To recapitulate, then, we must remember that increase in the tenacity (or breaking tension) and limit of elasticity do not necessarily imply greater working strength in a given bar of metal. We do, however, gain very much, as we all know, by subjecting metals to the operations of rolling, hammering, etc., for we obtain a higher limit of elasticity and tenacity in smaller bulk by making the mass more homogeneous. It will be seen that the tensile strength of a metal is by no means the same as the tenacity, which latter is often termed tensile strength, and which is measured here by the weight in tons that a bar of a square inch in sectional area will just support without breaking. The former is proportional to an area and the latter to a straight line in the figure above. In order to fracture steel of great tenacity, less work may in fact be done than is required to fracture a similar bar of soft wrought-iron. Again, the elasticity of the iron may equal that of the steel, but the limit of elasticity might be very different in the two cases. The elasticity is measured by the cotangent of the angle C A D, in the figure, while the elastic limit is represented by the tension measured by the line A J, and the work required to overcome it by the area H A J.

The metals used for the construction of ordnance are bronze, cast or wrought iron, steel, and numerous alloys of these metals. These are treated under specific headings. The fitness of metals for cannon depends chiefly upon their elasticity. It also depends, if the least possible weight is to be combined with the greatest possible preventive against explosive bursting, upon the ductility of the metal. Hardness to resist compression and wear is the other most important quality. Cast-iron has the least ultimate tenacity, elasticity, and ductility; but it is harder than bronze or wrought-iron, and it is homogeneous. The unequal cooling of solid castings leaves them under initial rupturing strains; but hollow casting and cooling from within remedies this defect and other minor defects. Wrought-iron has the advantage of a considerable amount of elasticity, a high degree of ductility, and a greater ultimate tenacity than cast-iron; but as large masses must be welded up from small pieces, the want of homogeneity becomes a serious defect. Another serious defect of wrought-iron is its softness and consequent yielding under pressure and friction.

Low cast-steel has the greatest ultimate tenacity and hardness; and, what is more important, it has the highest elasticity. It has the great advantage over wrought-iron of homogeneity in masses of any size. It is, unlike the other metals, capable of great variation in density, by the simple processes of tempering and annealing, and, therefore, of being adapted to the different degrees of elongation to which it is subjected in either solid or built-up guns.

Bronze has greater ultimate tenacity than cast-iron, but it has little more elasticity and less homogeneity; it has a high degree of ductility, but it is the softest of cannon-metals, and is injuriously affected by the heat of high charges. In view of the duty demanded of modern guns, it would seem that simple cast-iron is too weak, although it can be used to advantage in combination with other metals. Wrought-iron in large masses cannot be trusted, and is in all cases too soft. Bronze is impracticably soft, and destructible by heat. Low steel is, therefore, by reason of the associated qualities, which may be called strength and toughness, probably the only material from which we can hope to maintain resistance to the high pressure demanded in modern warfare. See *Bronze*, *Cast-iron*, *Iron*, *Ordnance*, *Wrought-iron*, and *Steel*.

CANNON-PERER.—An ancient piece of ordnance throwing stone shot.

CANNON-PRIMERS.—Both friction and electric cannon-primers have recently been remodeled and improved. Those made since 1882 differ from those formerly made in having the body, branch, and the serrated wire of the friction-primer made from cartridge copper instead of brass, and in having the end stopped with a tinfoil cup instead of a wax plug. To perfect and reduce the cost of their fabrication, improvements have been made in several details of the process. The platinum-wire "bridge" of the electric primer has been reduced in diameter and to one fourth of its former length. New machines

