreeable odor and a sweetish taste. Its specific gravity is 1.526. It is excellent in true cholera and in similar diseases of the stomach and bowels. Externally, it is much employed as an ingredient of rubefacient and anodyne liniments. Mixed with a large percentage of air (1:3000) and inhaled, it is one of the most valuable of general anesthetics, but occasionally causes death by cardiac paralysis. For a full discussion of the anesthetic use of chloroform, see Anesthetics (General). Deep injections in the vicinity of the sciatic nerve are recommended in sciatica.

Preparations.—**C., Aqua.** Saturated solution. Dose, 1 dram to 1 ounce. **C. Linimentum** contains chloroform 30, soap-liniment 70. **C., Emulsum,** chloroform 4, expressed oil of almond 6, tragacanth 1, water to 100. Dose 1 to 4 drams. **C., Spt.,** pure chloroform 6, alcohol 94 parts. Dose, 10 minims to 1 dram, well diluted.

CHLOROMA.—Formerly known as "green cancer" and regarded as a rare variety of sarcoma, is now classed among the leukemias because it is the result of a leukoblastic hyperplasia resulting in the formation of atypical leukocytes or leukocytes corresponding to some one of the normal types. Chloroma differs from other forms of leukemia in its marked neoplastic type and in the green infiltrations and metastases. The bone-marrow is paler in color and there results an intense anemia. An infectious origin has been suggested. It is of a greenish tint, usually situated upon the periosteum of the bones of the head or upon the dura. It is sometimes found in the orbit.

CHLOROSIS. Synonyms.—Green sickness; primary anemia.

Definition.—A form of anemia in which there is an excessive reduction of hemoglobin over that of the reduction of red blood-corpuscles.

Etiology.—It generally occurs in women or girls under the age of 20. Faulty hygiene, tight lacing, mental anxiety, overwork and improper food are probably some of the many causes. Sir Andrew Clark laid stress upon constipation as a causative agent. Virchow has observed that a hypoplasia of the circulatory system is often present. Association with hyperchlorhydria is common. Chlorosis is more common when there is a disturbance of the menstrual organs.

Pathology.—There is hypoplasia of the aorta and arteries, and a defective development of the uterus and ovaries has also been found in many cases. The heart is often in a condition of hypertrophy, with dilatation.

Symptoms and Course. The Blood.—The blood as it flows from the puncture appears watery and pale and coagulates very quickly. Cabot states that the fibrin is not increased. The red blood-cells may be much deformed, but only slightly reduced in number (4,050,000), yet there is an excessive reduction in the percentage of hemoglobin, 41.2 percent being the average found by Cabot.

The color index is always low. The number of red blood-corpuscles may be estimated very quickly by the use of a hematocrit. Stengel and Cabot prefer the Thoma-Zeiss hemocytometer. See Blood (Examination).

The stained specimens of red cells show a great loss in coloring-matter. There is a great diminution also in the average diameter of the cells (microcytes).

Many deformed red cells (poikilocytes) are present, showing the high grade of anemia. Nucleated corpuscles, so apparent in pernicious anemia, are scanty in chlorosis. There is no leukocytosis.

The skin is tinged yellowish-green, hence the name "green-sickness." The circulatory system is much altered. Palpitation and breathlessness are often complained of. Commonly a systolic murmur is heard near the base of the heart, and a peculiar hum over the right jugular vein. The pulse is soft but of good volume. Nervous manifestations are often present, and hysteria may be a common symptom.

Complications.—Gastric ulcer, phthisis, exophthalmic goiter, and amenorrhea.

Diagnosis.—The early stages may be mistaken for tuberculosis. The other forms of anemia may be confounded with chlorosis, but a complete examination of the blood will clear up doubtful cases. See Blood (Examination).

Prognosis.—Under proper treatment the patient should recover.

Treatment.—Iron is the sheet-anchor in the treatment of chlorosis. Mass of the ferrous carbonate beginning with 15 grains a day and increasing to 30 or even 35 grains, is the classic treatment and may be given for weeks. The tincture of iron, in doses of 10 drops after meals, may also be given. Any of the other prescriptions recommended under the head of anemia may be of benefit. French observers highly recommend sea-water injections. See Anemia, Iron.

℞. Arsenic trioxid, gr. 1/3
Sulphate of strychnin, gr. 1/2
Mass of ferrous carbonate, ʒ ij.
Divide into 20 pills or capsules. One after each meal.

CHOKED DISC.—See Optic Neuritis.

CHOLAGOGS.—Those agents that stimulate the flow of bile and produce free purgation at the same time, the stools being green-colored, or "bilious," and liquid. Podophyllin is the type of this group. Calomel is the most reliable.

The alleged cholagogs are the mercurials, aloes, colchicum, colocynth, rhubarb, euonymin, podophyllin, iridin, and phosphate of sodium.

Cholagog pills:

℞. Resin of podophyllin, gr. vj
Extract of belladonna, gr. iij
Powdered pepper, } each, gr. xxiv
Powdered white sugar, }
Powdered acacia, gr. vj.
Make into a mass with glycerin and syrup and divide into 24 pills. One or two as required.

To secure the best cholagog effect it is advisable to combine an hepatic stimulant with an intestinal stimulant which shall produce increased secretion from the intestinal mucous membrane and excite peristalsis. The hepatic stimulants are bile, bile salts, sodium salicylate, colchicum, the phosphates, sulphate, phenolsulphate of sodium, mineral acids, arsenic, hydrastin, etc.

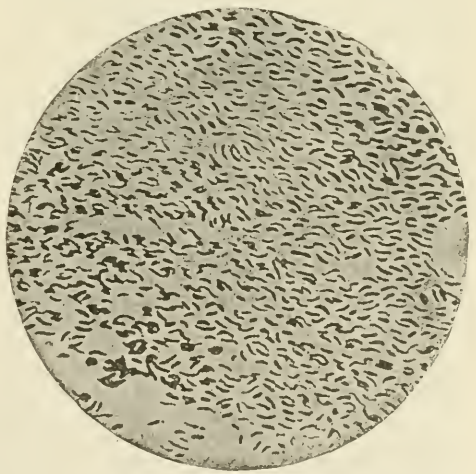
CHOLANGITIS.—Inflammation of the bile ducts. The acute catarrhal form is usually due to extension of inflammation from the duodenum. Suppurative cholangitis is caused by pyogenic organisms from the duodenum or conveyed in the bile. Chronic catarrhal cholangitis usually results from obstruction of the bile ducts by gall-stones, tumors, aneurysm, parasites, adhesions, prolapse of liver or kidney, strictures. See Gall-bladder (Diseases).

CHOLECYSTENTEROSTOMY.—See Intestines (Surgery).

CHOLECYSTITIS.—See Gall-bladder (Diseases).

CHOLELITHIASIS.—See Gall-bladder (Diseases).

CHOLERA, ASIATIC.—An acute infectious, epidemic disease, caused by Koch's comma bacillus,



Spirilla of Cholera, from a Culture on Starched Linen.—(*Fränkel and Pfeiffer.*)

and characterized by violent vomiting of a fluid resembling rice-water, with purging, and great wasting of the fluids and tissues of the body.

Period of Incubation.—Two to five days, as a rule. It may come on in a few hours.

Etiology.—The exciting cause is the **spirillum of cholera,** or the **comma bacillus of Koch.**

The spirillum of Asiatic cholera was discovered by Koch in the year 1884. It is a rather short bacterium, about half the length of the tubercle bacillus, somewhat broader, and usually curved.

The microorganism is exceedingly motile, and in the hanging drop is seen to move across the field of the microscope with great rapidity by means of flagella. Frequently two bacilli will be seen to join ends, forming a shape similar to the letter S.

The organism grows well upon artificial culture media, such as gelatin, potato, peptone bouillon, agar-agar, and milk. Probably the best medium is the gelatin, and its growth by the plate method is very characteristic. The isolated growths then appear as small white dotlets growing upward toward the surface and liquefying the medium, and causing small depressions with sloping sides. The growths have been compared to air-bubbles (McFarland). They stain well with ordinary aqueous solutions of anilin dyes—fuchsin being preferable.

In order to find the bacilli most abundantly a piece of the desquamated internal lining membrane of the bowel should be selected and stained in the ordinary way. The bacillus of Finkler and Prior, which causes ordinary cholera morbus, is larger and thicker, and grows differently on peptone bouillon. In order to cause the disease the organism must gain entrance into the alimentary canal through the mouth. Drinking water, milk, fresh uncooked vegetables, and fruits are the most common articles that convey the virus. The disease attacks old and young alike. The intemperate and debilitated are more susceptible. It is endemic in India, and is often carried by immigrants from this region to all parts of the world.

Pathology.—The face has a shriveled appearance (pinched features), and the whole frame is wasted to a great degree; the eyes are deeply sunken, the temples hollow, the nose pointed, the skin of an ashen color and shriveled. Rigor mortis sets in early, and is greatly prolonged; so strong is this change that the features may become entirely altered after death, and the body may assume new positions before interment. Occasionally the temperature rises 4 or 5 degrees while these changes are taking place. On section, the skin is devoid of serum; the blood is deprived of its watery constituents, and is thickened and darkened, being occasionally of a chocolate color in the vessels. The stomach and intestines contain a turbid material resembling rice-water, and are greatly congested, often showing ecchymotic spots where the epithelial lining has desquamated.

The liver and kidneys are normal in size and may show evidence of parenchymatous degeneration. The spleen is not enlarged. The heart is normal in size and flabby. The lungs are shriveled, collapsed, and devoid of blood except at the bases.

Symptoms.—(1) Stage of invasion, (2) stage of collapse, (3) stage of reaction.

Stage of Invasion.— Anorexia, headache, diarrhea, with colicky pains in abdomen, and generally borborygmus. Nausea and vomiting are not common. The temperature is generally normal. This stage may last a week or only a few hours and gradually disappear, when it is called *cholerine;* or it may be followed by the stage of collapse.

Stage of Collapse.—At this period the diarrhea is profuse, and large quantities of a rice-water material are ejected from the bowel with force and may be thrown several feet; tenesmus is usually absent. Copious quantities of the rice-water material are also forcibly ejected from the mouth and may be scattered over the attendants. Intense cramps often begin in the fingers and toes, extending to the calves of the legs and muscles of the abdomen. The temperature in the axilla is subnormal (90° F.), but the rectal temperature may show a rise of several degrees (103° or 104° F.). There is great weakness, the face and extremities appear shrunken, the eyes deeply sunken, the cheeks hollow, the nose pointed, the skin cold, clammy, and of a gray, ashen color, and the pulse very feeble. The urine is scanty and may contain albumin. This stage usually extends over a period of a few hours, when reaction sets in if a favorable termination is to be expected. Otherwise coma and death may ensue.

Stage of Reaction.—The bodily temperature begins to rise. The ashen-gray color gives way to a more normal hue; the urine, which has been deficient, is passed in increased quantities; the pulse becomes stronger; vomiting is less profuse and recurs at longer intervals; the stools assume a semisolid character; and convalescence is rapidly established. In this stage a typhoid condition may be developed, giving rise to a protracted illness, and finally death follows symptoms of uremia.

Diagnosis:

Cholera.	Cholera Morbus.
1. History of epidemic.	1. May occur at any time.
2. Due to specific organism.	2. Usually due to indiscretion in diet, especially late at night.
3. Evacuations in early stages free from tenesmus.	3. Tenesmus often great.
4. Material rice-water in character.	4. Often greenish cast.
5. Illness protracted.	5. Usually ends in recovery within a day or two.
6. Detection of comma bacilli by staining and culture methods.	6. Organisms are of a different character.

Prognosis.—In the beginning of an epidemic the death-rate is often above 70 percent; toward the

end it frequently falls to 30 percent. The disease is more severe in the young and the very old.

Prophylactic Treatment.—In a certain proportion of cases one attack protects from subsequent attacks. All cases must be isolated, and all clothes about the bed should be burned when taken out of the sick-room. Drinking water must be boiled, and the hands of the attendants thoroughly scrubbed with soap and water, then with a solution of bichlorid of mercury 1:3000. The dejecta should be thrown into a solution of carbolic acid 1:20, let stand half an hour, and finally buried. The bed linen should be boiled.

It should be remembered that fresh fruits and vegetables and salads are a frequent source of conveyance, and during epidemics of cholera should be thoroughly cooked before being eaten. All food and dishes should be screened from flies and handled only with clean hands. Dishes should be washed in boiling water and dried with sterile towels or by heat. Inoculation of cholera toxin or cholera vaccine, according to the Japanese method, apparently produces immunization.

The following **"Cholera Circular"** is used in the Philippines, and (with modifications) might be used anywhere:

Cholera can be introduced into the system only through the mouth. It is caused by organisms. too minute to be seen except with a microscope These organisms are readily killed by heat, and the disease may, therefore, be successfully combated by the proper use of fire and hot water, which are at the disposal of everyone.

To avoid cholera and prevent its spread, observe the following precautions:

1. Boil all drinking water and place it while hot in covered vessels. Do not dip up the water when needed, but pour it into drinking cups, otherwise cholera germs may get into the water from the hands.

2. Do not touch drinking water or food with the hands unless they have just been washed in water that has been boiled.

3. Eat only cooked food. Avoid all fruits, raw vegetables, and raw fish. Dried fish may be made safe by thoroughly heating. Fruits may be made comparatively safe by dipping them a few seconds into boiling water.

4. Flies may carry cholera germs on their feet from human excreta to food; therefore, to protect it from flies, cover all food immediately after it is cooked.

5. If cholera appears, build smudges under houses to drive flies away.

6. Boil all water used for diluting milk.

7. Cook all meats and fish thoroughly so as to heat the same throughout.

8. Keep kitchen and table dishes thoroughly clean and scald them before using.

9. Keep the place in which you live, the ground under the house, and everything pertaining to it, clean.

10. Outhouses, closets, and vaults can be made safe by putting in lime or carbolic acid. When this cannot be done, dejecta must be buried or thoroughly covered with earth.

11. Isolate all the sick. It is recommended that a house in each barrio be set aside for this purpose.

12. All the dead should be embedded in lime and buried three feet under the surface.

13. Filth, or vomit, and the dejecta of the sick should be promptly cleaned up with boiling water and buried.

14. Clothes and bedding used by sick persons must either be burned or boiled. Do not wash any clothes near wells or springs nor permit surface water to run into any well or spring.

15. Municipal presidents and municipal councillors should enact these rules as ordinances and see that they are enforced.

16. All school children are requested to inform their parents of these rules, which, if observed, will prevent great loss of life.

Treatment of the Attack.—To relieve the excruciating pains in the abdomen and extremities, hypodermic injections of morphin (1/4 grain) should be given every 4 hours if necessary. Phenyl salicylate has proved very beneficial given in doses of 5 to 15 grains every 2 or 3 hours. It may be combined with large doses of bismuth naphtholate or bismuth iodophthaleinate. Calomel also has been effective, an initial dose of 4 to 7 grains being given and followed by small doses at intervals of 2 hours.

Squibb's cholera mixture is composed of the following:

℞. Tincture of opium,
Spirit of camphor,
Tincture of capsicum, } each, ℥ j
Chloroform, ℥ iij
Alcohol, enough to make ℥ v.

Teaspoonful every 2 or 3 hours.

"Sun Cholera Mixture":

℞. Tincture of opium,
Tincture of capsicum,
Tincture of rhubarb, } each, ℥ j.
Spirit of camphor,
Spirit of peppermint,

A teaspoonful in water after each evacuation of the bowels.

For the extreme thirst, champagne or water containing cracked ice may be taken. Water acidulated with sulphuric acid or lemonade may be grateful to the patient, and may be taken in large quantities. Hot-water bags and fomentations should be applied over the abdominal region. For the feeble pulse, stimulants, such as whisky (1 ounce) or the aromatic spirit of ammonia (1 dram), may be largely diluted with water and taken every 2 or 3 hours. Possibly the best local application to the seat of disease is large quantities (2 quarts) of warm water containing laudanum

bed, and greatly disturbs sleep. It is best treated with such sedatives as potassium bromid. Camphor and opium, in the form of a pill or suppository, are of value (see CAMPHOR). The local application of cold, and a hot bath before going to bed, are highly recommended. A few drops of a 4 percent solution of cocain applied locally to the glans or injected into the urethra will frequently afford prompt relief. See GONORRHEA, PENIS.

CHOREA (St. Vitus' Dance).—Chorea is a subacute, nonfebrile disease, usually affecting children, and characterized by local or general irregular twitching and incoordinate movements of the muscles. It is a disease that is common in cities; less frequent in the country. It affects children, of all classes, chiefly between the ages of 5 and 15, and about in the proportion of 2.5 girls to every boy. Children with any neurotic heredity are more inclined to it than those in robust health and with sound family histories, but the heartiest are not exempt. It almost never occurs in pure-blooded negroes or Indians, and is rare in half-breeds, and mulattoes. It is of world-wide distribution, and with the exceptions noted, affects all races in every climate. More cases occur in spring and autumn than at other seasons. School pressure seems to exercise a decided influence, and subjects of this disease are usually children who are active-minded and stand well at school. Among exciting causes it is common to hear parents assign fright, slight injuries, and mental worries, but it is more than doubtful if such psychic causes have any direct influence upon the production of the disease. Reflex irritation (such as worms and nasal and genital irritation), and eyestrain were also formerly considered as etiological factors. Scarlet fever, whooping-cough, and measles are occasionally followed by attacks of chorea, probably owing to the impairment of tne child's system by these diseases, leaving it open to the attack. In young mothers, especially one bearing her first child, chorea is occasionally seen during pregnancy. A certain degree of anemia commonly accompanies chorea, although it is seen in robust children too often for anemia to be considered as having any causal relation to it.

The most important related condition is articular rheumatism. This is certainly a very frequent precedent phenomenon, apparently is not seldom a predisposing cause, though as yet it may not be said to stand in a direct causal connection with chorea. Of 554 cases studied by Osler on this point, 15.5 percent had a history of rheumatism in the family, 15.8 percent had at some time suffered with acute or subacute articular swellings; adding to these latter the cases doubttul in description, but probably rheumatic, the percentage reaches nearly 21. English authors place the percentage of occurrence of this complication at a much higher point even than this, but acute rheumatism is a much more common disease in Great Britain than in America.

At the Johns Hopkins Hospital there was a history of arthritis in 18.24 percent of 175 cases.

Symptoms.—The disease usually begins insidiously and with slight early manifestations. The child is noticed to twitch a hand, or the facial muscles move in grimaces, or it is observed to be dropping objects handled. For a week or more there is a little steady increase, then for 3 or 4 weeks the disease progresses more rapidly, or remains, in mild cases, at the same stage. Speech is very often affected from movements of the lips and tongue, of an irregular character, corresponding to those affecting the muscles of the trunk or limbs. In a developed case the child winks, grimaces, its hands can scarcely be used at all, it will even stumble in walking, and generally the movements are made much worse by attempts at voluntary motion. When at rest, the expression of the child is peculiar. A wistful, fixed look is common. Upon attempting to speak or smile, expressions of mirth, grief, or fright rapidly succeed one another, from the twitching of the facial muscles. One or both hands are in constant motion, the head is thrown about, and the trunk-muscles twitch the body. Movements are occasionally so severe that the child cannot feed itself; and in violent cases they may even recur with such force as to throw the child from its bed. Exceptionally, these irregular, incoordinate movements are replaced by a more or less constant tremor, sometimes coarse, sometimes fine. This may be present on one side of the body or on both, or may be small, fine, and rapid on the one side, and larger and slower on the other. Like the ordinary movements, this may be nearly continuous or may cease at intervals. Rhythmic tremors should, however, excite suspicion of a probable hysteric element.

Certain differences in the effect of will-control and of voluntary motion are to be observed in chorea that are interesting:

1. Certain cases, when at rest, present no movements at all, and only develop the incoordinate twitchings during muscular exertion. This may happen in either slight or severe cases.

2. The next group has continuous movements when no muscular exertion is made, which are greatly increased by muscular acts.

3. In another group the movements cease during intentional effort.

4. In a fourth group the movements are not at all affected by voluntary muscular effort, continuing, when the patient is at rest or when he makes exertion, at about the same grade.

Finally, it should be said that these differences in effect of voluntary effort are not continuous in any one case, but that any single instance of chorea may, in the course of the disease, present all these varieties of effect from voluntary effort.

Intelligence is not usually affected, except that the power of concentrated attention seems to be somewhat impaired. The temper alters greatly, the parents describing the children as irritable or even violent. Movements generally cease during sleep, but at times in severe cases they continue even then, or may keep the patient awake so constantly as to produce very serious effects.

Certain general symptoms are found in all cases; anemia has been mentioned, and this poverty of blood is further exaggerated by a poor appetite and by constipation, and if the case is a long one,

the child usually loses flesh. If close inquiry is made, it will be found that many cases, especially those suffering from the one-sided form (hemichorea), complain of vague pains in the trunk or limbs. In children old enough to describe their feelings headache will almost always be complained of. The electric reactions of the muscles are usually unaffected, or in occasional cases are slightly increased. In rare instances the reflexes are lessened or lost.

Course.—Typical ordinary cases last 6 weeks or less; many continue for 2 or 3 months. Occasionally a disorder of a very permanent character arises out of the first condition. Whether a case will last long or not may usually, but not always, be predicted from the severity of the symptoms. If the movements are very general, large, and constant, the case will be a long one. The reverse cannot always be said to be true, for many cases with but mild symptoms continue for months to resist the most careful treatment. The gravest possible complication in the course of an attack of chorea is the occurrence of disorder of the heart, which may take any one of several forms. Painstaking examination should always be made of the heart of children suffering from this disease, and the practitioner must not be content to examine through the clothing, but should strip the chest entirely naked, and see that the patient lies down for some minutes before the examination, in order that the heart, which is very liable to be overactive from the excitement of examination, may have time to quiet down. After examining in this way, the organ should be studied for the effect of exercise and of the erect position. The strictest attention needs to be given to the cardiac conditions, because young children are unlikely to complain of palpitation or to describe accurately the pains that may be present in the neighborhood of the heart. Rapidity, palpitation, and irregularity are tolerably frequent symptoms. If the movements are very severe and constant, there is often an excessive rapidity of the heart. A large percentage—probably not less than 30 percent—of all cases of chorea are found, if properly examined, to present some form of heart murmur. Functional murmurs are very frequent. The most common one is a basic systolic murmur, heard best at the pulmonary area. This so uniformly disappears when the patients are kept quiet in bed as to make it seem probable that it is due rather to overaction of the heart from the excitement of examination than to valvular disorders or hemic states. When the patient is anemic and enfeebled, a murmur, systolic in time and associated with a diffuse apex-beat, will be heard at the apex and in the pulmonary area and along the left edge of the sternum. It is very often only possible to hear these murmurs when the patient is recumbent; under such circumstances they may often be traced into the veins of the neck. Other less important murmurs may sometimes be detected. A mitral systolic murmur at the apex may occasionally be found; the split second sound is observed in a few patients. It is tolerably safe to assume that any murmur entirely basal in its distribution or heard *only* along the left margin of the sternum is functional in its character.

It must never be lost sight of in these examinations that a diagnosis of valvular disease cannot be made from the evidence of murmurs alone, however distinct in character and distribution they may be. The possibility of endocarditis requires the most serious consideration and study in every choreic patient. Not even acute rheumatism is more often associated with acute endocardial inflammation than is chorea. In the rare cases in which opportunity occurs for postmortem examination it is exceptional to find the heart of a choreic subject healthy. It is only by minute observation and close study that the presence of endocardial inflammation can be determined. The general symptoms of acute endocarditis are too inconstant and too slight for a basis of diagnosis; indeed, the physical signs themselves are too uncertain to be safely relied upon. The signs of slight dilatation of the left heart—viz., a diffused apex-beat, a slight increase of cardiac dulness to percussion—may be present; a mitral murmur, usually blowing in character and heard at the apex, if constant and not disappearing when the patient is erect, as functional murmurs are very likely to do, is a more useful sign. If in addition to this there should be fever, even if the rise of temperature is very slight, the diagnosis becomes more certain. A complaint of pain is of great importance, but it is rare to hear of it from the patient. Many attacks of cardiac disease in the course of chorea must pass unrecognized at the time, judging by the very large percentage of choreic cases that, when examined at a later date, present evidence of organic heart trouble.

In Osler's 140 cases examined more than 2 years after the attack of chorea, 51 3/7 percent had signs of distinct damage to the heart; 17 more cases he considers may be classed as functional disturbances. By no means all of his 72 patients suffering from cardiac disorder had had rheumatism, so that it must be concluded that heart-disease may occur and be serious in its results quite independently of rheumatic affection. Pericarditis occasionally occurs, but with much less frequency than inflammation of the lining membrane of the heart.

Diagnosis.—The diagnosis of chorea is an easy one, as there are few disorders with which it can be confused. The history of the beginning with slight and increasing movements, the age of the patient, the characteristic expression, can scarcely be simulated by any other disease, although in slight cases some question may arise of diagnosis from hysteric conditions. In fact, hysteric choreic movements are not uncommon, and probably the two neuroses are closely related. In hysteria the movements are more likely to be of a rhythmic character, and there is very often rigidity in addition. Convulsive tic may readily be differentiated, if the history is carefully examined.

Prognosis.—Chorea, in this country at least, is very rarely a fatal disease; in children it may be said almost never to end in death, and in adults but rarely. Under proper conditions the patients

recover entirely, usually without any permanent damage to the nervous system. In the more susceptible patients, or in those exposed anew to the operation of the same causes that brought about the original attack, relapses are likely to occur. One relapse is of quite frequent occurrence; 2, 3, or 4 attacks in the same patient are not unusual. The methods to be used in guarding against these recurrences will be considered under treatment. In 410 cases analyzed by Osler with reference to this point, 240 had but a single attack, 110 had two attacks, 35 had three, 10 had four, 12 had five, and 3 had six relapses.

Treatment.—The most important indication in the treatment is rest. If the case is a mild one, it is not necessary to put the patient to bed, but violent exercise or exciting games must be forbidden, and, among the poor at least, it is often easier to put a child to bed than to watch it carefully to keep it from overexertion. In the severer cases both rest and seclusion are essential, and in those in which anemia and debility are present, especially when the subjects are girls at the age of puberty, full "rest treatment" with all its details may be necessary. No other means will so soon or so easily bring about a cure as to place the patient in bed under proper care and restrictions. Attention must be paid to the diet, to remove all possible causes of irritation to the digestive organs, and to make sure that the patient receives wholesome and nourishing food of the best kind possible in his circumstances. Impairment of appetite is so common a feature that some insistence may be required upon this point. If sufficient ordinary food is not taken, it is well to direct that milk should be given in considerable quantities. Even if the case is not bad enough to warrant the child's being put to bed, it must, as a rule, be withdrawn from school during the continuance of the disorder and for some weeks after recovery. Candy, cake, and sweets must be absolutely proscribed, and the habits of the patient in regard to tea and coffee will often bear investigation, as it is not uncommon, especially among the working classes, for children of tender age to be dosed daily with tea and coffee of the same strength that their elders drink, and usually with disastrous results to their nervous systems. Such measures as these may be entirely successful without resort to drugs at all. It is not unusual to see a child after unsuccessful treatment for a week or two in the out-patient department make as much improvement during 2 or 3 days of complete rest in bed as would have required weeks of treatment had the patient been upon his feet. It is probable also that rest in this fashion diminishes greatly the chances of serious heart complications. If the movements are very severe, and the general twitching so great as to risk the child's being thrown from bed entirely, it is not safe to confine the patient by placing him in a crib, lest he injure himself against the headboard or sides. A safer measure is a soft mattress placed upon the floor, and guarded around with pillows and other mattresses.

A warm bath daily, especially if a little prolonged, will sometimes help to lessen the violence of the movements, and when it can be practised, systematic massage, in the form of deep but gentle and slow kneading of all the muscles, will be found useful and will add to the ease of cure. This is a method of treatment proposed by Lablache for this disease, and will greatly hasten the recovery. Descending galvanic currents may be applied to the spine with advantage. Sedative drugs, like bromids and chloral, should be altogether avoided unless absolutely required from the violence of the patient's jactitations. They have no effect on the course of the disease, and can only produce a temporary palliation, at the probable cost of disordered digestion and depressed nervous system. Indeed, it cannot truly be said that there is any safe drug that has much influence on the course of the disease or that decidedly lessens the movements. Arsenic in some form is the safest remedy for regular use in most cases. It is probable that it helps rather by its effects upon the general condition of the patient in modifying nutrition and improving digestion than that it directly controls the twitchings. The most available form is Fowler's solution, which may be ordered for a child from 6 to 9 years in 3-drop doses, well diluted, to be taken after food 3 times a day. The amount should be increased a drop every day, care being taken that the attendant understands that danger may result from too rapid increase of the drug, and comprehends clearly that "one drop every day" of increase does *not* mean "one drop at every dose." The person in charge should also be told that watch must be kept for possible symptoms of constitutional effect of the arsenic; the earliest is likely to be edema of the lower lids, or disturbance of the stomach or bowels, shown by vomiting, diarrhea, or pain. Pigmentation of the skin is now and then seen from the continued use of arsenic in this manner, but it is rare. Several cases have been observed of neuritis and troublesome consequent paralysis from long-continued administration of the arsenical solution. Children, however, bear arsenic rather better than do adults, and the solution may be increased in this fashion steadily until 12 or 14 minims 3 times a day are given, which is as high as it is desirable to go. If the child has borne this amount well, the dose should then be reduced to 10 drops 3 times a day, and this quantity continued for some weeks.

In out-patient practice, where visits are infrequent, often only once a week, it is a good rule to give clearly written or printed directions for the administration of the drug, with an added description of the possible bad effects, in order that the earliest symptoms of overdose may be noticed and the medicine stopped. Fowler's solution may be used hypodermically in proper doses by ordering it specially made without the addition of lavender, and this method is useful when the internal administration disturbs the stomach too easily.

If there is an extreme degree of anemia, as shown either by the pallor of the patient's skin and mucous membranes or by a functional cardiac murmur, iron may be advantageously given at the same time with the arsenic. Full doses will be required, such as 10 to 20 drops of the tincture 3

times a day in children 5 or 6 years old, or 5 to 15 grains of Blaud's pill of the subcarbonate after each meal in older patients. If expense does not forbid it, there are numerous elegant and useful forms of iron preparations available. None produce better results than freshly made pills of the subcarbonate, *when given in sufficient dose.* H. C. Wood used, and highly recommended, quinin in very large doses. Its favorable action he believed to be due to the fact that quinin is a stimulant to the inhibitory functions of the spinal cord, and he held that failure of spinal inhibitory power is a large element in the development of the choreic movements. There is, he says, an extraordinary tolerance of quinin in those cases in which it does good, and in one instance he gave as much as 1000 grains in a month to a child of 12 without producing cinchonism, but with cure of a chorea of 2 years' standing. The fluidextract of cimicifuga will sometimes succeed when other drugs fail; the preparation must be freshly made, and has the disadvantage of a most abominable taste and smell. It should be taken in increasing doses, beginning with 15 to 20 minims in a child 6 years old, until the point is reached at which it produces headache, dizziness, or gastric discomfort. Antipyrin has been recommended, but is scarcely a safe drug for constant administration. Trional or choralamid must be used if the sleep is disturbed.

Certain **complications** may require attention. Acute arthritic troubles should be treated, like rheumatism, with full doses of the salicylates, although the effect of this drug is less favorable in the arthritis of chorea than in ordinary acute rheumatism. Careful protection of the affected joints and local applications of laudanum may be needed. Endocarditis will require the placing of a frequently renewed ice-bag over the region of the heart, both to quiet the movements of the organ and to lessen the tendency to throw out exudate, and cardiac sedatives or mild anodynes may be given as required.

In order to prevent relapses great care of the child's general health will be needed, especially in the spring following the attack. The danger of exciting a return of the symptoms by overexertion, either physical or mental, must not be forgotten, and it is wise to direct that a patient be brought back for inspection, even when seeming perfectly well, during the early spring. In such cases, if the health appears not to be first-rate, the administration of sufficient doses of iron, perhaps with the addition of arsenic, may prevent a relapse, or, as Wood suggests, full doses of quinin.

Of the other diseases sometimes classed under the head of chorea it is necessary to say but a few words.

Chorea major includes those affections in which violent choreic movements, often general and simulating coordinate purposive actions, occur. The epidemics of chorea major described for many centuries by various writers have no doubt been largely hysteric. Indeed, it is difficult in most of these cases to separate the real from the hysteric disorder. **Salaam convulsions**, the **dancing chorea** of Laycock, and the **jumpers** of Maine and Canada, described by Dr. Beard, may be included under this classification; but the treatment is wholly moral or suggestive, except in those cases in which the hysteric element preponderates, when the general principles of treatment of hysteria would apply.

Electric chorea, as ordinarily described, is nothing but a violent form of the ordinary St. Vitus' dance. The name was originally used by an Italian observer, Dubini, for a fatal progressive disease bearing little resemblance to the ordinary chorea of childhood.

Hereditary chorea, or **Huntingdon's disease**, resembles chorea only in its movements. It is seldom seen except in adults. It is always hereditary, tends to grow worse, and is accompanied by steady mental failure, ending in total dementia. The vital points of difference are that while the movements resemble those of ordinary chorea, they are much more constant, are almost impossible to control by the will, and they are more steadily regular or rhythmic. As no cases of recovery are known, and no treatment seems to affect the course of the disease, it need not be further discussed here.

Hysteric Chorea.—Movements of choreic nature are occasionally seen in various classes of hysteric patients. They may affect one part of the body, sometimes even the muscles of the larynx. The spasm is usually rapid and rhythmic—two characters by which hysteric movements may be distinguished from those belonging to Sydenham's disease—and there is often, though not constantly, some degree of rigidity of the affected limbs.

Habit chorea, or habit spasm, as Gowers prefers to call it, is more nearly related to true chorea than the hysteric forms of choreic movement are. Its origin is nearly always in an acquired trick or habit of movement; it may affect any part of the body, sometimes limited to the smallest possible group of muscles, or even to a single muscle, sometimes affecting the whole of a limb, or appearing as a frequent, noisy breathing, or as blowing, whistling, a cough, a snuffle, shrugging of the shoulder, winking of one or both eyes, movement of the jaw, or some trick or play of the hands.

The treatment of such cases is not so hopeless as some writers upon the subject seem to think, but it certainly requires both minute care and great persistence on the physician's part as well as on the patient's. The first necessity is the bringing of the patient's health to the highest possible level by every means at our disposal. The second is, after having inculcated thoroughly the lesson of self-control and insisted upon it, to require the victim of habit to make many times a day for short periods the *effort* to stop the manifestations of his disease. Even if for a time no success attends his attempts, he must be encouraged, and made to understand that even to *try* to overcome his habit produces a good effect. It will soon be found that he will be able for a certain number of minutes to restrain the disposition to movement. Probably at first these periods of self-control will be followed by increase of the habitual trick, but no attention need be paid to this. Careful gym-

nastic movements of the affected muscles, massage, and constant encouragement will in the end succeed with any but the most inveterate cases.

A certain degree of success has been gained from hypnotic suggestion—a method scarcely safe, however, in cases of susceptible children. With adults, under proper control, less hesitation in its use may be felt.

CHORION.—The outermost of the fetal membranes. It lies between the amnion and the deciduæ reflexa and vera. A great number of minute finger-like projections (*chorionic villi*) develop on its outer surface, giving it a peculiar branched, bushy appearance. These villi are hollow at first, but later they contain blood-vessels and project into the decidua. About the third week of gestation the chorion is joined by the *allantois*, the whole forming the *complete chorion*. During the second month of gestation the villi projecting into the decidua reflexa atrophy (*chorion leve*), while those projecting into the decidua serotina hypertrophy (*chorion frondosum*). These latter form the fetal portion of the placenta.

Origin.—From the nongerminal layer of the epiblast.

Function.—The chorion leve protects the integrity of the ovum, while the chorion frondosum supplies nourishment to the early embryo.

Anomalies.—Occasionally there is failure of atrophy of that portion of the chorion that normally occurs, there being, instead, hypertrophy of the villi over the entire surface of the chorion. This gives rise to the formation of a placenta much larger in area and much thinner than normal (*placenta membranacea*).

Cystic Degeneration of the Chorionic Villi.—This is a rare myxomatous degeneration of the villi, with the formation of small, grape-like cysts. It occurs once in about 2000 pregnancies.

The causes of this peculiar affection are difficult to determine; probably some interference with the blood supply to the villi may occasion it. It sometimes shows a tendency to recur in the same individual.

The symptoms usually develop about the third month, with rapid increase in the size of the uterus, pain, nausea, hemorrhage, some rise of temperature, and possibly the extension of small, blood-covered cysts from the os uteri.

The diagnosis can only be made positively by the discovery of the characteristic grape-like masses.

The prognosis is rather grave, about 13 percent of patients losing their lives. There is sometimes a marked tendency to perforation of the uterine wall, the disease thus becoming malignant in character. Other dangers are sepsis and hemorrhage. The fetus is usually destroyed and frequently entirely absorbed.

The treatment should consist in complete and thorough evacuation of the uterus as soon as the condition is recognized. Care should be exercised in the use of the curet and placental forceps, as the uterine wall may be extremely thin.

Fibromyxomatous Degeneration.—This is an extremely rare condition, characterized by a fibroid formation in the connective-tissue portion of the chorion at the placental site. Subsequently the fibroid nodules undergo myxomatous degeneration. The condition is usually not recognized until after labor or abortion has occurred.

Inflammation (Chorionitis).—The chorion is subject to acute and chronic inflammation. The chronic variety is frequently syphilitic in origin.

CHOROIDITIS. Causes.—Inflammation of the choroid results from general diseases, such as syphilis, tuberculosis, scrofula, chlorosis, rheumatism, and gout. Senile choroiditis is probably preceded by choroidal apoplexy. Suppurative choroiditis is due to traumatism with infection; to metastatic infarction, empyema and endocarditis; and to severe infectious fevers. (See Colon Bacillus Infection.) High myopia, by causing extreme stretching of the choroid, often gives rise to a local or diffuse inflammation. Choroiditis may be an accompaniment of inflammation of the iris and ciliary body.

Varieties.—For convenience, choroiditis may be divided into the **exudative** and **suppurative** varieties, although many subdivisions, such as *disseminated, syphilitic, arcolar, central, guttate,* etc., have been studied pathologically.

Exudative choroiditis is distinguished by the impairment of vision due to the simultaneous involvement of the retina, and by the changes noticed with the ophthalmoscope. The disease runs its course without pain and without external symptoms, and the patient is only aware of his affection through the impairment of vision. It must be remembered that there is no definite relation between the amount of visual disturbance and the changes noted in the fundus. Alteration in the field of vision, the appearance of scotoma, metamorphopsia, night-blindness, flickering spots, and progressive lessening of the visual acuity are the most important subjective symptoms. The ophthalmoscope shows the presence of numerous dispersed patches in the fundus, thickly strewn near the equator, gradually diminishing toward the macula and optic disc, these being generally free from disease. If fresh, the patches are round, sharply defined, much smaller than the disc, and yellowish-red, lighter in color than the fundus. In addition, there are yellowish-white streaks along the vessels. As the disease advances the patches become larger and coalesce into irregularly shaped figures, showing the white sclerotic beneath, surrounded by hypertrophied pigment epithelium of the retina. In the majority of cases permanent white patches are left, either due to exposure of the sclera or to reflection from cicatrices. The optic disc is generally slightly red and cloudy. The term **disseminated choroiditis** is often applied to cases in which the spots in the fundus are numerous and diffuse. **Areolar choroiditis** consists of black patches and small pigment-blotches, gradually changing to whitish blotches with black edges. It is confined to the posterior pole of the eye, and endangers central vision. The **central** variety is located directly at the macula. Sometimes retinal vessels can be traced over spots of choroidal atrophy, showing that the choroid is the primary

seat of the lesion. The vitreous is generally clear, and good ophthalmoscopic images are obtained.

Syphilitic choroiditis is diagnosed by syphilitic history and speedy reaction to mercurial inunctions; the most characteristic symptoms are night-blindness and circumscribed scotomata in the field of vision. Vitreous opacities are also said to be more numerous in this variety.

Suppurative choroiditis begins with hemorrhage into the retina and choroid, which is soon followed by purulent infiltration of the whole interior of the eye. Externally, the lids and conjunctiva are red and swollen, and are covered with a purulent secretion; the cornea is hazy, and there may be hypopyon; the iris is inflamed, the pupil appears yellowish, and the eyeball is hard. The patient suffers intense pain, has acute febrile symptoms, and is blind in the affected eye. Viewed by the ophthalmoscope, the golden reflex, due to the exudative material thrown out between the choroid and the retina, confirms the diagnosis, although in children it may be mistaken for glioma of the retina. The inflammation may subside, but it is rare for any visual perception to be preserved. In the malignant form panophthalmitis ensues, and the whole eye becomes an abscess-cavity, and is lost. The infection may often be metastatic.

Myopic choroiditis is due to the ectasia or staphyloma of the sclera at the posterior pole, and is usually present in high degrees of myopia, and always in progressive myopia. The increased "myopic crescent," producing an enlarged blind spot, and the ordinary symptoms of myopia associated with the atrophic changes of the choroid, furnish a ready means of diagnosis.

Anterior sclerochoroiditis involves the anterior part of the choroid, inaccessible to the ophthalmoscope. It is differentiated from episcleritis, which is a benign local disease, while the former attacks the cornea, iris, and anterior portion of the vitreous, finally causing anterior ectasia of the sclera.

Prognosis of choroiditis is, on the whole, unfavorable. In the exudative variety and in high myopia it is only possible to retain part of the vision. In case of large ectasia there is constant danger of increase in inflammation and glaucomatous symptoms. If anterior ectasia is produced, blindness follows through flatness and opacity of the cornea, increased tension, and distortion of the eyeball. In suppurative choroiditis the eye may be preserved, but vision is inevitably lost.

Treatment of choroiditis must be directed toward any discoverable cause. In all acute cases, whether syphilitic or not, in which the patient is in fairly good health, mercurial inunctions should be begun. In debilitated cases constitutional and tonic treatment should be instituted, diaphoresis provoked, potassium iodid administered, and rest, with smoked glasses, ordered. Confinement in a dark room is unnecessary. In tuberculosis of the choroid, tuberculin treatment combined with the usual general measures of combating tuberculosis should be instituted. (See TUBERCULOSIS, ACUTE MILIARY.) In subacute or chronic cases, administration of the following is advised:

R. Mercuric chlorid, gr. ij
Extract of belladonna, gr. iv.
Make 40 pills; take 1 pill 3 times a day.

In the suppurative variety no more can usually be done than to quiet pain by narcotics or by the local use of atropin and hot compresses. Serum or vaccine therapy (*q. v.*) should be tried. If the eye is a virtual abscess it should be incised or enucleated under the strictest antiseptic precautions. In the anterior variety tension must be carefully watched, and if excessive, may be relieved by corneal puncture or iridectomy.

Tuberculosis of the choroid is of two forms, the first manifesting itself in small, whitish-yellow spots that are minute tubercles near the posterior pole of the eye; many are too small to be visible by the opthalmoscope. The second form is a spheroid tubercle causing detachment of the retina, and possibly inflammation of the eye. It is to be distinguished from sarcoma of the choroid, but in both cases enucleation may be peremptorily demanded.

Sarcoma of the choroid develops slowly at first, but later on involves the surrounding tissue with great rapidity. In the first stage, the only subjective symptom is disturbance of vision, the eye becoming more myopic, and distortion of images ensuing. The sarcoma is usually at the posterior pole. Viewed by the ophthalmoscope, as a rule, nothing but retinal detachment is distinctly elicited. In the second stage severe pain caused by increased tension is noticed, and total blindness ensues. The mediums become so cloudy that no reflex is obtainable. After this the growth penetrates the sclera, the whole eye becomes a malignant mass, and even if metastasis has not occurred, the patient may die of exhaustion. The disease is unilateral, and should be distinguished from glaucoma, in which there is no retinal detachment; and from simple retinal and choroidal detachment, in which there is no increase in tension. It is generally followed by sarcoma of the liver. The more fibrous the tumor, the less the liability to metastasis. As soon as the disease is recognized, the eye should be enucleated and the orbit thoroughly cleaned out, as death will speedily ensue if the disease is allowed to continue.

CHROMATOPSIA.—See COLOR BLINDNESS.

CHROMIDROSIS.—A rare condition of the sweat, in which it is variously colored, being bluish, blackish, reddish, greenish, or yellowish. *Black sweat* (*seborrhea nigra*) occurs usually in hysteric girls, the part affected being the face. It is associated with chronic constipation, and is due to the presence of indican in the sweat. *Red sweat* (*hematidrosis*) may be due to an exudation of blood into the sweat-glands or to the presence of a microorganism in the sweat. See SWEAT-GLANDS.

CHROMIUM TRIOXID.—Chromic acid, or, more properly, chromic trioxid, occurs in small, crimson, needle-shaped crystals, deliquescent in moist air, very soluble in water. It should be kept in glass-stoppered bottles, and great caution should be observed to avoid bringing it in contact with organic substances, such as cork, tannic

acid, sugar, alcohol, glycerin, etc., as dangerous accidents are liable to result. It is not used internally.

Preparation.—Potassii Dichromas, *potassium dichromate*, $K_2Cr_2O_7$—large, orange-red prisms of disagreeable, metallic taste and acid reaction, soluble in 10 of water at 59° F., an in 1 1/2 of boiling water, insoluble in alcohol. It is used locally in aqueous solution (5 to 60 grains to the ounce); and internally in doses of 1/10 to 1/2 grain, in trituration.

Incompatible *with chromic trioxid* are: Alcohol, bromids, chlorids, ether, glycerin, hypophosphites, iodids, oxalates, sulphids, tartrates; with *chromates* are the salts of barium, bismuth, lead, manganese, mercury, silver, and strontium; *with dichromates* are many alkaloids, also tannic acid, sugar, and other oxidizable substances.

Chromic trioxid is a powerful escharotic and penetrates deeply, but it is slow of action and is not very painful. It coagulates albumin and parts readily with its oxygen, oxidizing organic matter and decomposing ammonia and sulphuretted hydrogen; and is therefore an energetic disinfectant and deodorizer. When used as a caustic it is mixed with sufficient water to make a paste, which may be employed for the destruction of warts, hemorrhoids and other superficial growths; the neighboring parts being protected by cotton soaked in a strong alkaline solution. For syphilitic warts and condylomata, lupus, tinea tonsurans, etc., a solution of 100 grains to the ounce of distilled water is generally used. A solution of 1 in 40 is an excellent and inexpensive antiseptic lotion for putrid sores and wounds, syphilitic affections of the tongue, mouth and throat, ozena, leukorrhea and gonorrhea. In uterine catarrh and hemorrhages, a solution of 120 grains to the ounce has been injected into the uterine cavity with good results.

Potassium dichromate is a good antiseptic and escharotic of milder action than the trioxid. In doses of 2 to 4 drams it has proved fatal to life in adults, with symptoms of gastroenteritis, suppression of urine, and cardiac paralysis. It is chiefly employed as a local application in saturated solution to warts and venereal condylomata; and in dilute solution (1 to 10 grains to the ounce) for catarrhal conditions of the nasal, buccal or vaginal mucous membrane. Internally it has been employed with benefit in locomotor ataxia and in dyspepsia simulating gastric cancer; also in chronic gastric catarrh, the tongue having a thick yellow coat, in chronic diarrhea from intestinal ulceration, and in chronic ulcers of the pharynx and mouth. It is a good remedy in syphilitic sore throat, local rheumatism of the fibrous tissues, periosteal and syphilitic rheumatism, and acute catarrh and influenza, chronic nasal catarrh, chronic laryngitis, and chronic catarrhal affections of the bronchial mucous membrane, especially when the expectoration is tough and stringy. It has also been used with some success in diphtheria. In pharmacy it is employed in preparing chromic trioxid and valerianic acid, and as a test solution. Most of the medical galvanic and faradic batteries are run by a mixture of this salt with sulphuric acid.

CHROMOPHYTOSIS.—See TINEA VERSICOLOR.

CHRYSAROBIN.—$C_{30}H_{26}O_7$. A neutral principle extracted from Goa Powder. It is a gastro-intestinal irritant, and is almost a specific when applied locally in psoriasis. It stains the skin a dark yellowish-brown color, which may be removed by a weak solution of chlorinated lime. It is said to be a specific for warts when used in 10 percent solution. Dose, internally, 1/8 to 1 grain. **C., Ung.**, contains 5 parts of the drug with 95 parts benzoinated lard; for average use it should be diluted 2 or 3 times.

CHYLURIA.—The passage of milky-colored urine. It is thought to be caused by a disordered condition of the lacteals, and is also connected with the presence in the blood of filaria sanguinis hominis. The urine passed is generally above the normal in quantity, has the color of milk, and becomes jelly-like on standing, afterward again becoming liquid. It readily undergoes decomposition. The condition arises from an occlusion of the lymph-channels by the parasites. See FILARIASIS.

CICATRICES, AFFECTIONS OF.—A normal scar, or cicatrix, is at first smooth, hard, and, owing to its vascularity, red in color. Later, in obedience to the contraction of the fibrous tissue, it becomes white (avascular), more dense, and often wrinkled. It is insensitive, because of the absence of nerves, and contains no lymphatics. The itching or burning sensation sometimes referred to a scar is due to irritation of the nerve filaments in the adjoining skin or subjacent tissues. The principal deviations from the normal are the following:

Discoloration may be due to foreign substances, *e. g.*, gunpowder, particles of coal, or to partial retention of normal pigment, *e. g.*, in the negro. Excision, followed by careful apposition of the wound with a subcuticular suture, is indicated in some of these cases, as well as in some cases in which disfigurement is due solely to the shape and site of the scar, *e. g.*, a wide, irregular cicatrix on the face or neck.

Excessive contraction is most frequent after extensive superficial wounds, notably burns, the granulation tissue reaching the surface and undergoing conversion into fibrous tissue long before the completion of epidermization, hence, when possible, the necessity for early skin grafting in wounds of this character. On the surface of the body the evils of contraction are most marked about the face, the neck, and the joints. In these cases liberation of the parts by proper incisions, and filling the resulting gap by a plastic operation, is to be considered. In the various canals of the body contraction results in stricture.

Stretching may occur when a recent scar is subjected to an almost continuous strain, thus are produced the post-operative hernias of the abdomen. Stretching is sometimes utilized as a therapeutic measure, especially in the treatment of strictures.

Depression may be due to adhesion of the scar to deeper structures. A depressed scar, circular,

serpiginous, or semilunar in shape is suggestive of syphilis.

"Hypertrophied" scars are most frequent after infected wounds and in the negro. When the hyperplasia continues the growth is called a *false keloid.*

Painful scars are due to the pressure of the contracting tissue on a nerve filament. Relief is obtained by excising the painful area, or by finding and excising the involved nerve.

Ulceration is prone to occur in scars, because of their lack of nourishment, and for the same reason such ulcers are difficult to heal, unless the scar tissue is removed.

Epithelioma may develop in any scar, but is most frequent in those exposed to constant irritation, and in those following X-ray burns. Pain and lymphatic metastases are absent, so long as the growth is confined to the scar (Stewart).

CILIA.—See EYELIDS. (Trichiasis, and Distichiasis.)

CILIARY MUSCLE, PARALYSIS AND SPASM.—**Paralysis** of the ciliary muscle is known by destruction or diminution of the normal range of accommodation that usually corresponds to the age of the patient. The causes may be peripheral, as by atropin; or central, due to disturbance of the oculomotor nucleus. General intoxication by the poisons of infectious diseases, and conditions producing exhaustion or debility, may result in paralysis of the ciliary muscle. In this condition objects seem minimized—**micropsia.** The treatment is directed toward the cause. Locally, miotics, convex glasses, and electricity may be of value. See PRESBYOPIA.

Spasm of the ciliary muscle is a condition in which the range of accommodation is shortened, causing an emmetrope or hyperope to have myopic symptoms. In this condition objects appear enlarged—**macropsia.** The causes are the miotics, strain on the accommodation, and severe disease of the spinal cord. The treatment is directed toward the cause. Mydriatics give temporary relief. See HYPEROPIA, MYOPIA, ASTHENOPIA, MIOSIS.

CIMICIFUGA.—Black snakeroot; black cohosh. The root of *C. racemosa,* ord. *Ranunculaceæ.* A stomachic, antispasmodic, aphrodisiac, expectorant, and diuretic. Its action on the heart is similar to that of digitalis. It is efficient as a tonic in many cardiac diseases, in functional impotence, and in ovarian neuralgia. In simple chorea it ranks next to arsenic. It is used in chronic rheumatic affections of nerves and muscles, like myalgia, pleurodynia, sciatica, and lumbago, but is of little value in articular rheumatism. In atonic amenorrhea, menorrhagia, and sudden cessation of menses from cold or nervous shock, and as an expectorant in bronchitis and phthisis, it is useful; and in combination with gelsemium it is highly beneficial in the mental disturbances following pregnancy.

Preparations.—C., Extr. Dose, 1 to 6 grains. **C., Flext.** Dose, 5 to 20 minims. **C., Tinct.,** 20 percent in strength. Dose, 10 minims to 2 drams.

CINCHONA.—Peruvian bark. The official species are:

Cinchona, *Cinchona,* the dried bark of *Cinchona Ledgeriana, Cinchona Calisaya, Cinchona officinalis,* and of hybrids of these and of other species of cinchona, yielding, when assayed by a prescribed process, not less than 5 percent of total alkaloids.

Cinchona Rubra, *Red Cinchona,* is the bark of *Cinchona Succirubra* or of its hybrids, containing not less than 5 percent of cinchona alkaloids. From it is prepared the compound tincture of cinchona.

Cinchona bark contains 21 alkaloids, of which 4—quinin, cinchonin, quinidin, and cinchonidin—are the most important. Cinchona has the same physiologic action and therapeutic uses as its chief alkaloid, quinin. At first it promotes appetite, digestion, and the flow of saliva and of the gastric juice; long continued it causes gastric catarrh, indigestion, and constipation. See QUININ. It is also an astringent, bitter, and stomachic tonic, beneficial in atonic dyspepsia and adynamia, but especially useful in malarial affections.

In intermittent fever and certain nervous diseases:

℞.	Powdered cinchona,	ʒ vj
	Ammonium chlorid,	ʒ ij
	Powdered cinnamon,	ʒ j
	Syrup of orange,	ʒ iij.

Make into an electuary; a large teaspoonful 3 times daily.

For gastric atony:

℞.	Tincture of nux vomica,	ʒ j
	Compound tincture of cinchona, enough to make	ʒ iv.

Teaspoonful after each meal.

Preparations.—Fluidextractum Cinchonæ, *Fluidextract of Cinchona.* Dose, 10 to 30 minims.

Tinctura Cinchonæ, *Tincture of Cinchona,* has of cinchona 20, in alcohol 67 1/2, water 25 and glycerin 7 1/2. Dose, 1/2 to 2 drams.

Tinctura Cinchonæ Composita, *Compound Tincture of Cinchona,* has of red cinchona 10, bitter orange peel 8, serpentaria 2, in alcohol 85, water 7 1/2 and glycerin 7 1/2; and is intended to replace Huxham's tincture of bark. Dose, 1/2 to 2 drams.

Huxham's Tincture of Bark, 1788 (unofficial), is still used. Red cinchona, ʒiv, orange-peel ʒiij, serpentaria gr. lxxx, Spanish saffron gr. clx, cochineal gr. lxxx, brandy ʒxl, digested for 4 days, expressed and filtered. Dose, 1/2 to 2 drams.

CINCHONIDIN.—An alkaloid derived from cinchona. It is a crystalline substance resembling quinin in general properties. **C. Sulph.,** less bitter than quinin and valuable as an antipyretic. Dose, 1 to 20 grains or more. See QUININ.

CINCHONIN.—An official alkaloid derived from cinchona. It is a colorless crystalline body, similar to quinin in therapeutic effects, but less active, producing much headache and some muscular weakness. **C. Sulph,** soluble with difficulty in water, but soluble in acidulated water. Dose, 5 to 20 grains or more. See QUININ.

CINCHONISM.—The disagreeable symptoms that come on in persons who have an idiosyncrasy

to cinchona, quinin, or its salts, or who are poisoned by the drug. Buzzing in the ears is a most common result of overdosing by quinin, and severe epistaxis has ensued from the ingestion of 4 grains. Aural congestion and hemorrhage, deafness, amblyopia, and skin eruptions are possible complications. The bromid of sodium, 10 grains, with a little ergot, will give relief.

CINNAMIC ALDEHYD, *Cinnaldehydum*, C_9H_8O, is an aldehyd obtained from oil of cinnamon or prepared synthetically: soluble in alcohol, ether, and fixed and volatile oils. Dose, 1/2 to 2 minims.

CINNAMON.—The inner bark of the shoots of several species of *Cinnamomum*, native to Ceylon and China. Its properties are due to a volatile oil, which contains cinnamic aldehyd. It is an agreeable carminative and aromatic stimulant, useful, when combined with opium, for flatulence, colic, enteralgia, etc. **C., Aqua,** 2 parts of oil in 1000 of water. Dose, indefinite; average, 4 drams. **Fluidextractum Aromaticum,** contains aromatic powder in alcohol. Dose, 10 to 30 minims. **C., Oleum,** the volatile oil. Dose, 1/2 to minims. **C., Spt.,** percent of the oil in alcohol. Dose, 5 to 60 minims. **C., Tinct.,** 20 percent of the powdered bark in alcohol. Dose, 20 to 60 minims. **Pulvis Aromaticus** (aromatic powder), cinnamon, ginger, of each 35; cardamom, nutmeg, of each 15. Dose, 10 to 30 grains.

CIRCULAR INSANITY.—A mental disease characterized by regularly alternating and recurring periods of mental exaltation, depression, and sanity.

There is often hereditary predisposition. The exciting causes are any of those conditions that depress the brain or general system. There is no characteristic lesion associated with circular insanity.

It is essentially a chronic condition, and probably incurable. The disease usually begins as a melancholia, the depression being an apathy and torpor rather than a mental pain; and suicidal feelings and impulses are rare; this condition is soon succeeded by a mania, a mental exaltation with hyperesthesia and exaggeration of nervous functions, the reasoning power well retained; this is in turn followed by a lucid interval, often giving promise of recovery, to be sooner or later followed by another cycle. These periods follow one another with remarkable regularity, each being of the same duration. Rarely the various periods are of irregular duration. The general health is well maintained, the patient gaining in flesh during the stages of depression and lucidity and losing during the period of exaltation. The regularity of the different periods soon establishes the diagnosis. The disease is generally incurable.

Treatment consists in attention to the general health and meeting the symptoms of the different periods as they recur.

CIRCULATION, FETAL.—See FETUS (Circulation).

CIRCUMCISION.—See PENIS.

CITARIN.—Sodium anhydromethylene citrate. It liberates formaldehyd in the blood and thereby forms soluble combinations with uric acid.

Citarin is indicated in all forms of the uric acid diathesis including lithemia, gout, rheumatoid arthritis, and renal calculi. Dose, 15 to 30 grains well diluted with water.

CITRIC ACID.—$C_6H_8O_7$. Occurs free in lemons, black currants, bilberry, beets, and in various acid fruits. It crystallizes with one molecule of water in large rhombic prisms that melt at 100° F., are colorless, inodorous, and extremely sharp in taste. It is refrigerant, antiseptic, and diuretic.

CITRINE OINTMENT.—Mercuric nitrate ointment. See MERCURY.

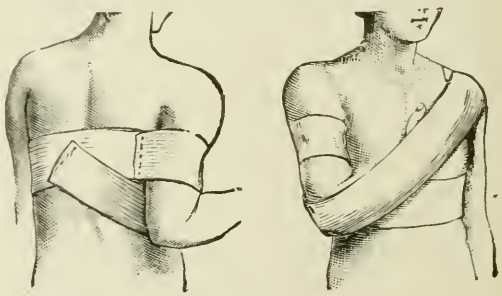
CLAP.—See GONORRHEA.

CLAVICLE, INJURIES.—Fracture of the clavicle is usually due to indirect violence, such as falls on the arm or shoulder; it is generally oblique in direction; it may be caused by direct violence, when it is commonly seated near the acromial extremity.

Symptoms.—The shoulder sinks *downward, forward,* and *inward*; the distance from the acromion to the sternum is less on the injured than on the sound side. In consequence of the sinking of the shoulder and the outer fragment, the sternal portion of the bone projects over the fractured extremity, and it may be distinctly felt by tracing the usual course of the clavicle with the finger.

Treatment.—A fractured clavicle is easily reduced, but the difficulty is to retain the broken ends in exact apposition. The arms and shoulders of the patient are to be firmly drawn backward by an assistant, when the fractured extremities come in apposition; the shoulders must be raised and supported in a direction *upward, backward,* and *outward.* The parts are then to be covered with adhesive plaster, and a bandage is to be applied, to retain them in their reduced apposition.

Sayre's dressing is one of the best that can be employed. Two strips of adhesive plaster 3 or 4 inches wide, and long enough to extend around the chest one and one-half times, are prepared.



SAYRE'S DRESSING.—(*Stewart.*)

Lint powdered with zinc stearate is placed in the fold of the elbow and between the arm and the chest. A collar of lint as wide as the adhesive strip is placed about the arm just below the axilla, and over this is applied the end of one of the strips of plaster, so as to form a loop; the strip is now used to pull the arm backward, and is fastened around the chest. The hand of the affected side is placed on the opposite shoulder, and the second strip of plaster, with a hole for the point of the elbow, is run from the back of the sound

shoulder, under the elbow of the affected side, over the sound shoulder, to the back, thus drawing the elbow forward and upward and, with the aid of the first strip, which acts as a fulcrum, forcing the shoulder backward and outward. A pad, held in place by a strip of adhesive plaster, may be placed just above the clavicle to press the fragment downward.

Velpeau's bandage is also often employed. (See BANDAGES.)

Dislocation.—The sternal end of this bone may be dislocated forward, and also backward; more frequently forward, when it is thrown upon the upper part of the sternum. When the dislocation is in front of the sternum, the reduction is easily effected; place the knee against the spine, draw the shoulders backward, and the clavicle will assume its natural position; then apply the clavicle bandage, placing a pad on the displaced end of the bone. The dislocation behind the sternum is a very rare occurrence; it may be produced by curvature of the spine, and in such case there is no method of reducing it.

The *outer extremity* of the clavicle is most frequently dislocated upward on the acromion; it is, more correctly speaking, a dislocation of the acromion from the clavicle, where the bone is thrown upon the *upper surface of* the acromion, or upon the *anterior part of the spine of the scapula.* It is usually caused by violent falls upon the shoulder.

Symptoms.—There is a distinct prominence, formed by the displaced bone, upon the surface of the acromion, which disappears on raising the arm; the limb hangs closely along the trunk, the shoulder is somewhat flattened. The facility of reduction, and the prominence of the clavicular portion of the trapezius muscle, indicate the nature of the accident.

Treatment.—Reduction is effected by raising the shoulder, drawing it backward and carrying it outward by placing a pad in the axilla and bringing the elbow well to the side. After reduction, the treatment is the same as for fracture of the clavicle. A thick pad, with the base directed upward, is placed in the axilla, and the arm and forearm must be well secured to the chest; direct pressure must be made by means of a pad and guttapercha plate laid on the projecting clavicle, and strapped tightly down by a band passing parallel to the arm and under the flexed forearm. This is retained in position by being attached to a strap passed around the opposite axilla.

CLAVUS.—See CORN.

CLEARING AGENT.—A substance used in microscopy to render tissues transparent and suitable for mounting. *To replace alcohol in a dehydrated section,* creosote, turpentine, xylol, and the oils of bergamot, cedar, cloves, and origanum are used. *For celloidin sections,* bergamot or cedar oil or creosote is preferable. *Before mounting vegetable sections,* glycerin, solution of carbolic acid, liquor potassæ, alcoholic solution of postash, liquor ammoniæ, solution of chloral hydrate, Javelle water, Labarraque's solution, are used. See PATHOLOGIC TECHNIC.

CLEFT PALATE.—A congenital defect due to an arrest of development of the processes that normally grow inward from the superior maxillary and palate bones, and meeting each other and the vomer in the middle line, and the premaxillary bone in front, form the hard and soft palates. This arrest of development may be complete, the fissure extending in the middle line through the uvula and the soft and hard palates, and hence through the alveolar process in the line of suture either on one or both sides of the premaxillary bone. It will in this case generally be combined with double or single harelip respectively. When the arrest is only partial, the cleft may extend through the uvula alone, or through the soft palate as well, or through the soft palate and part of the hard; while in other instances the alveolar process only on one or both sides of the middle line may be notched, as occurs so often in harelip. The vomer, which is continuous in front with the premaxillary bone, either presents a free border in the middle of the cleft or is attached to one or the other margin of the cleft.

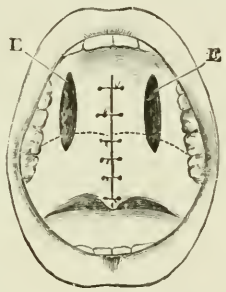
The consequences of cleft palate vary with the age of the patient and the extent of the cleft. In infancy suction and deglutition are seriously interfered with, while later the voice, articulation, taste, smell, and hearing may all be impaired.

Treatment.—The infant, if unable to take the breast in an erect or semirecumbent posture, must be fed with the mother's milk by a spoon passed well to the back of the mouth, or by a feeding-bottle with a large teat to act as a plug to the cleft. The operation for the cure of the deformity should be undertaken before the child begins to speak, which is generally about a year later than usual; but not in infancy, as bleeding is then badly borne, and the cleft of the bony palate diminishes in width during the first 3 years of life. Infants moreover, are very liable to such ailments as catarrh of the pharynx and lungs, and coughing and sneezing tend to tear the parts asunder. The cleft in the hard and soft palates should be closed at the same time. Harelip, if present, should be operated on in infancy.

Staphylorrhaphy, or Closure of the Soft Palate.—Chloroform having been given by Junker's apparatus, with the tube passed through the nose and the mouth widely opened by a Smith gag, which depresses the tongue at the same time, one end of the bifid uvula is seized with long forceps and the edge of the cleft pared from below upward, and the paring repeated on the opposite side. The uvula and the lower part of the palate are then united with horsehair; the upper part with silver wire. The wire sutures are best passed by Smith's needle, by which they can be carried through both sides of the cleft by one transit of the needle. This needle has "a small reel attached behind the handle to hold the wire, and a small serrated wheel half way up the handle to protrude the wire from its tubular point." The horsehair is passed across the cleft, and as the point of the needle protrudes from the palate, the end of the horsehair is seized and drawn out by nibbed palate forceps or by the suture-catcher, and the needle withdrawn. The silver sutures should be fastened by a wire-twister and cut

off short, care being taken to hold the edges of the cleft merely in apposition and not to apply any tension. The horsehair should be tied with a triple surgeon's knot. When the parts have been brought together, any undue tension should be relieved by making lateral incisions through each side of the soft palate parallel to the cleft and just internal to the hamular process, with a tenotome on a long handle. By these incisions the levatores palati muscles are divided. The palatopharyngei may also be divided, if necessary, by notching the posterior pillars of the fauces with scissors.

Uranoplasty, or Closure of the Hard Palate.—The soft palate having been previously brought together in the way described, the operation on the hard palate may be begun at that stage when the tension becomes such that the soft parts can no longer be brought together. The edges of the cleft having been pared, an incision from 1/4 to 3/4 of an inch long should be made on each side of, and parallel to, the cleft through the mucoperiosteum down to the bone. The incisions should fall a little distance from the alveolar process, so as to avoid wounding the anterior palatine artery. Into one of these incisions a raspatory or an aneurysm needle with a short curve should be introduced, and the mucoperiosteum separated from the bone along the whole length of the cleft in the hard palate, avoiding the neighborhood of the posterior palatine foramen, through which the posterior palatine artery runs. The attachment of the mucoperiosteum to the posterior margin of the hard palate should be divided with curved scissors passed through the cleft and behind the soft palate, which should be drawn forward to facilitate this step of the operation. Pressure should be made upon the parts with a small sponge by an assistant, while the mucoperiosteum is being separated in like manner on the opposite side. Wire sutures should now be passed, in the way described for uniting the soft palate, and any tension relieved by prolonging the cuts made for the introduction of the raspatory forward or backward, as the case may require. Hemorrhage, though often sharp, is seldom severe, and may generally be checked by pressure or by syringing with ice-cold water, the head being turned over to one side to let the blood escape; or, if it becomes serious, by plugging the posterior palatine canal with a small peg of wood.



Position of the Lateral Incisions, E, E, through the Mucoperiosteum, in the Operation for Cleft of Hard Palate. (*After Bryant.*)
The dotted line indicates the line of junction of the hard and soft palates.

After-treatment.—The patient should be fed on iced milk for the first few days, and then on soft food for a fortnight. The sutures may be left in for 3 weeks or a month; if the patient is unruly, they should be removed under chloroform. The cleft should heal by first intention, and the lateral cuts for taking off tension, by granulation. If a portion of the cleft fails to unite by first intention, it will often heal up subsequently by granulation; if not, a second operation must be undertaken. It is somewhat doubtful whether the mucoperiosteum ossifies.

CLIMATOLOGY.—It is very common for persons to speak of climate and weather as the same thing, while in truth there is a difference between them.

Climate consists of the values of the average of the current conditions of the weather in a given district, taken in connection with its soil, vegetation, topography, latitude, and elevation.

Weather consists of the individual atmospheric conditions experienced from day to day.

A visitor to a resort may encounter for a time weather that is below the average, yet the weather of the season or year may show an average equal to its reputation, and so he may gain in the long run the benefit for which he came.

Soil.—The quality of the soil at a resort is of great importance. Two different resorts with the same rainfall may have very different degrees of dampness, because of the difference in the capacity of the soil for holding or absorbing moisture. More humidity arises from arable than from meadowland. Shade trees increase both the humidity and the coolness of the air. Evergreens require and give off less moisture than deciduous trees. The climate is greatly modified by the configuration of the ground; thus, that of a plain country is usually windy, variable in temperature, and generally more or less dry. Mountain slopes vary in temperature and dryness according to their aspect toward the sun and their relation to the ocean and to the main direction of the winds.

The sunshine as it strikes the earth falls upon the mountain sides more at a right angle than upon the valleys or plains, and so has greater force; and after sundown the cold, and therefore heavier, air sinks to the bottom of the valleys, while the warmer and lighter air rises along the slopes. For these reasons the mountain slopes are usually warmer in the evenings and cooler in the mornings than the valleys. The day temperature of a valley depends upon its aspect toward the sun and wind. The walls of a valley, while they give shelter from wind, detract from its ventilation and sunniness. The air of a valley is usually damper and more sedative than that of mountain slopes or of plains.

Air, like water, tends to purify itself by motion; so in places where causes exist that make the air impure, the presence of breezes has a mitigating influence. A slight decrease in oxygen or a slight increase in carbonic acid in the atmosphere that surrounds us is of enormous relative importance. Ozone, or allotropic oxygen, is most abundant in open places, such as the ocean, deserts, and mountains. It is an evidence of the abundance of oxygen.

Wind.—Continental and oceanic currents have more to do with the occasional big stroms than with the daily breezes. At the seashore, owing to the difference in the heating of the air that lies over the surface of the sea and that that lies over

the land, there is usually a breeze blowing from the ocean during the day and from the land during the night; and where plains border upon mountains, the day breeze is from the plain and the night breeze from the mountain, because of the difference of heating, owing to the greater obliquity of the sun's rays falling on the plains than on the mountains. In the valleys the day breeze is from the bottom of the valley, where the air is more quickly warmed, toward the mountain slopes; and the night breeze descends from the slopes, where the air has cooled more rapidly, to the valleys. Winds ventilate and purify the atmosphere, but they transport dampness, heat, cold, and impurities, and so they may to some extent engraft one climate upon another. Wind increases or decreases the climatic characteristics of a resort. A cold wind is more severe than still cold; an extremely hot, dry wind, such as the sirocco or chinook, is more irritating or trying than still heat of the same temperature, and a cold, damp wind is more depressing and dangerous than still, damp cold. On the other hand, with moderate warmth, either damp or dry, a breeze, if not directly stimulating, may yet be refreshing through causing increased evaporation from the skin, even when the actual temperature of the air is not lowered. With moderate cold a breeze is usually stimulating whether it is damp or dry.

Water.—The modification of climate by water is chiefly through the increase of atmospheric humidity. A light rainfall does not necessarily mean a low humidity; on the contrary, the resort may have a very damp air, partly because the rainfall is light; for if air charged with moisture remains at a temperature that enables it to retain that moisture, it follows that the humidity will be high. The number of rainy days in a resort is of importance as limiting the hours of exercise, and, also, the time of the day or night when rain occurs has an influence on the value of the resort. Rain in moderation is often beneficial in purifying the atmosphere, and moderate cloudiness is often a relief from the glare and heat.

The proximity of seas, lakes, and rivers increases the humidity and the local rainfall, and, through the difference in radiation from the dry and liquid surfaces, intensifies the day and night breezes. If those bodies of water are at all extensive, the breezes thus caused carry an abundance of the pure air over the land.

Dew.—A dry soil with sparse vegetation lessens dew deposit. A low dew-point and a low relative humidity at a resort are evidences of the infrequency of dew, mists and fogs.

Sunlight.—The effects of the light of the sun, apart from its heat, check the growth of bacteria and increase oxidation. Sunlight has a greater intensity in dry climates, and lasts longer during the summer in high than in low latitudes. While during the winter the hours of sunshine are shortened, still, as a general rule, the temperature of a resort rises with its proximity to the equator, though its temperature may not be entirely governed by its latitude. Its warmth may be increased by the shelter from cold winds formed by a mountain range, or by the nearness of warm water currents, such as the Gulf Stream and Kurosiwa, which warm the air-currents passing over them toward the shore. On the other hand, a resort may be colder owing to the proximity of large bodies of cold water, of Arctic currents, of snow fields, of glaciers, or from its altitude, or from frequent cloudiness. All these matters are therapeutically of greater importance than the mean annual temperature, which may be the same, or which may approximate that in climates which are in reality very different. The temperatures of the seasons, of day and night, and the range, are of most importance to the invalid, as hindering or promoting the opportunities for outdoor life. Humidity increases the effects of heat and diminishes those of cold.

Electricity.—The electricity of the earth is negative and that of the atmosphere is positive. Its therapeutic effects are little understood.

Heat promotes growth, but diminishes muscular power. The appetite and the amount of food needed are also lessened. These effects of heat are intensified in proportion to the increase of atmospheric humidity.

Heat is less healthful than cold. This is shown by the fact that the rate of mortality increases toward the equator.

Cold limits growth, but tends to preserve it and to increase muscular power. The appetite and the need of food are increased, as are also the waste of substance and the exhalation of carbonic acid. These effects are lessened in proportion to the increase of atmospheric humidity.

Humidity, as has been stated, increases the special effects of heat and diminishes those of cold. Absolute humidity, as it increases, lessens the amount of water vapor that is given off from the lungs and from the surface of the body. Relative humidity, as it increases, has the same effect, because warm air contains more vapor than cold air. Dry air, when cold, lessens the bodily temperature by increasing the evaporation from the body, though, because of the lessened evaporation from the skin, the depressing effect of cold can be guarded against by extra clothing. Thus dry air, whether hot or cold, is less depressing than damper air at whatever temperature it may be. Wind increases these effects.

Air Pressure.—The phenomena that appear in consequence of the marked increase or decrease of barometric pressure upon living beings is due almost entirely to the difference of the amount of oxygen in the air.

Increased barometric pressure as a factor of climate is of very slight importance, as it is only found in a few places and in a very moderate degree. It is through the study of caisson disease that the effects of increased air pressure are best known. More oxygen is absorbed and more carbonic acid exhaled, and the effects are the exact opposite of those brought about by decreased air pressure.

Decreased Barometric Pressure.—In considering its effects upon the human economy as exhibited at high altitudes, the great difference must be recognized between those that are immediate and

those that ensue after acclimatization has taken place. At first the phenomena are the direct result of oxygen starvation. There are hyperemia of the lungs and skin, with anemia, or rather spanemia, of the internal organs, increased pulse rate, lowered tension, rapid and shallow respiration, a tendency to nausea and vertigo. Within a month, in normally constituted beings, and in invalids according to their condition, there is a relief from the oxygen starvation, owing to an increase in the number of red blood-cells and hemoglobin in direct ratio to the decrease of air pressure. By this time the respiration has become normal in rate, but deeper, from an increase of chest expansion; the heart cavities are extended and its muscle strengthened, so that the pulse becomes normal in rate and increased in strength and volume; the appetite and power of assimilation are also unusually developed.

The classification of climates is the crux of the climatologist. Because general laws are so greatly modified by local peculiarities and seasonable variations, and because of the intimate relation that the various climatic factors sustain to one another, the subject can only be treated in a broad general way. The principles of the subject, however, are sufficiently definite to allow of a physical classification into sea and land climates, and into a meteorologic classification.

Sea Climates.—The climate of the ocean is always damp, by reason of the constant evaporation of the sea-water, which keeps it equable in temperature.

Owing to the humidity of the air the radiation from the body is increased, and when the air is cool, it seems to be cooler than it really is. Sea-air has a sedative effect upon the nervous system; increases metabolism, weight, appetite, and inclination to sleep, and so, to those with whom it agrees, the air of the ocean acts as a sedative tonic.

Island Climates.—The climate of small islands, unless they possess high mountains with deep valleys or thick forests, closely resembles that of the ocean, and is often as beneficial, without the objections that may justly be urged against life on board ship.

Coast Climates.—Coast climates have some of the advantages of the ocean and of islands, as well as that of inland; but in consequence of the difference in radiation of heat from the land and from the water, they are subject to much greater variability, and are less equable, and make a greater demand upon the strength of the invalid. There are, however, some coast climates that are so sheltered from the land breezes that they very closely resemble the climate of the ocean.

Inland climates of low elevation (under 2500 feet) lessen in humidity as the distance from the ocean increases, though this quality is often modified by the proximity of mountain ranges or of bodies of fresh water. Such climates exhibit a decreased barometric pressure as the land ascends, but they are less equable. The changes from day to night and from season to season are more marked.

All low inland climates of an extreme temperature, either hot or cold, are, of course, unsuited for therapeutic use.

Moderately moist, warm climates usually possess equability and a moderate rainfall, thus allowing of pleasant outdoor life, and exerting a sedative effect upon the mucous membranes and nervous system. Southern California, southeastern Georgia, Florida, and the Riviera are good examples of such climates. In these places delicate persons can escape the rigors of their home winters and so invalids to whom climatic extremes are unsuited, resort to them with benefit.

Moderately moist, cool climates are, for the most part, negative in their characteristics and effects, but they are rather more stimulating than the last group considered, and are well suited to those who require a slight change, mild stimulation, and active life. It is in these climates that most of the mineral springs are found, such as Saratoga and Baden-Baden.

Many mountain resorts below 3000 feet, where there are pine woods and plenty of waste land, so that hunting and camping can be enjoyed, have such climates. The Adirondack, the Allegheny, and the Cumberland Mountains contain such resorts.

Moderately dry, warm climates have a positive and stimulating character, and are of much value when the more extreme effects of high ground are not desirable. They would be more frequented were it not that their chief qualification, that of dryness, has prevented them from being settled, and so they are likely to be deficient in accommodations and amusements. For permanent residence they have the objection of being too hot in summer. They are desirable especially for the purity and abundance of the air and for the simple open-air life that may be led by those who resort to them. Egypt and Algeria are the most frequented and best known of such climates, but the lower ground of Arizona, New Mexico, and southeastern California is coming into use, and, except in the matter of accommodations, interest, and enjoyment, the American climates offer greater advantages.

Moderately dry, cold climates, such as the winter climates of parts of Canada, Dakota, Nebraska, and Minnesota, are healthful and stimulating to the robust, but are too severe for all but the strongest class of invalids.

Depressed climates are found in the sinks, notably around the Dead Sea, the Caspian Sea, and in southeastern California. Being surrounded by deserts, these sinks are hot and dry, and enjoy in a moderate degree the therapeutic advantages that follow the use of compressed air; but they are usually monotonous and disagreeable to reside in.

Elevated Climates.—The important characteristics of elevated climates are present, but not marked, below an altitude of 4500 feet. These climates have a cool air and a wide range of temperature—that is to say, the difference shown by the thermometer in the sun and in the shade, during the daytime and at night, is very decided. This is especially true in the winter, though the seasonable

changes themselves are not very extreme. The classification of a climate as "dry" does not necessarily imply a scanty precipitation, but as a good deal of rain or snow falls at a time, the number of clear days is very large. The direct rays of the sun have exceptional power, both for light and heat, but the temperatures are not excessive; for, as a rule, temperature decreases a degree for every 300 or 400 feet ascended. Winds are of frequent occurrence, but are rarely dangerously high. The air is aseptic, containing few germs and a large amount of ozone and positive electricity. The soil is likely to be of a composition that promotes good drainage, and it is, therefore, usually dry; but the chief claim of elevated climates upon the attention lies not in these details, important though they undoubtedly are, but in the lessened barometric pressure, as causing blood regeneration and increased power of the lungs and heart.

Winter days in such localities usually have warm sunlight and cool shade, the nights being cold; but the night air, like the air in daytime, is ordinarily dry.

Spring is, as a rule, the least desirable season, melting snow on the mountains making it objectionable to many invalids, though this is less apparent on the high continental plateaus, such as are found at the base of the Rockies, than among the mountains of Switzerland.

During summer it is cool in the shade and at night. The sun is hot, but its heat is usually modified by the cloudiness that accompanies the short thunderstorms occurring in the afternoons.

Autumn, in the elevated resorts of the United States, is the most desirable season; but in Europe the early falls of snow with intervals of thaw make it less beneficial than either winter or summer. The dryness of the air modifies the effects of both heat and cold.

Summer Climates.—In estimating the value of a summer climate the question of greatest importance is the sensible temperature—that is, the effect of the evaporation from the surface of the body in lowering its internal temperature. This evaporation, of course, increases as the humidity of the air diminishes. For these reasons the extremes of summer heat in Eastern cities are hardly bearable, while the same or actual higher temperatures in many Western elevated districts are quite compatible with a comfortable existence.

Winter Climates.—In choosing a winter climate other factors than the temperature are to be considered. The value of similar temperatures in winter is different from their summer value. This may be judged by the feeling of the air, which in a very moist climate may be chilly at 56° F., while in a very dry climate at the same temperature no feeling of chilliness will be noticed. Dry, cold air is stimulating. In the selection of a satisfactory winter climate only a moderate amount of cold is desirable.

A cool, dry atmosphere will be found near the Rocky Mountains above latitude 35 degrees. **A warm, dry atmosphere** is found in western Texas, southern New Mexico and Arizona, and in southeastern California.

Owing to the warm, humid air from the Pacific Ocean, the greatest softness and mildness of climate in the United States are found along the California coast, the daily variation of temperature during the winter months scarcely exceeding 2° F. Arizona and the interior valleys of California average 3°, as do the Gulf coast and Florida, south of St. Augustine. The rest of the country varies from 4° to 6°, increasing toward the Canadian border; from the Gulf coast northward the variability increases 1° or 2° during the months of January to March.

The resources of the United States in the matter of climate are extremely varied, from the mountains, lakes, rivers, and elevated plains along the Canadian border to the extreme southern limits of Florida and Texas.

The best climatic advantages of the Alps can be found in an improved form—because available all the year round—in the ranges, valleys and plains of the Rocky Mountains; climatic conditions similiar to those of Egypt prevail in the deserts between El Paso (Texas) and Palm Springs of Mohave (California); while the equable climate of the Riviera, with the same advantage of the protection afforded by the mountains above the coast, with a smaller amount of annual rainfall and less discomfort from harsh, cold winds, is to be found in southern California. Florida, too, offers an asylum for winter visitors, especially on the Atlantic coast, at St. Augustine and southward to Lake Worth; while Key West is an excellent example of a warm, equable, and very moist climate.

Among interior health resorts in the Southern States, Aiken, Thomasville, and Asheville have many advantages for invalids needing moderate elevation with medium warmth, dryness, and good accommodations.

Climatology in Disease

Phthisis.—In passing to the consideration of the treatment of disease by climatic change, it is best first to discuss its effects upon phthisis, as the most important and most frequent cause of invalids changing climates. Speaking broadly, in their influence upon phthisis, cold is better than heat, dryness than dampness, sunshine than cloudiness, high ground than low; wind in moderation is healthfully stimulating, unless it is damp, in which case it is depressing. Variability of temperature with dryness is generally beneficial, and with dampness the reverse. For most cases of phthisis the ideal condition of the atmosphere is one in which cool, dry air can be taken into the lungs while the surface of the body is pleasantly stimulated by the warmth and light of bright sunshine, and in which the chamber windows may safely remain open at night, so that the patient may breathe dry air while sleeping under a warm cover.

The first essential of air is plentifulness. For this reason it is better to be outside than inside the house. Within, the air changes too slowly. The next essential of the air is purity.

In the early stage of pulmonary tuberculosis, before the phthisis or wasting is marked, almost any change of climate where there is abundance of

pure air, such as is usually found on the ocean, seashore, desert plains, moorlands, or mountains, is beneficial and often curative. The climate may be damp or dry; but if damp, it may be cool, but not cold; if dry, it may be either hot or cold. That patients will get well under all kinds of climatic conditions, provided they get abundance of pure air by living out of doors, is shown by the results obtained, even in England, by the open-air treatment; but to insure a permanent cure in a majority even of the earlier cases, or an arrest in those in whom wasting has begun, a more radical climatic change is demanded. When we consider that, though all tuberculous cases are dependent for their special character and development upon the same cause—namely, the tubercle bacillus—yet we must remember that the antecedent causes that prepare the tissues of the patient for the reception and which foster the growth of the disease are often very different, and so the climate that tends to remove these underlying conditions, though it may not be ideal for the cure of the tuberculosis pure and simple, is often the best for the individual case. Again, the personal equation enters into the problem of selecting the climate, and it is unwise to place a patient in a climate, however otherwise suitable, if he is mentally depressed by the surrounding circumstances of his residence there. Therefore, to some extent, in choosing the appropriate climate each case is a law unto itself. There are, however, certain general guiding principles that have been established (1) from a study of the geographic distribution of phthisis. This study (which was chiefly made by Hirsch) shows that in isolated or sparsely settled places phthisis is infrequent, because the element of infection is largely absent; that among people given to outdoor occupations it is less frequent than among those who pass their time in houses; that phthisis is less prevalent in dry than in damp climates—this, however, applies more to the soil than to the air; that the most remarkable diminution in the distribution of phthisis is found on high ground, the rate diminishing in proportion to the elevation above sea-level, and this, as shown by the investigations of Müller and others, is not dependent upon, though modified by, the density of the population and the nature of the occupation, and other conditions of the residents.

(2) The guiding principles have been established by clinical evidence. In order to ascertain, as far as possible, what climates have been found best for the majority of phthisical health-seekers, a collection has been made of all the reports to be found of the influence of change of climate upon phthisical persons. A search through all the literature known resulted in finding some 9000 cases. In separating these into groups under the chief types of climates resorted to—namely, ocean, island, seashore, lowland, desert (also lowland), and highland climates—the two facts were clearly demonstrated that, as a rule, the subjects of phthisis improve in greater numbers as they remove from the sea to the interior of the continent, even when the elevation of the ground is but slightly increased. The marked increased percentage of benefit in those resorting to desert climates over those who frequented the sea and its borders proves very clearly that dryness is better than dampness, while the still greater percentage of improvement indicated in cases resorting to high climates, even over the dry climates of the desert, proves the second fact—namely, that diminished barometric pressure is even more powerful than dryness in arresting the progress of phthisis. So it may be said that while desert air is good, mountain air is better. The reasons for this undoubtedly lie mainly in the increase of the hemoglobin and of the red blood-cells brought about by the diminished air pressure with the accompanying increase of the capacity of the lungs and the increased strength of the heart, and probably the increased germicidal power of the blood. These general propositions may be considered proved; but to distinguish between the effect of climate upon the different forms of phthisis suitable for the different climates, it is most convenient to group them as the tuberculous, catarrhal, and pneumonic, as giving their chief characteristics and tendencies, though remembering that in all cases tuberculosis is present, generally catarrh, and often pneumonia. In this sense, then, the broad statement may be made that the chief climatic factors are of value in the order given.

For the tuberculous: first altitude, second cold, third dryness.

For the catarrhal: first dryness, second medium elevation, third warmth.

For the pneumonic: first warmth, second moderate humidity, and third a low altitude.

Tuberculoses other than pulmonary, as a general rule, are benefited by climate along the same lines as the pulmonary cases.

Convalescents from croupous pneumonia, pleurisy, and empyema should go to a warm seashore, or to a dry, sunny, inland resort; but later the cure is often hastened by removal to higher altitude and, therefore, to a more bracing climate. The high altitudes are often of great value when the heart is not involved and when there is sufficient breathing space.

Catarrhal pneumonia generally is better in a more equable climate and lower altitude.

Chronic bronchitis does best in low, warm, dry, sheltered resorts.

Asthma.—The climate must be stimulating or sedative, according to the neurotic conditions, and warm or cold, damp or dry, according to the catarrhal conditions. Both increased and decreased air pressure, as demonstrated in the laboratory and by climatic change, markedly benefit asthma.

Heart-disease is usually somewhat affected by any moderate climatic change, and greatly affected by a considerable change, especially in elevation. In the young, with fair compensation, and if great watchfulness is exercised, a higher altitude is often of the greatest benefit; but most cases, and particularly cases occurring in persons past middle life, are best suited to a sedative, warm, equable climate.

Nervous Disorders.—Organic lesions, if acute

or inflammatory, need low, sedative climates; when stationary and anemic, to a bracing seashore or even a high altitude is often the best change. In neurasthenia the first essential of a climate is to give rest; the second to cure the anemia. The irritability of the nervous system that is inherent is most relieved in a sedative air; the irritability that is caused by the anemia is soonest removed by change to a high altitude, or if this is too great a change, then to a bracing seashore or an ocean voyage.

Kidney-diseases.—The majority of cases do best in warm, dry, low climates; but when there is great anemia, a cool, dry, and even high climate is often better.

Liver-diseases.—Serious organic cases should not be subjected to marked climatic change unless it is necessary to remove them from a bad climate, such as that of a malarial or tropic country. In functional disease, however, a radical change is indicated. The fair and full-blooded are usually less subject to hepatic disturbance at the seashore, and the dark-skinned and anemic on the mountains.

Stomach disorders need climatic change in accordance with their causes.

Gout and rheumatism are more often benefited by a warm and dry than by a cold or damp climate.

CLONUS.—Involuntary, reflex, irregular contractions of muscles when put suddenly upon the stretch. According to the part stimulated, the phenomenon is spoken of as *ankle-*, *jaw-* or *wrist-clonus*, etc. See Reflexes.

CLOVES (Caryophyllus).—The dried flower buds of *Eugenia caryophyllata*, distinguished by their aromatic odor and pungent, spicy taste. Its properties are due to a volatile oil, which is antiseptic, stimulant, and irritant. It also contains a crystalline body, *eugenin*, $C_{10}H_{12}O_2$, a camphor, *caryophyllin*, $C_{10}H_{16}O$, *caryophyllic acid*, and tannin, gum, etc. It is useful as a stomachic, and to prevent griping when combined with purgatives. As an external application it is efficiently employed for anesthetic and counterirritant purposes, to relieve pain in chronic rheumatism, myalgia, lumbago, superficial neuralgia, toothache, etc. The oil of cloves is an effective deodorizer for sponge-tents, a good application to a painful tooth, and is occasionally applied over the course of an aching nerve with relief to the pain. The oil is an efficient local application for pediculus pubis and similar parasites. It is in common use as a clarifying agent in microscopy. Cloves are one of the ingredients of the **spice poultice**, which consists of powdered cloves, ginger, and cinnamon, each 1 or 2 teaspoonfuls; flour, a tablespoonful; whisky, enough to moisten so as to spread on a soft flannel. It is a useful counterirritant for applying to the stomach of children with diarrhea.

Preparations.—**Oleum Caryophylli**, *oil of cloves*—a volatile oil distilled from cloves, soluble in alcohol, and of sp. gr. 1.060. It consists of a light and a heavy oil, the latter containing *eugenol*, a phenol, and *caryophyllin*, which yields as a product of its oxidation, *caryophyllinic acid*. Dose of the oil, 1 to 4 minims.