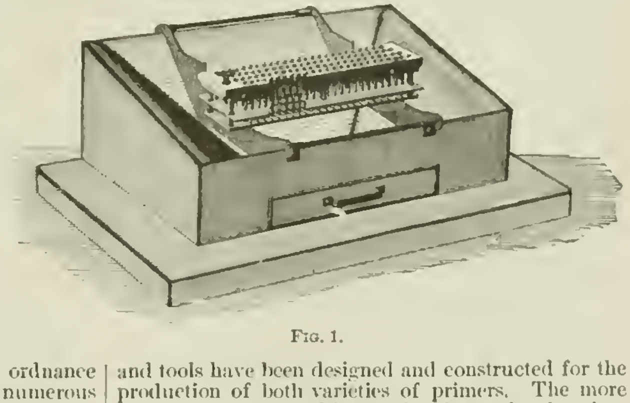

Fig. 1.

and tools have been designed and constructed for the production of both varieties of primers. The more important of the machines and tools are the charging-machine, the foiling-machine, and their auxiliary tools.

The charging-machine, represented in Fig. 1, is a tin-lined wooden hopper, having two supports across its upper end, serving to hold a rack containing the primers to be charged and the charging-tool. A drawer under its lower end receives the overflow of powder from the charging-tool. "Rifle" powder is used to charge the primers, each charge containing about 7 grains by weight. Before charging, both varieties of primers are "primed," the friction-primer, with its serrated wire, packed in friction composition, of which the tersulphide of antimony (sulphuret) is the basis; and the electric primer, with its bridge of platinum wire and copper connecting-wires, a small wisp of gun-cotton being attached to the bridge. For the charging and foiling operations the primers are assembled in a metal rack which has dowels to receive and adjust the charging-tool over the open ends of the primers. The charging-tool consists of two plates held together, but susceptible of a slight movement of the upper upon the lower one. The upper one has tapered holes and the lower one cylindrical holes, corresponding to the primers in the rack. The upper one measures the charges, and its movement, by means of a cam and thumb-nut, upon the lower one, opens or closes the lower end of the tapered charge-holes. The charging-tool, having the charge-holes closed at the bottom by its motion on the lower plate, is placed upon the rack of primers. A quantity of powder is poured over the charge-holes, filling them, and the surplus is stroked off with a straight-edge. The upper plate is now moved so as to empty the charges, through the holes in the lower plate, into the primers. A slight shock or jar settles the powder in the primers, the charging-tool is lifted off, and the rack passed to the foiling-machine.

The new foiling-machine, represented in Fig. 2, is a

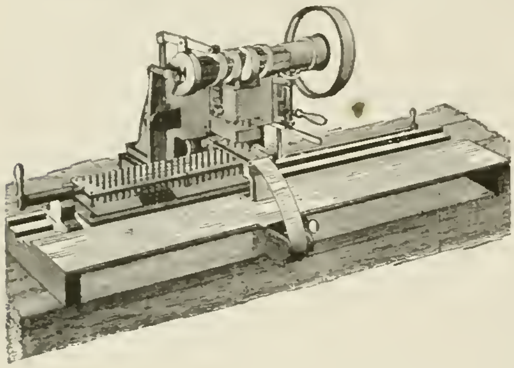

FIG. 2.

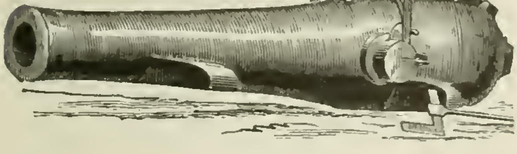
double-action press, arranged to feed the rack of primers horizontally under a gang of punches and dies. The tinfoil, in the form of a coiled ribbon about 1.25 inch wide and .004 inch thick, is fed in between the punches and dies. These cut and form the tinfoil cup, in the usual way, and the cupping-punch presses it down through the die into the end of the primer, at the same time slightly compressing the charge of powder. The tinfoil cup is subsequently secured by means of shellac varnish. The cartridge copper is a more durable metal than brass, which is liable to rot and break easily after long storage or exposure to the atmosphere. The tinfoil stopper is more permanent under wide variations of temperature than the wax one. At high temperatures the latter was sometimes softened and forced out by the expansion of the air, etc., confined in the primer. The charging-machine insures a full charge of powder in every primer, which was not made certain by the old method of charging them by hand. The foiling-machine effectually closes the charge in the primer until it is exploded. It is not improbable that many reported failures of both varieties of primers may have been due to an insufficient charge, if not to its entire absence; and that primers fully charged have often lost their powder by the displacement of the wax stopper. These machines and tools not only work with certainty, but with a rapidity that effects a considerable saving in the cost of their products. See *Electric Primer* and *Friction-primer*.