Eugenol—an unsaturated, aromatic phenol, miscible with alcohol in all proportions. Dose, 1 to 5 minims.

CLUBBED FINGERS.—Knobbed deformity of the fingers' ends, with curvature of the nails, seen in some cases of pulmonary and cardiac disease.

CLUB-FOOT.—See Talipes.

CLYSTER.—See Enema.

COAL-GAS.—Poisoning by coal-gas most commonly occurs from the gas-tap in a bedroom being left open, but it is sometimes due to a sudden rush of undiluted gas from meters or mains. In severe and fatal cases the symptoms are nausea or vomiting, vertigo, loss of consciousness, deep coma and muscular prostration, livid features, stertorous breathing, and frothing at the mouth. Death usually occurs quietly in coma, but occasionally with convulsions. The fatal period is variable, and remittent symptoms often give rise to fallacious hopes of recovery. The odor of gas on the clothes, breath, and perspiration, which continues after removal from the polluted atmosphere, is the best indication of the cause of coma.

Instant removal from the vitiated air is the first thing necessary, and then attempts to oxygenate the blood. Artificial respiration for at least 2 hours, and reflex stimulation of the face, chest, etc., by cold and heat and slapping, may be practised. In severe cases pure oxygen gas should be given. Venesection with infusion of normal salt solution is a plan of treatment likely to succeed. See Artificial Respiration, Asphyxia.

COCA.—See Erythroxylon.

COCAIN.—$C_{17}H_{21}NO_4$. The chief alkaloid extract of *Erythroxylon coca*. It is at first stimulant and afterward narcotic, and resembles *caffein* in its action on the nerve-centers, and *atropin* in its effects on the respiratory and circulatory organs. Its long-continued use (*cocain habit*) is followed by insomnia, decay of moral and intellectual power, emaciation, and death. Locally, it is a powerful anesthetic in a limited area of surface. It acts most rapidly on mucous tissues. Applied to the conjunctiva of the eye, it causes dilatation of the pupil and slight paralysis of the function of accommodation. Applied to the tongue, it temporarily destroys the sense of taste. Dose, 1/8 to 1 grain.

It is used principally to induce anesthesia for purposes of surgical application and exploration, and to secure temporary constriction of the smaller blood-vessels. After the impression last named ceases, a stage of dilatation ensues. It is thus hemostatic only in its primary impression, the secondary impression tending to induce bleeding. A cocainized surface is at first paler and more compressed than is the normal, and afterward it becomes reddened and somewhat turgescent. Since dilated states of vessels favor secretion, it follows that the secondary impression of cocain is accompanied by increased outflow when the application has been made to a gland-bearing surface. The effects above named will be varied by the peculiarities of the anatomic region, habits of patients, etc. Thus, pallor is more noticeable in the conjunctiva than elsewhere. The constricting and dilating effects in erectile tissues are espe-

cially marked in the nasal chambers, and the secretory effects are often noticeable in the larynx, where the untoward result of a full impression is noticeable in the impaired quality of the voice.

An overimpression of cocain may arise from almost any strength of solution, though it is more likely to occur in concentrated preparation; marked toxic symptoms have been known to follow an injection of a few drops of a 4 percent solution into the urethra; while, on the other hand, cases are reported in which large quantities of the drug have been injected without producing any unsought-for effect.

Cocain intoxication is characterized by vertigo, depression, nausea, difficult articulation, followed by restlessness. Flushes of heat are sometimes complained of. The duration of the impression lasts from 5 to 8 hours. Many cases of cocain poisoning have been reported. In all operations demanding the use of the knife it is well, after an application of cocain, to allow the parts to bleed freely after incision, in order to remove as much as possible of the drug from the circulation. It has been noted that persons addicted to alcoholic stimulants are peculiarly susceptible to the action of cocain. Cocain intoxication appears to be oftener seen after application about the head than elsewhere. For the relief of cocain intoxication inhalations of the nitrite of amyl should be resorted to, and the impression of caffein secured, while the patient's strength is being sustained. Among other measures may be mentioned the exhibition of belladonna, the inhalation of the vapor of ammonia, and external friction.

Cocain Anesthesia.—The following rules are requisite for the safety of the patient: The solution should always be fresh, the patient should invariably be in the recumbent position, and no longer than 5 minutes should elapse before operation is begun. Injections about the head are more dangerous than in the trunk or limbs. A 20 percent solution may be applied to the larynx, whence it is less readily absorbed than from the pharynx or esophagus (Stoerk). The ordinary strength is from 20 grains to 1/2 of a dram to the ounce. A 2 percent solution is used in the eye. Adrenalin chlorid solution is frequently used with the cocain in order to increase the effect of the latter. For hypodermic use, a 4 percent solution of cocain is used by Wyeth. Half a minim of this strength injected into the Malpighian layer of the derma will whiten the epidermis. The anesthesia spreads from 1/4 to 1/2 of an inch from the center of the injection. The needle, in hypodermic cocain anesthesia, is withdrawn and again inserted 1/4 to 1/2 of an inch from the first point of insertion, and another half minim or minim forced from the point at the same level, and the incision made previously to second entrance of the needle over the first area of anesthesia is now extended, and so on. An incision 1 inch long may be made into the subcutaneous areolar tissue after using in this manner 2 to 4 minims of a 4 percent solution. See also Intraspinal Anesthesia.

Preparations.—**C. Hydrochloridum,** $C_{17}H_{21}NO_4$. HCL, most commonly used for local anesthesia in 2 to 4 percent solution. Dose, internally, 1/8 to 1 grain; by hypodermic injection, 1/8 to 1/2 grain. **C. Oleas,** a 10 percent solution in oleic acid. olive oil and alcohol, for external use. See Antinarcotic Legislation, Harrison Law.

COCAINISM.—This pernicious habit is especially prevalent among physicians and others who are active mentally. A neurotic tendency predisposes to it. The use of cocain is an American practice and is extensive among the negroes of the South. Morphin habitués may acquire the habit by resorting to the drug as a substitute for morphin. It is estimated that over 4/5 of the output of cocain goes to habitués. The habit is a direct incentive to crime, the individual entirely losing his moral sense. Symptoms not unlike those due to alcohol and opium may arise. The patient is subject to insomnia, hallucinations and mental delusions especially of a persecutory nature; there is a peculiar sensation of worms or insects beneath the skin; nystagmus, ocular and circulatory disturbances may also occur. See Antinarcotic Legislation, Harrison Law.

Treatment consists in absolute withdrawal of the drug. It is imperative in cases complicated with alcoholism or morphinism that the patient be confined in an institution. Tonics and stimulants and good nourishing food are indicated. See Lambert Treatment for Narcotic Addiction.

COCCYGODYNIA.—An obstinate affection of the region of the coccyx, marked by severe neuralgic pain radiating from the sacrococcygeal joint. It occurs chiefly in parous women, though it has been ascribed to accidental injury, to excessive horseback riding, and to uterine or ovarian disease. Generally, no external evidences are visible. Sitting and defecation are painful.

General tonic treatment, together with rest, is to be tried. An aperient to insure a daily soft evacuation (sulphate of magnesium, 1 dram; wine of aloes, 1 dram;—in water every morning) will cure most cases in time. Morphin may be subcutaneously injected over the coccyx. Subcutaneous division of all the ligaments,muscles, and fasciæ about the coccyx has given good results.

COCCYX.—Injuries of the coccyx are generally dislocations, mainly of an incomplete kind. Dislocation may occur backward as the result of parturition, or forward from kicks or from falls in a sitting posture. Reduction may be effected by the finger placed in the rectum to reduce the forward displacement. Prolonged coccygodynia is likely to follow injury of the coccyx, since absolute rest is not obtainable, and the nerves become implicated in the inflammatory thickening that results.

CODEIN.—$C_{18}H_{21}NO_3$. An alkaloid of opium, and often contaminated by morphin. It somewhat resembles morphin in the general character of its action, but while it is powerfully analgesic, it is much less toxic and its hypnotic influence is quite limited. It has a decidedly stimulating effect upon the spinal cord, the medulla, and the lower parts of the brain, and is much less constipating than morphin or opium. It is especially useful in relieving cough of all kinds, and is more efficient

than opium in diabetes. It is often employed in cases where, as often happens in malignant disease, an anodyne effect must be maintained more or less continuously. It is free from odor and of a faintly bitter taste, soluble in 80 parts of water and in 3 parts of alcohol. The dose is 1/4 to 1 grain. See OPIUM, ANTINARCOTIC LEGISLATION, HARRISON LAW.

In diabetes:

℞. Codein, gr. xx
Extract of nux vomica, gr. xv
Extract of cascara sagrada, gr. xx.

Make into pills; give one 3 times a day.

For bronchitis with hard coughing:

℞. Ammonium chlorid, gr. v
Extract of licorice, gr. ij
Powdered cubebs, gr. iij
Codein, gr. j

Make into 20 pills; 1 every 2 hours until relieved.

The following are the salts: **C. Phosphate**, soluble in water. Similar to morphin in action, but less toxic. Dose, hypodermically, 1/4 to 1 grain. **C. Sulphas.** Dose, 1/4 to 1 grain.

COD-LIVER OIL (Oleum Morrhuæ).—The fixed oil obtained from fresh livers of the *Gadus morrhua* and other species of the codfish. It is a colorless or pale yellow, thin, oily liquid, of slightly fishy odor and taste, and faintly acid reaction, soluble in ether. It contains the fixed bases *Aselline* and *Morrhuine*, volatile bases, acids, etc.; also traces of iodin and bromin, the ordinary inorganic salts of animal tissue and products, and perhaps bile constituents. When saponified it does not yield glycerin, but oxid of propyl. Three varieties are found in the market, the pale, the light-brown and the dark. The pale is the official oil and the purest. Dose, 1 to 6 drams, beginning with a small dose, and increasing as assimilated. It has alterative powers, maintains bodily temperature, and directly influences the blood, increasing the red corpuscles. It is useful in persons whose mucous membranes are of low vitality, in the pretubercular stage of phthisis, in chronic rheumatism, in strumous skin-lesions, in scrofulosis, in enlargement of the lymphatic glands, in strumous ophthalmia, in advanced syphilis, in early stage of rickets, in marasmus, sciatica, lumbago, neuralgia, and in emphysema of the lungs.

It is generally administered in emulsion, but the oil itself is the best form for use. This may be given in large capsules, or a teaspoonful thrice daily for an adult, after meals, may be given in black coffee, beer, or lemon-juice. Oil of eucalyptus, in the proportion of 1 part to 100 of cod-liver oil, will extinguish the odor and taste. Extemporaneous emulsions are made with white of egg, mucilage of tragacanth, extract of malt, or any syrup, and flavored with lemon, cinnamon, or bitter almond. Ether, 4 minims to each dram of the oil, promotes its digestion.

An equal quantity of glycerin with from 1/2 to 1 drop of the oil of bitter almonds is of service to hide the taste. Syrup of bitter orange-peel also covers it. Tomato ketchup has been used. Cod-liver oil is most readily digested when given in nightly doses after supper, or after a light meal just before going to bed. In a few days it may be given after dinner, and after breakfast in about a week. It is readily combined with creosote.

Cod-liver oil may be used by inunction, especially in the wasting diseases of children. A tablespoonful may be rubbed into the skin of the abdomen twice a day, followed by the use of a flannel binder with oiled silk or mackintosh cloth. It passes readily through the skin and is absorbed.

Cod-liver oil is contraindicated in high febrile states and in chronic gastrointestinal inflammation.

Preparations.—Emulsion Olei Morrhuæ, *emulsion of cod-liver oil*, has of the oil 50, acacia 12 1/2, syrup 10, oil of gaultheria 0.4, and water to 100. Dose, 1 to 6 drams.

Emulsum Olei Morrhuæ cum Hypophosphitibus, *emulsion of cod-liver oil with hypophosphites*, has of the oil 50, acacia 12 1/2, calcium hypophosphite 1, potassium hypophosphite 0.5, sodium hypophosphite 0.5, syrup 10, oil of gaultheria 0.4, and water to 100. Dose, 1 to 6 drams.

An emulsion:

℞. Cod-liver oil, ℥ iv
Oil of wintergreen, gtt. xij
Calcium hypophosphite, gr. l
Sodium hypophosphite, gr. l
Acacia,
Water, enough to make ℥ viij.

Make into an emulsion; give a tablespoonful 3 times a day, after meals.

COFFEE.—The seeds of *Coffea arabica*. The dried and roasted seeds are almost universally used in infusion as a beverage, forming a cerebral stimulant and stomachic tonic. Coffee is valuable in promoting digestion and in allaying hunger and fatigue. It frequently causes excessive palpitation of the heart. Its properties are due to an alkaloid, CAFFEIN (*q. v.*), $C_8H_{10}N_4O_2.H_2O$, identical with *thein*.

Roasting the seeds changes the sugar into caramel, and several volatile substances are formed that give to coffee its peculiar aroma and some of its stimulant qualities. As a beverage, used with moderation, coffee assists digestion, promotes intestinal peristalsis, allays the senses of fatigue and hunger, lessens tissue waste, and decreases the formation and excretion of urea. In excess it disorders digestion and causes functional disturbances of the nervous system. The brief stimulation of the intellect consequent on drinking a cup of coffee is probably due to the volatile constituents developed in roasting. The wakefulness ensuing upon taking coffee is usually preceded by a brief period of drowsiness. The coffee bean contains from 0.2 to 0.8 percent of caffein.

COHOSH.—See CIMICIFUGA.

COLCHICIN.—$C_{17}H_{19}NO_5$. A yellowish, exceedingly bitter powder, freely soluble in water. It is a very active poison. Its dose is 1/120 grain, or 1/2 of a milligram, hypodermically.

COLCHICUM (Meadow-saffron).—The corm and seed of *C. autumnale*, with properties due to

an alkaloid, *colchicin*. It is an emetic, diuretic, diaphoretic, and drastic cathartic. It is one of the most powerful cholagogs. It is valuable in acute gout, and is used with good results in gonorrhea.

It is official in two forms: **Colchici cormus**, colchicum corm, the dried corm, less active than the seed. Dose, 2 to 8 grains. **Colchici semen**, colchicum seed. Dose, 1 to 5 grains.

For acute gout:

℞. Potassium iodid, ℥ j
Potassium bicarbonate, ℥ iij
Wine of colchicum seed, ℥ j
Camphor water, enough for ℥ vj.
A tablespoonful in a wineglass of water after meals.

Preparations.—**Extractum Colchici Cormi**, *extract of colchicum corm*, made with acetic acid 35 parts to 100 of the root, and sufficient water. Dose, 1/2 to 2 grains. **Fluidextractum Colchici Seminis**, *fluidextract of colchicum seed*. Dose, 1 to 5 minims. **Vinum Colchici Seminis**, *wine of colchicum seed*, 10 percent. Dose, 10 to 60 minims. **Tinctura Colchici Seminis**, *tincture of C. seed*, 10 percent. Dose 10 to 60 minims.

COLD, EFFECTS.—The usual effect of exposure to cold is to lower, even to extinction, vital activity. The more special effects vary in degree and kind: (1) With the degree of cold, the duration of the exposure, and the medium or manner of application; (2) with the part and extent of surface exposed; and (3) with the general constitution and physiologic condition of the sufferer.

Moderate cold acting for a short time, or severe cold for a shorter time, followed by speedy reaction, is tonic and stimulating. Continued exposure to cold keeps at low ebb the activity of nutrition and function. Dry cold is less injurious; and cold water cools sooner than cold air of the same temperature. The young and the aged suffer from exposure to cold, and among the healthy, hunger, fatigue, sleep, anxiety of mind, fear, and mental depression lower the power of resistance to cold. The list of maladies most commonly fostered by exposure to the influence of cold is: General depression of the vital powers; congestion and functional derangement of various internal organs (*e. g.*, the lungs, liver, and kidneys); catarrhal and other forms of inflammation of mucous membranes, especially of the respiratory tract, the intestinal canal, and the bladder; paralysis from central or peripheral lesion; rheumatism; chilblain; frostbite; and gangrene.

Treatment of sufferers from cold consists in the restoration of warmth and the reestablishment of the processes whereby natural heat is maintained. This must be done gradually. The patient is wrapped in blankets, and put in a room in which the air is dry, still, and cold, but that can be gradually warmed. He is then subjected to gentle and continuous friction, but no rough manipulation, of the injured parts. Ice or ice-cold water may be used at first, afterward dry flannel or the bare hands, and later stimulating liniments. Tea, coffee, soup, aromatic infusions, beef-tea, and warm and stimulating drinks may be given at first, but no spirits. Alcohol is beneficial only when judiciously administered in the restoration from exposure. If insensibility exists, efforts to restore animation should be continued for a long time. In severe cases temperature must not be restored too quickly. The bladder must always be examined, and urine not allowed to accumulate but for a short time. The general health often needs attention long after recovery from immediate effects.

COLD, THERAPEUTICS.—Cold as a remedial agent acts, according to the manner and degree of its application, as an anesthetic, antiphlogistic, antiseptic, hemostatic, or tonic. The simplest and cheapest, but a painful, method of producing anesthesia for minor operations by cold is by the direct application of ice crushed in a cloth, or a mixture of about equal parts of ice and salt. Sprays of volatile liquids may be used so as to produce the same effect. Pure anhydrous ether may be sprayed from a hand-ball. Chlorid of ethyl or methyl sprays are sold in glass tubes with brass caps for use in blanching and freezing surfaces. Rhigolene is used as a spray in an atomizer.

Injuries to the head are greatly benefited by the application of cold. India-rubber bags serve well as containers, and animal membranes—*e. g.*, bladders—insure comfort, but require watching. In strangulated hernia and in swollen joints the even pressure of an ice-bag adds to the efficiency of the cold, while coils of rubber tubing, or Leiter's metallic coils, or irrigation based on the action of the siphon may be of great avail.

Wetting the surface of the skin that is exposed to the air, and thus maintaining constant evaporation, is a most useful way of reducing high temperatures. The **cold pack** is a valuable means of reducing the body temperature in cases of hyperpyrexia. The patient is wrapped in a sheet wrung out of cold water; as this becomes warm, it is replaced by a fresh cold one, or iced water may be poured upon it, or lumps of ice placed upon and around it. When the temperature is reduced, the wet sheet should be removed, and a light covering applied, but not a blanket. This is not so efficacious as the cold bath.

A cooling lotion consists of:

℞. Sweet spirit of niter, ℥ ss
Ammonium chlorid, ℥ ij
Vinegar, Acetic acid, Methylated spirit of wine, each, ℥ jss
Water, O j.

By increasing the niter and sal ammoniac to 5 ounces of each, a good substitute for ice is obtained.

In sprains, in superficial neuralgias, and in the treatment of pneumonia and pleurisy by means of an ice-jacket or poultice, and to stay peristalsis and check hemorrhage in enteric fever, this agent is very useful. Cold injections by vagina or rectum may succeed in checking severe uterine hemorrhage. In bleeding internal piles and as an antipyretic enema cold water injections may be used.

A cooling lotion may be made from spirit of wine and water or from dilute cologne water. Potassium nitrate, 4 drams, or ammonium chlorid, 4 drams, to 15 ounces of the lotion will add to its cooling and sedative effect. One part of alcohol to 3 parts of camphor water is highly praised in gout.

The tonic action of cold baths is well known. Cold to the face and hands is a popular method of reviving fainting persons. Cold hip-baths and enemas are useful in piles, varicocele, and general pelvic weakness. Cold salt-baths, particularly if sea-baths, are more stimulating and not so relaxing as fresh-water baths. Cold water dashed or sopped against the perineum is a remedy advised for nocturnal seminal emissions, or the scrotum may be submerged in a tumblerful of cold water for a few minutes. In dysentery 1 or 2 quarts of ice-cold water may be injected into the rectum, and this treatment may be of use for piles. Cold may also be used in pruritus ani, in prolapse of the anus, in prostatic disorders, in atonic impotence in the male, and in pruritus of the vulva and vagina in females.

COLD IN THE HEAD (Coryza).—See CORYZA, RHINITIS (Acute).

COLEMAN-SHAFFER DIET.—See under TYPHOID FEVER.

COLIC. Definition.—A severe griping pain in the bowels or adjacent organs. In intestinal colic the pains radiate over the abdomen from the region of the umbilicus. The abdomen is usually distended, and pressure will generally relieve the pain.

Etiology.—(1) Indigestible food, such as green fruit or insufficiently cooked vegetables; (2) overfeeding, especially in children; (3) reflex from the ovaries, kidneys, liver, or uterus; (4) certain drugs, as lead; (5) the result of intestinal obstruction or enteritis; (6) autoinfection.

Symptoms and Clinical Course.—Paroxysms of sharp pain set in over the abdominal region, especially around the umbilicus, frequently being so severe as to make the patient flex the thighs upon the abdomen. The face has an anxious expression or is entirely distorted; the eyes are closed tightly, the fingers clenched, and the teeth firmly set. The intestines are filled with gas, and expulsion of flatus from the stomach and bowels generally occurs. Romberg thus describes a paroxysm of intestinal colic: "There are attacks of pain, spreading from the navel over the abdomen, alternating with intervals of ease. The pain is tearing, cutting, pressing, most frequently twitching, pinching, accompanied by peculiar bearing-down pains. The patient is restless, and seeks relief in changing his position and in compressing the abdomen; the surface of the body may be cold and the features pinched. The pulse is small and hard. The abdomen is tense, whether puffed up or drawn inward. There are often nausea and vomiting, and desire for stool. There is usually constipation, but sometimes the bowels are regular or even too loose. These symptoms last from a few minutes to several hours, relaxing at intervals. The attack ceases suddenly, with a feeling of the greatest relief, although some soreness remains for a few days."

Diagnosis.—Gastralgia differs from colic in the pain being in the epigastric region and associated with disorders of digestion.

In **hepatic colic**, or the passage of gall-stones, the pain is in the hepatic region, attended with soreness over the gall-bladder, and retching and vomiting, followed by jaundice and the presence of bile in the urine.

In **nephritic colic** the pain follows the course of one or both ureters, shooting to loins and thigh, with retraction of the testicle of the affected side, strangury, and bloody urine.

In **uterine colic** the pain is in the pelvis, and associated with menstrual disorders—in fact, a dysmenorrhea.

In **ovarian colic** or neuralgia there is pain on pressure over the ovaries, with hysteric phenomena.

Inflammatory disorders of the abdomen differ from colic by the presence of fever and of tenderness on pressure.

Lead colic is always preceded by symptoms of lead-poisoning: to wit, slate-colored skin, dark gums showing a blue line, heavy breath, with sweetish metallic taste, obstinate constipation, impaired appetite, slow pulse, and contracted abdominal walls.

INTESTINAL COLIC.	BILIARY COLIC.	RENAL COLIC.	LEAD COLIC.
1. History of having eaten improper food.	1. History of colic, vomiting, followed by icterus.	1. History of previous attacks and passage of calculi.	1. History of having been exposed to inhalation of lead: blue line on gums.
2. Pain chiefly in region of umbilicus.	2. Pain in region of liver, radiating toward umbilicus and right scapula.	2. Pain in region of affected kidney, radiating down thigh, often accompanied by retraction of testicle.	2. Pain in region of umbilicus.
3 Abdomen tympanitic.	3. Abdomen tympanitic.	3. Abdomen tympanitic.	3. Abdomen very hard.
4. Absence of rigor.	4. Sweats and chills frequent.	4. Rigors pronounced.	4. Rigors absent, constipation persistent.

Treatment.—First eliminate the possibility of mechanic obstruction, such as hernia, twist or, adhesions. Pain should be relieved by subcutaneous injection of morphin (1/8 to 1/4 of a grain), or of morphin (1/8 of a grain) and atropin (1/60 of a grain); by inhalations of amyl nitrite, chloroform, or ether; or by drop doses of chloroform. A large warm-water enema may be administered, and a combined sedative and purgative given, such as a grain of opium with 5 to 10 grains of calomel, or 20 grains of rhubarb followed by a saline cathartic. One of the best purgatives in colic, no matter from what cause, is calomel, 1/2 of a grain every half hour until 4 or 5 grains are taken, followed by citrate of magnesia. A suppository of

1/2 of a grain each of morphin hydrochlorid and extract of belladonna may give immediate relief from pain. The warm bath, mustard or turpentine stupes, hot fomentations sprinkled with laudanum, or large, light linseed poultices are grateful. Steady but not severe friction with warm oils or liniments gives relief. Liquids, with small quantities of stimulants, constitute the best diet. Copious drafts of hot water to relieve the pain and to favor evacuations.

The colic-like enteralgia of women is relieved by sodium salicylate in 20-grain doses. In malarial subjects colic is best relieved by quinin and arsenic, and, generally, aperients should be given with sedatives. Treatment subsequent to an attack of colic should include regulation of the diet and prevention of the lodgment of solids and gases in the bowel. The abdomen should be kept warm by a flannel roller or belt, and the feet by thick woolen stockings or by a foot-warmer.

Hepatic or biliary colic requires the use of anodynes to relieve the pain and to facilitate the escape of the stone. Morphin, 1/4 to 1/2 of a grain, together with 1/60 of a grain of atropin, should be given hypodermically. A turpentine stupe may be placed over the liver, and gentle rubbing employed. Nauseating emetics are contraindicated. Cotton-seed oil or olive oil, in the dose of at least half a pint, may be given during the attack, with the addition of 1/2 of a dram of ether with each dose. The inhalation of chloroform or ether may be resorted to if the pain is not relieved by previously stated means. See GALL-BLADDER (Diseases).

Renal Colic.—Treatment is by rest in the recumbent position, hot fomentations of belladonna over the whole side, and repeated injections of morphin in free doses hypodermically. In the case of blood-clots, calculi, or tissue shreds, free kneading and manipulation over the tract of the ureter may assist the passage of the foreign body into the bladder. See KIDNEY (Stone).

In **lead colic** purgatives are indicated, and opium or belladonna are to be used. Magnesium sulphate is the best purgative, and potassium iodid is usually given to remove the lead from the system. Sulphur baths are also recommended. Excellent results often follow one or more small venesections in lead-poisoning. Gratifying results have been reported from large doses of olive oil, repeated until some 6 ounces have been used. This substance is said to be curative in lead-poisoning, in daily doses of 2 ounces, continued for some time. See LEAD.

COLIC, INFANTILE.—Colic may be a symptom of intestinal inflammation; it may be due to swallowing foreign bodies, as the seeds of fruit; or possibly to the presence of round-worms in great numbers; but the usual colic of infancy is that associated with flatulence and caused by indigestion. This form of colic is seen the first 6 months of life, but is most frequent the first 3 months, and it may be present at any time when the digestion is very feeble. Many young infants suffer from colic a greater part of the time; others have only occasional attacks. It is not likely to occur at night. Colic is seen quite as often in nursing infants as in those artificially fed. It may be produced by an oversupply of food, by a deficiency in the amount of food, or as a result of decomposition in the digestive tract. In most cases, however, it is due to the character of the milk. Excessive proteids are nearly always the cause of colic in nursing infants, as well as in the bottle-fed babies, though it may be caused by an excess in the proportion of sugar; it is a common symptom in infants fed on farinaceous foods.

Symptoms.—Soon after taking food the infant becomes restless, picks and draws up its legs, twists its body, and has frequently repeated paroxysms of loud crying. The abdomen is full and hard, the hands and feet are cold, and in severe cases the fontanel is depressed. After a varying time eructations of gas or curdled milk occur or gas is expelled by the bowels, and the symptoms disappear for a time.

The cry of colic may sometimes be difficult to distinguish from that of hunger, as a child with colic will often take food eagerly, and for a time the warm fluid in the stomach will give it relief. In these cases the pain will be quieted but for a short time.

Treatment.—One of the following formulas will in most cases give relief:

℞. Lime-water, Compound tincture of cardamom, each, ℥ j.

Give a teaspoonful every half hour.

℞. Spirit of chloroform, gtt. xvj
Aromatic spirit of ammonia, ℥ ss
Sodium bicarbonate, gr. xvj
Syrup, ℥ss
Peppermint water, q. s., ℥ ij.

One teaspoonful, as necessary, for pain.

℞. Oil of cajuput, gtt. v
Acacia, Sugar, Water, q. s., ℥ j.

Make an emulsion and give 1/2 of a teaspoonful as necessary.

In severe cases the following is very helpful:

℞. Chloral hydrate, gr. xvj
Sodium bromid, Sodium bicarbonate, each, ℥ ss
Syrup, ℥ ss
Peppermint water, q. s., ℥ ij.

Give 1/2 to 1 teaspoonful every half hour until quiet.

In many cases the most efficient method of relieving the pain is an enema of 3 or 4 ounces of warm water and sodium bicarbonate (1/2 a teaspoonful).

Hot applications should be made to the abdomen, and when symptoms of collapse appear, a hot bath should be given.

COLITIS.—See DYSENTERY, ENTERITIS, FECES.

COLLAPSE.—A condition of lowered vitality induced by reflex inhibition, and affecting all the functions of the nervous system. The chief object of treatment is to restore the function of heart and

vessels. For this purpose the recumbent position, external heat, cessation of hemorrhage, and cardiac, stimulants, like ammonia, by inhalation or by the mouth (diluted), hot drinks, brandy or spirits, strychnin, etc., are to be administered. Hot milk and coffee are useful.

Collapse is a condition of nervous prostration. When extreme, the vital nervous functions are sometimes completely in abeyance. Death may ensue, or there may be gradual reaction and complete recovery. Strictly speaking, collapse and shock should not be classed together. Shock is the term applicable not only to the state or morbid condition, but also to the cause of that condition. Collapse arises from many causes, shock being one of them, and collapse may occur when no shock has preceded. Collapse presupposes nervous exhaustion. Shock occurs in a healthy state as well.

The severity of collapse depends on the age and vigor of the individual. A moderate amount is seen in fevers, and well-marked collapse exists in severe injury or results from loss of blood. Severe purging and tobacco poisoning produce a condition resembling traumatic collapse. Some malignant fevers terminate in collapse, and in cholera collapse gives high internal temperature with cold external parts. Collapse from loss of blood differs from syncope. In syncope the prominent symptom is loss of consciousness. The more we know of shock and collapse, the less we pin our faith to drugs (Bastedo). If we employ them, we must not let the stress of the emergency lead us into giving them in too large doses. In such an emergency drugs have been administered in amounts that might have proved fatal to a healthy person; and it seemed as if the patient might have died from the drugs rather than from the collapse. See Exhaustion, Shock.

COLLARGOL.—Colloidal silver. Argentum Credé. It is said to contain 97 percent of silver. Collargol is a general antiseptic and germicide producing neither local reaction nor general poisonous effects. It is said to cause marked and rapid leukocytosis, to be completely excreted within a month, to be incapable of producing argyria, and to have inhibitory action in the blood on bacteria. It has been used with benefit in skin and venereal diseases, local suppurations, and septic disorders; also in diphtheria, scarlet fever, pneumonia, pericarditis, and typhoid fever. Dose, by mouth, 1 grain tablet, or 1 teaspoonful of a solution of 1 to 500 or 1 to 100; for irrigation, 1/50 percent to 1 percent solutions; 5 percent dusting powder; in most cases it is best used locally in the form of a 15 percent ointment (Collargol ointment, Unguentum Credé).

COLLES' FRACTURE.—See Forearm, Fractures.

COLLODION.—Ordinary collodion is a solution of gun-cotton in alcohol and ether. It is a clear, syrup-like fluid, smelling strongly of ether, and is used externally, making an air-tight dressing for wounds and abrasions, and rendering small dressings waterproof. A camel's-hair brush may be used to apply the solution. In boils collodion may be used as an abortive, but not after rupture. In small-pox collodion may prevent the pitting, and it is serviceable in gouty inflammations when mixed in equal parts with iodin. There are 4 official collodions: Collodion, flexible collodion, cantharidal collodion, styptic collodion. The flexible collodion contains 5 percent of Canada turpentine and 3 percent of castor oil; styptic collodion contains 20 percent of tannic acid; and cantharidal collodion contains 60 percent of cantharides.

COLLYRIUM.—A lotion for the eyes, generally containing a soluble astringent salt dissolved in rose water or distilled water in the proportion of 1 to 4 grains to the ounce.

Boric acid is extensively used as a mild antiseptic lotion in solutions of 10 grains to the ounce. It is hardly to be classed as an antiseptic, but, on account of its soothing qualities, is to be recommended in cases in which only a simple lotion is necessary.

The following are common formulas:

℞.	Boric acid,	gr. xl
	Distilled water,	℥ iv.

Bathe the eyes freely several times a day.

℞.	Boric acid,	gr. xl
	Camphor water, Distilled water, each,	℥ ij.

Bathe the eyes freely several times a day.

The following mixture may be used freely in all mucopurulent inflammations about the eye:

℞.	Boric acid,	gr. xl
	Sodium chlorid,	gr. ij
	Zinc chlorid,	gr. ij
	Distilled water,	℥ iv.

Stain with pyoktannin, and doubly filter after standing.

The patient should be told that this lotion will smart at first, and that he should instil it in the eye when lying on his back, and not close the eyes violently and squeeze it out, but draw the lids together gently and roll the eye slowly about for a minute.

A very satisfactory combination is:

℞.	Boric acid,	gr. xij
	Mucilage of sassafras pith,	℥ ij
	Mercuric chlorid,	gr. 1/75
	Sodium chlorid,	gr. j
	Camphor water, Distilled water, each,	℥ jss.

COLOCYNTH.—The dried fruit of *Citrullus colocynthis*, from which the seeds and rind have been rejected. Its properties are due to a bitter glucosid, *colocynthin*, $C_{56}H_{84}O_{23}$, the dose of which is 1/20 to 1/5 of a grain. It is a tonic and astringent purgative, and is used mainly as an ingredient of compound cathartic pills. It is somewhat useful in colic, sciatic rheumatism, and neuralgia.

Preparations.—**C. Ext.**, dose, 1/4 to 1 grain. **C. Ext. Comp.**, contains colocynth extract 16, aloes 50, cardamom 6, resin of scammony 14, soap 14, alcohol 10. Dose, 5 to 20 grains. **Pilulæ Cathartic. Comp.**, compound cathartic pills have: compound extract of colocynth 8, calomel 6, resin of jalap 2, gamboge 1 1/2, water to make 100 pills.

Dose, 1 to 3 pills. **Pil. Catharticæ Vegetabiles** contain compound extract of colocynth 6, extract of hyoscyamus 3, resin of jalap 2, extract of leptandra 1 1/2, resin of podophyllum 1 1/2, oil of peppermint 0.8, water to make 100 pills. Dose, 1 to 3 pills.

COLON BACILLUS INFECTIONS.—Bacillus coli communis is a term clinically applied to a variety of organisms answering to a series of class reactions of the bacteriologist, but of which a number of specific ones have been isolated. In a general way this subdivision of the bacteriologist has but little clinical interest as yet, and the specific methods of identification are still matters of some dispute, but sufficient work has been done to make it desirable that the clinician speak of one or other organism as a "member of the colon group" rather than as this or that particular variety, unless approved methods of identification have been employed in addition to the general class methods.

While *members of the colon group* are regular inhabitants of the intestine in health, there is ample evidence that they vary decidedly in toxicity and in pathogenic quality. No rule is yet established why this change in toxicity should occur and it seems reasonable to suppose that the lowered resistance of debilitated subjects favors the development of the increase in pathogenic quality. The organisms in question are certainly pyogenic under certain circumstances and produce suppurative processes without the presence of any other organism, but they also occur in conjunction with other pus-producing bacteria in which event it is sometimes difficult to determine which organism was the original infective agent.

Infections from which pure cultures of colon bacilli are obtained are most frequently observed in the genito-urinary tract, but no portion of the body is immune to this type of infection. It may occasion local inflammatory lesions in the meninges, ear, eye, throat, breast, lung, pleura, pericardium, peritoneum, liver, pancreas, gall-bladder, biliary passages, spleen, appendix, intestinal wall and uterine adnexa. It produces abscesses and may be the cause of a general systemic sepsis with bacillemia. The direct mode of infection is by no means clear in all cases and the frequency with which colon bacilli can be demonstrated in blood cultures justifies the general belief that the infection is hematogenous in many if not most instances.

The recognition bacteriologically of the colon bacillus is not as simple as in the case of organisms which can practically be identified by their morphology, as it demands cultural characteristics in addition to microscopic appearance and staining qualities. The organism is a medium-sized bacillus with rounded ends varying somewhat in length and very sluggish, if at all motile. It does not stain uniformly, usually showing a few but faintly stained portions and is Gram negative. On nutrient gelatin or agar slant it shows a rapidly growing grayish translucent strip with irregular margins and does not liquefy the medium. It produces gas formation in media containing sugar. The essential features for the differentiation of the colon bacillus aside from its morphology are, the marked indol production in peptone solution and the fermentation of dextrose and lactose media, in all of which it differs from the typhoid bacillus, the Shiga bacillus and the paratyphoid bacillus which do not produce indol and do not ferment the media mentioned.

Genito-urinary Tract.—Colon bacillus infections are most frequent in this region and a careful consideration of the cases usually allows at least a suspicion that an underlying cause for inflammation, if not directly for colon bacillus infection, exists. An enlarged prostate with residual urine will usually soon lead to a cystitis. This catarrh of the bladder is one of two types, either there is alkaline fermentation or a colon bacillus infection with acid urine. The colon bacillus infection may ascend the ureter, sooner or later leading to a pyelitis or pyelonephritis, which extension may be sudden or gradual. If sudden there usually are pronounced characteristic symptoms with a rather high range of temperature. If gradual this may occur with few if any symptoms, and no rise of temperature and the diagnosis may have to rest on the conditions found on urine examination. In these cases it seems reasonable to suppose that the enlarged prostate and residual urine are the direct causes allowing the colon bacillus infection. There is no apparent reason why in one case an alkaline fermentation of the urine in the bladder is found and in the other case a colon bacillus infection, unless in the latter the colon bacilli in the intestine have become abnormally virulent as the result of faulty intestinal processes or for reasons unknown. The latter idea is prompted by the frequency with which cases of colon bacillus infection of this kind have a history of long-standing intestinal disturbance. The diagnosis rests on the same clinical symptoms noted in the respective lesions due to any cause and on the presence of a pure culture of a member of the colon group in the urine in addition to the changes characteristic of a cystitis, pyelitis or whatever the condition may be. The urine usually shows a pronounced macroscopic bacteriuria with an acid reaction and rather characteristic offensive odor, and it is not difficult generally to demonstrate the nature of the causative organism as previously described.

Cases are certainly met with in which there is a colon bacillus infection of the bladder with or without involvement of the kidney in which no underlying cause for inflammation, as in the cases just described, can be found. The ease with which fecal matter can soil the female urethra has frequently been described as a cause of colon bacillus infection. Further investigation will be necessary before the statement is justified that these infections are due to increased virulence of the colon bacillus in the intestine of the patient as the result of faulty metabolism or what not.

Cystitis, pyelitis and pyelonephritis developed during pregnancy are conceded by most writers as due to the colon bacillus in the majority of cases, and are invariably ascribed to this cause by others. In these cases the onset may be sudden with severe symptoms and high temperatures, or gradual with slight symptoms and no fever. Here also an un-

derlying cause for inflammation exists, namely, the pressure of the gravid uterus particularly on one ureter. The frequency of colon bacillus pyelitis in pregnancy in the women who for months have shown evidences of intestinal toxemia, as compared with those without such evidences, is certainly noteworthy and serves as an indication for the prompt relief of intestinal toxemia in pregnancy when it occurs.

Acute pyelitis and pyelonephritis due to colon bacillus infection in infants and young children has had the close attention of the clinician, particularly of late, in explanation of high ranges of temperature. This condition is by no means infrequent and, in most of the cases at least, a distinct history of intestinal disorder is obtained which tends to strengthen the belief that faulty intestinal processes increase the virulence of the colon bacillus and subject the child to infections of this kind. The frequency of this condition (if no other reason) should prompt a careful examination of the urine in the case of any child with unexplained fever particularly if there is a history of gastrointestinal disorder. Trautner argues that colon bacillus infections may be responsible for the formation of uric acid in the kidney, particularly in infants, although it is rather the exception than the rule to find renal calculi and colon bacillus infection associated.

Meningitis.—Pure cultures of colon bacilli have been obtained in cases of meningitis but the suspicion always seems justified that this is not the only organism concerned.

Ear.—Cases of purulent otitis media in which colon bacilli only are obtained on examination are not very uncommon. The infections are usually quite mild and an extension to the mastoid is not at all probable. Thrombosis of the sinus has not been described.

Eye.—A purulent conjunctivitis now and again shows colon bacilli only, which must be looked upon as the causative factor. The cases are usually not severe and the ordinary methods of treatment in which cleanliness is the chief feature usually result in prompt relief. Morris recently reported a case of severe choroiditis which threatened to end in total blindness which was due to colon bacillus infection. This patient had severe intestinal disturbances. On removal of the appendix not only the intestinal fault was relieved but the choroiditis also disappeared.

Tonsillitis.—Some cases have been described in which pure cultures of colon bacilli were obtained, but usually other organisms are found in addition and in that case it is possible that the colon bacillus represents a secondary infection. Pure cultures of colon bacilli have been obtained from the throat in practically every described case of similar infection of the lung.

Mastitis.—In the resulting abscesses pure cultures of colon bacilli are sometimes obtained, though usually this is due to a secondary infection after incision. The occurrence of colon bacillus abscesses of the breast in cases of colon bacillus puerperal sepsis with bacillemia suggests probable hematogenous infection.

Pneumonia.—Cases have been described with the physical signs of pneumonia in which pure cultures of colon bacilli were obtained. v. Schrötter and Weinberger published a case in which there was consolidation of both lower lobes with a normal blood picture instead of a leukocytosis and polynucleosis, the disease lasting four months.

Empyema.—Records are occasionally found in the journals of cases of empyema in which pure cultures of colon bacilli were obtained. Schmidt describes a case of a student with a severe colitis which was followed by an empyema on the left side showing pure cultures of colon bacilli, the infection evidently being hematogenous.

Pericardium.—As in the case of the pleura, colon bacillus infections occur and can be ascribed to hematogenous origin.

Peritonitis.—Inflammations of the peritoneum due to colon bacillus infection are commonly observed without solution of the continuity of the intestinal wall. The produced matting together of the structures and the inflammatory exudate have in a number of instances been taken for a tuberculous process or a neoplasm, which mistakes can be avoided by proper bacteriological examination. Severe infections of the peritoneum are invariably preceded by pronounced evidences of intestinal disturbance and accompanied by outspoken symptoms particularly those referable to the toxemia.

Liver, Pancreas, Bile Passages and Gall-bladder.—On account of the direct connection of these organs with the intestinal tract a colon bacillus infection can easily be understood. These infections are particularly common and generally very severe when they occur after typhoid, which disease is known to increase the virulence of the colon bacillus. Suppurative inflammations in the ducts, abscesses in the parenchyma of the organ and perihepatic abscesses occur. Colon bacillus infection of the gall-bladder is one of the chief causes of inflammation and suppuration and these infections are also looked upon as a common cause of gall-stones. It has been shown that the organism decomposes the biliary salts and causes a precipitation of cholesterin.

Spleen.—In a considerable proportion of the cases of splenic abscess pure cultures of the colon bacillus are obtained and it is probable that the infection enters through the blood stream. Ruptures of abdominal organs are also at times followed by colon bacillus infections.

Appendicitis.—The frequency with which pure cultures of colon bacilli are obtained in cases of acute or chronic appendicitis has led to the belief that this organism in its more virulent state is the direct cause of the inflammatory process. Instances such as the cited case of Morris where a choroiditis and a protracted intestinal disorder due to the colon bacillus were immediately relieved by the removal of the appendix would tend to corroborate this view. On the whole it would seem that caution should be exercised in pronouncing the lesion as invariably due to the colon bacillus as other pyogenic organisms are found associated with it in many cases.

Intestinal Wall.—Lesions in the intestinal wall due to disturbances in circulation or injury as in incarcerated hernia, intestinal obstruction from any cause, etc., usually lead to invasion of the tissues by the colon bacillus which may give rise to inflammation or suppuration.

Uterine Adnexa.—Acute suppurative processes in the uterine adnexa particularly when the inflammation extends into the pelvis usually show the presence of colon bacilli in addition to other pyogenic organisms though pure colon bacillus infections are also met with.

Abscesses, Wound Infections and General Sepsis.—Not infrequently pure cultures of colon bacilli are obtained from abscesses probably caused by hematogenous infection, and secondary infections of wounds by the colon bacillus are also not uncommon. The literature both in America and in Europe offers a considerable number of cases of general septicemia due to the colon bacillus which can be recovered in pure culture from the blood. Clinically they seem characterized by particular prominence of brain symptoms evidently referable to the toxemia produced. While some cases are acute and terminate fatally, the majority can be classed with the cases of chronic sepsis terminating in death or recovery after a longer period. The diagnosis must rest on positive blood cultures as in general sepsis due to other organisms.

Prognosis.—While exceptional cases of exceedingly mild and scarcely noticed infections occur as well as very severe ones, particularly those seen after typhoid, in general it may be said that colon bacillus infections are not as severe as those due to the streptococcus or staphylococcus and are also less likely to produce general systemic invasion.

Treatment.—In cases of colon bacillus infection of the urinary tract urotropin or a similar preparation has usually met with success. Urotropin can be obtained in one-half gram tablets which are given in water one every three hours to one three times a day. W. H. Thomson strongly advocates giving the benzoate of sodium with urotropin, ten grains of each every three hours in acute cases. Owing to the probability that the colon bacillus in the intestine is unduly virulent, measures for the frequent emptying of the bowel should be taken. In addition to laxatives, frequent and long continued high irrigations are undoubtedly of benefit, using normal saline solution or the addition of some antiseptic such as thymol. The administration of the bacillus bulgaricus either in tablet form or in one of the prepared milks has a decided influence on the growth and virulence of the colon bacillus and is to be recommended.

Colon bacillus infections other than of the urinary tract usually do not respond nearly as well if at all to urotropin and in these, symptomatic treatment is generally employed.

Vaccine therapy has found an unusually good field in colon bacillus infections. While its usefulness in acute infections, particularly those with a bacillemia, is still a matter of controversy, Wright and others claim that beneficial results are obtained by the use of very small doses injected rather more frequently than usual.

There is no doubt that vaccines do accomplish splendid results in the subacute and chronic localized colon bacillus infections. The use of autogenous rather than stock vaccines is strongly advised particularly as the organism in question is a member of the colon group rather than a true entity; and vaccines, as all immunizing substances, are specific in the strictest sense. The dose and interval between doses depend largely on the manner in which the vaccine is prepared so that absolute rules cannot be made; but in general it may be said that the initial dose is about 100 to 200 million and the interval from 5 to 8 days. If the initial dose produces no local or systemic reaction, subsequent doses may be increased but the interval between doses should not be shortened.

COLON, IDIOPATHIC, DILATATION.—See HIRSCHSPRUNG'S DISEASE.

COLOR-BLINDNESS. Varieties.—Total and partial; congenital and acquired.

Total color-blindness, in which the solar spectrum appears uniformly grayish, is very rare.

Partial color-blindness is quite common. Statisticians declare that the proportion is 1 in 25 among males, and 1 in 400 among females. There may be blindness to blue, yellow, red or green. However, the colors that most often fail to make proper impressions are red and its complementary color green. These colors do not appear as absolutely black, but they cannot be distinguished from each other and from certain shades of gray and brown. In extreme cases there is total blindness for red and green, and even the brightest shade of red cannot be distinguished from green. Unfortunately, the colors most often at fault have been selected by railroad companies and navigators as their signal colors; hence it may be seen how important it is for the employees of transportation companies to have the color-sense absolutely perfect.

Congenital color-blindness is the most common form. It is often hereditary, and sometimes skips several generations. The discoverer of color-blindness was Dalton, a distinguished professor of chemistry, who himself was color-blind, a fact that he ascertained by accident.

Acquired color-blindness may be the result of disease or accident. Defective color-sense often appears after disease of the optic nerve, and is a particular symptom in optic neuritis and in atrophy due to excessive use of tobacco and alcohol. However, central color-blindness may be seen in all forms of toxic amblyopia. A peculiar point to be noted in tobacco amblyopia is the fact that the patient may be able to distinguish colors close to the eye, but when they are further removed he is color-blind, particularly for green and red. This makes it quite important to test for color-blindness at the normal signal distance in addition to the skein-test at close range. Color-blindness is sometimes the result of traumatism; occasionally, after blows upon the head, color blindness is noticed in one-half the field of vision only, the other half being normal in its color-perception.

Chromatopsia is a condition in which all objects become tinged with certain colors. It is common

after cataract extraction. Large doses of santonin have the peculiar property of rendering the whole field of vision yellow.

Diagnosis.—In the ordinary **Holmgren test** the person is given a test-skein of wool of a light-colored pink, and told to *select* (and not name) from a mass of similar skeins those that most nearly resemble the skein to be matched. If he is color-blind, he will confuse the grays, the greens, the pinks, the browns, and the reds. As a confirmative test, he is then given a light pure-green skein to match in the same way.

Dr. William Thomson has devised a convenient apparatus for testing for color-blindness, which has been widely adopted by railroad examiners. It consists of a stick to which numerous bundles of yarn are attached, a light green being used as the test-skein. The method of using the **Thomson stick** is described by its inventor as follows: Using the light-green test-skein, the patient under examination is asked to match it in color from the yarns on the stick, which are arranged in alternate green and confused colors, and which are numbered from 1 to 20. The selection of 10 tints is required, and the examiner notes the number of the tints chosen. The odd numbers are green and the even ones the confusion colors. If the patient has a good color-sense, his record will exhibit none but odd numbers; if he is color-blind, the mingling of even numbers betrays the defect. To distinguish between green-blindness and red-blindness, the *rose test* is used, and the color-blind patient will select, indifferently, either the blues intermingled with the rose, or, perhaps, the blue-greens or grays. Finally, the red test is used as a control.

There are other color-tests, but these two are sufficient for practical purposes. The field of vision for different colors is tested in the same manner as the field for white, using a colored object instead of a white one.

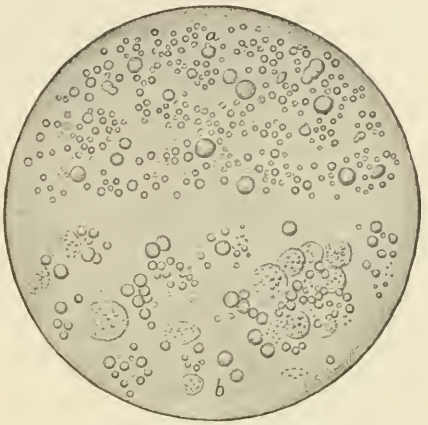
In the *peripheral* field of vision there is a contraction for colors ranging from white, thus: Yellow, blue, red, and green. In contradistinction to this the *central* vision for red is found to be the most distinct, and violet least distinct. Hence the use of red for signals.

The tests for distant color-vision should be made with colored lamps or lanterns, under normal conditions, either on the track or in the depot.

Treatment for the congenital form is useless. The treatment for acquired color-blindness is directed to the cause. In the toxic forms abstinence from tobacco and alcohol is necessary.

COLOSTOMY or COLOTOMY.—See Intestines (Surgery).

COLOSTRUM.—This is the secretion that appears in the breasts after the third month of gestation. It is a whitish, turbid fluid, containing **colostrum corpuscles.** These corpuscles are the epithelial cells of the mammary gland that have undergone fatty infiltration. About the third day of the puerperium these corpuscles burst and discharge their fat globules, thus forming true milk. Colostrum corpuscles disappear about the eighth or tenth day of the puerperium; they may, however, return at any time from some disturbance of the maternal health. Colostrum contains a laxative that is useful in expelling the meconium from the child's bowel during the first few days after birth. See Milk (Mother's).



The Upper Half is Normal Milk; the Lower Half Colostrum.—(*Hawk.*)

COLPORRHAPHY.—See Cystocele.

COMA.—Abnormally deep and prolonged sleep, with the cerebral functions in abeyance; it is due to many conditions affecting the cerebrum directly or indirectly. The well-marked form is characterized by stertorous breathing, relaxation of the sphincters, lividity of the face, and loss of parallelism of the optic axes.

Coma may be gradual or sudden in its onset, complete or incomplete. Stupor, or partial insensibility, has been used to designate incomplete coma. Coma due to hyperpyrexia, typhoid fever, cancer in other portions of the body than the brain, and from yellow atrophy of the liver (likely to be mistaken for disease of the brain), occurs so infrequently that description is unnecessary. The remaining causes of coma may, for the sake of convenience, be divided into 7 groups (described by Eskridge):

I. Transient Coma.—Syncope—as in fainting.

II. Coma from Lethal Doses of Medicinal Agents.

1. Chloral.
2. Opium.
3. Belladonna.
4. Hyoscyamus and its alkaloids.
5. Alcohol.
6. Lead.

III. Coma from Poisons Other than Medicinal Agents Circulating in the Blood.

1. Asphyxia from poisonous gases.
2. Ptomains.
3. Uremia.
4. Diabetes.

IV. Convulsive States from Coma.

1. The preeruptive stage of the exanthems, sometimes preceded by a convulsion.

2. Reflex convulsion, such as teething, overloaded stomach, etc., in children.

3. Epilepsy.

4. Hysteria.
5. Epileptiform and apoplectiform attacks due to paretic dementia or other organic brain-disease, such as syphilis and chronic alcoholism.

V. Voluntary Coma.
Feigning.

VI. Coma from Profound Disturbances of the Cerebral Circulation, but Unattended by Organic Lesion of the Brain-substance.
1. { Shock. / Concussion of the brain.
2. Congestion of the brain.
3. Anemia of the brain.

VII. Coma from Organic Disease of the Brain.
1. Simple apoplexy of the aged.
2. Traumatism of the brain.
3. Syphilis of the brain.
4. Cerebral meningitis.
5. Abscess of the brain.
6. Tumor of the brain.
7. Cerebral hemorrhage.
8. Cerebral embolism.
9. Cerebral thrombosis.

It will be seen that the subheadings of these 7 groups are quite numerous, and the effects of syphilis, alcohol, and a few others may be placed under more than one group. Were it not that many of these causes of coma are so infrequently factors in giving rise to unconsciousness, mistakes in diagnosis would be much more frequent than they really are.

Transient Coma

Syncope.—A sudden weakening or temporary arrest of the heart's action produces anemia of the brain, and results in unconsciousness, more or less profound. The symptoms are paleness of the surface of the body, especially of the face; extreme pallor of the gums and lips; dilated pupils; surface of the body cool and covered with cold perspiration if the syncope is very pronounced; the pulse weak, small, and rapid, or entirely absent at the wrist; respiration weak, but not restricted unless the heart's action is seriously interfered with, when it may become slightly stertorous; face cyanotic, and a puffing of the lips with each respiratory act. The negative symptoms are an absence of all those of a localizing nature, such as convulsions, muscular rigidity, paresis, or paralysis. The patient lies as if dead, except that the organic functions are performed in the quietest possible manner. The fact that the symptoms are fleeting in character and pass away on a return of the blood to the head is an important point in the diagnosis. It must be remembered that occasionally there are repeated attacks of syncope, the patient reviving from one attack and almost immediately passing into another.

In almost all cases the diagnosis will rest between syncope from temporary disturbance of the heart's action, degeneration of the heart, apoplectiform attacks of cerebral origin, and hysteria. When the loss of consciousness is due to degeneration of the heart, there will be other evidence of cardiac degeneration—such as the probable history of previous attacks, the weak action of the heart, the age of the patient, the condition of the radial arteries, and the fact that the unconsciousness has come on after exertion or on passing from a low to a high altitude. During the syncopal condition there will be a tendency to cyanosis.

The slight apoplectiform attacks sometimes seen in persons suffering from atheroma of cerebral vessels are called "fainting spells." The symptoms, as described by the friends of the patient, are very similar to those of syncope, and they, too, are fleeting in character. If, however, an attack is seen by the physician, or if an intelligent attendant or nurse is on her guard and observes closely, it will be found that there is a striking difference between the symptoms of the two conditions. In the slighter apoplectiform attacks that not infrequently precede occlusion of an artery from thrombosis, the pallor of the face and lips is less pronounced than in syncope, and frequently the lips present a slight cyanotic tinge. Sometimes there is a slight twitching of the facial muscles, with a tendency to stertor of the respiration for a few seconds. The symptoms are less fleeting than those of syncope, and rarely pass away immediately on lowering the head. The patient very frequently complains of headache for some time subsequently. In a few instances these slight apoplectiform attacks may recur 2 or 3 times within a few hours.

Hysteric Syncope.—Repeated attacks of syncope are always suggestive of hysteria, although, as we have seen, they may be due to other causes; and, further, a single attack of syncope may be of hysteric origin. Syncope, when due to hysteria, is not attended by intense paleness of the surface of the body, and the pulse at the wrist is neither absent nor greatly changed from the normal. Again, there may be present other evidences of hysteria, such as inversion of the color-fields, peculiar paralyses, globus, etc.

Coma from Lethal Doses of Medicinal Agents.

Chloral.—A condition of nonfatal coma from which it is very difficult to arouse the patient, except possibly for a momentary response, may be produced by chloral. In this condition the temperature is lowered; respiration is quiet, less rapid, but often fuller than normal; the pulse is weak and somewhat slow; the pupils are usually small.

The patient is in a profound sleep, with a lessening of the activity of all the vital functions. In toxic doses the temperature is often lowered several degrees, although a rise, with a subsequent fall to 91.20° F., has been observed soon after taking large quantities of chloral into the stomach; respiration is slow and full, until just before dissolution, when it may be irregular and very rapid; the pulse, at first soft and slow, becomes irregular and rapid; and the pupils, small at first, dilate later. There is complete muscular relaxation, and the patient lies as if dead, save that the action of the heart and lungs proves that life is not extinct. There are no localizing symptoms from chloral coma.

Opium-poisoning.—The slow pulse (reduced to

10, 8, or 4 beats a minute) and the noisy respiration, the contracted pupil, with a dilated condition of the capillaries of the face, are almost positive evidences of the second stage of opium-poisoning. Later, just before death, the pulse becomes very rapid; the pupils next begin to dilate, and finally respiration becomes very irregular. In some cases respiration is rapid but arrhythmic before death. The temperature is practically normal, except shortly before death, when it may rise. There is little danger of mistaking a case of coma from opium-poisoning for coma from any of the other narcotic poisons. The contracted pupil, slow pulse, and labored respiration sometimes found to occur from a hemorrhage at the base of the brain, especially into the lateral ventricles or into the pons, may, at first, lead one to suspect poisoning from opium; but the subnormal temperature from hemorrhage into the ventricles and the sudden increase of the body-heat from pontile lesions, together with localizing symptoms, renders the diagnosis quite easy.

Coma from **belladonna poisoning** is often preceded by delirium and convulsions. The skin, covered with a scarlet rash, is hot and dry, pupils dilated, temperature raised, pulse rapid, and respiration may at first be deep and slow, but before death becomes rapid. The scarlet color of the skin, the delirium, and the absence of localizing symptoms serve to distinguish coma from belladonna poisoning from coma due to brain-lesion. The scarlet-colored skin, the delirium, and the excitement of the heart aid in distinguishing coma caused by belladonna from coma due to the other mydriatics, especially hyoscyamus and its alkaloids.

Alcoholic Coma.—A noisy delirious condition points to alcoholic coma. The patient may be so profoundly unconscious as to fail to respond to an irritant or to attempt any response when his name is loudly called. If it is possible to arouse him, he will often strike at any one who is annoying him. The temperature is usually normal, and equal on each side of the body; the pupils may be normal, contracted, or dilated, and the conjunctiva congested. It should be remembered that a person who is intoxicated may also be suffering from organic disease of the brain, either acute or chronic. In all cases of alcoholic coma a careful examination should be made, lest a brain-lesion escape detection.

Coma from **lead-poisoning** is usually preceded by vomiting, purging, and convulsions. An analysis of the urine will reveal lead, and a blue line may be found on the gums if the metal has been taken into the stomach during a period of several days. Sometimes it is extremely difficult to diagnose a condition of encephalopathy from lead, unless a careful analysis of the urine is made for this poison, or unless the history should point to a source by which the metal has found its entrance into the system.

Coma from Poisons Other than Medicinal Agents Circulating in the Blood

Asphyxia from Poisonous Gases.—The surroundings of the patient, such as escaping gas in a room, charred wood that has filled the room with smoke, or the fact that the sufferer has become unconscious while working in an old sewer, etc., will make the diagnosis quite easy. Lividity of the tongue and lips and embarrassed respiration are commonly found in these cases.

Coma from Ptomains.—The cases of coma that have resulted from the ingestion of putrid food have usually been preceded by symptoms of an irritant gastrointestinal poison, such as vomiting and diarrhea, extending over a period of several hours or one or more days.

Coma from Uremia.—The onset of uremic coma is often attended by delirium or convulsions. Albumin and tube-casts in the urine suggest uremia; but albumin is frequently found in considerable quantity in the urine in cases of cerebral hemorrhage. It must be borne in mind that renal disease, especially the senile form (granular disease of the kidney), occurs in about one-third of the cases of cerebral hemorrhage. The peculiar physiognomy of a person suffering from renal disease, with local edema, equal pupils, often less profound coma than in cerebral hemorrhage, and usually normal temperature (according to Gowers, it is always subnormal except in cases in which local inflammation exists), the presence of the odor of urine in the breath, and the absence of hemiplegic symptoms, occurring in a young subject, are usually sufficient to enable one to diagnose uremic coma. Gowers states: "Rigidity of limbs or local muscular twitching during the coma is, if constant in seat, in favor of cerebral disturbance; if variable in position, it is in favor of uremia." Some writers lay stress on the normal or subnormal temperature in uremic coma, while others state the temperature is usually elevated. Besides local inflammation, repeated convulsions, and probably other complications, will cause an elevation of the body-heat in uremic coma. On the general temperature alone little stress can be laid. The fact that the temperature is the same on the two sides of the body in coma from uremia is an important point in excluding a unilateral brain-lesion.

Coma from diabetes is usually gradual in its onset. The presence of sugar in large quantities in the urine of a comatose person would point strongly to diabetic coma, and in the absence of any localizing symptoms the diagnosis would be justified; provided, however, there was no evidence of the ingestion of any poison.

Convulsive States

Coma ushered in by a convulsion is occasionally observed in children during the preeruptive stage of the exanthematous fevers, especially scarlet fever. The diagnosis would lie between the exanthematous fevers, reflex convulsions from an overloaded stomach, etc., and acute meningitis. A positive diagnosis is not always possible during the first 24 hours. The temperature of comatose children during the preeruptive stage of scarlet fever is usually very high—104° to 105° F.—the pulse exceedingly frequent, and, as a rule, there are only one or two convulsions. The respirations are very

rapid. The coma usually passes away as soon as the eruption appears.

Coma from teething or from an overloaded stomach is rarely attended by a temperature above 103° F., although in one case that has been observed the body-heat in the rectum was 104° F. The pulse and respirations are usually less rapid than in the exanthemata. The face is usually flushed. The coma passes away on removal of the cause.

When convulsions and coma usher in the obtrusive symptoms of **meningitis**, the convulsions may recur every few minutes, or hours, until several have occurred. The temperature in these cases is often very high—104° F., or even 106° F. —but the pulse is less rapid than in scarlet fever. A high temperature, a pulse of from 140 to 180, and a single convulsion would be in favor of scarlet fever. A moderately high temperature (103° F.), a pulse of 120, and a flushed face would indicate an overloaded stomach. Repeated convulsions, high temperature, and a pale face should create suspicion of meningitis. A diagnosis is not always possible during the first 24 hours, and in some cases not during the first 36 hours.

Coma from Epilepsy.—If the history of the patient is known and the onset of the convulsive seizure has been witnessed, little difficulty will occur in differentiating this from coma due to other causes. It should always be borne in mind, however, that persons suffering from epilepsy are equally subject to the other causes of coma. If the patient is first seen in the comatose stage following an epileptic fit, and the physician has no knowledge of his previous history, the absence of hemiplegic symptoms and the short duration of the coma would serve to distinguish the case from one of unilateral brain-lesion. On the one hand, it must be noted that in status epilepticus—a condition rarely reached without the history of the patient being known by the attendants—it may be impossible, in the absence of a history, to make a diagnosis between this condition and a sudden cerebral lesion without unilateral symptoms. On the other hand, it must not be forgotten that in some cases of epilepsy the convulsive seizure is followed by a weakness of one arm or leg, especially at the distal portion of the extremity. In nearly all cases of cerebral hemorrhage attended by convulsions, and following one another in rapid succession, unilateral symptoms exist, but multiple thrombi and emboli may give rise to a condition resembling that of status epilepticus without being attended by a single unilateral symptom.

Coma from Hysteria.—The subjects of this condition are usually women, and the coma comes on suddenly and is often preceded by delirium, or it may alternate with it. The face is flushed and hot and the temperature may be elevated, especially if the delirium that has preceded it has been prolonged and noisy and attended by much physical exertion. The pupils are either normal and respond to light, or slightly dilated and react imperfectly. The latter condition is only found in hysteria, while the patient is making considerable muscular effort. The pulse is normal, except in those cases in which the patient has exhausted herself by violent muscular exertion, when it may be rapid. The urine is retained. There is no vomiting or diarrhea, and the respiration is rapid, but not stertorous. A careful study of the symptoms will enable one to exclude the narcotic and irritant poisons. The diagnosis will rest between the subject under discussion, feigning, and some organic disease of the brain, especially cerebral congestion, meningitis, or a vascular lesion. Feigning may be excluded by the absence of all symptoms except those that may be produced by physical exertion.

With reference to hysteric coma, we may conclude (1) that the initial symptoms of a case of organic disease of the brain may be apparently purely hysteric in character; (2) the case may be purely hysteric in character in the beginning, yet as it progresses organic changes, or others equally intractable, may develop from exhaustion, disturbances in circulation, or from the results of metabolic processes.

Coma from Epileptiform and Apoplectiform Attacks due to Paretic Dementia or Other Organic Brain-disease, such as Syphilis and Chronic Alcoholism.—In paretic dementia the history of the patient would be the only reliable guide in the diagnosis, as the coma is similar in almost every respect to that which follows a vascular lesion. When, however, the convulsion with the resulting coma is the first apparent symptom of paretic dementia, time only would enable the physician to distinguish whether the attack was epileptic or epileptiform in character. Coma from syphilis or chronic alcoholism can only be diagnosed by evidence of certain organic brain changes. Even in such cases it is well to remember that syphilitic and alcoholic subjects who are suffering from brain-disease in consequence of these poisons are also liable to the other causes of coma.

Voluntary Coma

Feigning.—Malingerers occasionally feign coma, but more commonly the simulated coma is preceded by convulsions.

"Everything usually observed in an epileptic fit may be easily simulated by a clever malingerer except the change in the color of the face, the condition of the pupils, and insensibility to suddenly inflicted and unexpected irritation" (Eskridge).

Color of the Face.—A simulator, by muscular action, can produce redness of the face, and by holding his breath this color will change to a darker hue. It is very difficult voluntarily to cease breathing until the face becomes deeply cyanosed, as occurs in genuine convulsions. It is rare for a simulator to be seen sufficiently early for the absence of paleness of the face to be noted.

Condition of the Pupils.—In the early stage of the fit the pupils are said to be occasionally contracted. If this phenomenon is present, it must be very evanescent in character. At all events, during most of the tonic stage and throughout the clonic

stage the pupils are dilated, and the irises will not often respond perceptibly to light. As consciousness begins to return the extreme dilatation passes away, and the pupils may alternately contract and dilate every few seconds.

Keen, Mitchell, and Morehouse, in an article on malingering, state: "We ourselves are of the opinion that when, in a fit, the pupils, largely dilated, remain impassive and motionless before a bright light, the case is almost certainly a real one. But, unfortunately, this state of things is of very rare occurrence, even in severe fits. The pupils unquestionably contract in the presence of a bright light in many such cases. Sometimes the movement is sluggish and slight; in others it is almost normal as to range of speed and movement." These observers, experimentally demonstrated that violent muscular action will cause the pupils to dilate rapidly, and that so long as the muscular action is kept up, the irises will move only slightly and sluggishly to a bright light. From their observations they deduced the conclusion that only in those cases of epileptic fits in which the irises fail absolutely to respond to light is the pupillary test of the genuineness of the convulsion of any value.

Insensibility to Suddenly Inflicted Irritation.—In the unconsciousness from an epileptic convulsion, if the cornea is touched with the end of the finger, the eyelids may move a little, and if the supraorbital nerves are firmly pressed with the thumbs, the skin of the forehead may slightly corrugate, or if a pin is thrust into a limb, it may be flexed, but no purposive movements will be made to get rid of the irritant. In feigned epilepsy, if acute pain is suddenly and unexpectedly caused, an intelligent effort will at first be made by the simulator to avoid the irritant.

When the feigned coma is not preceded by simulated convulsions, the pupils will be normal, unless the malingerer is throwing himself around and making considerable muscular exertion, thus causing the pupils to dilate and to lessen their normal response to light. The face is usually flushed, showing the results of physical effort. Under such circumstances, if the malingerer lies quietly, the pulse, temperature and pupils will be normal. Respiration will be rapid or slow, according to the subject's notion of feigning unconsciousness. Sensibility to suddenly inflicted pain, if the simulator is unaware of what the observer is doing, will be manifest. The administration of an anesthetic is probably the best method of detecting feigned coma, as well as epilepsy.

Coma from Profound Disturbances of the Cerebral Circulation, but Unattended by Organic Lesion of the Brain-substance

Coma from Shock and Concussion of the Brain.—In the severer forms of shock consciousness may be completely lost. It immediately follows the depressing influences that have caused it. The pupils are usually dilated, muscles relaxed, face pale, surface of the body cool, temperature lowered, pulse weak and rapid, sometimes slow and irregular, respirations shallow and often frequent; the sphincters are sometimes relaxed, and vomiting may occur. In fact, the normal functional activities of all the organs of the body are lessened. Recovery, when it begins, is progressive. It is to be distinguished from so-called "delayed shock," which comes on some time after the injury, and shock followed by delayed or imperfect reaction, both of which are due to concealed hemorrhage or to some other complication. When the shock has been caused by a blow on the head, it is not always an easy matter to determine whether the symptoms are due to shock or cerebral concussion, or to these and an intracranial lesion. The absence of any localizing symptoms, and the presence of slightly subnormal temperature, equal in each axilla, a weak and rapid pulse, noiseless respiration with evidence soon after the injury of beginning reaction, which is continuous after it has become manifest, point toward the functional nature of the brain disorder. It is sometimes impossible to exclude organic disease of the brain in these cases until hours or days have elapsed, and even then the physician may be in doubt. In those cases in which the coma or semicomatose condition lasts for several days or weeks, even in the absence of all positive symptoms of an organic nature, it is probable that laceration of the brain has occurred—that slight capillary hemorrhage into the brain-substance has taken place.

Coma from Cerebral Congestion.—It is rare for coma to result from cerebral congestion, unless the cause is insolation or the vasomotor disturbance found in paretic dementia. The lighter forms of cerebral congestion, passive or active, sometimes pass into a stuporous condition. In either event the coma is gradual in its onset, and is often preceded by headache and delirium. In the active form there will be the history of exposure. The face is flushed, the carotids throb, the pulse is rapid, full, and strong, temperature elevated, pupils contracted, conjunctivæ injected. There are no localizing symptoms, and the attack soon ends in recovery if inflammation does not result, or if the patient is not exhausted by the hyperpyrexia. In the passive form the appearance of the patient's face indicates venous stasis. The respiration is rapid and noisy, pulse rapid, and temperature is elevated 1 or 2 degrees above the normal. If death does not result, recovery soon takes place. In neither form of congestion are there any localizing symptoms or evidence of cranial nerve involvement. Meningitis would be excluded by the absence of rigidity of the posterior neck-muscles, or of cranial nerve symptoms, together with the history of the case. A vascular lesion would be negatived largely by the absence of unilateral symptoms.

Coma from cerebral anemia is most commonly caused by sudden loss of blood. The appearance of the patient and the condition of the temperature and pulse would be just the opposite of those of cerebral congestion. Delirium and convulsions often occur if the loss of blood has been sudden

and profuse. The diagnosis is usually evident from the history and symptoms.

Coma from Organic Disease of the Brain

Coma from Simple Apoplexy of the Aged.—In persons advanced in life a condition sometimes occurs with a train of symptoms that resemble perfectly those of a vascular lesion of the brain, but at the autopsy no trace of hemorrhage or other gross lesion is found. The age of the patient and the history of previous similar attacks would aid in the diagnosis. It must be confessed, however, that a first attack of "simple apoplexy" might puzzle the most skilled diagnostician, especially if unilateral symptoms are present, as is sometimes the case.

Coma from Traumatism of the Brain.—If an injury has occurred to the head and coma results, the diagnosis will lie between simple concussion, or shock, and an organic lesion of the brain. Delayed coma—that is, coma coming on some time after the receipt of the injury—deepening coma, and delayed reaction from a deep comatose state would be almost positive evidence of organic intracranial disease, usually vascular in nature. Coma coming on immediately after the injury may be due to an organic lesion or to a functional disturbance. The sooner reaction begins to take place, and the more complete it is a few hours after the head injury, the greater the probability of the disorder being functional in nature. Stertorous respiration, congestion of the face, slow, full pulse, unilateral symptoms, and convulsions would indicate intracranial hemorrhage.

Coma from Meningitis.—In the absence of a history the diagnosis would depend upon rigidity of the posterior neck-muscles, cranial nerve involvement, heightened temperature, irregular respiration, and slow and irregular pulse if pressure-symptoms were still present, but rapid pulse if the stage of exhaustion had been reached. Changes in the optic discs are not always present. If the case had been of short duration, the discs might show simple hyperemia, or, if a rather prolonged course of the disease had preceded the comatose condition, beginning of optic nerve atrophy might be manifest. Optic nerve changes would enable the physician to exclude all vascular lesions, except possibly thrombosis. Choked discs, with evidence of meningitis, would indicate that the meningeal inflammation was secondary to tumor or abscess. The greater the swelling of the disc, the greater the probability of the primary intracranial lesion being a tumor. A tubercular tumor or nodule is probably the only growth of the brain that causes general meningitis.

Coma from Abscess of the Brain.—The history of the case, with a probable cause of intracranial suppuration, vacillating temperature, slight swelling of the optic discs, and unilateral symptoms, if these were present, would be the principal aids in the diagnosis. If there was optic neuritis, and the other causes of the condition, except tumor of the brain, were excluded, the diagnosis would consist in differentiating between tumor and abscess. The greater the swelling of the optic discs, the stronger would be the probability of the existence of a tumor. The greater the variation of temperature from the normal, and the more profuse the perspiration during the comatose condition, the more likely the presence of abscess. The terminal stage of abscess of the brain is usually attended by high temperature, and the body is bathed in perspiration.

Coma from Tumor of the Brain.—It sometimes happens that one sees a case of tumor of the brain for the first time when the patient is in a state of coma. It may be the coma that immediately precedes death, or such a condition may occur any time during the progress of the intracranial growth, especially if it is located in the region of the cerebellum, so as to give rise to pressure on the veins of Galen and cause effusion into the lateral ventricles. Pronounced choking of the optic discs would suffice to settle the diagnosis in favor of tumor, provided that renal disease, anemia, and lead encephalopathy had been excluded. It is only in those cases of tumor of the brain in which there is extensive softening of the brain-substance that a vascular lesion is simulated by the coma and paralysis, which come on suddenly and at the same time. In the absence of any history in such a case the presence of choked disc would be the only guide in excluding a vascular lesion.

Coma from Nontraumatic Vascular Lesions.—These include hemorrhage, thrombotic and embolic occlusion of vessels. The coma that occurs as a result of a vascular lesion is, as a rule, sudden in its onset and more or less profound, depending upon the nature of the vascular disturbance. One of the most common symptoms attending the coma from a vascular lesion is hemiplegia. Having determined that the coma in a given case is due to hemorrhage or occlusion of a vessel, it is of considerable importance, before treatment is instituted, to seek further and determine the nature of the vascular lesion; in other words, is it embolic or thrombotic occlusion, or hemorrhage?

Embolic Occlusion.—It is probable that no one is justified in diagnosing cerebral embolism in the absence of an apparent cause. Endocarditis, chronic in nature, with subacute attacks, is the most common cause. The next most frequent cause is a suppurative process in some portion of the body, especially in the thoracic or abdominal cavity. The parturient state, and the blood changes often found in chronic syphilis, with exhaustion, favor the formation of an embolism. The coma from embolism is shorter in duration and less profound than in hemorrhage. In cases in which a more or less complete hemiplegia has taken place in a young person, without profound coma of several hours' duration, the chances would be against hemorrhage and in favor of embolism, except in certain conditions in which a thrombotic occlusion of the vessel would be more probable than embolism. The less the primary disturbance of temperature, provided the paralysis is extensive, the greater are the probabilities against the cerebral lesion being due to hemorrhage.

Coma from Thrombotic Occlusion of a Cerebral Vessel.—Atheroma of the vessels, a potent factor in

the causation of thrombosis, does not occur before the thirty-fifth or fortieth year, except possibly in association with Bright's disease or as a result of it. Syphilitic arteritis is a frequent cause of thrombosis from the twentieth to the fiftieth year, and it may occur earlier or later, but the frequency diminishes as the two extremes of life are approached. Thrombotic occlusion of a vessel may occur from the extension of an inflammatory process from a tuberculous nodule in the brain. This is the rarest of all causes of cerebral thrombosis.

Following are some points in the differential diagnosis between coma of thrombotic origin and coma from hemorrhage (Eskridge):

Thrombotic Occlusion.	Cerebral Hemorrhage.
1. Prodromata frequent.	1. Prodromata infrequent.
2. Great degeneration of arteries of limbs, or history of syphilis.	2. Turgid face and strongly beating arteries of the neck.
3. Pulse soft and often very compressible.	3. High arterial tension regardless of the size of the pulse.
4. Heart feeble, dilated, and irregular.	4. Heart hypertrophied; beating strongly.
5. Coma less marked in depth and duration.	5. Coma more intense; longer in duration.
6. Following grief and other depressing influences.	6. More likely to be induced by mental excitement.
7. Local convulsions more frequent.	7. General convulsions more frequent.
8. Slight initial temperature disturbance.	8. Often great initial temperature disturbance.
9. Slight variation of the temperature within a few hours.	9. Often a considerable rise of temperature from 12 to 24 hours after the attack.
10. Secondary inflammatory symptoms frequent and well marked.	10. Secondary inflammatory symptoms less in frequency and in degree.

Treatment.—The treatment of coma is, of course, immediately referable to the cause. Examination of the urine should speedily be made. In the absence of any history or indicative signs, the stomach-tube should be applied, in order to be on the safe side. One drop of croton oil is the speediest and least harmful revulsive. The patient should be put in a dark room, the head should be high, and should be shaved if there is much hair. Cold applications to the head are indicated. The diet should be very light. Hot applications or sinapisms may be applied to the back of the neck, spine, abdomen, or back of the legs. All these general methods are of value, but if the cause is serious, it must be discovered at once, and appropriate treatment administered, or the patient will be beyond help.

COMA-VIGIL.—A symptom of unfavorable import, in which continuous sleeplessness is associated with partial unconsciousness. It occurs toward the end of diseases in which the nervous system is directly or indirectly involved, and frequently appears in the latter part of a severe attack of typhoid or typhus fever or of delirium tremens. Coma-vigil is distinguished from coma by a certain amount of consciousness, by the quick pulse, and by the stertorous breathing. It differs from the coma of concussion of the brain, since the uncontracted pupil, the history, the absence of coldness of the skin and of signs of shock are not present. It is almost invariably a fatal symptom, and may last from a few hours to 3 or 4 days, 24 hours being its usual length. It may deepen into actual coma, but more usually the pulse quickens and weakens, respirations become more feeble, and death from asthenia results.

The treatment does not regard the coma-vigil itself, but nutritive and stimulating measures for the primary disease. Hydrotherapy is valuable, but it must be subject to a consideration of the ensemble of the conditions.

COMEDO (Blackheads; Flesh-worms).—Comedo is a condition characterized by black, pinhead-sized, sebaceous plugs lying in the mouths of the excretory ducts.

Symptoms.—Comedos appear as yellow, brown, blue, or black points, involving chiefly the nose, forehead, and cheeks. They may, however, occur upon other parts of the body. When the comedo is squeezed out, a yellowish-white, maggot-like body with a dark external point may be seen. The dark color is due partly to dust from without and partly to chemic changes in the secretion. Comedos are liable to undergo inflammation and to give rise to acne papules or pustles.

Crocker mentions a variety of comedo (*grouped comedones*) characterized by closely aggregated, often symmetric lesions, occurring upon the temples and cheeks of children, and not subject to inflammation.

Etiology.—Puberty, dyspepsia, anemia, constipation, and menstrual disturbance are frequent causes. They probably produce a lack of tonicity in the follicular walls.

Comedos are often produced artificially by deposition from the atmosphere of various solid impurities. Thus, workers in tar, brass, and iron are frequent sufferers from this affection.

Pathology.—Unna claims that there is a thickening of the corneous layer of the external surface, and consequently a closure of the duct. The horny lining of the ducts undergo similar change, and scales are thrown into the canal, which, combining with the sebum, form the comedo.

The *Acarus*, or *Demodex folliculorum*, is sometimes accidentally present in comedos.

Prognosis.—Favorable. The condition is likely to recur.

Treatment.—The systemic treatment aims at a correction of the predisposing causes. Strychnin, iron, cod-liver oil, and the hypophosphites are often required.

Locally, applications designed to remove the plugs are indicated. The larger ones should be squeezed out either with the fingers or a comedo extractor. Soaps containing sand or chalk are

sometimes used. The tincture of green soap is an excellent remedy in sluggish cases. Equal parts of alcohol and ether make a useful sebaceous solvent.

The appended formula is at times very efficacious:

℞. Precipitated sulphur, Soft soap, } each, ʒ j
Pulverized chalk, ʒ j to ij
Zinc oxid ointment, ʒ j.

Or the following lotion may be used:

℞. Boric acid, ʒ j
Alcohol, ʒ iij.

COMPENSATION.—See HEART-DISEASE.

COMPRESS.—See PRESSURE.

COMPRESSION AND CONCUSSION, CEREBRAL.—See BRAIN (Injuries).

CONDENSED MILK.—Milk that has had most of its watery elements evaporated according to a known process. Condensed milk prepared with the addition of cane-sugar is a white or yellowish-white product of about the consistency of honey, and ranging in specific gravity from 1.25 to 1.41. It should be completely soluble in from 4 to 5 times its bulk of water, without separation of any flocculent residue, and then possess the taste of fresh, sweetened milk. Condensed milk prepared without the addition of cane-sugar is not boiled down to the same degree, and therefore remains liquid. Battershall gives the following analysis of both classes:

CONDENSED MILK WITH ADDITION OF SUGAR.

BRAND.	WATER.	FAT.	CANE-SUGAR AND MILK-SUGAR.	CASEIN.	SALTS.
Alderney	30.05	10.08	46.01	12.04	1.82

See MILK.

CONFECTIONS are medicinal substances formed into a mass with sugar, honey, water, etc., with the object of rendering them palatable and preserving them from change. There are two official confections: C. Rosæ, and C. Sennæ.

CONFINEMENT.—See LABOR.

Methods of Determining Date. Naegele's Rule.—This is the most convenient rule, and is accurate enough for all practical purposes. Ascertain the date of the appearance of the last menstruation, count back 3 months, and add 7 days to the result. This date will be the middle of the probable fortnight in which labor will occur.

The Date of Quickening.—When no menstrual history is obtainable, the probable time of confinement can be ascertained by the date of quickening. As this occurs about 4 1/2 months after impregnation, the addition of 4 1/2 months to this date will give approximately the date of confinement.

The Height of the Fundus Uteri.—This method gives at best a rather imperfect idea of the date of confinement. It is based upon the size of the uterus at the varying months of pregnancy:

At the fourth month the fundus uteri is midway between the umbilicus and the symphysis pubis.
At the sixth month the fundus uteri is on a level with the umbilicus.
At the seventh month the fundus uteri is midway between the umbilicus and the ensiform cartilage.
At the eighth month the fundus uteri is on a level with the ensiform cartilage.
At the ninth month the fundus uteri is midway between the umbilicus and the ensiform cartilage.

It will be seen from the foregoing table that the fundus uteri occupies practically the same position at the seventh as at the ninth month. This need occasion no confusion, as at the seventh month the presenting part is above the superior strait, while at the ninth month it has descended into the pelvis.

And see TABLE ON NEXT PAGE.

Preparations for confinement and directions for the care of the mother and child are given under the heads of LABOR, NEW-BORN INFANT (*q. v.*).

CONIUM.—Hemlock. The green, full-grown fruit of the spotted hemlock, *Conium maculatum*. It contains 3 alkaloids and a volatile oil. Its properties are mainly due to the alkaloids *coniin*, $C_8H_{15}N$, and *methylconiin*, $C_8H_{14}NCH_3$. It produces motor paralysis, without loss of sensation or of consciousness. Toxic doses cause death by paralysis of the organs of respiration. All the preparations of conium are uncertain in action, as the active principle is very volatile. The dose of conium is 1 to 5 grains. The dose of the fluidextract is 1 to 10 grains.

Incompatibles with *Conium*, are: Vegetable acids, alkalies, tannic acid; with *Coniin:* albumin, aluminum, salts, alkaloidal precipitants, chromic trioxid; copper, iron, manganese, and zinc salts; nux vomica and its alkaloids, and picrotoxin.

Therapeutics.—Conium is indicated in diseases characterized by excessive motor activity. Large doses are required, as some physiologic action is necessary. Children bear it well, their constant activity preventing its full action. In chorea and paralysis agitans it is useful, by depressing the motor nervous system. In acute mania

ELY'S TABLE OF THE DURATION OF PREGNANCY

EXPLANATION.—Find in the upper horizontal row the date of appearance of last menstruation; the figure beneath will show the expiration of 280 days, or 10 months of 28 days each.

and delirium tremens, to quiet motor excitement and prevent exhaustion, it is remarkably efficient, especially when given conjointly with morphin. When pain and spasm are present, it will prove a useful agent; and in tetanus, blepharospasm, asthma, whooping-cough, and other spasmodic affections it is frequently used with benefit. Added to poultices, it makes a useful sedative for painful ulcers, cancer, etc.

Poisoning.—A prominent symptom due to conium poisoning is ptosis, or drooping of the eyelids. There is also much staggering and inability to walk. The treatment of poisoning consists in the use of strychnin as a respiratory and nervous stimulant and the use of external heat and of cardiac stimulants. Emetics or the stomach-pump are to be used before administering any antidote. Picrotoxin and other excitomotors are antagonistic.

CONJUNCTIVA, BURNS.—Burns of the conjunctiva are usually on the bulbar portion, which is most exposed. The treatment consists in cleansing the eye, unless the burn has been caused by lime, when the parts should be washed with a piece of cotton soaked in oil. Acids and alkalies should be neutralized at once. Olive oil or liquid vaselin should be instilled. Cocain and atropin are advisable to relieve the pain, and may be applied in the form of an ointment: Atropin, 0.1; cocain, 0.2, vaselin, 10.0.

CONJUNCTIVITIS. Simple Conjunctivitis.—Hyperemia of the conjunctiva is a symptom rather than a disease, and is generally the sequence of some irritation of the membrane, such as foreign body, weeping, heat or cold, exposure to light, etc. The treatment consists in removing the cause, which, in many instances, is a small foreign body that the patient has been unable to locate.

Chronic hyperemia or **dry catarrh** of the conjunctiva is caused in many ways. Irritation by dust, peculiar to such occupations as those of the miller, stone-mason, etc., is a fruitful source. Any derangement of the secretion or excretion of the tears is a cause. Firemen, puddlers, and others who work continually in a strong light; students using their eyes excessively, and often by poor light, and persons subject to any kind of eye-strain may be afflicted with dry catarrh of the conjunctiva. The symptoms are itching and sensation as of a foreign body or of heat in the eye. The distress increases toward evening, showing the indubitable presence of eye-strain. The upper lids feel heavy, and there may be blepharospasm in a mild degree. Upon examination the lids are seen to be congested, there is a uniform redness, and all the accompanying signs of a catarrhal condition are present. At the sides and over the tarsus there are often nodules resembling raw flesh. There is no pathologic secretion.

The treatment consists in correcting any error in refraction or any muscular disturbance. To avoid the deleterious influences of some occupations, protective glasses may be ordered. If there is ex-

posure to sunlight, smoked glasses should be prescribed. Astringent and antiseptic applications are advisable. Boric acid (10 grains to 1 ounce) is the solution most commonly employed; zinc sulphate and zinc chlorid (1 grain to 1 ounce) are useful. Camphor water is often used as a base for eye-drops. Alum may be used in solution of 6 grains to 1 ounce. In case the catarrh is persistent, applications of a 2 percent solution of silver nitrate every second day are recommended. Touching the eyes with a pencil of alum is sometimes of use. Often, in old and refractory cases, a variation in the astrigent employed is of advantage. Irrigation with hot or cold lotions of plain water is always advisable; besides the pleasant local effect, absolute cleanliness is assured.

Simple catarrh is one of the commonest diseases of the conjunctiva. In addition to being due to the irritative causes already mentioned, it is a frequent accompaniment of the ordinary infectious diseases, such as measles, scarlet fever, etc. A simple cold is a frequent source of conjunctival catarrh. Tobacco smoke and other irritant vapors are causes. Finally, any bacterial invasion producing inflammation elsewhere in the body may cause trouble in the conjunctiva.

Symptoms.—It begins with a hyperemia, followed by a profuse watery discharge. The lashes are matted, and the lids are glued together in the morning. There is profuse lacrimation, called forth to remove the excessive secretion from the conjunctiva, and, as the capacity of the drainage apparatus is overtaxed, epiphora results. Aside from the ordinary symptoms of conjunctival congestion, the patient is annoyed by the optic defects caused by flakes of mucus on the cornea. Photophobia is sometimes distressing. Again, the symptoms are worse in the evening. The patients complain that they have a sensation as of sand in the eye, and they are inclined to prolong the irritation by rubbing.

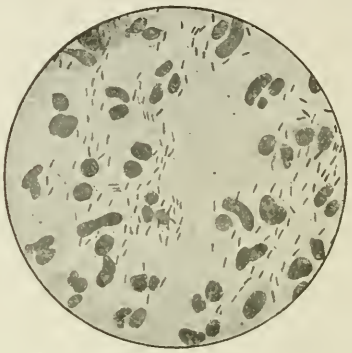
The course of the disease varies from one week to an indefinite period.

Treatment.—Ordinary measures with astringent and antiseptic washes will alleviate the symptoms; but when there is a hidden cause, the process continues. Occupation, habits, and continued eye-strain are causes that are often left uncombated. In such cases local treatment is of little avail. Anointing the lids with pure or medicated vaselin every evening should be insisted upon. Generally, the use of an astringent is advisable—alum, tannic acid, silver nitrate, and zinc sulphate are most commonly used. No direct rule can be given for the strength and frequency of the applications. Each case needs a special treatment. In intractable cases the applications, once or twice daily, of a 50 percent solution of boroglycerid in glycerin is often of great service.

Acute Contagious Conjunctivitis

This is also called "Pink Eye," acute mucopurulent conjunctivitis, and epidemic conjunctival catarrh and is due to a small bacillus first studied by Koch and Weeks.

Symptoms.—After an incubation period of two or three days the disease begins as an ordinary conjunctivitis. In the course of two or three days the discharge becomes thick and often purulent, the lids are glued together in the morning, and sometimes markedly swollen, and there is deep injection of the entire conjunctiva. Generally there is some extension of the catarrh to the nose and sinuses. The disease may last only a few days or recovery may be delayed for several weeks



THE KOCH-WEEKS BACILLUS. ×950 (*Hansell and Sweet.*)

by the intervention of a subacute stage. Rarely corneal complications arise. Recurrences are not infrequent.

Diagnosis is made by the finding with the microscope of the Koch-Weeks bacillus in the cells or discharge, by the yellowish secretion that adheres to the lashes and by the occurrence of other cases in the house.

Treatment.—The treatment is similar to that of simple conjunctivitis. Cold compresses may be applied during the first two days. Argyrol and protargol are generally valuable; in the more severe cases nitrate of silver should be applied to the everted lids.