CANNON-ROYAL.—An old grade of service-cannon, 8½ inches bore and firing a 66-pound shot.

CANNON-SIGHTS.—In order that a projectile fired from a gun may strike a required object, it is necessary to adjust the line of fire with reference to the horizon and the vertical plane passing through the object in such a manner that the trajectory will reach it. The axis of the gun is not visible, and it is necessary to resort to notches or sights on the exterior surface to determine practically the position of the axis. The line of metal is a visual line, joining the notches cut on the highest points of the base-ring and swell of the muzzle. The inclination of the line of metal to the axis of the bore varies in guns of the same class as well as in those of different classes. Aiming, therefore, by the line of metal cannot be relied on for definite ranges; besides that, within those ranges it is apt to mislead by giving too much elevation to the piece. If a gun be pointed at an object by means of a line of metal, it will be seen, by prolonging that line and the axis of the bore, that the latter will pass over the object.

A dispart is a piece of metal placed on the top of the gun to give a line of sight parallel to the axis of the bore. Half the difference between the diameters of the gun at the base-ring and swell of the muzzle, or at any intermediate point on the line of metal, will give the proper height of the dispart-sight at the point where the least diameter was taken. In the absence of other means of sighting, wooden dispart-sights lashed on the cylinder can be used. A narrow groove in the upper surface of the wooden sight, made to coincide with the plane of the line of sight marked on the gun, will assist in getting the true direction. The guns of the Dahlgren pattern are cylindrical for a certain distance forward of the base-line, always giving a line of sight parallel to the axis of the bore. Guns are marked on the top of the base-ring, the sight-masses, and swell of the muzzle, by notches, which indicate a vertical plane passing through the axis of the bore at right angles to the axis of the trunnion. In range at level, the bore being horizontal, the dispart-sight is directed at a point above the water-line or point struck equal to its own distance above that line. If the gun is pointed by dispart directly at an object, the projectile will fall short, more or less, depending upon the distance. In pointing by dispart, therefore, it is necessary to direct the sight a certain height above the object, to allow for the fall of the projectile during flight; the height to be pointed above must depend upon the distance of the object. To facilitate the operation of pointing guns according to the distance of the object aimed at, sights are prepared and fitted to each gun, distinguished as top sights and side sights. The top or ordinary sights consist of two pieces of bronze gun-metal, one of which, called the front sight, is a fixed point, firmly secured to the sight-mass, upon the upper surface of the gun between the trunnions. The other, or rear sight, is a square bar or stem with a head, in the top of which is a sight-notch. It is set diagonally so as to expose two faces to the rear; the rear angle chamfered, to afford a bearing for the clamp-screw. This bar or stem is made to slide in a vertical plane, in the sight-box fixed to the breech-sight mass, and is held at the various elevations for which it is graduated by means of a thumb-screw. Its length is sufficient for all the elevation which can be given—about 5°—before the muzzle appears above the front sight, after which a long wooden sight must be used, graduated for the whole length of the gun, using the notch in the muzzle. The rear sight may be said to be a tangent to an arc the radius of which is the distance from the outer point of the front sight to the fore part of the rear sight, and the divisions are calculated accordingly; this distance is called the short radius. The rear sight is marked on the two rear faces for every hundred yards; on one face for the shell and its proper charge, and on the other for shot. The wooden rear sight may be said to be a tangent to an arc of which the radius is the distance from the notch on the swell of the muzzle to the front of the rear sight; this distance is called the long radius. The rear sight is set at an angle of 60°, so that it may slide up and down without touching the breech of the piece. Every gun is furnished with two sight-bars, a long wooden and a short brass one; the longer is used for ranges over 1700 yards; for all ranges less than this, which is the extreme distance at which accurate practice may be expected at sea, the short bar is used. Pivot-guns are fitted with side-sights placed on the side of the breech, and on the trunnion or rimbase. The advantage of this arrangement is that the sights can be used at any elevation; for, being placed at the side of the gun, the muzzle of the piece does not interfere with the line of sight when pointing. The sights of all howitzers are fitted in this way; the front sight is a notch in a small mass cast on the muzzle; the rear sight is a bronze cylinder pointed at the top and marked for seconds to correspond with the Bormann fuse. The rear sight slides in a small mass cast on the breech, and is held by a thumb-screw. Sights for Parrot M. L. R. guns consist of a fixed sight upon the rimbase, and a movable sight in a socket which is screwed into the breech of the gun. The movable sight is furnished with a sliding eye-piece, and is graduated up to 10°. The eye-piece is also capable of lateral adjustment to allow for the *drift* as far as 10′, and for the effect of the wind. It is desirable that the sights should be placed on both sides of the breech; otherwise, in firing from a port at extreme train, there may be considerable loss of lateral aim. The 8-inch M. L. rifle is furnished with the usual top sights, and has also side sights, the rear one being set at a permanent angle of 1° 47′. The rear sight is a rectangular bar with a square shoulder slotted for a movable eye-piece to allow for deviations due to the force of the wind, etc. It is marked on the rear side for charge, kind of powder and shell; on the left side, range in yards, time of flight in seconds, charge, kind of powder and shell, and initial velocity; the same on the right side for a different charge, and in front for degrees of elevation. The front sight is screwed into the rimbase and is pierced with two holes connected by a slit.