Purulent Conjunctivitis

Purulent conjunctivitis is a term used to cover highly infectious processes of the membrane. It varies according to the mode of infection. The most serious cases are generally due to the gonococcus of Neisser. And see COLON BACILLUS INFECTION.

Simple blennorrhea of the conjunctiva is distinguished by redness, swelling, profuse yellowish secretion, and involvement of the lids, skin, and even the neighboring lymph-glands. Crusts are formed at the edges of the lids, and pseudomembranes on the internal surface. In the height of the inflammation the conjunctiva may be so swollen as to push between the lids, constituting what is called **chemosis** of the conjunctiva. The discharge is at first watery, then purulent, and at the subsidence of the disease it is similar to that of a simple catarrh.

Gonorrheal Conjunctivitis.—This disease is due to infection by the gonococcus.

Symptoms.—For the first 24 hours it may present only the symptoms of a simple catarrh.

The violence of the onset is dependent upon the stage of the inflammation from which the inoculation was made. Inoculation from an eye in the full stage of suppuration may cause violent symptoms in 6 hours. The conjunctiva becomes congested and the lids are edematous and swollen. As the disease progresses, the signs of inflammation are more marked. There is grayish infiltration of the conjunctiva, intense pain, and the lids become so swollen as to hide the eye, and project as boggy tumors from the face. Drops of yellow pus ooze between the lashes. Upon opening the eye pus fairly gushes forth, and the examiner must be cautious that none of the contagious secretion falls upon his face. In fact, it is well to wear protective glasses in examining such cases. At this stage the bulbar conjunctiva is scarlet in color and so chemosed that the cornea may be completely hidden. The disease attains its height on the third or fourth day, and slowly subsides, the catarrh usually running a course of from 4 to 6 weeks. Indications of abatement of the process are diminution of discharge and signs of inflammation and the gradual return of the normal wrinkles of the eyelids as the swelling subsides. There are often severe constitutional symptoms. The temperature is elevated and the pain may be agonizing.

Complications.—The most frequent complication is corneal ulceration, which is due in great part to the deprivation of vascular supply to the limbus from the constriction of the conjunctival vessels by the great chemosis of the conjunctiva. The ulcers may not perforate, but when they heal they leave a disastrous scar upon the cornea. Prolapse of the iris may follow perforation. If the perforation is small, it may heal, with synechial attachments of the iris; if large, anterior staphyloma may occur. The whole cornea may slough and panophthalmitis result, leaving nothing but a sightless stump.

Diagnosis.—A history of gonorrhea or discovery of the gonococcus in the secretions at the onset of the disease makes the diagnosis positive. At its height the disease will be plainly recognized.

Prognosis is always serious, and is dependent entirely upon the amount and location of corneal involvement. Large peripheral leukomas are less dangerous to vision than small central ones.

Treatment.—The patient should be put to bed, and if one eye is sound, it should be protected with a **Buller's bandage.** This contrivance consists of a watch-glass held in place before the eye by a perforated adhesive bandage. It must cover and exclude the sound eye entirely, and must be impervious to the irrigations upon the diseased eye. The attendants and patient must be cautioned against the infectious nature of the discharge, and all compresses must be destroyed. Ice compresses should be applied to the eye every minute, night and day. This treatment eases the pain, limits exudation, and prevents swelling and conjunctival edema, so fatal to the cornea. If the cornea ulcerates early, cold must be discarded for hot compresses, wrung out in water of from 115° to 120° F. An atropin solution may be instilled unless the perforation is quite peripheral.

The next important part of treatment is thorough **irrigation** at short intervals. This is the fundamental principle in the therapeutics of all autoinoculable and purulent processes: Remove the self-multiplying cause, and assist nature to combat the original infection. Strong antiseptic applications are usually unnecessary. The infection soon gains access to tissues possibly beyond the reach of local antiseptics, and, moreover, such substances in germicidal strength have generally a devitalizing effect on the tissues involved, and this is exactly what is to be avoided. Let cleanliness be nature's assistant, and only when the curative process is delayed, let stimulating applications be used.

In view of its importance, it is unfortunate that thorough and repeated irrigation of the sulcus is seldom effected. To cleanse at intervals of a half hour every portion of an infected conjunctiva in an active state of purulent inflammation is a difficult task. The lids are tense and swollen. The palpebral and bulbar conjunctival surfaces are glued together, making the depths of the sulci almost inaccessible. The pain in the manipulation is intense. A child vigorously resists all efforts to open the lids, and even in the case of adults it is often quite impracticable under these circumstances. To be effectual, irrigation must be thorough, and in the active inflammatory stage it should be repeated at least every half hour. What might be called the "golden rule" in these cases is: *Without careful irrigation, all other treatment is unreliable.*

With a retractor syringe the eye may be thoroughly washed at the shortest intervals, as there is little pain in its introduction. Every 20 minutes is the shortest interval ever necessary. At least 1/2 of a pint of water should be used at each irrigation, and during the cleansing the retractor should be moved about slightly in the sulcus. The liquid should be drained over the side of the face into a basin, care being taken that it does not enter the ear, nose, or mouth. This is particularly necessary in infants. Any solution may be used, although sterile water, or possibly a weak boric acid solution or permanganate of potassium, will be found effective. The fluid should be used at body temperature, unless for special reason the application of heat or cold is desired, either of which may be readily applied in this manner. The solution, gently run through the syringe, also offers an excellent substitute for wet packs[1] and fomentations in certain cases of ocular inflammation.

In addition to the irrigation the lids should be everted, if possible, and brushed 3 times a day with a copious 50 percent solution of boroglycerid in glycerin. Often this solution may be flooded into the conjunctival sac without everting the lids. This substance has given better results than the more widely known silver preparations. Nitrate of silver (10 grains to 1 ounce) and its substitutes (such as protargol and argonin) are widely recommended. Sometimes the chemosed conjunctiva is freely incised. As the disease subsides into a simple catarrh, the ordinary antiseptic and astringent

treatment is instituted. In cases of corneal opacities, frequent massage with a weak yellow oxid ointment (1 grain to 3 drams) is recommended. An iridectomy is often resorted to for optic purposes. An artificial pupil downward may give serviceable vision, although the lower part of the cornea is not always clear. The treatment of the other complications is discussed under their separate headings. In the course of the disease the pain may be so intense as to necessitate hypodermic injections of morphin in the temple. Constitutional and hygienic treatment is often necessary. Pure air, cleanliness, light diet, free bowel movements, etc., are demanded. The rigorous treatment precludes the possibility of much sleep.

Ophthalmia Neonatorum.—This disease is analogous to the gonorrheal conjunctivitis of adults, although the symptoms are less violent and the consequences not so severe. It is usually due to the gonococcus in the secretions of the parturient tract, although severe cases have been caused by the secretions of nonspecific vaginitis.

Symptoms.—The inflammatory symptoms are similar to those of a mild case of gonorrheal conjunctivitis in the adult. They appear between the first and third days of life. Later appearance strongly indicates postnatal infection. In lying-in hospitals the disease may be transmitted from one infant to another, unless the proper precautions are exercised.

The course of the disease is shorter than adult gonorrheal ophthalmia. Both eyes are usually involved.

The diagnosis is easily made by the appearance of inflammation of the eyes in a newly born child. A history of a vaginal discharge in the mother or urethritis in the father is confirmative evidence. Bacteriologic examination makes the diagnosis positive.

The complications are chiefly corneal ulcers, although destruction of the eye may result. If the ulcers do not perforate, the **prognosis** for the scars becoming more or less transparent is much better than in the adult affection. Perforating ulcers cause adherent leukomas, which are always great hindrances to vision.

Treatment.—As both eyes are usually involved, it is not necessary to protect one; in fact, this would be most difficult; but at all times care should be taken to avoid transference of secretions or irrigations from one eye to its fellow, as there is not always the same virulence of infection in the two eyes.

The prophylactic treatment consists in: (1) Removing the disease from the mother before labor if possible; (2) thorough disinfection of the vagina before labor with solution of creolin, carbolic acid, boric acid, salicylic acid, mercuric chlorid, or other antiseptic; (3) thorough cleansing and disinfection of the child's eyes as soon as the head is born. These precautions should be carried out in all suspicious cases.

Crédé's method should be employed in all cases in hospital or midwife service, and in suspicious private cases. In fact, there is a law to this effect in many communities. It consists of instilling a few drops of a 2 percent solution of nitrate of silver exactly on the cornea of a child born of a mother who is suspected of vaginal infection. Other solutions have been suggested, but have no advantages over this simple method. We think, however, as a prophylactic measure this strength is greater than necessary, and liable to cause inflammation. A 1 percent solution, together with cleanliness, etc., seems sufficient until decided symptoms appear.

The routine treatment is practically the same as that of gonorrheal conjunctivitis: cold applications, frequent and thorough irrigation, the application of boroglycerid, silver nitrate, etc. At the first sign of corneal complication, hot compresses should be employed and atropin instilled. Massage with weak yellow oxid ointment is indicated for the corneal opacites. The child must be well nourished and kept clean and warm. Early operation is indicated if the opacities are central and dense. The earlier an artificial pupil is established, the better for the child's mental development. Of course, operation should be deferred a reasonable number of months while waiting for the opacities to clear up. In treating these cases the physician himself should inspect the cornea, and make the applications at least once a day. Nurses or family attendants often fail to open the lids sufficiently to cleanse the culdesac and to administer the local treatment.

Diphtheritic conjunctivitis is an intensely disastrous disease, due to infection of the conjunctiva by the Klebs-Loeffler or similar bacillus. There is a painful, board-like swelling of the lids, and a scanty, seropurulent, or serous discharge. The ordinary constitutional symptoms of diphtheria may accompany the affection. The treatment does not differ from that of other purulent affections of the conjunctiva, except in the relief of pain by atropin and the ordinary diphtheritic measures, the most important of which is the administration of the antitoxin. Pyocyanase dropped in the eye is another valuable remedy according to some observers. Disease of the cornea is seldom avoided in this affection, and the prognosis is very grave. Fortunately, the disease is rare in this country.

Croupous conjunctivitis differs from true diphtheritic conjunctivitis in that it is characterized by a soft, painless swelling of the lids, and a membranous exudation on the surface of the conjunctiva. It must be remembered that the secretions of ophthalmia neonatorum may take on a membranous appearance. The treatment is virtually the same as for other purulent infections of the conjunctiva. Caustics are contraindicated.

Follicular conjunctivitis is an inflammation accompanied by the formation of follicles or nodules in the conjunctiva. It is more infectious than simple catarrhal conjunctivitis, and is more prone to relapses, although no cicatrices are left after the follicles disappear. The disease may be acute or chronic. The follicles cannot be seen until the congestion recedes, when they appear in rows, glistening through the overlying membrane. Accompanying pericorneal injection is a precursor of shallow ulcers at the corneal margin. From

its infectious character a special germ is supposed to be the cause. It is distinguished from trachoma by the small secretion, absence of cicatrices, and appearance in the lower culdesac only.

Treatment should be first directed to measures to prevent the transmission of the affection to those about the patient. The secretion should be kept washed away by sublimate solution. Applications of boroglycerid, blue-stone, or alum may be of use. Smarting can be soothed by cold compresses. The conjunctiva may be cocainized and the follicles squeezed out with cilia forceps.

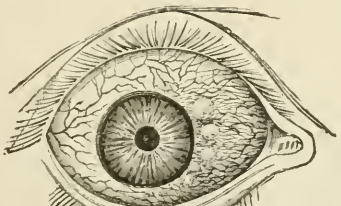
Granular Conjunctivitis.—See Trachoma.

Tubercular conjunctivitis resembles trachoma, but is, as a rule, confined to one eye. The ulcers are decidedly greater than in trachoma. The diagnosis may be definitely established by bacteriologic examination and by the symptoms of tuberculosis elsewhere. The prognosis is unfavorable. The local treatment is to effect destruction of tissue involved. The general treatment is that of systemic tuberculosis.

Vernal conjunctivitis, or spring catarrh, is a conjunctival inflammation recurring each spring or summer and disappearing with the frost, characterized by a pericorneal epithelial hypertrophy. The affection is binocular, and occurs chiefly in the young. It is characterized by a swollen and injected limbus and the signs of general catarrhal inflammation. The conjunctiva is pale, and looks as if it were covered with a thin film of milk. The cornea itself is not involved. There may be localized hypertrophies on the conjunctiva of the upper lid. The disease disappears spontaneously, only to return in the majority of cases the next season. The average duration is about four years. In a few cases slight opacities are left on the cornea.

Treatment.—The refraction should be carefully examined, and any ametropia corrected. In some cases it is even advisable to put the ciliary muscles at rest for several weeks, by the daily instillation of atropin. A mild, soothing lotion should be prescribed, and protective glasses ordered.

Phlyctenular Conjunctivitis. Symptoms.—This disease is characterized by the eruption of tem-



Phlyctenular Conjunctivitis.

porary vesicles or pustules on the bulbar conjunctiva. These blebs are called phlyctenules, and are grayish-red and flattened prominences from 1 to 4 mm. in diameter, with deep-red surroundings. Sometimes only a single bleb is seen. When a number of these phlyctenules are present, there will arise signs of irritation, congestion, pain, photophobia, and even blepharospasm. The lid is swollen and red, the conjunctiva injected and velvety, and there is mucopurulent discharge. The vessels supplying the infected region are swollen and become tortuous as they approach the phlyctenule. In the purulent form the disease soon reaches its height, remains severe for a few days, and then subsides. The milder varieties cause the patient slight inconvenience. Scrofulous children are particularly susceptible, and the disease is often seen in children with signs of eczema elsewhere on the body. It may follow the common infectious fevers. In debilitated children there is a tendency to relapse, and the disease may continue for years.

Unless the cornea becomes involved, the prognosis is good. Bacterial infection has been suggested as a cause.

Treatment.—The constitutional treatment consists of cleanliness, fresh air, good food, tonics, cod-liver oil, etc. Local treatment consists of the daily application of a mild Pagenstecher ointment and irrigation with a mild antiseptic solution. Calomel may be dusted over the affected area, unless the child is taking some preparation of iodin. The applications should not be made in too rapid succession. Massage with a 10 percent iodoform ointment, or with a weak salve of the yellow oxid, is often of value. A 1 : 1000 aqueous solution of pyoktanin has proved useful. Boroglycerid, 50 percent, is a useful application. The more severe applications such as silver nitrate and the zinc salts, were formerly used. Stimulating applications should be avoided if there are signs of a corneal ulcer. See Cornea (Diseases).

CONSCIOUSNESS, LOSS OF.—See Coma.

CONSTIPATION.—It is expedient to consider both extremes of intestinal evacuation together, the difference between the two being frequently more apparent than real. The course and the treatment of both conditions coincide in many points, and justify the attempt to describe them simultaneously. One evacuation, although it occurs at intervals of 48 hours, is not abnormal, and does not constitute costiveness, provided it is sufficient and causes no distress. Two soft evacuations in the same day similarly do not necessarily constitute diarrhea. See Diarrhea.

When the bowel evacuations occur rarely, are hard, and out of proportion to the food ingested, constipation exists; but even when an evacuation occurs daily, constipation may be present if the feces are insufficient in amount. It is important in doubtful cases to watch the quantity of ingesta for several days and to weigh the feces. Foods that can be readily recognized in the feces should be given as a test for the rate of peristalsis.

Constipation may exist even when a daily liquid stool occurs that is insufficient in the amount of feces; in fact, diarrhea may show itself and in reality constipation may exist. As feces consisting of bacteria and epithelium are formed even during periods of starvation, it is impossible to judge from the quantity of the evacuation whether it corresponds to the amount of ingesta, nor can

it be accurately determined how long food requires to pass through the intestine. The elements of time of passage of food, and the relation between the amount evacuated and the amount ingested, can only be approximately determined.

Symptoms

The characteristic symptoms are few: (1) Retardation beyond the normal duration. When an individual has no full evacuation in forty-eight hours, he may be considered constipated. (2) A disproportion between the amount of ingesta and the amount of feces. (3) The evacuations are of abnormal shape, deficient in water, hard, and dry. (4) Numerous other systemic symptoms and remote consequences.

Causes

Acute constipation is produced in various ways:

1. By direct obstruction of the lumen of the intestinal tube. This occurs in intussusception; in volvulus of the rectum or sigmoid flexure; in twisting or inverting of the cecum; in strangulation by the edges of the foramen of Winslow, perforations in the mesentery, mesocolon, great omentum, or other duplicatures of the peritoneum; in strangulated hernia; in obstruction by foreign bodies.

2. By pathologic changes in the intestinal tissues, impairing their functions. This occurs in the acute inflammation of the various sections of the colon or intestines, producing infiltrations of the muscularis—adhesions; occasionally in typhoid fever (here also the muscular layer has been found tumefied and the mucosa very much infiltrated, so much so as to project into the lumen of the canal).

3. By direct inhibition of peristaltic function through the nerve-centers. This occurs in acute meningitis; in tubercular meningitis; in apoplexy; in acute mania; in acute diseases of the spinal cord and its envelopes; in acute infectious diseases; in hysteria.

4. By absence of impairment of the quality of the bile. This occurs in acute diseases of the liver; in cholelithiasis and stenosis of the gall-duct.

5. By inhibition of the aid of the diaphragm and abdominal muscles. This occurs in acute diseases of the lungs and pleura; in rheumatism, and hyperesthesia of the abdominal parietes; in paralysis of the diaphragm and abdominal muscles; in acute diseases of the female genital tract.

6. Reflexly: Inflammation of retained testicle; some of the diseases of the female genital tract; acute diseases of the bladder and prostate.

7. By a combination of these various ways: In acute inflammation of the stomach; in gout.

The causes of chronic constipation are as follows:

1. Well-defined morbid processes.
2. Obstruction from foreign bodies.
3. Congenital malformation of a section of the colon; defective development or dislocation of the intestine.
4. Impairment of physiologic function.

1. **Chronic Constipation from Disease.**—The morbid processes that cause constipation are various:

(*a*) Obstruction of the lumen of the tube: Cicatricial narrowing of any portion of the intestine; constriction of intestine by bands; constriction of the cecum and jejunum (after appendicitis, typhlitis, or perityphlitis); cancer of colon or rectum; abdominal tumor; pelvic hematocele, retroverted uterus; rectal tumors; folds of mucosa.

(*b*) Impairment of the secretions poured into the intestines: In chronic hepatic diseases, deficient or abnormal bile; in pancreatic diseases.

(*c*) Inhibition of peristalsis through the nerve-centers: In chronic diseases of the brain, spinal cord, and its envelopes in insanity; saturnine intoxication (lead paralysis, saturnine encephalopathy); diphtheritic paralysis.

(*d*) Chronic venous congestion of the intestinal circulation: In organic cardiac diseases; in asthma, emphysema, etc.

(*e*) Voluntary abstention from stool; diseased conditions of the rectum: In hemorrhoids; rectal ulcers; anal fissure; chronic proctitis; irritability of the rectum.

(*f*) Changes in the mucosa that impair its irritability: In chronic and membranous enteritis; intestinal atrophy.

(*g*) Atony of the intestinal muscles: Gastric atony and dilatation; prolonged colitis.

2. **Chronic Constipation from Foreign Bodies.**—
(*a*) Intestinal obstruction from hair tumors.
(*b*) Voluminous intestinal concretions.

3. **Malformation of the Intestines.**—
(*a*) Abnormally developed colon.
(*b*) Undue length of sigmoid flexure.
(*c*) Diverticula of colon.
(*d*) Diaphragms in colon: (1) Enormous congenital development and primary atrophy of the colon; (2) congenital arrest of development of the muscularis.

4. **Chronic Constipation from Impaired Physiologic Function.**—
(*a*) Perverted action.
(*b*) Imperfect performance of function (habitual constipation).

Diagnosis

The diagnosis of constipation is, as a rule, an easy matter; in those cases in which there are daily apparently insufficient evacuations, but nevertheless a gradual accumulation of excremental matter occurs in the intestines, the diagnosis presents some difficulty. A patient may complain of diarrhea and nevertheless be constipated. In these cases distention of the colon and careful percussion and palpation will reveal the presence of stagnating masses of feces. It is well to bear in mind all of the causes that have been enumerated, in order to be able to make the all-important distinction between secondary constipation due to one of these causes and typical habitual or idiopathic constipation. It is difficult to determine whether the constipation is due to a reduced irritability of the nerves of the colon and rectum or to a defective

development (atrophy) of the intestinal musculature. If the coprostasis has been present from the earliest periods of childhood and has existed through life, the existence of defective development of the musculature is probable. But if the constipation has occurred later in life and is attributed to psychic and emotional causes, or assigned to the wilful suppression of stool, it may be assumed that there is an inhibition of the nervous supply of the colon and rectum. If idiopathic constipation is relieved or cured by treatment directed to the nervous system, without special regard for influences on the colon and rectum, it may be considered as due to neurasthenia. A serviceable method to facilitate the diagnosis of constipation is to observe the time required for any food to pass through the gastric intestinal canal. Raisins, eaten with the skin, and milk can be recognized in the stool.

Microscopic examination of the feces gives valuable information. Inspection of the rectum by Kelly's or Kelsey's tubes will prevent errors of diagnosis when the disease is caused by stricture or neoplasm in the sigmoid flexure or rectum. In persistent cases the colon should always be distended with carbon dioxid gas generated from a siphon of vichy. This will, in most cases, reveal the seat of strictures of the colon by the difficulty with which the bowel is inflated beyond the point of stenosis. In women the kidneys should always be examined for possible dislocation. The electrodiaphane has been successfully used for the diagnosis of stenosis and for determining the location of stenosis of the colon.

Prognosis

In the large majority of cases the prognosis is favorable as regards life. One case of death has been reported from asthenia despite apparent recovery from the constipation. Constipation of long standing may cause irreparable and anatomic changes in the bowel. Dislocations, atrophy, peritonitic adhesions, and perforations—these accidents are rare.

The prognosis as regards recovery is, as a rule, favorable. The prognosis is unfavorable (1) in marked dislocation of the bowel; (2) when the abdominal walls are very relaxed and with pendulous abdomen; (3) in old persons with chronic atony.

Treatment

The causal indication in the treatment of constipation is the removal of the stagnating fecal masses; this cannot be done in a manner that will unfailingly lead to recovery unless the diagnosis is accurately established (see Causes).

The various means of treatment may be classified, according to their curative value, in the following order: Diet, massage, electricity, gymnastics, hydrotherapy, medicines, mineral spring water, psychic or suggestive methods, mechanic methods. The management of constipation will differ according to whether it occurs in children, in middle age, or in senile persons. It is only by a severely individualizing management that constipation can be radically cured.

The detection of the causes of constipation presents many difficulties, and occasionally it is entirely impossible. The disease may sometimes be founded in an incurable fundamental condition, such as coloptosis or defective development of the muscularis or an acquired intestinal atrophy. But even when the cause seems irremovable, the physician will be enabled to select a more correct treatment when it is once clearly recognized: for instance, in inherited defective development of the musculature a diet should be selected that will make but slight demands upon the peristalsis of the intestines, while in other cases of constipation a diet is usually serviceable that leaves considerable undigested residue, thereby stimulating the peristalsis. Constipation is frequently caused by a faulty method of nutrition and irregular habits of life; it is a partial phenomenon of neurasthenia. Hence it is important to regulate and prescribe a suitable diet; insist upon proper habits and upon regularity of living, and urge the use of climatic, hydropathic, and physical methods of cure. The administration of purgatives is only palliative, and in some cases is directly injurious. Purgatives cannot, however, be entirely dispensed with. There is no treatment or therapeutic method of which it could be said that it is applicable to all cases of constipation or even to a larger portion of such cases.

There are three reasons why constipation often becomes intractable: First, in irremediable anatomic cause; second, the cause may be remediable, but the method of treatment may not be conformable to the cause; and, third, even when the treatment is correct, failure may result because it is imperfectly executed or not continued long enough.

In all cases of constipation purgatives should be withheld at first, and small doses of opium given whenever there is pain and the diagnosis is obscure. Opium can do no harm in such cases, but purgatives can and frequently do.

The first step in the treatment is to determine whether it is to be directed to constipation (*a*) due to atony, (*b*) due to spastic condition of the musculature, (*c*) to dislocations of the intestine, (*d*) to abnormal nervous inhibitions of the peristalsis.

The Diet.—Gastric hyperacidity being a cause, the state of gastric secretion must be determined and the diet adapted thereto. In this case alkalies are indicated. In the atonic form foods that do not form much residual matter are forbidden, also concentrated foods, and in their place foods rich in water and cellulose are recommended, these latter being adapted to excitation of peristalsis. Cocoa, chocolate, milk, tea, claret, Burgundy, rice, soup made of flour, and huckleberries are forbidden. Instead of wheat bread the patient should use only Graham or rye bread, together with butter and honey; all fruits are permissible excepting persimmons. Equal parts of plums and figs stewed together are serviceable. Soups may be taken if made from bouillon and herbs, leaves or roots; butter milk, kefyr, cider, and beer are serviceable. Fresh vegetables in the form of

cabbage, carrots, turnips, radishes, spinach, tomatoes, cresses, rhubarb, should enter extensively into the dietary. Sauerkraut favors evacuation. Fats should be liberally taken in the form of butter and rich gravies; meats should be eaten with sauces. When there is much flatulence, the addition of spices, such as pepper, salt, caraway seed, etc., is of utility. If constipation is due to enteritis, the diet cannot be taken in the form of vegetables; then the only vegetables that are permissible are cauliflower, spinach, tender asparagus, and perhaps mashed potatoes. A sufficient ingestion of cold water between meals is all important. One pint of fresh buttermilk or kefyr should be taken twice daily. The following is suggested for a detailed *diet list.*

Morning:
Before breakfast, Bedford magnesia spring water, 1/2 of a liter.
8 ounces of milk and coffee.
1 ounce of butter.
1 ounce of honey.
3 1/2 ounces of Graham bread.
8 ounces of buttermilk.

Noon:
8 ounces of bouillon.
8 ounces of mutton.
8 1/2 ounces of crisped cabbage.
8 ounces of plums.
8 ounces of apple-cider or beer.

Afternoon:
9 ounces of buttermilk.

Evening:
5 ounces of meat.
1 ounce of butter.
10 ounces of stewed apples.

For the several meals 8 ounces of Graham or rye bread. After the evening meal 1 pint of beer.

Excessive ingestion of food predisposes to constipation. The drinking of hot water early in the morning is not productive of regular evacuations, and must be emphatically forbidden. A drink of cold fresh water about 1 hour before breakfast and just before going to bed will assist defecation. A mixture of stewed apples, prunes, raisins, and figs, seasoned with sugar and lemon-peel, is palatable and efficacious.

Massage.—The main object is gradually to produce the independent healthy peristalsis of the intestines by proper manipulation. In order to be effective this mechanic treatment must be persisted in for several months; no permanent benefit can be expected even after a treatment of one month. In the beginning of this treatment it may be necessary to use laxatives occasionally. Massage must be practised by skilled hands, and must be executed correctly. Although the entire abdominal region must be treated, the greatest importance is attributed to massage of the colon. This is executed by short pushing and beating movements, by kneading and rubbing, and even attempting to grasp the colon between the fingers and systematically squeezing it along its anatomic course. Some expect from abdominal massage the direct working out of the intestinal contents. This is quite a mistake. The great benefit derived from systematic and skilled abdominal massage is the stimulation which the intestinal peristalsis receives and the improvement in the tonicity of the intestinal blood-vessels.

Electricity.—Most favorable results have been obtained in constipation due to atony, but not in the spasmodic form, by the faradic and galvanic currents, even when complete intestinal occlusion had been caused by fecal accumulations, and also in stenoses that had arisen from invagination.

The exact way in which electricity acts is not yet understood. Favorable results are obtained by a combination of both currents used at the same time.

Gymnastics, Body Movements, Swedish Movements.—That exercise will be the most advantageous that produces the most frequent contractions of the abdominal muscles. But in the absence of any special direction and conduct of exercises, constipated patients should systematically carry out whatever outdoor exercise is most congenial. At least 2 hours should be allowed to transpire after meals before extensive walks are undertaken by patients. Other favorite exercises are swimming, rowing, horseback riding, bicycle riding. All exercises should be taken in the open air, and must never be carried to exhaustion. The best guide as to whether the exercise has done good is the feeling of refreshment and invigoration, together with a stimulated appetite. Gymnastics and Swedish movements are best carried out under the guidance of an instructor; they must be kept up for several months.

Cannon-ball Massage of the Abdomen.—Sahli recommended a cannon-ball, from 3 to 5 pounds in weight, covered smoothly with chamois skin or flannel, to be rolled over the course of the colon by the patient himself. The procedure is best carried out early in the morning in bed, after the bladder has been evacuated; the knees are drawn up and the rolling over the colon continued for 10 minutes.

Hydropathic Procedures.—The external application of water may occasionally be effective in the treatment of constipation; but, as a rule, it is only an adjuvant to the methods mentioned.

An efficacious hydropathic method has been an alternating hot and cold douche directed against the abdomen (the Scotch douche). Cold sitz-baths are advisable, but great caution is necessary in their application in female patients, particularly in the period preceding menstruation. Clysters or enemas or irrigations of the colon with warm or cold water act mechanically, thermically, and antiseptically.

When injections are carried to excess, the necessity for abdominal pressure, which is an important element in the act of defecation, is avoided; the abdominal muscles, therefore, become unaccustomed to exerting the necessary pressure for defecation, and constipation may actually become aggravated.

Colon irrigations are indicated in the constipa-

tion due to chronic intestinal catarrh, to internal hemorrhoids, and to icterus. Cold tub-baths, cold moist compresses on the abdomen, and cold moist rubbing are also very valuable.

Medicines.—Excessive dilatation of the intestinal wall by fecal accumulations seriously injures the musculature and reduces the irritability of the intestinal nerves. It is advisable not to delay with the administration of purgatives in these cases until the intestine empties itself by unusual exertion. Such strenuous expulsive efforts are fraught with great danger to the contractile elements of the bowel. In old patients, paralytics, and those suffering from infectious fevers and confined to bed, the administration of purgatives cannot be avoided. On the whole, it may be said that the more rarely a purgative is used, the more effective will be its action when it is employed in an emergency. In the selection of drugs for this purpose the practitioner must carefully distinguish between atonic and spastic constipation and that due to obstruction.

In inflammation of the colon there may be constipation alternating with diarrhea, and the treatment will be regulation of diet, irrigations, hydrotherapy, massage, and oil enemas. The remaining treatment for this form of constipation will be considered under DYSENTERY, ENTERITIS, etc.

Purgatives are contraindicated when the constipation is the result of peritonitis or intestinal ulcerations, and in tonic spastic contraction of the musculature, as occurs in meningitis and lead-poisoning; in these cases the pains are increased by the purgatives, and they do not produce an evacuation. Spastic contractions of limited portions of the intestine may occur as a result of neurasthenia. Here, and in recent hemorrhage from the stomach and bowel, purgatives must be prohibited. All stenoses of the intestine, when they have reached an advanced degree, are aggravated by purgatives, because they favor the development of paralysis. During long-continued use of the same purgatives their effectiveness is lost; it is, therefore, necessary to change them when they must be used for a long time.

The secretory, motor, and absorptive condition of the stomach should be examined and defects corrected. C. Cleveland has reported favorable results in constipation treated by forcible dilatation of the sphincter ani. Fissure of the anus and hemorrhoids should have proper attention.

Of the large number of drugs used for this disease in its atonic form, 4 are chiefly to be relied on: viz., nux vomica, with its alkaloid strychnin, aloes, jalap, and cascara sagrada. The use of physostigma bean, ergot, and belladonna for this purpose should be discontinued. Phenolphthalein is a recent addition to the list. It is apparently harmless even in excessive dosage. Usually 1 or 2 grains at bedtime suffices, but as much as 5 grains 3 times a day is recommended. Various confections of sweetened chocolate, sugar and the like, medicated with phenolphthalein, may be obtained for children and are easily taken. The dose for a child of two years is 1/2 to 1 1/2 grains. In case of evident decrease of mucus as a result of atrophy of the glandular layers of the intestine, the action of the glands may be stimulated by sodium phosphate and ammonium chlorid. Belladonna seems to have a transient good effect in those cases of constipation that are due to excessive hyperacidity, but it cannot be given frequently. In this form the following formula is advised:

℞. Calcined magnesia, ℥ ss
Powdered rhubarb, ℥ ijss
Sodium carbonate, ℥ j
Extract of belladonna, } each, gr. ij.
Extract of nux vomica, }

One-half of a teaspoonful 3 times daily, half an hour after meals.

When atonic constipation is associated with absence of HCl or subacidity:

℞. Dilute hydrochloric acid, ℥ ss
Strychnin sulphate, gr. 1/3
Tincture of rhubarb, q. s. ad ℥ vj.

One tablespoonful in a wineglassful of water 3 times a day 1 hour after meals, through a glass tube.

Each group of the purgatives has an individual and peculiar action, and should be used according to special indications only; thus, when constipation is combined with acute indigestion and much intestinal sepsis, calomel, in doses of 1/2 of a grain, repeated every 2 hours, has no superior; in acute constipation without sepsis or pain, castor oil is advisable. In constipation of the adipose, with inclination toward passive congestion in the intestinal canal and hemorrhoids, the neutral salts, such as magnesium and sodium sulphate, sodium and potassium tartrate, sodium phosphate, and the purgative bitter waters have gained a reputation.

The following is a favorite pill with Nothnagel:

℞. Podophyllin, gr. ivss
Extract of aloes, } each, gr. xlvjss
Extract of rhubarb, }
Extract of taraxacum, q. s.

Make 40 pills; 1 pill at bedtime.

For constipation with flatulence the following pill, 2 or 3 times a day, is recommended:

℞. Compound extract of colocynth, gr. 1/3
Turpentine, gr. j
Powdered socotrine aloes, gr. jss
Extract of nux vomica, gr. 1/4
Extract of hyoscyamus, (English), gr. j.

With some persons the following electuarium of manna, as recommended by Strümpell, will for a long time be serviceable:

℞. Manna, } each, gr. xxx
Sugar, }
Fennel water, }
Powdered iris root, gr. ij
Oil of sweet almonds, gtt. xv.

Dose, a heaping teaspoonful.

The confection of scammony or of tamarinds, prepared according to the German or British Pharmacopeia, is sufficient in some cases. Senna and colocynth can only be used occasionally. The saline purgatives, sodium and magnesium sulphate, and the various purgative bitter mineral waters, such as the Hunyadi János, Friedrichshall, Homburg, Carlsbad, etc., in Germany; the Hathorn, Congress, and Kissingen Springs in Saratoga, N.Y.; the Estill and Irvine Springs in Kentucky, should not be used habitually.

The very drastic purgative waters, such as the Hunyadi János and the Rubinat-Condal, do more harm than good.

The Use of Mineral Waters.—These waters do not act curatively, but simply as all other purgatives do; they produce an evacuation the day they are used, and do not effect the underlying causative conditions of the constipation.

Injections.—These consist either of water, to which various medicines are added, of oil, or of glycerin. Injections of water to be effectual should always be slightly cooler than the temperature of the body—about 75° F. will answer. When there is much putrefaction in the colon, it is well to order the injections every day. They are best administered before breakfast in the morning or before retiring at night. The quantity to begin with should not exceed 1 liter (1 quart). It is sometimes advisable to follow the suggestion of Hühnerfauth, and produce an evacuation of fecal matter contained in the sigmoid and rectum by injecting 1 pint of water, and then follow it by a larger injection of about 2 pints of water, persuading the patient to retain it as long as possible. With excessive putrefaction disinfectants may be employed in the colon irrigation; the following may be recommended: Thymol 5 parts, lysol 1 to 2 parts, or boric acid 20 to 30 parts, to water 1000 parts.

Oil Injections.—Only the very best olive oil or cotton-seed oil is serviceable for this purpose. The oils of the poppy and rape seed are used in Germany. About 250 to 500 c.c. of this oil are warmed by placing the bottle in a vessel containing hot water. The rectal or Langdon colon tube is introduced into the sigmoid flexure, while the patient is either placed on the back with the pelvis elevated by several noncompressible pillows, or in the knee-elbow position. The injections must be repeated daily if benefit is to be derived from them. When the entire colon becomes coated with oil, the stools resemble those of the contents of the small intestines. In case abnormal putrefactive processes are to be combated, the addition of the same substances and in the same quantity as stated heretofore for the water injections is advised. The most desirable effect of the oil injection is the inhibition of the resorption of toxins from the intestinal contents. When the bowels have been brought to act several times daily, the number of injections may be reduced to 1 in every 2 or 3 days.

Glycerin injections have been recently replaced by suppositories containing about 80 percent of glycerin; they should only be used occasionally; sometimes, by their great dehydrating effect, they act as irritants upon the rectal mucous membrane.

Mechanic or Instrumental Methods.—When the rectum has become enormously dilated by hard impacted masses of fecal matter, it sometimes becomes necessary to remove them by manual or instrumental interference. Fecal colic caused by coproliths has been cured by manual kneading and breaking up of the fecal tumors, when injections of water and oil did not suffice to soften them. In constipation that has existed a long time, in which repeated attacks of fecal colic have recurred, one must bear in mind the possible existence of ulceration and friability of the intestine before manual interference is undertaken.

Psychic or Suggestive Treatment.—The treatment of constipation by hypnosis and suggestion has been proposed by Forel, but this method has found but few advocates.

CONSUMPTION.—See Tuberculosis (Pulmonary).

CONTRACTURE.—See Ankylosis.

CONTUSION.—A bruise or injury inflicted by a blunt weapon, or received in a collision, without breaking the skin or covering. See Wounds (Contused), Bruise.

CONVALESCENCE.—Restoration to health after the subsidence of a disease. The period of convalescence is that time during which progress toward recovery is made, and there is a returning state of health after illness. The word is most commonly associated with fevers, inflammatory diseases, and other acute affections. It may occur by crisis and be speedily established, but is generally slow and protracted, and interrupted by relapses, complications, and sequels. Careful watching and judicious treatment are necessary, or recovery will be delayed or the foundation for permanent disease laid. Injudicious administration of medicine inflicts much injury. Dietary precautions and general hygienic measures are most important. Sudden exposure and exertion must be guarded against.

CONVALESCENT SERA.—See Serum Therapy.

CONVALLARIA.—The dried rhizome and roots of *Convallaria majalis*, lily of the valley. The preparations in the market vary in action, according to the quantity of the resin present, it being emetocathartic. Convallaria contains two glucosids —namely, convallamarin, on which the cardiac action depends, and convallarin, a crystalline, purgative principle, insoluble in water; also an acrid resin which probably contains the latter glucosid. Dose, 2 to 10 grains. Convallaria is a decided cathartic and a prompt and powerful diuretic, but its cardiac action has excited attention, and it is considered a close analogue of digitalis, while free from the so-called cumulative action which makes the latter drug so frequently a dangerous remedy.

Preparation.—Fluidextractum convallariæ is the only official preparation, and probably contains convallarin, which is not present in aqueous preparations, being insoluble in water. Dose, 2 to 10 minims.

CONVOLVULIN.—See Jalap.

CONVULSIONS.—A convulsion may be defined as a general involuntary paroxysm of muscular contraction. It should have a comparatively abrupt beginning and an early termination, and may or may not be attended by a loss of consciousness. Convulsions are commonly divided into clonic and tonic forms, the former referring to more or less rhythmic contractions of opposing muscular groups, with a varying excursion of the affected limbs, the other to a simultaneous contraction of opposing muscles, with a rigid, fixed position of the limbs. In some cases these two types may be combined.

It is difficult to give an accurate definition of the term convulsion, as it has been loosely applied by writers and clinicians. It is sometimes use to designate tremor, contracture, or cramp; indeed, almost all varieties of disturbed muscular tension. Localized convulsions are more appropriately called spasms. Nothwithstanding these uncertainties, there is a fairly well-defined clinical use of the term, and physicians generally understand by it the typical forms as seen in uremia, hysteria, and epilepsy. The idea of a seizure or attack, and not a continuing state, is generally conveyed by the term. The voluntary muscles are always involved, though analogous conditions have been described under the name **internal convulsions,** in which the involuntary muscles are affected.

It is apparent that many classifications of convulsions, based on their varying clinical aspects, could be constructed; they could be divided into organic or functional, according to the organs involved or according to their etiologic relations. For convenience they will be divided into two groups—one in which consciousness is retained, and the other in which it is lost. Such a division is not strictly accurate, but is a practical one from the standpoint of diagnosis and treatment.

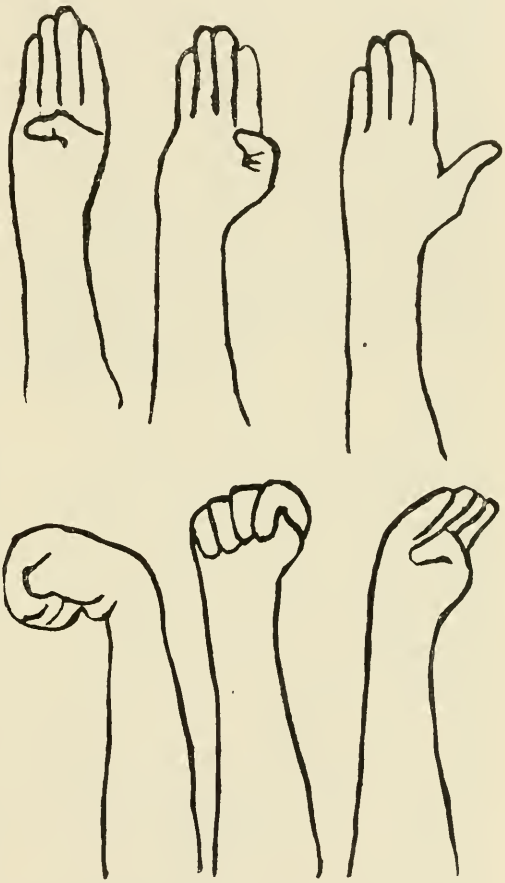
The next article considers the convulsions of childhood. The partial convulsions (tics), confined to a single muscle or group of muscles, and the recurring general tics, those included by French writers under the term **tic convulsif,** will not be considered. The attempt will not be made to describe every variety of convulsion, but only the more important, and those of most frequent occurrence. It is well to state at the outset that convulsions are symptomatic, having a widely varying pathologic basis; such being the case, but little can be said that is applicable to the causes of treatment of convulsions in general.

Diagnosis.—When the practitioner first sees a case of convulsions of sudden onset in an adult, if there is **loss of consciousness,** the condition, in the vast majority of cases, is epilepsy, including the status epilepticus, uremia, or apoplectiform convulsions. If consciousness is retained, the case is one of hysteria, tetanus, hydrophobia, or strychnin poisoning.

The diagnosis of the first group presents the greatest difficulties. In epilepsy consciousness is, with rare exceptions, completely abolished when there is a general convulsion. In other than the status epilepticus the convulsion is of short duration; but in cases in which the status is not fully developed there may be a succession of seizures without a full return of consciousness. A history of former attacks easily fixes the diagnosis of epilepsy. The position of the hand and relation of the thumb to the fingers is one of the most conclusive signs of epilepsy and of the status.

This position of the hand is also found in uremic and apoplectiform seizures. It is one of the most important diagnostic means of distinguishing between feigned convulsions and those of hysteria attended by apparent loss of consciousness.

Without a history it is impossible to distinguish some apoplectiform seizures from epilepsy. The history of antecedent brain-disease alone will guide us to a diagnosis. The apoplectiform convulsion is of longer duration and is usually attended



Positions of the Hand and Relations of the Thumb and Fingers in Convulsions.

by a marked rise in temperature. The latter may take place in the epileptic status if it lasts for several hours.

In uremia the condition of the heart is one of the most important available means of diagnosis. A hypertrophy without valvular lesion almost invariably points to uremia. Of course, an antecedent history of kidney-disease or an existing

dropsy would be quite as conclusive in fixing the diagnosis. The urine should be examined as soon as possible in all convulsions attended by loss of consciousness. The coexistence of pregnancy would point to the kidneys. Any convulsive seizure in pregnancy, however slight, should lead to the suspicion of uremia.

The diagnosis of convulsions not attended by loss of consciousness is much simpler. Hysteria presents the greatest difficulty. Convulsions in this disorder may imitate somewhat closely those of other disorders. They do not, however, present the characteristic position of the hand as shown in illustration. The fingers are usually extended; indeed, the whole attitude of the hysteric seizure is one of extension. Charcot has described the several attitudes of the hysteric attack—first the clonic, and then the tonic contractures with the opisthotonos. A brief inspection will show that there is only a pseudo loss of consciousness.

The convulsions of tetanus, of hydrophobia, and of strychnin poisoning are readily distinguished from other varieties by the history that the patient is able to give in the intervals of the paroxysm. The spasms of strychnin may be distinguished from those of tetanus by their intermittency (the latter being constant), by the meaningless smile, *i.e.*, the risus sardonicus, the less marked trismus, the absence of a wound, and the rapid course of the symptoms. In hydrophobia, trismus and opisthotonos are lacking and there are present laryngeal symptoms, and spasms on swallowing, and mental depression. If the patient is conscious and hysteria can be excluded, recurring convulsions are almost certainly due to one of these three conditions.

The treatment of convulsions necessarily depends upon the underlying pathologic conditions.

The emergency treatment largely includes that class that is attended by loss of consciousness. The first step is to place the patient in as comfortable a position as possible—a large wide bed. If this cannot be obtained, use the floor covered with a blanket. Constricting collars, bands, or corsets should be removed. Pillows, if thick, should be taken away, that nothing may obstruct respiration. Such restraint of the convulsed limbs should be used as will prevent the patient from injuring himself. A piece of soft wood or a cork should be placed between the teeth to prevent biting the tongue. The lower bowel should be immediately washed out, and a rectal injection of 30 grains of chloral administered. A drop or two of croton oil, rubbed up with sugar of milk, secures quick action of the bowels.

There are no forms of convulsions in which bleeding is contraindicated, excepting the apoplectiform seizures of advanced brain-disease, in which there is emaciation. These can hardly furnish an emergency case. There are practically none in which morphin is contraindicated. This should always be given hypodermically. Finally, if the convulsions are very severe, the tentative employment of chloroform inhalations is indicated.

CONVULSIONS, INFANTILE.—Convulsions are common during infancy, owing to the instability of the nerve-centers at this time. They occur as a symptom and as a result of many different disorders (perfectly healthy children not being subject to these seizures); the most frequent predisposing causes are nutritional disturbances, especially rickets, of which condition convulsions are often an early and a prominent symptom.

Etiology.—Among the **exciting causes** are meningeal hemorrhage, due to injuries of the brain during birth; organic diseases of the brain, as tumor, abscess, or meningitis. The onset of the acute infectious diseases is frequently marked by convulsions. Convulsions may be caused by poisons in the system, from uremia, ptomains in the digestive tract, lead-poisoning, etc. They are quite common during the paroxysmal stage of pertussis, and may arise in the course of any disease accompanied by high temperature or exhaustion.

Among the reflex causes are irritation from dentition, nasal obstruction, phimosis, worms, and severe injuries, as scalds or burns.

In seeking for the cause of an attack, it should be remembered that the most common exciting, reflex, or toxic cause is gastrointestinal disturbance.

Symptoms.—There may be prodromal symptoms, as restlessness, slight twitching of the hands, feet, eyelids, or face; or the convulsion may begin suddenly, and the first symptom noticed is that the face is pale and the eyes fixed, and perhaps rolled upward. In a moment after, this convulsive twitching will begin in the muscles of the eyes and face, or one extremity, and will rapidly extend until all the muscles of the body participate. At this time the thumbs are held in the palms of the hands, and the fingers are tightly clenched over them; there are opisthotonos and frothing at the mouth; the bowels and bladder may be evacuated involuntary; and in all true convulsions the patient becomes unconscious. After from a few minutes to a half hour the movements gradually cease, and there is a period of extreme prostration —the child usually sleeping heavily.

Except when due to the onset of the acute infectious diseases, the attacks are likely to be repeated, and may follow one another in rapid succession, as many as 40 or more a day occurring. It is not unusual for any of the causes mentioned to produce slight twitching of certain muscles only, without a complete convulsion. Especially may this condition be present as a symptom of tumors or injuries of the brain, when one side only of the body may be convulsed.

The prognosis depends upon the cause. Occurring during a severe illness, or when the child is weak and debilitated from malnutrition, a fatal issue is not uncommon; but when due to digestive disturbances, dentition, or other reflex causes in a fairly robust child, recovery may be expected.

Treatment.—Chloroform, or equal parts of chloroform and nitrite of amyl, should be given by inhalation during the convulsion. A few drops will almost immediately quiet the child, when the drug should be discontinued, but repeated whenever there are signs of a recurrence. Morphin (1/48 of a grain to a child 6 months old) may be

given hypodermically at the same time, and repeated in a half hour if the child does not become quiet; or, instead of this, 5-grain doses of chloral may be given by the rectum. The chloral may be conveniently given in milk, and should be introduced high up in the colon through a soft-rubber catheter, the colon having been previously cleared by irrigation. The dose may be repeated in an hour if the convulsive movements have not ceased.

The patient should be kept in a quiet room and disturbed as little as possible, and for several days, or until the danger of a repetition of the attacks has passed, he should be given chloral and bromid every 3 or 4 hours, either by the mouth or rectum, in sufficient doses to keep him quiet. For this purpose one of the following formulas may be used for a child 6 months old:

℞. Chloral hydrate, gr.xl
Sodium bromid, ʒ j
Syrup of acacia, ℥ j
Water, ℥ iij.

Give a tablespoonful, injected high up in the rectum, every 3 or 4 hours (half the amount by the mouth).

Or—

℞. Mixture of asafetida.

Two teaspoonfuls every 2 hours, as an enema.

Or—

℞. Musk, gr. xx
Chloral hydrate, gr. xxx
Camphor, ʒ jss
Syrup of acacia, ℥ j
Water, ℥ ij.

A tablespoonful every 3 or 4 hours by the rectum.

If there are symptoms of collapse, with weak pulse and a cold and cyanotic state of the skin during the convulsion or between the attacks, means should be used to restore the peripheral circulation and to increase the heart's action. Hot bathing would accomplish this to a certain extent, but would disturb and excite the child, and the ultimate result would be enervating. The mustard pack best meets the requirements, and is employed as follows: A towel is saturated in warm water, to which a tablespoonful of mustard to the quart has been added; the child is wrapped in the towel and then rolled up in a woolen blanket and allowed to remain thus for 10 or 15 minutes, or until the skin becomes red from the effects of the mustard. This may be repeated every 2 or 3 hours if necessary, in the intervals keeping the child's body warm with hot-water bottles. Cold applications should be kept on the head.

The cause of the attack must be ascertained. If due to the eruption of a tooth, lancing the gum may give relief; if to high fever, cool sponging or cool bathing should be employed to reduce it; and, finally, if it is due, as a majority of the cases are, to indigestion, appropriate measures should be instituted to relieve this condition and to prevent its recurrence. It is necessary to evacuate the contents of the stomach by lavage, to clear out the intestines with calomel in small frequently repeated doses, and to thoroughly irrigate the large bowel with warm water. Discontinue improper, and institute proper, feeding, and adopt general hygienic measures to improve the child's nutrition.

CONVULSIONS, PUERPERAL.—See ECLAMPSIA.

COPAIBA.—The oleoresin of one or more species of *copaiba*. It is a translucent, viscid liquid, of yellow color, aromatic odor, and acrid, bitter taste. It is soluble in alcohol, ether, and chloroform. It is not a balsam as it contains no cinnamic acid; but it is composed of a volatile oil and a resin, the latter containing about 99 per cent. of copaibic acid.

Therapeutics.—Copaiba is a stimulant, diuretic, diaphoretic, expectorant, and a gastrointestinal irritant. Its taste is bitter and nauseous. In the stomach it causes heat, unpleasant eructations, heaviness, frequently anorexia and diarrhea, and if continued for any length of time, gastrointestinal catarrh and desquamative nephritis may result. The various secretions have the odor of the drug, especially the urine. In moderate doses it increases the quantity of urine and its solid constituents, but large doses will cause scanty urine, containing albumin, casts, and blood, with pain in the loins, and other signs of renal congestion. It often produces itching and several forms of eruption on the skin. Copaiba has been largely used in gonorrhea after the acute symptoms have subsided, also in chronic cystitis, acute and chronic bronchitis, and in dropsies, particularly ascites.

In chronic urethritis:

℞. Oleoresin of copaiba, ʒ j
Oleoresin of cubebs, gtt. iv
Citrate of iron and ammonium, gr. xx.

Make into 10 capsules; 1 capsule 3 times daily, after meals.

In early acute gonorrhea:

℞. Citrate of potassium, } each, ʒ iij to vj
Balsam of copaiba, }
Fluidextract of hyoscyamus, ʒ ss to ij
Syrup of acacia, ʒ ss
Peppermint water, enough for ℥ iij.

Shake. Teaspoonful in water.

An emulsion in subacute gonorrhea:

℞. Balsam of copaiba, } each, ʒ j
Spirit of nitrous ether, }
Liquor potassæ, ʒ ij
Extract of licorice, ʒ ss.

Mix and add—
Oil of wintergreen, gtt. xvj
Syrup of acacia, ʒ vj.

One tablespoonful 3 times a day.

Preparations.—**Oleum copaibæ**, oil of copaiba. Dose, 5 to 15 minims. **Compound copaiba mixture**, also called **Lafayette Mixture** (unofficial), contains copaiba, spirit of nitrous ether, liquor potassæ, compound tincture of lavender, syrup, and mucilage of dextrin. Dose, 1 to 4 drams.

COPPER (Cuprum).—A reddish-brown metal, not used in medicine in its metallic form, but represented by several salts. These are gastro-intestinal irritants, producing nausea and emesis. Sulphate of copper, in from 2 to 5 grain doses, is a rapidly acting emetic. The dose should not be repeated, but the sulphate of zinc or mustard used in its stead. In phosphorus-poisoning, being the chemic antidote, it is the best emetic. In pill form it may be given in diarrheas in from 1/4 to 1/2 grain dose, combined with opium. In skin-diseases of the dry type and in persons of tubercular tendencies it acts better than arsenic. Locally applied, it is used in pencil form in chronic conjunctivitis, in tinea of the margin of the lids, and in weak solution of 1 to 3 grains to the ounce of water in subacute conjunctivitis. In relaxed sore throat, as a gargle, it is of service. It is a valuable stimulant to chronic ulcers everywhere.

Poisoning.—The more important salts from a medicolegal aspect are the sulphate (blue vitriol or blue stone), the acetates, constituting artificial verdigris, and the carbonates or natural verdigris. Half an ounce of the sulphate will probably cause death. The greenish or blue color of the vomited matters, which turn bright blue on the addition of ammonia, makes the diagnosis easy.

The stomach should be evacuated by vomiting or by the stomach-pump; and albumin, as in milk or the whites of eggs, given to precipitate the copper. Iron filings may be given for a like purpose. In chronic poisoning the cause must be discovered and removed, or the individual removed from the cause.

Preparations.—C. Sulphas, $CuSO_4.5H_2O$, blue vitriol, soluble in water, valuable as an emetic. Dose, as an emetic, 2 to 5 grains; as a tonic, 1/6 to 1/2 grain.

Alkaline Cupric Tartrate Volumetric Solution, *Fehling's Solution.*—The official reagent for glucose is prepared as follows: (1) Dissolve 34.64 grams of pure cupric sulphate in water, to measure exactly 500 c.c. (2) Dissolve 173 grams of potassium and sodium tartrate and 75 grams of potassium hydroxid in water to measure exactly 500 c.c. Keep the two solutions in small, rubber-stoppered bottles, separate; and for use mix exactly equal volumes of the two at the time required. One cubic centimeter of the mixed solution reduces 0.005 gram (1/12 grain) of anhydrous glucose.

COPREMIA.—A form of general blood-poisoning arising from absorption of unduly retained feces. This condition is occasionally met in chronic constipation. The symptoms are anemia, sallow complexion, anorexia, frontal headache, vertigo, nausea, flatulence, thirst, lithemia, fetid breath, lassitude, hypochondriasis, and irritability of temper. See Autointoxication. Constipation.

COPROSTASIS.—Fecal accumulation in the bowel. See Feces.

CORD.—See Spermatic Cord, Spinal Cord, Umbilical Cord, etc.

CORIANDER.—The fruit of *Coriandrum sativum,* an aromatic carminative and stimulant, used mainly to give flavor to other remedies and as a corrective to griping purgatives. Dose, 5 to 20 grains. **C., Ol.,** the volatile oil. Dose, 1 to 5 minims.

CORN.—A local induration and thickening of the skin from friction or pressure. Corns usually begin as callosities, but differ from these mainly in the involution or downward growth of the hypertrophied horny layer to form the so-called "root" in the center, which, pressing upon the subjacent papillæ, either cause their inflammation or atrophy. The underlying nerves undergo enlargement. Owing to their hygroscopic qualities, some corns give rise to pain in damp weather. When situated between the toes, corns are called "soft." The most usual sites for corns are on the dorsal surfaces of the phalanges, on the outer surface of the little toes, and over the heads of the first and fifth metatarsal bones.

By removal of the cause—*i. e.*, friction or intermittent pressure—the corn will soon disappear. The top of a corn may be peeled off, and a little nitric or glacial acetic acid applied on one or two occasions. In a few days the thickened cuticle may be peeled off and a fresh application made. A solution of caustic soda, well diluted, or one of bicarbonate of sodium, may be applied at night on lint or cotton-wool. Silver nitrate is painful and liable to be followed by inflammation and lameness.

The favorite remedy is salicylic acid, which is the basis of nearly all corn cures. The usual formula is:

℞.	Salicylic acid,	ʒ j
	Extract of cannabis indica,	gr. x
	Flexible collodion,	ʒ vj
	Ether,	ʒij.

To be painted over the corn daily.

The laminated corn, or callus, produced by pressure, congestion, and increased formation of epidermis, may be softened by moisture, as by soaking in warm water, by the application of a starch or soap poultice; and, being softened, the thick cuticle may be thinned by scraping with a blunt knife, or the albuminous epidermis may be dissolved by an alkaline solution with moderate friction. When the thickening has been reduced sufficiently, it may be kept down by daily washing with soap. The soft corn requires removal with the knife; if of moderate size, a single pinch with a pair of pointed scissors will effect its removal, while the hard callus will require patient digging with the point of not too sharp a knife. The "eye" of the corn may be always made visible by rubbing the part with eau de cologne or alcohol, and any remains of the core may be detected in this way, either during or after the operation; the corn should be covered with a piece of soft plaster for a day or two, and a perforated plaster of buff leather or amadou subsequently worn to keep pressure from the center of the growth. The removal of a corn may be very considerably aided by the use of the compound tincture of iodin painted on the swelling. When the corn is painful, this application subdues the

sensibility and renders the corn dry and pliable and easy of removal by means of a file. Soap and water are beneficial to feet afflicted with corns, and particularly when they are soft corns. Daily washing with soap, and the subsequent interposition of a piece of cotton-wool between the toes, may be considered a cure for a soft corn. In these cases the skin may be hardened by sponging with spirits of camphor after the washing. The cotton-wool should be removed at night. Properly fitting shoes and socks should be worn. In the case of intractable soft corns, the adjacent sides of the two toes have been freshened, and then stitched together, thus making one toe of them.

CORNEA, DISEASES.—Inflammations of the cornea demand special attention, as they are very liable to result in opacities, leaving irremediable optic disturbances. Since the cornea is inelastic and nonvascular, the ordinary signs of inflammation are not present, and the diagnostic sign is cloudiness of the tissue, resulting from a collection of leukocytes that have passed into the cornea from the adjacent blood-vessels. In corneal inflammation there is generally swelling and inflammation of the lids and congestion of the conjunctiva. *Pericorneal injection* is due to congestion of the deep conjunctival vessels arising from the ciliary arteries. Inflammations of the cornea may be divided into two classes—*superficial* and *deep*.

Pannus is a vascular growth of connective tissue on the superficial layer of the cornea; it may, however, extend and affect the deeper layers. It begins with an inflammation of the cornea in which large areas become clouded and infiltrated with superficial blood-vessels. The newly formed and tortuous vessels are largest at the periphery, and are directed toward the center of the cornea. There may be only one vessel, or the vascular formation may be so luxuriant that a great part of the corneal surface is transformed into a fleshy-looking mass having the appearance of raw beef. This condition is called *pannus crassus* or *pannus carnosus*.

The cause of pannus is generally the friction of roughened granular lids against the cornea, or there may be an extension of the trachomatous process into the cornea. See TRACHOMA. The upper half is the part usually affected. Prolonged irritation of the cornea by inverted lashes or entropion may cause pannus unassociated with ulcers. The eczematous variety of pannus is a sequence of a phlyctenular process.

The symptoms of pannus are pain, photophobia, lacrimation, swelling, and conjunctival and ciliary injection, together with the characteristic vascular appearance.

The prognosis depends upon the extent of corneal infiltration and destruction of the epithelium.

The important sequels are corneal opacities and, rarely, conic cornea and corneal staphyloma.

The treatment should be directed to the cure of the granular lids, or to remedying the trichiasis or entropion. Should the pannus outlast the causes of the disease, massage with yellow ointment or the application of such preparation as boroglycerid and blue stone should be tried. Eserin and iodoform, or one of its substitutes, and constant bandaging of the eye are of value. The extreme measures are **peritomy,** which consists in removal of a ribbon of conjunctiva about 2 mm. wide, parallel with the edge of the cornea, thus severing and obliterating the superfluous vessels (unfortunately, the vessels repullulate); or the induction of an acute inflammation of the conjunctiva with an extract of JEQUIRITY SEEDS (*q. v.*). For the relief of pain, atropin and hot-water applications are useful.

Interstitial or Parenchymatous Keratitis.—Diffuse inflammation of the substantia propria of the cornea.

Symptoms and Diagnosis.—In this disease the deeper tissues of the cornea become infiltrated by lymph-cells, which slowly increase until the whole cornea becomes more or less opaque. Without a lens the cornea presents the appearance of a piece of ground glass, but focal illumination shows that the parts are not uniformly affected, and sometimes unaffected portions may be seen between local opacities. Pericorneal injection is marked, but the conjunctival vessels may be but slightly affected. The epithelium may be partly destroyed. The iris may be affected sympathetically and posterior synechias formed; in fact, the whole ciliary region and the choroid may be affected and the nutrition of the vitreous disturbed. In very severe cases blood-vessels form in the interstices of the cornea. This disease is the result of general infection, and, according to Horner, in at least 80 percent of cases both eyes are attacked eventually. The disease occurs chiefly in hereditary syphilis, and is associated with the other signs of this malady, such as Hutchinson's teeth, thickening of the periosteum, glandular swellings, middle-ear disease, etc. A syphilitic history may be obtained from the parents. The mother may bear evidences of specific infection and may give a history of sickly children or recurring miscarriages. The chief subjective symptoms are dimness of vision and lacrimation; but there may be much pain or photophobia. Some cases may be of tuberculous origin. See TUBERCULOSIS, Ocular.

The prognosis is unfavorable, although complete loss of vision is seldom to be feared. The disease is of long duration, and restoration of the visual acuity is doubtful, especially if the patient is not very young.

The treatment is directed to the systemic condition, and consists in mercurials, iodids, cod-liver oil, and tonics, cleanliness, good food, and fresh air. The following is a good formula:

℞.	Mercury biniodid,	gr. ij
	Potassium iodid,	ʒ ij
	Syrup of sarsaparilla, q. s.	℥ iij.

A teaspoonful in water after meals.

The local treatment is by atropin, warm compresses, and protective glasses. When the disease has passed its climax, massage with yellow ointment or dusting with calomel is of advantage.

Phlyctenular Keratitis.—Although there is no especial reason for separating this disease from phlyc-

tenular conjunctivitis, it is usually also described under diseases of the cornea. It is in 85 to 90 percent of the cases, a disease of children of scrofulous diathesis or those suffering from improper nourishment, or who show signs of eczematous affections in other portions of the body. Adults and healthy children are also affected. It is characterized by one or more phlyctenules, or small cysts, formed on the limbus of the conjunctiva, and extending upon the cornea. These phlyctenules cause an opacity that may clear up or may be followed by the formation of a bundle of new vessels on the cornea. This leash of vessels may disappear, but the ulcer beneath them generally leaves an opacity.

Symptoms.—The chief symptoms are acute pain, photophobia, lacrimation, and the characteristic bundle of vessels, with a yellow crescent at the apex, its concavity toward the vessels. Every phlyctenule does not necessarily change to an ulcer, but may be dissolved under proper treatment. The photophobia may be so intense as to cause blepharospasm, as irritation of so highly nervous a tissue as the cornea gives rise to severe reflex symptoms. The belpharospasm may be so severe as to necessitate the administration of a general anesthetic before the cornea can be properly examined.

The treatment consists of an abundance of good food, improved hygienic surroundings (in fact the general treatment of tuberculosis, since the scrofulous diathesis, more properly called the tuberculous diathesis, is merely latent tuberculosis), and soothing local applications. Of the latter, atropin and warm compresses are advised. The eye should be douched with sublimate 1:5000. If an ulcer is already formed, the general treatment, as before described, should be instituted. When the ulcer is healed, it should be dusted with iodoform or calomel and massaged with yellow ointment. If this is ineffective a 2 percent. guaiacol ointment may prove valuable. It has been found that the instillation of eserin into the eye, followed by dusting fine iodoform over the cornea, and a constant application of a bandage, securing local heat, produces good results in promoting absorption of the vessels. See Tuberculosis, Ocular.

Herpes of the cornea is characterized by the formation of small blebs filled with a watery fluid. It may be the general accompaniment of herpes zoster or febrile herpes. The blebs should be treated with the gentlest measures, such as the instillation of atropin, disinfection, and a bandage. Should they form ulcers, they should be treated as such.

Neuroparalytic keratitis is an ulcerative condition of the cornea, due to some disturbance of the corneal nerve supply. The prognosis and treatment of the disease depend upon the cranial lesion causing it.

Bullous keratitis is characterized by the formation on the cornea of large vesicles filled with a clear fluid. The vesicles break after a few days and the symptoms of irritation subside. This condition has been seen associated with glaucoma, iritis, and inflammation of the uveal tract. The disease has been attributed to some affection of the corneal nerves and to malarial fever. A peculiar chronic form is sometimes seen after corneal injury. It is called **recurrent traumatic keratitis.** It is said that the recurrent attacks are preceded by a peculiar aura, and that they may be aborted by large doses of quinin. The vesicles should be incised early, and local treatment instituted.

Keratitis from lagophthalmos is a condition in which there is ulceration of the cornea, due to exposure from incomplete closure of the lids. The chief causes are lack of sensation in the cornea from paralysis of the peripheral nerves—a condition in which the patient lies comatose for a long time—and possibly some paralysis of the lid-muscles. Protection by anointing with vaselin or a bland oil is indicated.

Corneal ulcer is caused by an external wound leaving an opening for the entrance of a suppurative process, by intense conjunctival inflammation, or by some deep inflammatory process that leads to a destruction of the superficial layers and epithelium.

Diagnosis and Symptoms.—It is very important immediately to recognize any superficial loss of substance in the cornea. The ordinary optic aids, such as oblique focal illumination and high plus lenses, or the ophthalmoscope, are generally sufficient. In doubtful cases and in young children a drop of fluorescin placed on the conjunctival sac and at once washed out is a ready means of diagnosis; any spot of the cornea denuded of its epithelium will be colored green. If an ulcer is present, it is necessary to determine whether it is due to external infection, or whether it results from extension of some conjunctival disease, from nervous disease, or from some systemic affection, as the subsequent treatment depends much on the origin. However, if pain, photophobia, lacrimation, and attendant swelling of the lids and conjunctiva, together with extensive and progressive destruction of tissue, are present, it is necessary to proceed immediately, regardless of the mode of origin, which may be left to a subsequent examination. An ulcer with a ragged edge and a grayish, uneven base, with general cloudiness around the circumference, and with acute associate local disturbance and subjective symptoms, is probably in an active stage of inflammation. If the cloudiness is clearing up, the edge round, the ulcer looks clear and smooth, and the patient's symptoms are subsiding, the healing process has probably begun. As the ulcer becomes filled up the opacity becomes more dense; and the younger the patient, the sooner the scar will clear up. Central ulcers cause the most damage to vision.

The sequels of most importance are: *Corneal opacities; staphyloma,* or hernia of the cornea, due to weakening of its structure by scar formation which condition sometimes includes a staphyloma of the iris as well as of the cornea; *perforation,* followed by discharge of aqueous and prolapse of the iris, which may remain permanently adherent to the white corneal scar—a condition

called *leukoma adherens;* atrophy of the eyeball, called *phthisis bulbi,* following extensive destruction of the cornea; and prolapse of even the lens and vitreous.

The prognosis varies with the age of the patient, the location and extent of involvement, and the general systemic condition.

The treatment is, first, to put the eye at rest, which is best accomplished by a pressure-bandage and by atropin, which subdues pain and overcomes inflammation. If there is much congestion of the conjunctiva, leeches to the temple will give great relief and hasten the subsidence of symptoms. Disinfection is best accomplished by a sublimate solution 1:5000, or the ulcer may be dusted with iodoform. After dusting iodoform on the cornea the upper lid should be drawn down over the cornea and held in position for a few minutes; otherwise movement of the eye will brush all the powder off the cornea. If the ulcer progresses, stronger disinfection, preferably with sublimate 1:1000, boroglycerid 50 percent, or formalin 10 percent, will be needed. Finally, if the ulcer resists all treatment and is progressive, the whole of the infected surface should be cauterized by the direct heat of the galvanocautery. Moist heat, applied in the shape of mild antiseptic compresses, will lessen the pain, increase the development of blood-vessels, and arouse a general reaction in the affected parts.

If **perforation** seems probable, it is best to hasten it by puncture with a needle or a small cataract knife, as experience has shown that perforated ulcers heal spontaneously, and better drainage is established. After perforation, the eye should be carefully washed, eserin instilled, a pressure-bandage applied, and the eye allowed to remain undisturbed for at least 24 hours. If the iris prolapses, it must be drawn from the wound and excised. When the ulcer shows signs of healing, daily massage with a weak Pagenstecher ointment is advisable. The membrane of Descemet is very resistant, and sometimes, instead of perforating, it prolapses through the ulcer and prevents its healing, causing a **corneal fistula.** In such cases the edges of the ulcer should be stimulated or cauterized. The treatment of the sequels will be discussed separately. Constitutional treatment, particularly administration of tonics, should be inaugurated at the beginning of the disease, and any causal disease corrected. The patient should not be kept in a badly ventilated, dark room.

Abscess of the cornea may run its course without ulceration, or it may result in the formation of an ulcer—usually the ulcus serpens. Abscesses in the superficial layers of the cornea are most prone to ulceration.

The chief **causes** of abscess are infection through an abrasion or distinct wound, or infection through the blood, as seen in some acute exanthematous diseases, such as measles, scarlet fever, small-pox, etc.

The appearance presented is that of a yellowish, circumscribed opacity near the middle of the cornea, and surrounded by a grayish zone. It is usually round or crescentic in shape. The surface over the abscess appears elevated and dull, and the whole cornea may lose its luster and appear as if breathed upon. There is usually much conjunctival and ciliary injection. The abscess is attended by severe pain, photophobia, blepharospasm, etc. Hypopyon, onyx, and iritic involvement are usually constant attendants. The common termination is ulceration through the superficial corneal layers; but occasionally the abscess spreads through the corneal stroma, and gradually becomes absorbed without undergoing ulceration.

The treatment consists of atropin, warm fomentations, iodoform, and a light bandage. If these measures do not check the process, resort must be had to the cautery. Hypopyon is relieved by paracentesis, repeated if necessary. Compound tincture of cinchona in full doses is recommended. Stimulating diet should be instituted.

Ulcus serpens, or serpiginous ulcer, is a destructive inflammation of the cornea, usually attacking debilitated and aged persons. The typical form contains the pneumococcus alone or associated with other organisms. Disease of the lacrimal passages predisposes to it. Its chief characteristic is its remarkable inclination to extend and to destroy tissue. It most commonly results from some injury to the eye, often only a small scratch, through which some form of infecting germ is introduced. Infection may be derived from the article causing the injury, from some purulent discharge about the eye or its appendages, or from some article used to wipe the eye. At the posterior part of the ulcer there is generally seen a grayish cloud, which may extend into the anterior chamber. This is caused by a collection of pus-cells, either in the lamellæ of the cornea, called **onyx,** or in the anterior chamber, which renders the aqueous opaque, and, settling in the bottom of the anterior chamber, forms what is called **hypopyon.** The disease begins as a round, yellowish abscess near the center of the cornea, which breaks and forms an ulcer rapidly increasing in surface and depth. Serpiginous ulcer often follows severe infectious diseases, particularly small-pox.

The prognosis is unfavorable, as there is generally left an extensive opacity, and most likely anterior and posterior synechiæ.

The treatment is the same as for an ordinary severe ulcer or abscess. Occasionally, Saemisch's operation at the base of the ulcer is necessitated. Antipneumococcic serum has been recommended but is apparently beneficial only in beginning ulcers.

Ulcus rodens is a chronic inflammation, beginning on one margin of the cornea and slowly eating its way to the opposite margin, but rarely extending into the deeper layers. Its edges must be cauterized.

CORNEA, INJURIES.—Foreign bodies in the cornea, if not removed, are very apt to cause cell-infiltration and destruction of the adjacent tissue, thus inviting infection. However, the subjective symptoms so well known to everybody are usually so severe as to demand immediate treatment.

Although simple inspection may be sufficient, focal illumination and fluorescin, for the detection of the denuded area of epithelium, are sometimes necessary for locating the foreign body. In every case it is safer to examine the eye by focal and oblique illumination.

Foreign bodies in or on the cornea can generally be removed without the use of cocain and without instrumental aid. A wisp of cotton is wound on itself or on a small stick; the patient is told to look downward, and the cotton is pressed firmly against the cornea. The patient immediately rotates the eyeball upward, and the cornea is brushed against the fibers of cotton, which usually entangle the foreign body. This simple method has been found almost invariably successful, and is advised before resorting to the spud or needle.

The removal of a foreign body from the cornea by instrument is a procedure that should be carried on with especial caution. If the substance is embedded, the cornea should first be cocainized and rendered aseptic.

Under focal illumination, a small curet, chisel, or spud will generally accomplish the removal. If, however, the foreign body is close to the anterior chamber, it may be lost in the iritic angle. In such a case a small keratome should be introduced into the anterior chamber and pressed against the posterior surface of the cornea, thus preventing penetration of the foreign body into the anterior chamber. The electric magnet is often of great value in removing pieces of iron and steel. A boric acid wash or iodoform ointment should be used for at least 24 hours after the use of an instrument in the cornea.

Burns of the cornea are treated on the same principle as burns of the conjunctiva, (See CONJUNCTIVA, Burns of). Ulceration, opacities, and symblepharon are the important sequels to be feared.

Wounds of the cornea are always dangerous, not only from the destruction of corneal tissue and subsequent opaque cicatrix, but they are also often attended by sudden escape of the aqueous and prolapse of the iris. Results of infection through a corneal wound vary from the formation of an ulcer to the destruction of the eyeball.

The treatment is the application of a simple aseptic bandage. The eye should be kept clean, and if there is much irritation, atropin should be used. Should the iris become prolapsed, an effort must be made to replace it and to retain it in position by eserin, complete rest, and a bandage. If this treatment is not successful, the iris should be drawn out and excised. Very large prolapses should not be excised, as they will recur, and much iris tissue will be needlessly lost. In such cases no operative interference is indicated until the wound closes. The cornea and iris are cleansed, an attempt made to partially reduce the prolapse, atropin instilled, a pressure-bandage applied, and the patient placed on his back.

CORNEA, OPERATIONS.—Paracentesis of the cornea is an operation done for the purpose of emptying the anterior chamber of aqueous, and thus relieving any increased intraocular tension, or for evacuating hypopyon. It is best done with a paracentesis needle or a slender Graefe knife. The eye is thoroughly cleansed, and the point of an aseptic knife is *perpendicularly* introduced at the lower outer border of the cornea. If it is introduced at an angle, there is danger of splitting the layers of the cornea, and not directly perforating it. After perforation of the cornea the blade of the knife is turned horizontally, and a corneal wound of about 2 mm. in length made. The knife is then carefully withdrawn, allowing the aqueous to escape slowly. Depression of the lower edge of the wound by a curette will aid in the evacuation of hypopyon.

Saemisch's operation is performed for the relief of corneal abscess or serpiginous ulcer. It consists in introducing a Graefe knife through healthy corneal tissue at the margin of the involved area, carrying it into the anterior chamber, and making a counterpuncture in healthy tissue at the other side of the abscess. The cutting-edge is then turned forward and the abscess bisected. Any pus may be removed by irrigation or by a scoop. The wound must not be allowed to close completely so long as the disease is active.

Transplantation of cornea consists in removing, with a fine trephine, a piece of a rabbit's cornea and transplanting it over the denuded area. It is of doubtful value in any case.

Abscission of Staphyloma of Cornea and Sclera. —Critchett's operation is the simplest and most effective. Five threaded needles are inserted, equidistant and parallel with one another, through the base of the staphyloma; the involved tissues are then excised with a knife or scissors, and the needles drawn through and the sutures tied. This leaves a very desirable stump upon which to place an artificial eye. This operation is to be preferred to enucleation of the eye in children, as it favors symmetric growth of the face.

CORPULENCE.—See OBESITY.

CORROSIVE SUBLIMATE.—See MERCURY.

CORROSIVES.—See POISONING.

CORYZA (Cold).—Catarrh, or an acute inflammatory affection of the upper air-passages, resulting from cold, and attended by a discharge from the nostrils, soreness of the throat, hoarseness, and cough. In debilitated or delicate persons it is often difficult to get rid of a cold. Change of air may be most efficacious. The milder forms of cold require household remedies—the feet in hot water, a warm, diluent beverage, a diaphoretic, as Dover's powder, and a light diet for several days. In more serious cases a febrifuge medicine may be given, with an anodyne to relieve the cough, if troublesome, and to procure rest at night. A stimulating diet is given after a day or two of the cold, and tonics may be required.

Ferrier's snuff, for early-acquired colds:

℞.	Morphin hydrochlorid,	gr. ij
	Bismuth subnitrate,	ʒ vj
	Powdered gum acacia,	ʒ ij

From one-fourth to one-half may be taken in the course of 24 hours.

Eucain may be substituted for morphin in this

formula; this alkaloid is free from the objection of producing the drug habituation which contraindicates the routine use of cocain.

Inhalations of menthol will relieve the congestion of early colds in the head. A spray of cocain may precede, in order to reduce the congestion, followed by a spray of menthol, to hold the contracted vessels and to relieve the tumefaction of the turbinated bones.

Wunsche says that menthol, dissolved in chloroform, is the most efficacious of all remedies. A solution of 1 or 2 parts of menthol in 20 parts of chloroform will not only arrest the progress of a cold in its initial stage, but it is also an excellent influenza prophylactic. From 4 to 6 drops of the solution should be quickly rubbed between the hands, which should then be tightly pressed together and placed before the face, when the remedy is energetically inhaled alternately through the nose and mouth. It will immediately be noticed that the volatile parts of the solution thoroughly impregnate the mucous membranes of the nose, mouth, and throat, and even penetrate deep down into the air-passages. During the first 2 or 3 inhalations the sweetish chloroform vapor predominates. Afterwards, however, only menthol in attenuated condition is inhaled, odor and feeling remaining apparent for some time after the inhalation. As a rule, the first inhalation suffices to cure the severest tendency to sneezing, and often to arrest the progress of the cold altogether. Two further applications of the remedy in the course of the day suffice to suppress the attack completely. The first inhalation at first slightly increases the flow from the mucous membrane of the nose; afterwards, however, this symptom diminishes quickly. Pains in the pharynx and larynx may be quickly eased and often entirely relieved by the remedy.

Prophylaxis.—The modern toilet is not complete without rinsing the mouth and spraying the nasal passages and the throat with an alkaline antiseptic solution frequently. By these means the upper air-passages are kept in an antiseptic condition, unfavorable to the development of germs, and disease is prevented. Lemoine states that by these simple precautions numbers of persons have passed through the winter and rainy spring without once catching cold, although they had previously been extremely sensitive, and troubled with severe colds most of the time. He recommends to rinse the mouth with a glassful of 1 ounce of Labarraque's solution mixed with 1 pint of water, or the following:

℞.	Thymol,	gr. viij
	Alcohol,	℥ j
	Water,	O j.

With an ordinary toilet atomizer the nasal passages and upper part of the throat should be thoroughly sprayed with some solution like the following:

℞.	Phenolsalyl,	gr. viij
	Chlorid of sodium,	℥ j
	Distilled water,	O j.

He adds that the teeth should be well brushed, and the fingers never put in the mouth or nose. A few menthol drops should be carried in the pocket and dissolved in the mouth occasionally. He concludes with the remark that it may be possible to break up a cold in the early stages by taking, during the first day, from 4 to 6 capsules or pills of essence of turpentine in addition to the rinsing or gargling and spray, with a glass of purgative water the next day, followed in a few hours by 7 grains of quinin. See Rhinitis.

COSMETIC.—A remedy designed to improve or to hide defects of the skin or other external parts. It may be a white powder, such as starch, magnesic oxid, calcium carbonate (levigated), zinc oxid, mercurous chlorid, or bismuth subnitrate applied externally; it may be a white substance dissolved in dilute alcohol, which is left upon the face after the evaporation of the solvent; or it may be a stimulant to the skin used internally, such as arsenic.

A cosmetic operation is one performed to give a natural appearance to a defective or unsightly part. See Plastic Surgery.

COSMOLIN.—See Petrolatum.

COTARNIN HYDROCHLORID.—See Stypticin.

COTTON.—"The hair of the seed" of *Gossypium herbaceum* "and of other species of gossypium" (U. S. P.). The cotton contemplated by the United States Pharmacopeia is "absorbent cotton," or cotton freed from the oil and other impurities; it is usually prepared by boiling with a solution of an alkaline soap, washing this out thoroughly, possibly washing again with a weak solution of caustic potash or soda, washing this out, pressing, and drying. When dried absorbent cotton is thrown upon water, it should immediately absorb the latter and sink. From the seeds of the cotton-plant a fixed oil is expressed that is much employed for soap-making and as an adulteration of, and a substitute for, olive oil. The oil also is official and enters into the composition of the ammonia, lime, camphor, and subacetate of lead liniments. Cotton-seed oil is largely used, among other oils, as an adulterant to linseed oil. It is less innocent than any other agent so introduced, since it has a bad effect upon the skin.

Styptic cotton may be prepared by first passing the cotton through a 4 percent solution of soda; then washing, drying, and subsequently dipping 2 or 3 times in a weak solution of the chlorid of iron, and again drying. It is then teased out with the fingers, leaving a brown, cottony mass, thoroughly impregnated with the salt of iron.

Raw cotton is so familiar that description is unnecessary. Owing to the oil it contains it will not absorb water, and, consequently, is practically useless for washing or cleansing wounds. It is employed chiefly as a padding for splints, and for protecting the extremities and cutaneous surfaces from contact with the air. Raw cotton, laid over the chest in layers 2 inches thick, forms a good chest dressing in pneumonia. In the local treatment of erysipelas one of the best methods is to keep the part wrapped in raw cotton, for the temperature of the part should be as nearly uniform as possible, and the cutaneous functions as-

sisted. Painful and sensitive rheumatic joints in old persons are often relieved by being wrapped in raw cotton, which is retained by means of a bandage. Cotton is often employed as a protective dressing for burns with advantage, if the burn is of the first or second degree; but it may irritate if in contact with a vesicated surface. Yet it at times forms one of the best dressings for blistered surfaces, laid evenly over the part and retained by the clothing or a bandage.

Absorbent cotton is now employed extensively in the washing and cleansing of wounds in the place of sponges. Small pledgets on an aluminum applicator are constantly used in general surgery and in all the specialties.

See also Gossypium.

COUGH. Varieties.—(1) Dry and (2) moist.

Etiology.—Cough generally results from irritation somewhere in the respiratory tract. Thus, any irritation or inflammation of the nasopharynx, larynx, or bronchi may give rise to cough. The most common etiologic factors are: (1) Inflammatory diseases of the nasopharynx, larynx, bronchi, lungs, and pleura. (2) Inhalation of irritating particles, as dust. (3) Sudden changes in the temperature. (4) Reflex causes, as heart- and kidney-disease, which give rise to relaxation and edema of the respiratory mucous membrane; pressure of tumors upon the recurrent laryngeal nerve (aneurysm of thoracic aorta); pressure arising from abdominal tumors, as uterine fibroids. (5) Foreign bodies. (6) Infectious diseases, as tuberculosis, measles, whooping-cough, scarlet fever, and influenza. (7) Elongated uvula. (8) Nervousness, hysteria. (9) In children adenoid vegetations and hypertrophied tonsils are very common causes of cough.

Treatment.—Persistent effort should be made to find the source of irritation before drugs are used. Thus, in children it is found very frequently that removal of adenoid growths or hypertrophied tonsils may give rise to relief.

A thorough history of a case might develop the fact that the patient suffers from the abuse of tobacco, or lives in an atmosphere of dust. When the occupation is one that renders the patient subject to sudden changes in the temperature, a dry, "hacking" cough is very common. In the *moist* cough, or that accompanied by increased secretion, bronchitis is generally present, and treatment must be directed accordingly.

In acute "colds," when pharyngitis is present, an application of silver nitrate (15 grains to 1 ounce), glycerite of tannic acid, or menthol (3 grains to 1 ounce), to the nasopharynx once a day will frequently give relief. In certain cases inhalations do well:

℞. Chloroform, ♏ v
Menthol, gr. iij
Compound tincture of benzoin, enough to make ʒ j.

One teaspoonful to a pint of hot water, and inhale once or twice daily.

In using inhalants patients should be directed to remain in the room for an hour at least after the medicine has been used.

Internally:

℞. Codein sulphate, gr. iij
Glycerin, } each, ʒ ij
Syrup, }
Solution of potassium citrate, enough to make ʒ iij.

Two teaspoonfuls every 3 or 4 hours.

See Bronchitis, Tuberculosis, Pneumonia, Laryngitis, Whooping-cough, etc.

COUNTERIRRITATION.—A method of overcoming pain, inflammation, or other change in a part or organ by an effect produced upon the skin in the immediate neighborhood or at a distance. Three stages are recognized: (1) Rubefaction, or the mildest form; (2) vesication; and (3) the most severe, pustulation, or local destruction of tissue.

The best rubefacient is mustard; liquor epispasticus is one of the best vesicants; while a liniment of croton oil or antimony will produce pustulation.

Rubefacients produce local warmth and redness, are usually quick in action, and with trifling after-effects, such as peeling of the epidermis and local soreness. Mustard plasters and poultices, the volatile oil of mustard, and oils of turpentine and cajuput, tincture of iodin, and hot water, are most available rubefacients. Vinegar should not be added to mustard poultices, but oil of turpentine or a little powdered capsicum added to a mustard poultice will increase its rapidity as a stimulant. If gentle action is desired, with warmth and moisture, a linseed meal poultice may be sprinkled with mustard meal. For delicate skins a layer or two of muslin should be placed between the poultice and skin. Mustard foot-baths are effective revulsives and counterirritants, especially in brain congestions.

Rubefacients are used in many chronic inflammations, in bronchitis, in the troublesome cough of phthisis, for lingering irritation about a joint, in sleeplessness (applied to the nape of the neck), in gout, in lethargy or torpor from narcotic poisoning, alcohol, or febrile coma, in acute kidney inflammations, and commonly for the relief of pain.

A **mustard plaster** is made by mixing mustard flour with warm vinegar or water and adding flour. Half mustard and half flour may be employed for a child. A piece of muslin spread on a newspaper and smeared with the mustard, over which is a more or less thin piece of muslin, will prevent sticking to the skin and modify the burning. The edges of the newspaper may be folded so as to cover the plaster and aid in retaining its heat.

A **spice plaster** is made by mixing equal parts of allspice, cloves, cinnamon, and nutmegs, and adding 1/2 part of pepper. Warm brandy, whisky, or vinegar may be used to wet it. A turpentine stupe should not be allowed to remain very long lest it blister the cuticle.

Vesicants.—For blistering, the most common agent is cantharides, in the form of a plaster or in collodion. Glacial acetic acid will produce rapid vesication, but it must be watched lest it become

caustic and cause a sore. Aqua ammoniæ on lint, applied to the skin and covered with a watch-glass, will soon vesicate. Liquor epispasticus applied with a brush will blister, and blistering collodion is only slower in action.

Blisters should be applied to one side, not directly over an inflamed area, nor when the skin is loose, nor over any bony prominence, nor to the breast-bone in pregnancy. The absorption of cantharides may be prevented by sprinkling powdered camphor over the plaster or by interposing a piece of silver paper. If vesication is desired, a blister need not be left on continuously for 12 hours or more. It may be removed in 6 or 8 hours and a warm linseed poultice applied. A blister is opened by pricking the most dependent part with a disinfected needle. Sweet oil and cotton-wool make the best dressing.

Vesication is of service in brain affections attended by congestion, as in the chronic forms of hydrocephalus and tubercular meningitis. In pleuritic and pericardiac affections, in effusions into joints, in the joint affections of acute rheumatism, in obstinate acid vomiting, in pleurodynia or mastodynia, and for the removal of products of inflammations, vesication is serviceable.

In diseases of the eye a blister should be applied behind the ear; in abdominal neuralgia or pleurodynia, to the vertebral column where the disturbed nerve takes its exit; in early hip-disease, to the knee or ankle; in peritonitis, directly over the seat of tenderness; in cerebritis, to the nape of the neck; and in gleet, along the under surface of the penis or upon the perineum.

Pustulants.—The red-hot (not white-hot) iron and the use of escharotics, such as caustic potash or soda, may be resorted to for severe counter-irritation or pustulation. Antimonial ointment may be applied constantly until a slough forms, to accomplish the same purpose. Croton oil, tartrated antimony, and strong solutions of silver nitrate produce eruptions at first papular, but they soon become pustular. Tartrated antimony is used in the form of an ointment and in hot aqueous solution. Silver is seldom used. Burns from counterirritation may be treated by applying simple cerate, cosmolin, or sweet oil, to which carbolic acid in proportion of 1:100 may be added.

COWPOX.—See Vaccination.

COXA VALGA.—Coxa valga is the increase of the angle of the neck and shaft of the femur beyond 140°. It is an uncommon deformity which may occur after infantile paralysis or extreme atrophy from any condition, allowing the leg to hang down. The leg is abducted and lengthened and the trochanter lies *below* Nélaton's line. The deformity is corrected by osteotomy of the neck or subtrochanteric osteotomy. See Hip-joint Disease.

COXA VARA.—The lessening of the angle of the neck and shaft of the femur below 120°. It may be congenital or due to rickets, trauma, softening of the bony parts from any cause and constant standing while supporting heavy weight. It may occur in one or both hips.

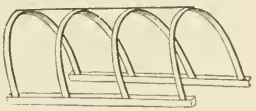
Symptoms.—Onset is slow, pain usually present early and increases, limping and interference with abduction, shortening and the location of the trochanter *above* Nélaton's line, but the head lies in the acetabulum. This fact and the absence of riding motion differentiate it from congenital dislocation of the hip.

Treatment.—Crutches and traction splint in the unilateral cases and recumbency for the bilateral ones. This method failing, forcible abduction should be tried with fixation in plaster of Paris. In the older cases, subtrochanteric osteotomy (Gant's) should be done and a plaster spica applied in corrected position. See Hip-joint Disease.

COXALGIA.—See Hip-joint Disease.

COXITIS.—See Hip-joint Disease.

CRADLE.—A wire or wicker frame so arranged as to keep the weight of the bed-clothing from an injured part of the body. It is employed in the treatment of fractures, wounds, etc.



Cradle for Supporting Bed Clothes.—(*From Fullerton.*)

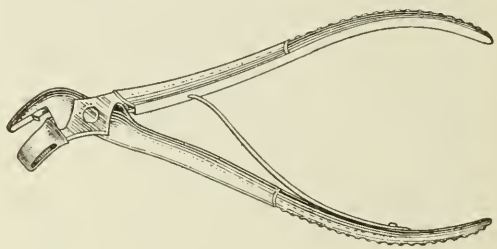
CRAMP.—A spasmodic tonic contraction of the muscles, attended with sharp pain. It is especially prone to attack the muscles of the calf of the leg. It occurs frequently in those of neurotic tendency, and is often the forerunner of epilepsy. **C., Auctioneers',** one of the professional neuroses affecting mainly the left side of the orbicularis oris muscle. **C., Ballet-dancers',** a neuralgic affection occurring in ballet-dancers, especially premières danseuses; characterized by pain and paralytic symptoms, affecting the muscles of the calf of the leg. It is the result of local strain upon the parts. **C., Blacksmiths'.** See C., Hammermen's. **C., Car-drivers',** a professional neurosis seen in car-drivers, and perhaps also in brakemen, characterized by spasm and weakness of the hand from the effort of tightening car-brakes. **C., Chisel,** a professional neurosis occurring in smiths, affecting the left hand, and produced by the continuous holding of the chisel or similar instrument. **C., Cigarmakers',** one of the rarer professional neuroses, consisting in a tonic contraction of the flexor muscles of the fingers, with pain. The painful sensations also extend up the arm and shoulders. **C., Cigaret-makers'.** See C., Cigarmakers'. **C., Clarionet-players',** a cramp of the tongue and of the laryngeal muscles, experienced occasionally by players on this instrument. **C., Coachmen's,** contraction of the palmar fascia, occasionally seen in coachmen. **C., Cornet-players',** a rare and peculiar neurosis of the tongue in cornet-players, in which certain notes cannot be sounded, from inability to direct the tongue for that purpose. **C., Dancers'.** See C., Ballet-dancers'. **C., Flute-players',** slight laryngeal spasms occurring occasionally in flute-players from excessive use of the instrument. Also a cramp of the flexors and extensors of the hand, from constant use of the instrument. **C., Glassblowers',** a painless, but decided and permanent, flexion of the fingers, the thumb excepted, due to the continuous grasping of the tube with which the glass is worked. **C.,**

Gold-beaters', a cramp of the muscles of the arm, due to excessive use in beating gold-leaf. **C., Hammer.** See C., Hammermen's. **C., Hammermen's**, a spasmodic affection of the muscles of the arm and shoulder, at times unattended by pain, due to the repeated act of hammering. **C., Knitters'**, a peculiar affection of the hands of those who knit, consisting in a contraction of extensor muscles, with numbness of the ends of the fingers. **C., Milkers'**, a spasmodic contraction of the extensors and flexors of the forearm in consequence of continuous exertion in milking. **C., Milkmaids'.** See C., Milkers'. **C., Musicians'**, a general term, including pianists' cramp, violinists' cramp, flutist's cramp, the cramp of clarionet-players, etc. **C., Nailsmiths'.** See C., Hammermen's. **C., Photographers'**, a rare professional neurosis. **C., Pianists'**, a neurosis of the hands and fingers of piano-players, characterized by fatigue, pain, and weakness. The pain extends up the arm to between the shoulders. **C., Piano-players'.** See C., Pianists'. **C., Sawyers'**, peculiar incoordinate movements of the saw-arm and corresponding side of the body, from excessive use. **C., Scriveners'.** See C., Writers'. **C., Seamstresses'**, a professional neurosis, consisting in a spastic condition of the flexors of the fingers, from constantly plying the needle. **C., Smiths'.** See C., Hammermen's. **C., Swimmers'**, a painful cramp of the muscles of the calf of the leg of swimmers, frequently causing death by drowning. **C., Tailors'**, a spasmodic affection of the muscles of the thumb, forefinger, hands, and arms, sometimes occurring in tailors, from overwork. **C., Telegraphers'**, a partial paralysis of the muscles of the hand and fingers with spasm, produced by fatigue from long continued use of Morse's instrument. **C., Treadlers'**, one of the professional neuroses; it is met with in treadlers, and consists in cramps of the leg-muscles from constant use of the machine. **C., Violinists'**, a painful cramp, most common in the left shoulder of violinists; it is due to the peculiar position assumed in holding the violin. **C., Watchmakers'**, a cramp in which there is a flexion of the metacarpophalangeal joints, with extension of the other joints of the hand. Also, an inability to retain the glass in the eye-socket. **C., Writers'**, scriveners' palsy; a difficulty in writing, due to spasmodic action of the muscles of the hand and arm, to pain, to tremulousness of these muscles, or to fatigue and weakness of the extremity. These constitute the 4 forms: *spastic*, *neuralgic*, *tremulous*, and *paralytic*.

CRAMPS.—See Colic.

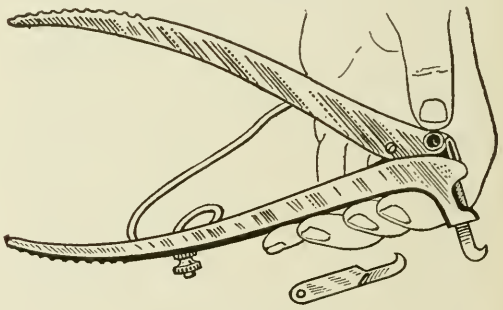
CRANIAL INDICES.—Altitudinal, the height of a skull multiplied by 100 and divided by its length. **Alveolar**, the degree of prominence of the jaws, measured by the basialveolar length multiplied by 100 and divided by the basinasal length. When the alveolar index is less than 98, the skull is *orthognathic;* when more than 103, *prognathic;* when intermediate, *mesognathic*. **Cephalic**, the breadth of a skull multiplied by 100 and divided by its length. When this is below 75, the skull is called *dolichocephalic;* when above 80, it is called *brachycephalic;* between these limits, *mesaticephalic*. **Cephaloorbital**, the ratio of the solid contents of the two orbits to the contents of the cranial cavity, multiplied by 100. **Cephalospinal**, the ratio of the measure of the foramen magnum in square millimeters to that of the cranial cavity in cubic centimeters, multiplied by 100. **Cerebral**, the ratio of the greatest transverse to the greatest anteroposterior diameter of the cranial cavity, multiplied by 100. **Gnathic**, the ratio of the distance between the basion and the alveolar point to the distance between the basion and the nasal point, multiplied by 100. **Vertical Index of Height**, the ratio of the vertical diameter of the skull to the maximum anteroposterior diameter, multiplied by 100.

CRANIECTOMY.—Craniectomy for Microcephalus.—On the theory that certain forms of idiocy are due to a premature closure of the skull preventing development of the brain, Lane, Fuller, and Lannelongue advised that portions of the skull be removed by operation (craniectomy).



Keen's Forceps.

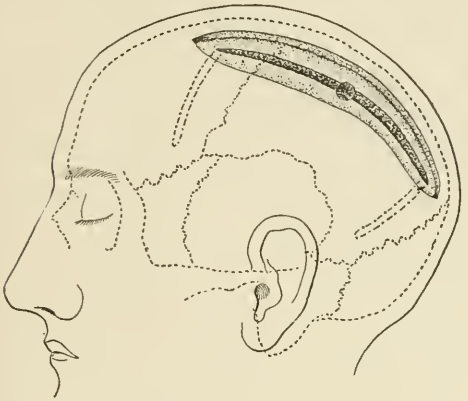
The Operation.—*Step* 1. Make an incision down to the bone from the anterior margin of the hairy scalp backward to the occipitoparietal suture.



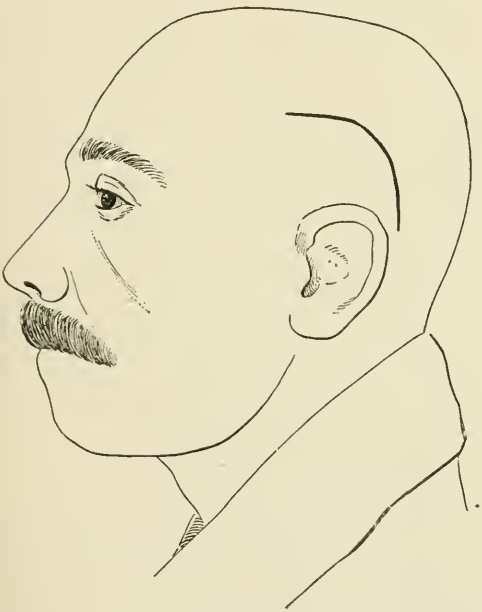
De Vilbiss' Forceps.

This incision is parallel to and about 1/2 inch to the side of the sagittal suture. Stop the bleeding, and separate the scalp and pericranium outward from the incision for a distance of 3/4 inch so that the osseous incision (to be made in the next step) will not lie under the line of the cutaneous incision. *Step* 2. With a Doyen burr or a small trephine, penetrate the skull at any point along the line selected for section of the bone. Through the opening in the skull introduce a dural separator and separate the dura from the bone for a short distance along the line of proposed section. *Step* 3. Introduce the blade

of a proper rongeur forceps (Keen's or De Vilbiss') through the opening in the skull and cut away a narrow strip of bone along the line of section. The longitudinal resection may be supplemented by the removal of transverse strips of



bone at one or both ends. This of course requires corresponding incisions through the scalp. Bleeding from the bone may be arrested by the application of hot pads, by slightly crushing the bone with forceps, or better by pressing Horsley's wax

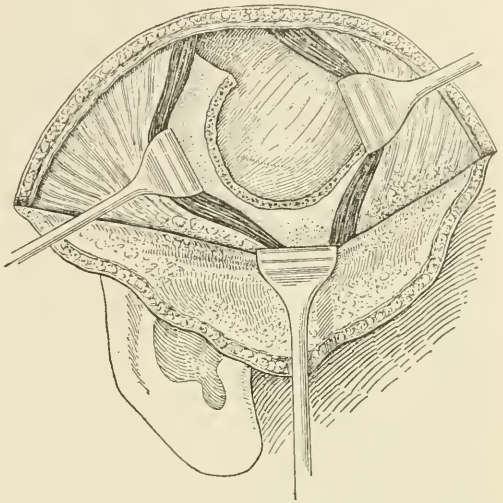


Line of Incision in Cushing's Subtemporal, Decompressive Operation.

(bees wax 7; almond oil 1; salicylic acid 1) against the cut surface of the bone. *Step* 4. The scalp wound is closed and dressings are applied.

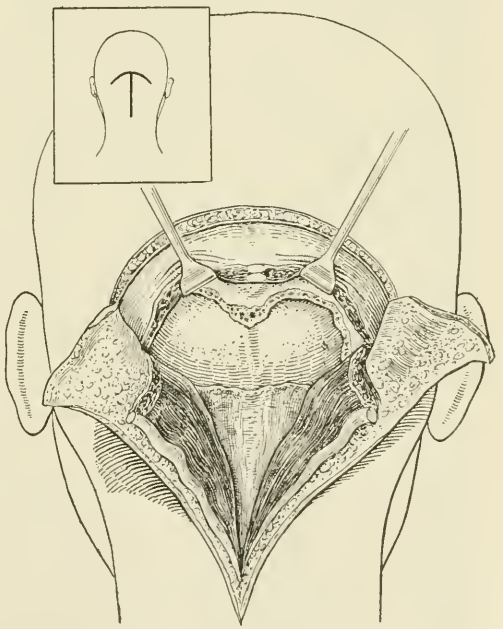
Craniectomy for microcephalus has proven most unsatisfactory and has been practically abandoned.

Decompressive Craniectomy.—Apart from the injuries inflicted on important structures, the principal dangers incident to fractures of the base of the skull are due to hemorrhage and to infection. If the bleeding can be stopped and the extravasated blood removed; if infection can be treated at



Cushing's Intermusculo-temporal Operation.

its inception or its products drained away, then the patient has much better chances of recovery. An attempt may be made to attain these results by



Occipital Craniectomy.—(*Cushing.*)
(Note the high transverse cut of the "cross-bow" incision.)

opening the skull near the junction of its lateral walls and floor.

A similar operation is of great value in treating the results of compression when the cause of the

compression (tumors, etc.) cannot be localized or, if localized, cannot be removed. The distressing symptoms of compression which may be relieved by decompressive operations are vomiting, headache, choked disc, etc.

Subtemporal Craniectomy.—(Cushing's subtemporal decompressive operation.) *Step* 1. Make a curved incision about 1/2 inch within the line of origin of the temporal muscle at the temporal ridge. This cut should be entirely within the hairy scalp. Cut through the skin and subcutaneous tissue alone. Reflect the skin flap downward. Do not injure the temporal fascia. An additional flap may then be made of the aponeurotic layer. *Step* 2. Split the temporal fascia in the direction of its fibers where these run downward and forward. (If the fascia is split where its fibers run vertically less room is obtained.) Carefully retract the edges of the wound in the fascia. *Step* 3. Split the temporal muscle between the bundles of its fibers, taking care not to cut any muscular fibers transversely. Divide the periosteum corresponding to the wound in the muscle. Separate the periosteum from the bone in front of and behind the wound. Retract the edges of the wound so as to expose the bone as thoroughly as possible. *Step* 4. Penetrate the skull, preferably with a Doyen burr. With rongeur forceps remove as much of the skull as possible from under the elevated soft parts. Before attacking any portion of the bone be sure to separate the underlying dura from it. Bleeding from the bone may be controlled by Horsley's wax. An opening 2 1/2 to 3 inches in diameter is easily made and is usually sufficient. *Step* 5. Open the dura and incise it radially to the margin of the defect in the bone. The anterior incisions should be made parallel to the posterior branch of the meningeal artery which may need ligation. *Step* 6. Close the muscle wound with a few fine interrupted sutures. Carefully close the wound in the temporal fascia with fine sutures each of which takes as small a bite of tissue as is possible. Accurate approximation is most important. Close the aponeurotic layer and finally the skin wound.

Cushing makes use also of the above method for explorations of the temporal lobe for abscess, etc., for cases of meningeal (extradural) hemorrhage, for drainage in cases of fracture of the base of the skull. Under such circumstances both sides of the skull may be opened and the removal of bone need not be so extensive.

Occipital Craniectomy.—(Decompressive operation over the cerebellum.) It is doubtful whether this method has any advantage over the subtemporal method as a decompressive measure in cerebellar tumors. The difficulties and dangers of the operation are considerable. Hemorrhage from the bone and dura, and especially from the veins leading into the midoccipital sinus may be hard to overcome. *Step* 1. Make a curved incision a little above the superior curved line of the occiput. Make a longitudinal median incision running downward from the middle of the curved incision. The two triangular flaps of skin thus outlined are reflected downward and outward until the upper portion or origin of the flap superficial cervical muscles is exposed. Divide the muscles parallel to and about 3/4 inch from their line of origin. Make a median vertical incision between the muscles down to the spines of the upper cervical vertebræ and divide the ligamentum nuchæ in the middle line. Retract the soft parts. Expose the base of the occiput by separating the periosteum from it and with the periosteum separate the attachments of the deep muscles. *Step.* 2. Open the skull on each side through the prominent thin bosses of the occiput. Enlarge the openings with rongeur forceps. The ridge of bone in the middle line must be attacked with great care because of the occasional midoccipital sinus and emissary veins. Cushing finds it helpful "to crowd wisps of sterile cotton ahead of the dural separator when freeing the membranes from this midridge, a procedure which necessarily ruptures and blocks these emissary vessels in case they are present." *Step* 3. When the bone defect is large enough, ligate the median occipital sinus and excise the dura corresponding to the opening in the bone. *Step* 4. Close the wound preferably without drainage. On account of oozing of blood a drain of folded rubber tissue or of oil silk may be employed but it should be withdrawn within forty-eight hours.

CRANIOCEREBRAL TOPOGRAPHY.—See Brain (Injuries).

CRANIOTABES.—An atrophy of the cranial bones occurring in infancy, with the formation of small, shallow, conic pits in the bone-substance. These pits are granular within, and present a worm-eaten appearance around the margin. They are most usually found in the posterior inferior region of the parietal bone, but may be seen in any of the other cranial bones. They form from within outward, so that they are not often found in living subjects. Craniotabes is probably a result of Rickets, Syphilis, or Marasmus (*q. v.*). The craniotabetic pits are in some way associated with the rapid growth and development of the brain; they may be due to a premature formation of the markings of the convolutions on the skull. They are only encountered during the first months of life—that is, up to the sixteenth month. This disease is not a serious one as regards danger to life. See also Skull (Diseases).

CRANIOTOMY.—See Embryotomy.

CRANIUM.—See Skull.

CRAW-CRAW.—See Filariasis.

CREOLIN.—A dark brown liquid obtained from the distillation of coal-tar, of alkaline reaction, and forming a milk-like mixture with water. It mixes with alcohol, ether, and chloroform. The dose is 1 to 3 minims in capsule. It is a powerful antiseptic and disinfectant, superior to phenol. It is also hemostatic, and is chiefly used in obstetric and gynecologic practice. Its solution is opaque and somewhat unstable, but it is unirritating and free from astringency.

Creolin was highly vaunted by von Esmarch and other authorities as the ideal antiseptic for external use, being possessed of great germicidal power, and a most efficient deodorant and disinfectant,

while its absorption caused no toxic results whatever. Experience has justified these claims in the main, but the drug has given rise to serious symptoms when used to excess. As a vaginal wash, in puerperal cases, the 2 percent solution is reported as fully equal to sublimate solutions, while better as a deodorant, and free from danger by absorption. The weaker solutions have given satisfaction as local applications in the treatment of otorrhea, nasal ulcers, rhinitis (1 : 1000), blepharitis, keratitis, etc.; and in female cystitis a 1 percten solution as a vesical wash, gradually increased to 2 percent, is highly praised by Parvin. The ointments and gauze are used for wounds and other solutions of continuity, in the same manner as carbolized preparations, and with better satisfaction, creolin being less volatile than phenol, and of a more agreeable, though powerful, odor. Internally, it has been employed in gastric fermentation, dysentery, and typhoid fever.

CREOSOTE.—A mixture of phenols, chiefly *guaiacol* and *creosol*, obtained during the distillation of wood-tar, preferably of that derived from the beech. It occurs as an almost colorless, or pinkish, inflammable, oily liquid, of smoky odor, caustic taste, and neutral reaction; soluble in about 150 parts of water, and in all proportions in absolute alcohol, ether, chloroform, benzin, carbon disulphid, acetic acid, and fixed and volatile oils. Much of the commercial creosote is an impure carbolic acid, or a heavy oil distilled from coal-tar, and containing carbolic and cresylic acids. Dose, 1 to 5 minims, well diluted in wine or whisky. Morson's beechwood creosote is the best for internal use. There is only one official preparation, viz.: **Aqua Creosoti** (*creosote water*). This is a 1 percent solution, containing nearly 5 minims of creosote in each fluidounce. Dose, 1 dram to 1 ounce. Creosote carbonate (creosotal) is said to be nonirritant and nontoxic. Dose, 5 to 20 grains (or more) in milk, wine, coffee, or cod-liver oil.

Therapeutics.—Creosote is expectorant, astringent, antiseptic, styptic, escharotic, anesthetic, and narcotic. Its action is practically the same as that of Carbolic Acid (*q. v.*). Creosote has been almost entirely supplanted by carbolic acid for external use, and by guaiacol for internal administration. In intestinal hemorrhage, in gonorrhea, and in gleet it has been used as an antiseptic and astringent. In eczema, pruritus, ulcers, and scaly skin-diseases, and in toothache from an exposed nerve, it is serviceable. In inhalation in chronic bronchitis and gangrene of the lung, in abnormal fermentative processes in the stomach and intestines, and in reflex nausea and vomiting, it is a good agent. In pulmonary tuberculosis, when well borne by the stomach and continued for a long time, it is most efficient.

In diarrhea:

℞. Morphin sulphate, gr. j
Creosote (beechwood), gtt. vj
Bismuth subnitrate, ʒ ss.

Make into 12 powders; give one every 2 or 3 hours.

As an inhalation in phthisis:

℞. Creosote,
Spirit of chloroform } each, ʒ ij.
Alcohol,

Ten to 20 drops in inhaler several times daily.

See Guaiacol.

CRESOL.—Trikresol. A mixture of the three isomeric cresols derived from coal-tar, freed from phenol, etc. It is said to be a more powerful antiseptic than phenol, and less irritant and toxic. A 1 percent solution may be used in surgical work instead of phenol.

CRETINISM.—An endemic disease characterized by goiter and a condition of physical, physiologic, and mental degeneracy and nondevelopment.

The typical cretin is stunted in growth; his skin is of a tawny yellow hue, thickened and wrinkled; the tongue is large and thick, and often hangs from the mouth; the face is large, the lower jaw drooping; the eyes often strabismic, the lids puffy; the belly pendulous; the lower limbs short and deformed and the gait waddling; the forehead is retreating, the top of the head flat, the occipital region ill developed; the nose is broad and flat. The cretin is often unable to speak, and his hearing is often defective. Few live over 30 years. Sexual functions are abnormal; masturbation is frequent, although the subjects of cretinism are often impotent.

The treatment of cretinism consists in early removal to a locality where the soil is dry and porous. Frequent baths should be given; the diet must be nutritous, and consist chiefly of animal food. Cod-liver oil, lactophosphates of iron and lime, and thyroid extract are indicated.

Sporadic cretinism is a name given to a congenital form of myxedema, characterized by absence of the thyroid gland, diminutiveness of size, thickness of neck, shortness of arms and legs, prominence of abdomen, large size of face, thickness of lips, large and protruding tongue, and imbecility or idiocy. It is popularly supposed that coitus during intoxication is a cause of this condition. See Myxedema.

CROTON OIL. Oleum Tiglii.—The fixed oil of the seed of *C. tiglium*, native of India. The oil is of a pale or brownish-yellow color, somewhat viscid and slightly fluorescent, of fatty odor, acrid taste and slightly acid reaction; soluble in 60 of alcohol, freely in ether, chloroform, or carbon disulphid. Its composition is very complex and has not been thoroughly made out, but it is known to contain the glycerids of several fatty acids, also a peculiar acid named *tiglinic acid*, which is isomeric with angelic acid. Dose, 1/3 to 2 minims in pill, emulsion or tincture. Externally it is a powerful irritant, producing pustular eruptions. It is useful as a counterirritant in various chronic inflammatory conditions: *e. g.*, ovaritis, bronchitis, rheumatism, glandular swellings, etc. Internally, it is a drastic, hydragog cathartic; its use is indicated when prompt evacuation of the bowels is required, as in apoplexy, impaction of the intestines, dropsy, lead constipation and paralysis. It is contraindicated when either debility, organic obstruction or an in-

flammatory condition of the stomach or bowels exists.

CROUP, MEMBRANOUS. **Synonyms.**—Pseudomembranous laryngitis; membranous laryngitis; laryngeal diphtheria.

Definition.—An acute laryngitis characterized by the formation on the mucous membrane of a pseudomembrane similar in nature to diphtheritic exudate elsewhere.

Etiology.—In the great majority of cases this affection is caused by the Klebs-Loeffler bacillus. When the disease is secondary to pseudomembrane formation on the nares, tonsils, or pharynx, as a complication of scarlet fever, measles, or influenza, it is usually caused by other microorganisms, as the streptococci.

Symptoms.—The onset is gradual, and at first only the symptoms of simple acute laryngitis, with hoarseness and cough, are noticed; the early constitutional symptoms are not severe. In the course of 24 hours the condition becomes rapidly worse, the voice is lost, dyspnea is constant and very marked, with all the accessory muscles of respiration brought into active use; the face is pale and anxious; the breathing is noisy and stridulous; the pulse is rapid and weak; the child is evidently suffering greatly, and tosses about in bed; cyanosis is present, and the skin is covered with a clammy sweat; the temperature, which at first was slightly raised, now increases, and may reach 104° to 106° F. In fatal cases the child usually passes into a stupor before death occurs.

The course is usually rapid in infants, death ensuing in from 36 to 48 hours after the first symptoms. Older children may suffer for a week or 10 days from the attack.

Diagnosis.—From simple catarrhal laryngitis or catarrhal croup it is differentiated by the more gradual onset, the history of infection with diphtheria, the presence of membrane in the throat higher up, and the presence on the mucous membrane of the larynx of the false membrane, as shown by the laryngoscope. In some cases pieces of the exudate are coughed up, making the diagnosis easier.

The Prognosis is grave; the mortality rate among infants is especially high.

Treatment.—The hygienic and general treatment is the same as for pharyngeal diphtheria; and in the beginning of the attack, when there may be difficulty in differentiating it from a catarrhal laryngitis, or when there may be doubt as to the nature of the infection, in order to be on the safe side the case should be isolated and a curative dose of diphtheria antitoxin administered without delay.

It is important to keep the air in the room moist with the steam-kettle, and early in the attack an emetic, as syrup of ipecacuanha in teaspoonful doses, or the yellow subsulphate of mercury in a dose of 2 to 5 grains, may relieve the symptoms.

Hot-water applications externally to the throat are beneficial; but local applications to the larynx should not be attempted. Calomel fumigation is very beneficial when dyspnea is severe. A tent is constructed over the bed, and inside of this is placed a wash-bowl or other vessel, across the top of which is laid a strip of tin, and under this is set an alcohol lamp; the calomel is placed over the spot where the flame strikes the tin. Ten or 15 grains is the customary quantity used, and the child is allowed to inhale the fumes for 15 minutes, after which the tent should be opened and the room well aired. This process should be repeated every 1 to 3 hours, according to the severity of the symptoms. Children are seldom salivated by these inhalations, but the attendant is in danger of infection if care is not used.

In a large majority of cases of laryngeal diphtheria INTUBATION (*q. v.*) is necessary, and has been the means of saving many lives.

Antitoxin Treatment.—In these cases antitoxin has been most useful, and it should be given early when there is a suspicion of the larynx becoming involved.

See DIPHTHERIA.

CROUP, SPASMODIC.—Spasmodic or false croup is an acute catarrhal inflammation of the larynx, causing a peculiar cough and symptoms of severe dyspnea. It occurs most commonly in children between 6 months and 3 years of age, and is rare after the fifth year. It may be caused by exposure to wet or cold, by indigestion, or by extension of inflammation from the nose or pharynx. The tendency in many cases seems to be hereditary. Boys are more frequently affected than girls, and one attack predisposes to others.

Symptoms.—For a few hours previous to the attack there are usually present the symptoms of a mild laryngitis or a common cold, with perhaps some hoarseness and an occasional cough. These symptoms grow slightly worse during the evening, and toward the middle of the night suddenly become more severe. The child sits up in bed and struggles for breath, the breathing is noisy and difficult, and all the accessory muscles of respiration are brought into play. There is present a constant loud, hoarse, and metallic cough, but the voice may be nearly or entirely lost. After a short time in mild cases, or in a few hours in severe attacks the symptoms gradually diminish, and the child falls asleep. During the next day the child may appear as well as usual, except for a slight cough and hoarseness, but during the night a repetition of the attack of croup is to be expected. An attack rarely occurs on the third night, but when it does, it is likely to be but a mild one. Some cases, however, go on for a week or longer, with daily remissions and nightly exacerbations.

In children subject to croup the attacks may recur every few weeks during changeable weather.

Diagnosis.—

CROUP.	DIPHTHERIA.
Premonitory hoarse, metallic cough, without illness.	Premonitory illness, marked by shivers, fever, and sore throat, without cough.
A child's disease.	Attacks adults as well.
Tenacious mucus covering the swollen membrane.	Distinguished by a false membrane.
A local disease.	A blood poison; great general depression.

The prognosis is favorable, although the symptoms are so severe at times as to greatly alarm the parents or attendants.

Treatment.—Exposure to damp and cold should be guarded against in a child subject to these attacks. The diet should be carefully regulated, woolen clothing worn next to the skin, and the hygienic condition improved if faulty. If nasopharyngeal catarrh is present, it should be treated; enlarged tonsils or adenoid growths should be removed. Syrup of hydriodic acid in half-teaspoonful doses, or 5-drop doses of the syrup of the iodid of iron, given 3 times a day and continued for several months, are very useful in removing the tendency to croup. For the attack give an emetic: 1/2 of a teaspoonful of syrup of ipecacuanha, repeated in 20 or 30 minutes, if necessary. If constipation or symptoms of indigestion exist, the colon should be washed out with warm water, and, following the attack, calomel should be administered in doses of 1/12 of a grain every 2 hours until the bowels are freely moved.

A hot foot-bath is useful to shorten the spasm, and steam should be generated under a tent over the patient. The tent may be constructed with sheets over the bed or crib.

One of the following recipes may be found useful in the treatment of croup:

℞.	Chloral hydrate,	gr. xx
	Potassium bromid,	gr. xxx
	Syrup of acacia,	ʒ ij.

Teaspoonful every 1 or 2 hours until quiet.

Or—

℞.	Tincture of belladonna,	gtt. iv
	Paregoric,	ʒ j
	Powdered alum,	gr. vj
	Syrup of acacia,	ʒ iv
	Water,	ʒ ss.

A teaspoonful every 2 or 3 hours to a child 6 months old.

CRYOSCOPY.—The estimation of the freezing-point of an organic fluid by means of which it is determined how many solid molecules it holds in solution. The freezing-point of the fluid examined is compared with that of distilled water. The greater the molecular concentration of a fluid the greater is the degree of cold required to freeze it. This method is applied to urine and blood and is considered useful in determining the functional capacity of the kidneys. When renal activity is normal the freezing-point of the blood varies but slightly, ranging from 0.55° and 0.57° C. below zero, the latter being equivalent to that of distilled water. The freezing-point of healthy urine is not so constant, varying from 0.9° to 2.3° C. below zero. When the freezing-point of the blood is 0.6° C. below zero and that of the urine 1° C. it is maintained that the functional capacity of the kidneys is such that operation is contraindicated. Taken in connection with other methods of ascertaining the functional capacity of the kidneys, cryoscopy is undoubtedly of value.

CUBEB.—The dried unripe but fully-grown fruit of *Piper Cubeba*, cultivated in Java. It contains a volatile oil, which is official, an acrid resin composed in part of cubebic acid, also a fatty oil, gum, and cubebin, which is an insoluble, neutral, odorless and tasteless body. The volatile oil may be separated into cubebene, a camphor, and cubeben, a liquid portion. The active principles are the volatile oil and cubebic acid, both of which are contained in the oleoresin. Dose of the powdered drug, 10 to 60 grains.

Cubeb is an aromatic stimulant, diuretic in small doses, and is particularly useful in affections of the bladder and urethra. It is employed in the acute stage of gonorrhea, in chronic cystitis, prostatorrhea, and chronic bronchitis with excellent results. The powder is a useful application in hayfever, chronic nasal catarrh, and follicular pharyngitis, blown upon the mucous membrane by an insufflator. It may also be smoked in cigarets with temporary relief in cases of acute nasal catarrh with "stuffed" nasal passages. In some subjects the continued use of cubeb produces nausea, hemorrhoids, hematuria, and severe headache. Troches are useful preparations in chronic irritability of the fauces, pharynx, and air-passages, and are much employed by singers and public speakers for their tonic effect on these parts, and for the relief or prevention of hoarseness.

Preparations.—C., Fluidextract. Dose, 5 to 30 minims. **C., Oleoresina.** Dose, 5 to 20 minims. **C., Ol.**, the volatile oil. Dose, 5 to 20 minims. **Trochisci, C.,**—each contains of the oleoresin 2 grams, oil of sassafras 1 c.c., extract of glycyrrhiza 25 grams, acacia 12 grams, and syrup of Tolu q. s. to form 100 troches. Dose, 1 to 3.

CUPPING.—A method of blood-derivation by means of the application of cupping-glasses to the surface of the body.

A cupping-glass is a small, bell-shaped glass, capable of holding 3 or 4 ounces, in which the air is rarefied either by heat or exhaustion, and the glass then applied to the skin, either with or without scarification.

Dry cupping is chiefly employed in inflammatory affections of the bronchi, lungs, or kidneys; also in sthenic cerebral congestion, applied to the nape of the neck, in hyperemia of the spinal cord, and especially in renal ischemia. It is performed as follows: The site selected is moistened with a warm sponge, the contained air of the cupping-glass is exhausted by the flame of a spirit-lamp, and the glass is then placed evenly on the part to be cupped. The soft tissues within the rim should swell and project into the glass-cavity. After about a minute the glass is removed by tilting, the scarifier is applied, and the blades sprung, making a number of small cuts, from which the blood flows. Two or 3 ounces may be obtained from one application.

In wet cupping the skin is cut in several places previous to the application of the cup.

Situations available for cupping are regions that are smooth and fleshy: the nape of the neck, the loins, and the buttocks. Parts to be avoided are bony prominences; irregular surfaces of all kinds, as over the intercostal spaces; regions over

sensitive organs, as the breasts and the immediate neighborhood of inflamed skin or cellular tissue. See Bleeding.

This treatment, formerly popular has fallen into disuse, being largely supplanted by boric acid fomentations subsequent to punctures or incisions. Bier, however, has recently advocated the use of vacuum suction cups for chronic inflammation. See Bier's Hyperemic Treatment, Inflammation, Joints.

CUPRUM.—See Copper.

CURETTAGE.—See Uterus (Inflammation).

CURRENT.—See Electricity.

CUSSO (Kousso, Brayera).—The female inflorescence of *Hagenia abyssinica*, an Abyssinian tree. It contains tannic acid, a volantile oil, and a crystalline principle named *Koussin* which by itself is apparently inert. Dose, 2 to 8 drams.

Cusso has little or no effect except the nausea, vomiting, colic and slight diarrhea produced by large doses. Its chief action is anthelmintic against both varieties of tapeworm, but it rarely expels the head of the parasite, and is very nauseous to the taste and difficult of retention by the stomach in the large doses necessary to efficiency. Two drams to 1 ounce of the flowers infused in 4 ounces of boiling water is the usual dose, which should be taken on an empty stomach and followed by a castor-oil or saline purge after 3 or 4 hours. An emulsion of a 6 percent infusion with castor-oil, yolk of egg, a few drops of ether and oil of anise with 10 to 20 drops of the oleoresin of aspidium, is more agreeable and efficient than the infusion alone.

CUTANEOUS REACTION IN TUBERCULOSIS.—See Tuberculin.

CUT-THROAT.—The great majority of wounds of this nature are transverse and their most frequent situation is between the thyroid cartilage and the hyoid bone. The blood-vessels frequently escape injury. A wound of the common carotid artery or of the internal jugular vein usually proves fatal in a few minutes from loss of blood or from the suffocation that follows its entrance into the air-passages.

The first steps are to stop hemorrhage and to provide for free ingress of air to the lungs. The finger may be introduced at once to compress any large vessels. The patient should be placed upon his back, and after cleaning out the clots from the orifice of the glottis, breathing may be naturally resumed; or, if not, artificial respiration may be resorted to. The head and neck should be extended to find the source of hemorrhage. All bleeding points should be secured and all ligatures cut short. Divided tissues must be replaced, so as not to interfere with respiration. The divided trachea should be accurately conjoined with sutures; a warm moist atmosphere and the same precautions as after tracheotomy are indicated. In some cases a tracheotomy tube should be inserted below the true vocal bands. If edema of the glottis threatens, laryngotomy or tracheotomy may be performed. If the esophagus is wounded, chromicized catgut should be employed to bring its edges together. Food should be given by an esophageal tube through the mouth or nose, and especial care is to be observed that it does not enter the trachea. One or two sutures may be put in the extremities of the external wound to lessen the gaping and to prevent inversion of the skin, but it is of great importance that the external wound should be open, so that any blood or food that may get into its deeper cavities may escape.

The patient's neck should be kept slightly flexed by means of pillows and sand-bags. Carbolic or aseptic gauze should be secured over the wound by a few loose turns of a bandage, and thus the air may be to some extent purified. Constant watching by an attendant is advisable. Later on the wound is likely to become very foul, and some antiseptic will be necessary to cleanse the parts and to prevent the passage of discharges into the lung. Abscesses must be opened and drainage established. Quinin is to be used to combat the tendency to septicemia. Fistulous openings may persist, but will require secondary operations. See Neck (Injuries).

CYANIDS.—Compounds of cyanogen with a metal or radical. They are chiefly active poisons.

Potassium cyanid is the most common. It is one of the most dangerous of chemic compounds. It is a white, opaque salt, of alkaline reaction, bitter-almond taste, and a peculiar odor; soluble in 2 parts of water. Dose, 1/20 to 1/2 grain. Locally, a solution of 1 to 5 grains to the ounce is as strong as should be employed. It is used to allay pruritus, and in solution as a wash to remove stains of silver nitrate. In doses of 1/6 to 1/4 grain it is a useful ingredient of cough mixtures when opium or its alkaloids are inadmissable.

In **poisoning** by potassium cyanid, ferrous sulphate should be given after evacuation of the stomach. The nitrate of cobalt is also an antidote. Ammonia intravenously, digitalis, strychnin, and alcohol may be employed, and artificial respiration, galvanism, and general friction may be necessary.

Pure **hydrocyanic or prussic acid** is never used in medicine. The acid, however, is official in a 2 percent aqueous solution—a colorless liquid of acid reaction, with an odor and a taste of bitter almonds. The dose is 1 to 3 minims of a recent preparation. It gives rise to vertigo when inhaled in minute amounts, and to death when the fumes are concentrated. It should be kept in dark, tightly stoppered bottles. It is one of the most rapidly lethal poisons known. It is absorbed with great rapidity, and is eliminated almost immediately afterward. The drug is used almost solely to allay irritation of the peripheral nerves, and is given internally for the cough of phthisis and chronic bronchitis, for gastralgia, for obstinate vomiting, and externally to subdue the itching of pruritus, eczema, or urticaria. For the cough it is best administered with morphin or codein.

The following may illustrate:

℞.	Codein sulphate,	gr. iij
	Dilute hydrocyanic acid,	♏ xx
	Syrup of tolu,	ʒ j.

Give a teaspoonful 3 or 4 times daily.

In **poisoning** the drug is an active paralyzant, and exerts a lethal influence over every part of the body; the nervous system, the heart, respiration, brain, and all parts die at once if much of it is taken; hence, the survival of a patient 20 or 30 minutes after taking a poisonous dose is indicative of recovery. The poisoning by nitrobenzol or essence of mirbane, which has a similar odor, but one more permanent, produces symptoms resembling those of prussic acid poisoning. If given in time, ferrous sulphate will produce inert Prussian blue with the lethal acid. The stomach should be evacuated and artificial respiration performed. Ammonia may be given by intravenous injection. Cobalt nitrate is said to be an efficient antidote.

As the result of physiologic experiments, Lang found that nontoxic doses of cyanids were eliminated in the urine as relatively harmless sulphocyanates, the albumin of the living body furnishing the source of the sulphur. He also found that when sodium thiosulphate (hyposulphite) was given as an antidote, the effects of from 1 1/2 to 5 times the lethal dose of hydrocyanic acid were counteracted. When poison and antidote were simultaneously injected subcutaneously, no results were obtained, as the sodium thiosulphate is more slowly absorbed than the hydrocyanic acid. Beyond this, the method or means of administering the substances appeared to exert no influence on the result.

The use of oxycobaltous salts, more recently advocated, appears to show that these salts are even more powerful in their effects than sodium thiosulphate. Hydrogen dioxid and potassium permanganate were found to be valueless. A 5 to 10 percent solution of sodium thiosulphate should be kept constantly in readiness with a Pravaz syringe, although the usually rapid effects of hydrocyanic acid appear to render such provision useless.

CYANOSIS.—A bluish discoloration of the skin from nonoxidation of the blood, caused by local or general circulatory disease. It may be due to admixture of arterial and venous blood, as when a deficiency exists between the auricles and ventricles of the heart. It is seen in various diseases of the lungs and heart, in suffocation, and locally when an important vein is obstructed or compressed. It is commonly associated with certain forms of congential malformation of the heart. See Asphyxia.

CYCLITIS. Definition.—Inflammation of the ciliary body; the iris usually and the choroid often are simultaneously involved.

Varieties.—The **serous,** which is comparatively benign, and develops like a serous iritis; the **plastic,** which is the worst form, and produces a total posterior synechia; and the **suppurative** which is distinguished from the others by the presence of a purulent exudate in the chambers of the eye.

Symptoms and Diagnosis.—This is always a serious, and often a dangerous, affection, and should be differentiated from a rheumatic or benign iritis. Pain, photophobia, lacrimation, and visual disturbance are signs common to all. The characteristic symptoms of cyclitis are some sensitiveness to pressure in the ciliary region; cloudiness in the anterior portion of the vitreous, and the noticeable changes in the intraocular tension, which is increased at first and diminished later. The aqueous is also turbid, and may contain pus in the suppurative variety.

Causes.—Generally some injury to the ciliary body or adjacent tissues. Foreign bodies in the eye are almost certain to destroy the eye by a plastic cyclitis. Cyclitis may be due to inflammation of the tissues in continuity with the ciliary body, or to sympathetic ophthalmia. Idiopathic cases are said to result from syphilis, tuberculosis, and uterine disease.

Treatment is virtually the same as that for iritis, although atropin must be used with caution, as it is often very poorly borne. Plastic and purulent cyclitis must be rigorously treated with mercurial inunctions. For the reduction of tension, the local use of cocain, diaphoretics, and paracentesis are indicated. In purulent cyclitis, especially after operations, antiseptic douches are indicated. On account of the uncertain prognosis, the possibility of relapses, disorganization of the vitreous, and sympathetic ophthalmia, the patient must be carefully watched, and expectant treatment continued after the symptoms have subsided.

See Iritis.

CYCLODIALYSIS.—See Glaucoma.

CYCLOPLEGICS.—Agents effecting paralysis of the ciliary muscle. See Mydriatics.

CYPRIPEDIUM (Lady's-slipper).—The roots of *C. pubescens* and *C. parviflorum*, American valerian, with properties due to a volatile oil and an acid. It is an antispasmodic and stimulant tonic, used instead of valerian, which it resembles. **C. Fluidextractum.** Dose, 10 to 30 minims.

CYSTICERCUS.—The scolex of the tape-worm. A hydatid. **C. Bovis,** a form of hydatid existing in the muscles of the ox (chiefly in the calf). Its progenitor is the Tænia mediocanellata of man. It produces the disease called *beef measles.* **C. Cellulosæ,** the hydatid found inhabiting the intermuscular connective tissue of the pig, producing the condition known as "measles." Its progenitor is the Tænia solium of man. **C. Cellulosæ Cutis,** a hydatid, or immature form of Tænia solium, which is sometimes parasitic in the subcutaneous tissues of the skin. **C. Ovis,** a hydatid of uncertain origin, found in sheep in the condition called *mutton measles.* **C. Pisiformis,** a hydatid found mainly in the abdominal cavity of the rabbit and of the hare, and, in its immature state, in the liver of these animals. Its progenitor is the Tænia serrata of the dog. **C. Tenuicollis,** a slender or long-necked hydatid found in the abdominal and pelvic cavity of the sheep, the pig, the ox, and the fowl. Its progenitor is the Tænia marginata of the dog. See Worms (Tape-).

CYSTITIS. Etiology.—The more usual causes of inflammation of the bladder are foreign bodies, such as stone, obstruction to the outflow of urine by enlarged prostate or stricture of the urethra, and pathogenic organisms variously introduced, but especially by unclean catheters. Of acknowledged bacterial origin is also gonorrheal

cystitis, which, succeeding an attack of gonorrheal urethritis, is due to the invasion of the bladder by simple extension by continuity. Among organisms capable of exciting inflammation are the streptococcus pyogenes, staphylococcus pyogenes aureus, diplococcus, bacterium coli commune, tubercle bacilli, and perhaps others. See COLON BACILLUS INFECTION. Virulent causes are the bacteria contained in decomposing urine retained in the bladder.

Cold was formerly recognized as a cause of cystitis, especially in women and children, but it may be subject to the same conditions as the causes just named. On the other hand, substances introduced into the blood, as cantharides and capsicum, are capable of producing cystitis. Even the ingestion of certain articles of food has been followed by cystitis. Traumatic causes may be classed among predisposing causes rather than exciting, furnishing the conditions favorable to the action of bacteria.

Symptoms.—While a division of cystitis into acute and chronic is justified by the suddenness and severity of symptoms in certain cases, as contrasted with their slow development in others, yet the conditions so constantly verge into one another that a separate consideration of the two forms is not necessary. The first symptom of cystitis is usually frequent desire to urinate. Such frequency is often attended by painful straining. In severe cases there is always tenderness over the region of the bladder above the pubes, and in some there is constant pain. In these, tenderness may also be elicited by pressure from within the rectum, while catheterization is especially painful. In calculous cystitis pain is excited or aggravated by motion, especially such as is communicated to one riding in a wagon over a rough road.

As a rule, there is not often fever with cystitis. Even when there is fever, the temperature does not exceed 100° to 102° F., though it may be higher. In certain acute diphtheric cases of great virulence there are chills, sweats, and high fever. In advanced stages there may be sepsis, due to absorption of retained putrid matters from the bladder.

The *urine* presents striking changes, from which alone the diagnosis may be made. It contains pus in varying quantities, but it is especially characteristic of the pus of cystitis that it is associated with mucus, imparting a glairy, stringy character to the urine, which increases the difficulty of its discharge from the bladder. The reaction of the urine when passed is commonly either alkaline or faintly acid, and if acid, it promptly becomes alkaline. The pus, under the circumstances, is loaded with amorphous phosphates of lime and glistening crystals of ammoniomagnesium phosphate. It is so viscid that it will not rise in the pipet, and must be cut with scissors to be manipulated for microscopic study. Blood is an almost constant constituent of the urine in calculous cystitis, and in the grave diphtheritic forms shreds of gangrenous bladder tissue may be discharged.

Diagnosis.—Ordinarily the diagnosis of cystitis is easy. Yet there sometimes occur mild forms that it is difficult to differentiate from mild degrees of interstitial nephritis, while it not very rarely happens that the two conditions are associated. In contracted kidney numerous leukocytes are sometimes present. The presence of hyaline casts, even when scanty, points to nephritis, while hypertrophy of the left ventricle and increased arterial tension settle the question. Still more emphatic is the diagnosis if there is retinitis albuminurica.

The question as to whether there is pyelitis, separate or associated with cystitis, is still more difficult. Even spasm of the bladder, commonly regarded as peculiar to cystitis, may be present in pyelitis. It is better to rely upon tenderness in the neighborhood of the kidney. Marked intermission in the purulent discharge, especially if associated with attacks of nephritic colic, which imply an obstruction of the ureter, point to pelvic involvement.

Calculous cystitis may be suspected when pain in the region of the bladder is excited by motion, as in riding over a rough road, or when there is pain at the end of the penis after micturition; and when there is blood in the urine, or when the stream of urine is suddenly interrupted. These symptoms should immediately suggest the use of the sound, negative results with which must not, however, be accepted without qualification, as the stone may be concealed in a diverticulum.

Treatment. Acute Cystitis.—Of this form the treatment is far more satisfactory—at least so far as the removal of the acute symptoms is concerned—than that of the chronic form. Rest in bed is a primary and essential condition. Leeches to the perineum should be more frequently applied than they are. A poultice to this region and over the lower abdominal region is always useful, while a brisk saline cathartic should never be omitted.

As the feverish state that always accompanies cystitis is more or less constantly associated with a scanty urine, concentrated and irritating to the inflamed mucous membrane, it is desirable at once to increase the secretion and thus dilute it. Copious libations of pure water, to which the citrate or acetate of potassium is added, in from 15- to 20-grain doses for an adult, should be allowed. The ordinary spirit of nitrous ether, in dram doses every 2 hours, is an admirable adjuvant, and may be combined with the official liquor potassii citratis, which contains about 20 grains of citrate of potassium to 1/2 of an ounce. Formerly, the mucilage of flaxseed or flaxseed tea was much used as a diluent menstruum for the diuretic alkalies indicated, but it is doubtful whether it is any more efficient than a like quantity of water. When there are much pain and straining, as is often the case, especially when cantharides are the cause of the inflammation, opium is indispensable, always in the shape of a suppository, 1/2 of a grain to 1 grain of the extract, or a corresponding amount of morphin. Ice-water injections into the rectum, or pieces of ice similarly applied, are very efficient in allaying the pain and irritation when additional measures are needed. Injections of cocain into the bladder are useful in subduing the intense irritation.

Not more than 2 grains of cocain should be introduced into the bladder at one time (Tyson).

Chronic Cystitis.—The successful treatment of chronic cystitis is a much more difficult task, for 3 evident reasons: (1) The constant presence in the bladder of the urine with its irritating qualities, especially to an inflamed mucous membrane; (2) the difficulty in getting remedies to reach the inflamed surface; and (3) the pent up inflammatory products, which in their decomposition often make the urine still more irritating by exciting in it ammoniacal changes.

First, the irritating qualities of the urine may be diminished by the use of diluents, already recommended in the treatment of acute cystitis. Almost any of the negative mineral waters, so highly recommended by their owners, are useful for this purpose. Just as good is pure spring water, and even better is distilled water. From 1 to 2 quarts should be taken daily. If the kidneys are healthy, a large quantity of light-hued urine, of low specific gravity, and relatively weak in solids, will be secreted.

The indication is to render the urine acid, if possible, although the means to this end are unsatisfactory. Benzoic acid has the reputation of doing this, and it probably is true of it when administered in sufficient doses. It may be given in the shape of a 5-grain capsule, of which at least 6 must be given in a day to produce any effect. The same property has been assigned to citric acid, but this is a mistake, as all of the vegetable acids, when ingested, are eliminated as alkaline carbonates.

The second indication is to medicate the inflamed surface. Two ways suggest themselves—(1) by the internal administration of drugs, and (2) by the injection of medicated liquids into the bladder.

To carry out the first method an enormous number of infusions, decoctions, and fluidextracts of vegetable substances has been suggested, the vast majority of which are absolutely useless, except as they serve by the quantity administered to act as diluents. Among the best known of these are buchu, pareira brava, uva ursi, and triticum repens.

The only class of remedies Tyson has found of service in cystitis, through their internal administration, are the balsams. Of these, the balsam copaiba is practically unavailable, for it is rarely well borne in sufficient doses or for long enough time to permit it to be of any use. Sandalwood is easier borne, and is also an efficient remedy. It is best administered in capsules containing 10 minims. Contrary to the usual custom of giving these and like remedies after meals, Tyson has given them on an empty stomach before meals. They are as well, and even better, borne than when given after food, and they pass into the blood much more quickly. It is desirable to impregnate the blood and to impart to the urine a balsamic odor. This is scarcely possible with less than 8 capsules a day—2 before each meal and 2 at bedtime. Both boric acid and benzoic acid are useful adjuvants to the treatment of chronic cystitis, through their antiseptic effect on the urine, each in 5-grain doses, rapidly increased to 10 grains. Resorcin in 5- to 10-grain doses and naphthalin in 2-grain doses are recommended for the same purpose. Salol has become a popular remedy, very large doses being advised—15 to 30 grains every 3 hours; but in Tyson's experience these doses are not well borne, 10 grains being a maximum dose.

The application of remedies to the bladder by injections is best considered in connection with the third indication—the riddance of inflammatory products, the pus and mucus, and the matters resulting from their decomposition. The latter are not always present, but all who have had much experience with cystitis are familiar with the tenacious, glairy, mucoid matter that will not drop or rise up in a pipet, glistening with large crystals of triple phosphate, and exhaling a stinking, ammoniacal odor that quickly contaminates an entire apartment. There is only one way to get rid of this, and that is to wash out the bladder, and often this is too long deferred. Tepid water should be first used, and the injection made through the soft, flexible catheter. Four ounces may be used with entire safety; and after the capacity of the bladder has been determined, even more may be thrown in, because it is sometimes useful to distend the viscus slightly in order to reach the depressions and inequalities always present in advanced bladder inflammations. These simple injections, practised once a day, or in severe cases twice a day, often result most happily. After a few injections with plain water some medication may be added. Salicylate of sodium, in the proportion of a dram to the pint, is one of the best. Its disinfecting qualities are undoubted. Boric acid, in the proportion of a dram to the pint, is also very satisfactory. Sir Henry Thompson's soothing solution—of biborate of sodium 1 ounce, glycerin 2 ounces, water 2 ounces, and of this mixture 1/2 of an ounce to 4 ounces of tepid water—may also be used. Nitrate of silver of the strength of 1/4 of a grain to the ounce, increased to 1/2 of a grain, is often very efficient in diminishing pus. The bladder, if previously washed out by boric acid solutions, should be irrigated with plain warm, sterilized water, in order to avoid chemic reaction between the nitrate of silver and the boric acid.

When there is a foul odor present, the bichlorid of mercury may be used in exceedingly dilute solution—not more than 1 :25,000 at first, gradually increasing the strength if it is well borne. Carbolic acid may also be used in weak solution, 1/4 to 1/2 percent; also peroxid of hydrogen, 1 part to 4 or 5 parts of water.

Anodynes are indispensable in many cases of cystitis, to relieve the patient of extreme pain and of the frequent desire to urinate, which are the result of the same cause. Opium and its alkaloids are the most efficient, and they are best introduced by the rectum. There appears to be no absorbing power in the bladder for opium, and an attempt to administer anodynes by that channel will be useless. Cocain, from which so much might reasonably be expected, has been disappointing.

When there is greatly enlarged prostate, catheterization is indispensable, and is often attended with the most happy results. It is often too long deferred because of the natural repugnance to the use of the instrument. The patient or his friends should be taught to use the catheter and to wash out the bladder. The extremest precautions should be taken to cleanse the catheter after its use, in order to avoid sepsis. See CATHETER, PROSTATE. An absolute and total cure in chronic cystitis is a rare event; on the other hand, a life of suffering may be converted into one of comparative comfort (Tyson).

CYSTITIS IN WOMEN.—It may occur either as an acute or chronic condition; the latter variety is a very common disease in women.

Causes.—The principal cause of cystitis in women is infection at catheterization. See COLON BACILLUS INFECTION. It may be caused by urethritis, traumatism, constitutional diseases, displacements of the uterus, and the ingestion of certain drugs.

Symptoms.—In the acute stage there are pain, tenesmus, and frequent urination. These symptoms are all increased by exertion of any kind. There may be elevation of temperature. As the acute condition subsides, the symptoms become less marked. In the chronic stage there may be dull pain or a feeling of fulness in the pelvis, and some increased frequency of urination. Pressure upon the base of the bladder causes pain. Examination of the urine will show pus, blood at times, epithelial cells, and débris. In doubtful cases direct inspection of the bladder should be practised by means of the endoscope.

Treatment.—Mild cases of cystitis will usually yield to constitutional treatment. The patient should be placed in bed and the bowels and diet carefully regulated. An exclusive milk diet will be found advantageous. Rochelle salts should be given to the point of mild purgation. If the urine is acid, it should be neutralized by the administration of 1 to 2 drams of citrate of potassium daily; if alkaline, boric acid, in 10-grain doses, should be given 4 times daily. Large quantities of water should be taken in order to dilute the urine and thus render it less irritating. If the symptoms are very acute, suppositories of opium may be given.

As the acute symptoms subside, cubebs, copaiba, oil of sandalwood, or eucalyptus may be administered. These drugs have a stimulating effect upon the mucous membrane of the bladder.

If the foregoing plan of treatment fails, it should be supplemented by local treatment, which consists in irrigation of the bladder, applications to the mucous membrane, and finally cystotomy.

Irrigation of the bladder is a most effective treatment in chronic cystitis. A small two-way catheter should be introduced, and the bladder washed until the fluid returns perfectly clear. Sterile normal salt solution, at a temperature of 100° F., should be used for this purpose. This may be followed by the injection into the bladder of a weak solution of nitrate of silver—1 grain to 1 fluidounce. Not more than an ounce of this solution should be used. Daily irrigations should first be tried, the interval being lengthened, as the case improves, to 5 or 6 days.

Applications directly to the mucous membrane are of value when the disease is limited to localized areas. These applications are made through the endoscope. They should be made every 3 or 4 days, the best solution being nitrate of silver—10 grains to 1 fluidounce.

When extensive ulceration has occurred, and when the disease has resisted other treatment, cystotomy will be necessary. This consists in making an incision into the bladder through the anterior vaginal wall. To prevent closure of the incision, the mucous membrane of the bladder is stitched to the mucous membrane of the vagina around the edges of the fistula. The bladder should be irrigated daily, free drainage being secured through the incision. After the disease has subsided. the fistula may be closed.

CYSTOCELE.—Protrusion of the anterior wall of the vagina, accompanied by prolapse of the base of the bladder. The condition is caused by injury to the perineum during childbirth, which destroys the support of the anterior vaginal wall. A cystocele may vary in size from that of a walnut to that of a small orange; it is pale in color and easily reduced; it becomes more prominent as the patient coughs or strains, and it is associated with relaxation of the perineum. The displacement of the bladder causes the retention of a small amount of urine, which may decompose and cause a mild form of chronic cystitis. Frequent urination and vesical tenesmus are therefore usual accompaniments of this condition.

Treatment.—In moderate degrees of cystocele repair of the perineum will effect a cure. Perineorrhaphy restores the support to the anterior vaginal wall, and the relaxed tissues will gradually contract. In well-marked cases, however, an operation that removes redundant tissue from the anterior vaginal wall should supplement the perineal operation. Numerous operations have been devised for this purpose. The ordinary procedure is known as *anterior colporrhaphy.* An incision is made through the anterior vaginal wall into the connective tissue between it and the bladder wall. The relaxed tissue is removed and the wound closed with sutures of chromic catgut inserted in a vertical line. When the vaginal walls are markedly relaxed, the excision may be circular and the edges brought in apposition by means of Stolz's purse-string suture; or Martin's method may be used. In the latter procedure an oval denudation is made in the anterior vaginal wall extending from the position of the internal urinary meatus to just below the cervix. The broad end of the oval is toward the cervix, and the width of the denudation, at its widest part, varies from 2 to 3 inches. The wound is brought together by 3 tiers of running catgut stitches: the first tier bringing together the central part of the wound, the second the outer part, and the third the mucous membrane.

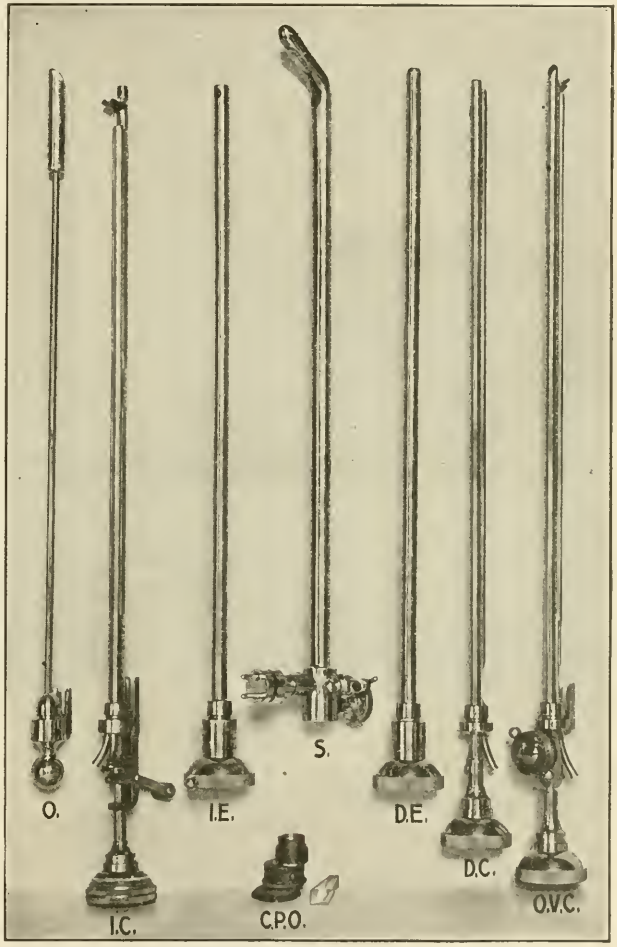
CYSTOSCOPE.—An instrument for examining the interior of the bladder. It consists of a hollow

shaft, of as large a caliber as the urethra will take, with a short beak set on the end at an angle.

Leiter's Cystoscope.

At the end of the beak is a miniature incandescent electric lamp; in one form of the instrument this is unprotected, in another it is covered in by a cap of metal with a rock-crystal window. At the junction of the beak and the shaft is a second window, closed by a prism, so that the rays of light entering it are reflected down the tube toward the eye of the observer. In the tube are lenses for the purpose of magnifying the image. For the anterior surface of the bladder (when the beak is turned up) the two windows are on the concavity; for the trigone and base, on the convexity of the curve. The current is turned on and off as required by means of a small key in the circular handle. Burned in air, the cap of the instrument becomes exceedingly hot, in water (and urine) it remains perfectly cool, and so long as it is prevented from touching the mucous membrane it causes no inconvenience. For this reason the bladder is partly filled with clear water, and the current is not turned on until the instrument is in position. For women a larger tube may be employed.

In addition to the simple examining cystoscopes various instruments have been devised for the purpose of catheterizing the ureters and performing endovesical operations. An instrument for catheterizing the ureters must be applicable to both sexes and so constructed as to permit the introduction of both catheters at a single sitting. The catheters, too, must be pliable and remain in the ureters when the metal instrument is withdrawn. These requirements are met in the instruments of Albarran, Casper, and Bierhoff. Chief among the operative cystoscopes may be mentioned the instruments of Nitze, Casper, and Bransford Lewis. In addition to intravesical operative work the last named instrument permits intraureteral manipulations for the removal of calculi and the dilatation of strictures, as well as irrigation of the pelvis of the kidney. The composite and universal cystoscopes are very ingeniously constructed instruments combining direct and indirect view, retrograde view, ureteral catheterization and operative manipulations. The principal instruments of this kind are the F. Tilden Brown composite cystoscope and the Bransford Lewis universal cystoscope. See Endoscope.



F. Tilden Brown's Composite Cystoscope. 1908 Model.

S., Common sheath for various telescopes; O., obturator; I.C., indirect vision (double catheter) telescope; I.E., indirect vision examining telescope; D.E., direct vision examining telescope; D.C., direct vision (double catheterizing) telescope; O.V.C., oblique vision (double catheterizing) telescope; C.P.N., correcting or compensating prism ocular, interchangeable with the ocular on I.C., and I.E.

CYSTOTOMY.—See Bladder (Stone).

CYSTS.—A cyst consists of a connective-tissue membrane or supporting wall lined by epithelium or endothelium, and forming a cavity the contents of which may be fluid or semifluid, uniform in composition, or made up of a mixture of similar or dissimilar substances.

When the wall of the cyst is passive and influenced by the retained or extravasated contents in a mechanical way only, the cyst is said to be *simple* or *unilocular*. When several similar cysts occur together, all arising from the same cause, and identical in structure, they are called *multiple cysts*. When one cyst springs from the wall of another and thus gives rise to a second or a third cyst, the process resembling proliferation, the resulting cysts are known as *proliferous cysts;* the cyst walls may be destroyed by pressure (reciprocal), and thereby many of the cyst cavities communicate. When the cysts remain distinct, they are spoken of as *multilocular*. When the cysts communicate, they are sometimes said to be *cavernous*. When the lining membrane of the cyst develops papillomatous masses, the process is called *papilliferous*.

For **classification of cysts**, see under *Tumors*.

Dermoid cysts are always of congenital origin, and arise as the result of cutaneous inclusion, or in consequence of the inclusion of a blighted ovum. The wall may contain all the elements of the cutis, may be thick or thin, and not uncommonly shows a slight growth of hair; the cells lining the interior of the sac are, of course, epithelial. The contents are usually sebaceous matter and a varying amount of hair; occasionally, teeth are found. When situated in the ovary, testicle, brain, eye, throat, or abdominal cavity, developing bone or cartilage may be contained within the cyst cavity; these distinctly connective-tissue products indicate the possibility of such cysts arising from fetal inclusion. Occasionally, dermoid cysts contain fat the melting-point of which is below the normal temperature of the body. Dermoids containing distinct connective-tissue bodies, such as cartilage and bone, are termed *compound dermoids*, thereby distinguishing them from dermoids containing no connective-tissue elements; the latter are called *simple dermoids*. The most common sites are near the orbit, the root of the nose, the angle of the jaw, the floor of the mouth, around the sheath of the carotid vessels, near the anus, and the sacrococcygeal and ovarian regions (Coplin).

CYTOLOGY.—The study of the cellular contents of exudates and transudates, more especially of the nonpurulent form. By such investigation, known as cytodiagnosis, differential diagnosis is made.

Technic.—The fluid is shaken up in a large sterile flask with small sterile glass beads in order to obtain a clot if there were none at first, or if a clot be present in order to disintegrate the clot and set free the cells. The fluid is then separated and centrifuged 10 minutes. The supernatant fluid is then poured off by means of a long pipet or by quickly inverting the tube. After the residue is shaken thoroughly, a smear is made of a drop and stained with Wright's stain and examined under the immersion lens. Webster prefers the eosin-hematoxylin method along with the Wright in order to differentiate clearly the nuclear structures. When it is desired to study the bacteria also, it is well to treat the slide first with eosin-hematoxylin then after washing it, with Gram's stain, or to make 2 slides, staining one with methylene-blue and the other with Gram's stain.

Lymphocytosis and endotheliosis are indicative of tuberculous or typhoid pleurisy, the endothelial cells, however, being arranged in large groups in typhoid. In malignant pleurisy tumor cells may be recognized in the specimen. Tuberculous peritonitis may be diagnosed from ovarian cyst and ascites by lymphocytosis and polynucleosis, few cells being found in ascites and ovarian cyst except endothelial cells, these being large and vacuolated in the latter condition. In tuberculous meningitis there is lymphocytosis in contradistinction to the polynucleosis of the epidemic type due to the meningococcus and the type due to the pneumococcus.

D

DACRYOCYSTITIS.—See LACRIMAL DISEASE.

DAKIN'S SOLUTION.—See WOUNDS.

DANDELION.—See TARAXACUM.

DANDRUFF.—See SEBORRHEA.

DATURA.—See STRAMONIUM.

DEAFNESS, CAUSES.—Deafness is mostly due to extension of inflammation of the nasopharynx into the middle ear. It is not infrequently the result of adenoids, hypertrophied tonsils, or nasal stenosis from any cause. Polypi and growths or swellings in the auditory canal are also causes. Sudden deafness is generally due to impacted cerumen, hysteria or syphilis of the internal ear. Nervous deafness, *i. e.*, the result of lesions in some part of the nerve, its nucleus or cortical center, is infrequent.

DEAFNESS, TESTS.—See EAR (Examination).

DEAF MUTISM.—Inability to hear and speak is a congenital condition, or acquired before the power of speech.

DEATH, CAUSES (International List of).—The Bureau of the Census of the Department of Commerce and Labor has issued the following list. Its use will tend toward scientific accuracy as well as increased value of vital statistics.

In naming the disease causing death it is urgently recommended that the exact names printed in bold-faced type in the List below be employed, whenever they are applicable, and that no other terms be used instead. Thus, *always* write **Typhoid fever**; not sometimes *Typhoid fever*, sometimes *Enteric fever*, or *"Continued fever," "Typho-malarial fever,"* etc. Of course many diseases are not given in the terms in bold-faced type below, but only the most important ones. *Terms printed in italics are indefinite or otherwise undesirable, and should never be used when a more definite statement can be given. "Heart failure,"* for example, is simply equivalent to cause of death unknown. *"Convulsions," "Marasmus," "Debility," "Old age,"* are terms of this character.

(I.—GENERAL DISEASES)

1. **Typhoid fever.**
2. **Typhus fever.**
3. **Relapsing fever.** [Insert "(spirillum)."]
4. **Malaria.**
5. **Small-pox.**
6. **Measles.**
7. **Scarlet fever.**
8. **Whooping-cough.**
9. **Diphtheria** and *croup.*
10. **Influenza.**
11. **Miliary fever.** [True Febris miliaris only.]
12. **Asiatic cholera.**
13. *Cholera nostras.*
14. **Dysentery.**
15. **Plague.**
16. **Yellow fever.**
17. **Leprosy.**
18. **Erysipelas.** [State also cause; see Class XIII.]
19. Other epidemic diseases:
    Mumps,
    German measles,
    Chicken-pox,
    Rocky Mountain spotted (tick) fever,
    Glandular fever, etc.
20. **Purulent infection and septicemia.** [State also cause; see Classes VII and XIII especially.]
21. **Glanders.**
22. **Anthrax.**
23. **Rabies.**
24. **Tetanus.** [State also cause; see Class XIII.]
25. **Mycoses.** [Specify, as **Actinomycosis of lung,** etc.]
26. **Pellagra.**
27. **Beriberi.**
28. **Tuberculosis of the lungs.**
29. **Acute miliary tuberculosis.**
30. **Tuberculous meningitis.**
31. **Abdominal tuberculosis.**
32. **Pott's disease.** [Preferably **Tuberculosis of spine.**]
33. *White swellings.* [Preferably **Tuberculosis of—joint.**]
34. **Tuberculosis of other organs.** [Specify organ.]
35. **Disseminated tuberculosis.** [Specify organs affected.]
36. **Rickets.**
37. **Syphilis.**
38. **Gonococcus infection.**
39. **Cancer**[1] of *the buccal cavity.* [State part.]
40. **Cancer**[1] **of the stomach, liver.**
41. **Cancer**[1] **of the peritoneum, intestines, rectum.**
42. **Cancer**[1] of *the female genital organs.* [State organ.]
43. **Cancer**[1] **of the breast.**
44. **Cancer**[1] of *the skin.* [State part.]
45. **Cancer**[1] of *other or unspecified organs.* [State organ.]
46. Other *tumors* (tumors of the female genital organs excepted.) [Name kind of *tumor* and organ affected. Malignant?]
47. **Acute articular rheumatism.**
48. **Chronic rheumatism** and **gout.** [Preferably **Arthritis deformans.**]
49. **Scurvy.**
50. **Diabetes.** [Diabetes mellitus.]
51. **Exophthalmic goiter.**
52. **Addison's disease.**
53. **Leukemia.**
54. **Anemia, chlorosis.** [State form or cause.]
55. Other general diseases:
    Diabetes insipidus,
    Purpura hæmorrhagica, etc.
56. **Alcoholism** (acute or chronic).
57. **Chronic lead poisoning.** [State cause. Occupational?]
58. Other chronic occupation poisonings:
    Phosphorus poisoning (match factory),
    Mercury poisoning (mirror factory), etc.
59. Other chronic poisonings:
    Chronic morphinism,
    Chronic cocainism, etc.

(II.—DISEASES OF THE NERVOUS SYSTEM AND OF THE ORGANS OF SPECIAL SENSE)

60. *Encephalitis.*
61. *Meningitis:*
    Cerebrospinal fever or **Epidemic cerebrospinal meningitis,**
    Simple meningitis, [State cause.]
62. **Locomotor ataxia.**
63. Other diseases of the spinal cord:
    Acute anterior poliomyelitis,
    Paralysis agitans,
    Chronic spinal muscular atrophy,
    Primary lateral sclerosis of spinal cord,
    Syringomyelia, etc.
64. **Cerebral hemorrhage, apoplexy.**
65. *Softening of the brain.* [State cause.]
66. *Paralysis without specified cause.* [State form or cause.]
67. **General paralysis of the insane.**

[1] "Cancer and other malignant tumors." Preferably reported as **Carcinoma of —, Sarcoma of —,** Epithelioma of —, etc., stating the exact nature of the neoplasm and the organ or part of the body first affected.

68. Other forms of mental alienation. [Name disease causing death. Form of insanity should be named as CONTRIBUTORY CAUSE only *unless* it is actually the disease causing death.]
69. Epilepsy.
70. *Convulsions (nonpuerperal).* [State cause.]
71. *Convulsions of infants.* [State cause.]
72. Chorea.
73. Neuralgia and neuritis. [State cause.]
74. Other diseases of the nervous system. [Name the disease.]
75. Diseases of the eyes and their annexa. [Name the disease.]
76. Diseases of the ears. [Name the disease.]

(III.—DISEASES OF THE CIRCULATORY SYSTEM)

77. Pericarditis. [Acute or chronic; rheumatic (47), etc.]
78. Acute endocarditis. [Cause?]
79. Organic diseases of the heart: [Name the disease.]
    Chronic valvular disease, [Name the disease.]
    Aortic insufficiency,
    Chronic endocarditis,
    Fatty degeneration of heart, etc.
80. Angina pectoris.
81. Diseases of the arteries, atheroma, aneurysm, etc.
82. Embolism and thrombosis. [State organ. Puerperal (139)?]
83. Diseases of the veins (varices, hemorrhoids, phlebitis, etc.)
84. Diseases of the lymphatic system (lymphangitis, etc.) [Cause? Puerperal?]
85. *Hemorrhage;* other diseases of the circulatory system. [Cause? *Pulmonary hemorrhage* from Tuberculosis of lungs (28)? Puerperal?]

(IV.—DISEASES OF THE RESPIRATORY SYSTEM)

86. Diseases of the nasal fossæ. [Name disease.]
87. Diseases of the larynx. [Name disease. Diphtheritic?]
88. Diseases of the thyroid body. [Name disease.]
89. Acute bronchitis. } [Always state as acute or chronic.]
90. Chronic bronchitis. }
91. Bronchopneumonia. [If secondary, give *primary* cause.]
92. *Pneumonia.* [If lobar, report as Lobar pneumonia.]
93. Pleurisy. [If tuberculous, so report (28).]
94. *Pulmonary congestion, pulmonary apoplexy.* [Cause?]
95. Gangrene of the lung.
96. Asthma. [Tuberculosis?]
97. Pulmonary emphysema.
98. Other diseases of the respiratory system (tuberculosis excepted). [Such indefinite returns as "*Lung trouble,*" "*Pulmonary hemorrhage,*" etc., vitiate statistics. Tuberculosis of lungs (28)? Name the disease.]

(V.—DISEASES OF THE DIGESTIVE SYSTEM)

99. Diseases of the mouth and annexa. [Name disease.]
100. Diseases of the pharynx. [Name disease. Diphtheritic?]
101. Diseases of the esophagus. [Name disease.]
102. Ulcer of the stomach.
103. Other diseases of the stomach (cancer excepted). [Name disease. Avoid such indefinite terms as "*Stomach trouble,*" "*Dyspepsia,*" "*Indigestion,*" "*Gastritis,*" etc., when used vaguely.]
104. Diarrhea and enteritis (under 2 years).
105. Diarrhea and enteritis (2 years and over).
106. Ankylostomiasis. [Better, for the United States, Hookworm disease or Uncinariasis.]
107. Intestinal parasites. [Name species.]
108. Appendicitis and typhilitis.
109. Hernia, intestinal obstruction. [State form and whether strangulated. Include only organic intestinal obstruction.]
110. Other diseases of the intestines. [Name disease.]
111. Acute yellow atrophy of the liver.
112. Hydatid tumor of the liver.
113. Cirrhosis of the liver.
114. Biliary calculi.
115. Other diseases of the liver. ["*Liver complaint*" is not a satisfactory return.]
116. Diseases of the spleen. [Name disease.]
117. *Simple* peritonitis (nonpuerperal). [Give cause.]
118. Other diseases of the digestive system (cancer and tuberculosis excepted). [Name disease.]

(VI.—NONVENEREAL DISEASES OF THE GENITOURINARY SYSTEM AND ANNEXA)

119. Acute nephritis. [State cause, especially if due to Scarlet fever, etc.]
120. Bright's disease. [Better, Chronic Bright's disease, Chronic interstitial nephritis, Chronic parenchymatous nephritis, etc. Never report mere names of symptoms, as "*Uremia,*" "*Uremic coma,*" etc.]
121. Chyluria.
122. Other diseases of the kidneys and annexa. [Name disease.]
123. Calculi of the urinary passages. [Name bladder, kidney.]
124. Diseases of the bladder. [Name disease.]
125. Diseases of the urethra, urinary abscess, etc. [Name disease. Gonorrheal (38)?]
126. Diseases of the prostate. [Name disease.]
127. Nonvenereal diseases of the male genital organs. [Name disease.]
128. Uterine hemorrhage (nonpuerperal.)
129. Uterine tumor (noncancerous). [State kind.]
130. Other diseases of the uterus. [Name disease.]
131. Cysts and other tumors of the ovary. [State kind.]
132. Salpingitis and other diseases of the female genital organs. [Name disease. Gonorrheal (38)?]
133. Nonpuerperal diseases of the breast (cancer excepted.) [Name disease.]

(VII.—THE PUERPERAL STATE)

NOTE.—The term puerperal is intended to include pregnancy, parturition, and lactation. Whenever parturition or miscarriage has occurred within one month before the death of the patient, the fact should be certified, even though childbirth may not have contributed to the fatal issue.

Abscess of the breast,	*Metroperitonitis,*
Albuminuria,	*Metrorrhagia,*
Cellulitis,	*Pelviperitonitis,*
Coma,	*Peritonitis,*
Convulsions,	*Phlegmasia alba dolens,*
Eclampsia,	*Phlebitis,*
Embolism,	*Pyemia,*
Gastritis,	*Septicemia,*
Hemorrhage (uterine or unqualified),	*Sudden death,*
	Tetanus,
Lymphangitis,	*Thrombosis.*
Metritis,	

Physicians are requested always to write Puerperal before the above terms and others that might be puerperal in character, or to add in parentheses (Not puerperal).

134. Accidents[1] of pregnancy: [Name the condition.]
    Abortion, [Term not used in invidious sense, Criminal abortion should be so specified (184).]
    Miscarriage,
    Ectopic gestation,
    Tubal pregnancy, etc.
135. Puerperal hemorrhage.
136. Other accidents[1] of labor: [Name the condition.]
    Cesarean section,
    Forceps application,
    Breech presentation,
    Symphyseotomy,
    Difficult labor,
    Rupture of uterus in labor, etc.
137. Puerperal septicemia.
138. Puerperal albuminuria and convulsions.
139. Puerperal phlegmasia alba dolens, embolus, sudden death.
140. Following childbirth (*not otherwise defined*). [Define.]
141. Puerperal diseases of the breast.

(VIII.—DISEASES OF THE SKIN AND CELLULAR TISSUE)

142. Gangrene. [State part affected, Diabetic (50), etc.]
143. Furuncle.
144. *Acute abscess.* [Name part affected, nature, or cause.]
145. Other diseases of the skin and annexa. [Name disease.]

(IX.—DISEASES OF THE BONES AND OF THE ORGANS OF LOCOMOTION)

146. Diseases of the bones (tuberculosis excepted): [Name disease.]
    Osteoperiostitis, [Give cause.]
    Osteomyelitis,

[1] In the sense of *conditions or operations dependent upon,* pregnancy or labor, not "accidents" from external causes.

Necrosis. [Give cause].
Mastoiditis, etc. [Following Otitis media (76)?]

147. Diseases of the joints (tuberculosis and rheumatism excepted). [Name disease; always specify **Acute articular rheumatism** (47), **Arthritis deformans** (48), **Tuberculosis of — joint** (33), etc., when cause is known.]
148. *Amputations.* [Name disease or injury requiring amputation.
149. Other diseases of the organs of locomotion. [Name disease.]

(X.—Malformation)

150. **Congenital malformations** (stillbirths not included:) [Do not include **Acquired hydrocephalus** (74) or **Tuberculous hydrocephalus (Tuberculous meningitis)** (30) under this head.]
Congenital hydrocephalus,
Congenital malformation of heart,
Spina bifida, etc.

(XI.—Diseases of Early Infancy)

151. *Congenital debility*, **icterus**, and **sclerema**: [Give cause of *debility*.]
Premature birth,
Atrophy. [Give cause.]
Marasmus. [Give cause.]
Inanition, etc. [Give cause.]
152. Other diseases peculiar to early infancy:
Umbilical hemorrhage,
Atelectasis,
Injury by forceps at birth, etc.
153. **Lack of care.**

(XII.—Old Age)

154. *Senility.* [Name the disease causing the death of the old person.]

(XIII.—Affections Produced by External Causes)

Note.—Say whether the death was due to **Accident Suicide**, or **Homicide**; and then state the **Means or instrument of death.** The qualification "*probably*" may be added when necessary.

155. **Suicide by poison.** (Name poison.]
156. **Suicide by asphyxia.** [Name means of death.]
157. **Suicide by hanging** or strangulation. [Name means of strangulation.]
158. **Suicide by drowning.**
159. **Suicide by firearms.**
160. **Suicide by cutting** or piercing instruments. [Name instrument.]
161. **Suicide by jumping from high places.** [Name place.]
162. **Suicide by crushing.** [Name means.]
163. **Other suicides.** [Name means.]
164. **Poisoning by food.** [Name kind of food.]
165. **Other acute poisonings.** [Name poison; specify **Accidental.**]
166. **Conflagration.** [State fully, as **Jumped from window of burning dwelling, Smothered—burning of theater, Forest fire**, etc.]
167. **Burns** (conflagration excepted). [Includes **Scalding.**]
168. Absorption of deleterious gases (conflagration excepted):
Asphyxia by illuminating gas (accidental),
Inhalation of — (accidental). [Name gas.]
Asphyxia **(accidental).** [Name gas.]
Suffocation **(accidental)**, etc. [Name gas.]
169. **Accidental drowning.**
170. **Traumatism by firearms.** [Specify **Accidental.**]
171. **Traumatism by cutting or piercing instruments.** [Name instrument. Specify **Accidental.**]
172. **Traumatism by fall.** [For example, **Accidental fall from window.**]
173. Traumatism in mines and quarries:
Fall of rock in coal mine,
Injury by blasting, slate quarry, etc.
174. Traumatism by machines. [Specify kind of machine, and if the Occupation is not fully given under that head, add sufficient to show the exact industrial character of the fatal injury. Thus, **Crushed by passenger elevator; Struck by piece of emery wheel (knife grinder); Elevator accident (pile driver)**, etc.]
175. Traumatism by other crushing:
Railway collision,
Struck by street car,
Automobile accident,
Run over by dray,
Crushed by earth in sewer excavation, etc.
176. Injuries by animals. [Name animal.]
177. **Starvation.** [Not "inanition" from disease.]
178. **Excessive cold.** [Freezing.]
179. **Excessive heat.** [Sunstroke.]
180. **Lightning.**
181. **Electricity** (lightning excepted). [How? Occupational?]
182. **Homicide by firearms.**
183. **Homicide by cutting or piercing instruments.** [Name instrument.]
184. **Homicide** by other means. [Name means.]
185. *Fractures* (*cause not specified*). [State means of injury.
186. Other external causes:
Legal hanging,
Legal electrocution,
Accident, *injury*, or *traumatism* (unqualified). [State Means of Injury.]

(XIV.—Ill Defined Diseases)

187. Ill defined organic diseases:
Dropsy. [Name the disease of the heart, liver, or kidneys in which the dropsy occurred.]
Ascites, etc.
188. *Sudden death.* [Give cause. Puerperal?]
189. Cause of death not specified or ill defined. [It may be extremely difficult or impossible to determine definitely the cause of death in some cases, even if a postmortem be granted. If the physician is absolutely unable to satisfy himself in this respect, it is better for him to write **Unknown** than merely to guess at the cause. It will be helpful if he can specify a little further, as **Unknown disease** (which excludes external causes), or **Unknown chronic disease** (which excludes the acute infective diseases), etc. Even the ill-defined causes included under this head are at least useful to a limited degree, and are preferable to no attempt at statement. Some of the old "chronics," which well-informed physicians are coming less and less to use, are the following: *Asphyxia; Asthenia; Bilious fever; Cachexia; Catarrhal fever; Collapse; Coma; Congestion; Cyanosis; Debility; Delirium; Dentition; Dyspnea; Exhaustion; Fever; Gastric fever; HEART FAILURE; Laparotomy; Marasmus; Paralysis of the heart; Surgical shock;* and *Teething.* In many cases so reported the physician could state the disease (not merely symptom or condition) causing death.]

DEATH, SIGNS.—It is not always easy to determine when life is extinct. The conditions of syncope, asphyxia, and trance most resemble death. It is safest not to rely exclusively on any one sign, but to combine several. The most reliable sign of death is proof of the cessation of the heart's action. Pulselessness is not conclusive. The use of the stethoscope requires technical skill. If a tight ligature is bound about a finger or toe, no change in its color will occur if circulation has ceased; but if there is a heart-beat, however feeble, a livid tint will, in a longer or shorter period, be observable. If it is absolutely established that there is cessation of the heart's action, other indications are unnecessary. Respiration may not be obvious, yet be going on. A cold mirror held before the mouth and nostrils may collect moisture from the breath, and a fleck of cotton-wool placed on the lips may indicate the existence of an air-current and of life. A cup of water placed on the chest will show any movement. The ashy color of the skin, the absence of the pink tint in transparent parts when examined under strong light, the diminished tension of the eyeball, the opacity of the cornea, the cessation of reaction

of the pupil to light, or the absence of vital reaction in the skin on the application of irritants are additional means by which death may be determined.

Subsequent changes in a dead body indicate not only the fact of death, but also the probable time when death occurred. These changes are (1) cooling of the body, (2) hypostasis, or gravitation of the blood to the most dependent parts, (3) rigor mortis, or cadaveric rigidity, and (4) putrefaction.

Dr. Richardson summarizes the more important tests of death as (1) absence of the pulsation of the heart, (2) absence of the respiratory murmur, (3) pressure on veins (*fillet test*), (4) electric test for muscular irritability, (5) the ammonia hypodermic test (*Monteverde's sign*), (6) coagulation of the blood in the veins, (7) rigor mortis, (8) decomposition.

The various tests are as follows: **Balfour's test:** A test for the action of the heart in apparent death. He proposed sticking into the skin over the heart needles having little paper flags fixed in their blunt ends. Should there be contraction of the heart-muscle, movement would be communicated to the paper flags. **Cloquet's needle-test:** A bright needle plunged into the body of the biceps muscle and left there for a time; then examined for signs of oxidation. If found, life is present. **Davis' (Leon) sign:** After death the arteries are pale or yellowish, and void of blood, while during life the vessels pulsate, and have the color of surrounding tissues. **Diaphanous test:** The scarlet-red color of the fingers' edges when held toward the light, due, if life exists, from the blood circulating through the tissues. The scarlet tint does not appear if life is extinct. The test is not to be relied on in all cases, as in syncope the red coloration may be absent. **Fillet test** (*Richardson's test*): A fillet applied to the veins of the arm will not cause filling of the veins on the distal side of the fillet if death is present. **Foubert's test** consists in cutting through one of the intercostal spaces and feeling the heart with the point of the finger. **Laborde's sign:** Same as Cloquet's Needle-test (*q. v.*). **Larcher's sign:** Soon after death the conjunctivæ exhibit externally gray, cloudy discolorations that rapidly become black. They are due either to the formation of films of mucus, or to cadaveric imbibition dependent on putrefactive changes. **Levasseur's sign:** The application of a scarficator and cupping-glass will fail to draw blood if life has been extinct for some hours. **Magnus' sign:** If a finger is tightly bound round with a ligature, the part beyond the constriction will, if the person is living, become bright red, the tint increasing in depth until it finally assumes a uniformly bluish-red color. At the spot, however, where the ligature is applied a narrow white ring becomes visible. No change results from the application of the ligature if life is extinct. **Monteverde's sign:** The injection subcutaneously during life of a little ammonia solution will be followed by a port-wine congestion in surrounding parts, which does not take place in case of death. **Ripault's sign:** During life the circular shape of the pupil is influenced by external pressure only during its actual application. After life, however, external pressure is capable of permanently affecting the normal roundness of the pupillary aperture.

DEATH, SUDDEN, CAUSES OF.—The main causes of sudden death are: Cerebral hemorrhage; rupture of a gastric ulcer; valvular disease of the heart, especially aortic; angina pectoris; rupture of an aortic aneurysm; suffocation during an epileptic fit; shocks of electricity; sunstroke; mental or physical shocks; diabetic coma; uremia; exertion on an overloaded stomach.

DEATH-RATE.—A term arbitrarily expressing the mortality of a place, based upon the number of deaths for each 1000 of population during a period of one year. To determine the death-rate, multiply the number of deaths by 1000 and divide the product by the population.

Death-rate in the Principal Cities.—From the report on Mortality Statistics of 1913, the following death rates for 1913 are taken. In the *United States:* Seattle, Wash., 8.4; Spokane, Wash., 8.9; Portland, Oreg., 9.5; St. Paul, Minn., 11.0; Minneapolis, Minn., 11.6; Oakland, Cal., 12.5; Milwaukee, Wis., 12.7; Grand Rapids, Mich., 13.3; Cambridge, Mass., 13.5; Paterson, N. J., 13.5; Denver, Colo., 13.7; Omaha, Nebr., 13.9; Cleveland, Ohio, 14.2; New York, N. Y., 14.3; Newark, N. J., 14.4; Jersey City, N. J., 14.6; Rochester, N. Y., 14.6; Scranton, Pa., 14.8; Kansas City, Mo., 14.8; Bridgeport, Conn., 14.9; St. Louis, Mo., 14.9; Los Angeles, Cal., 15.0; Chicago, Ill., 15.1; Providence, R. I., 15.2; Columbus, Ohio, 15.3; Philadelphia, Pa., 15.7; Syracuse, N. Y., 15.7; Indianapolis, Ind., 15.7; Worcester, Mass., 15.8; Buffalo, N.Y., 15.8; San Francisco, Cal., 15.9; New Haven, Conn., 15.9; Lowell, Mass., 15.9; Dayton, Ohio, 16.0; Toledo, Ohio, 16.2; Louisville, Ky., 16.2; Boston, Mass., 16.4; Cincinnati, Ohio, 16.9; Pittsburg, Pa., 17.1; Fall River, Mass., 17.2; Washington, D. C., 17.3; Detroit, Mich., 17.3; Atlanta, Ga., 17.4; Birmingham, Ala., 17.4; Nashville, Tenn., 17.8; Baltimore, Md., 18.5; Albany, N. Y., 19.8; New Orleans, La., 19.9; Richmond, Va., 20.4; Memphis, Tenn., 20.8. *Foreign Cities* (Death rate in 1912): The Hague, 10.9; Amsterdam, 11.2; Rotterdam, 11.3; Sydney, 11.4; Toronto, (1911), 12.6; Turin, 12.9; Dresden, 13.1; Christiania, 13.4; Brussels, 13.5; London, 13.6; Hamburg, 13.6; Melbourne, 14.0; Copenhagen, 14.1; Stockholm, 14.2; Berlin, 14.4; Munich, 14.7; Vienna, 15.4; Edinburgh, 15.7; Prague, 15.8; Milan, 15.8; Paris, 16.3; Glasgow, 17.6; Belfast, 18.1; Breslau, 18.4; Budapest, 18.5; Montreal, 20.0; Dublin, 20.5; Venice, 20.9; Trieste, 21.1; Rio de Janeiro, 21.3; St. Petersburg, 21.9; Moscow, 24.3; Bucharest (1911), 26.1.

DECAPITATION.—See Embryotomy.

DECIDUA, DISEASES.—The hypertrophied mucous membrane that lines the uterus during pregnancy. This hypertrophy is accomplished mainly by proliferation of connective-tissue cells (decidual cells) lying above the uterine glands.

Three different varieties of decidua are described: The decidua *serotina*, which forms the

maternal part of the placenta; the decidua *reflexa*, which grows about the ovum and completely envelops it; and the decidua *vera*, which lines the remaining part of the uterine cavity.

Apoplexy.—This not infrequently occurs during the early weeks of pregnancy, and is usually due to nephritis, excessive coitus, or traumatism. It is a very common cause of early abortions, particularly those occurring in newly married women.

Inflammation.—This is usually chronic in character, and comprises the various forms of *endometritis gravidarum:* the *hyperplastic*, the *polypoid*, the *catarrhal*, and the *cystic*. In the last two a thin mucous fluid is secreted, which accumulates between the membranes, and is finally expelled with a gush (*hydrorrhœa gravidarum*). Several such gushes of fluid, varying in quantity from a few drams to a pint or more, may occur throughout pregnancy. Abortion or miscarriage commonly results.

Acute inflammation of the decidua is very rare; it sometimes occurs as a complication of the exanthematous diseases.

Tumors.—The usual variety is the *deciduoma*, which may remain for a long time in the uterus, giving rise to hemorrhage, leukorrhea, and sometimes sepsis. It is due to hyperplasia of a retained portion of the decidua, and should be removed with the curet or placental forceps.

These growths occasionally become malignant in character (*deciduosarcoma*).

DECIDUOMA.—See Decidua (Diseases).

DECOCTIONS, Decocta.—Liquid preparations made by boiling vegetable substances with water. As very few drugs contain active ingredients which are not injured by heat, these preparations have never obtained favor with scientific physicians. The official general formula for decoctions prescribes that when the strength is not directed by the physician, nor specified by the Pharmacopeia, they shall be prepared in the proportion of 5 grams of the substance with 100 c.c. of water; but that the strength of decoctions of energetic or powerful substances should be specially prescribed by the physician.

DECOMPRESSION.—See Craniectomy, Trephining.