The adjustment of cannon-sights requires the most careful attention. The bore having been thoroughly cleansed, its axis is leveled by inserting a small steel T-square in the bottom of bore at the muzzle. The square itself is first leveled by placing an ordinary level on the transverse branch. When the T-square is leveled, the level is then placed on the longitudinal branch of the T-square lengthwise with the bore of gun, and the axis of gun is then leveled by striking the chocks previously placed on each side under chase of gun, which of course either raise or lower the muzzle. When the gun has been leveled as to axis of bore, it is to be leveled as to axis of trunnions. To level as to axis of trunnions: First, scrape off the paint on top of each trunnion, then place the trunnion-square as seen in the drawing, and put the spirit-



level on it as at S. Adjust the piece by means of the chocks under the trunnions until they are horizontal. This leveling the gun by axis of trunnions may throw the axis of the gun out of level, in which case return to that, and then to the other, approximating closer and closer each time until the gun is leveled. If the gun be lying on wooden skids, the leveling must be verified from time to time, as the great weight will cause it to sink trifle by trifle, thus throwing the level out. The distance that the sights should be apart is furnished by authority. With a straight-edge mark off this distance, and drill a hole for the front sight. Then counter-bore the front sight. As soon as it is screwed in, lay one end of the straight-edge on it, and its other end on the notch of rear sight. Place a level on the straight-edge. Now the level will generally be found to be slightly out, and it can be brought to a level by either screwing the front sight up or down as occasion requires, or by cutting down the notch of the rear sight if it should want to be lowered at that end. For side sights, the rear bar is generally supplied with the proper firing-distances marked on it. Whenever a sight-bar is received already marked with ranges, the level should never be remedied by cutting away the shoulder of the bar, as the edge of the shoulder is the initial point from which the bar is marked. If, however, the sight-bar is marked after it is fitted to the gun, the shoulder can be thinned down. The leveling-bar is not used in side-sighting a gun. The straight-edge is now applied as before, resting on front sight and notch of rear sight-bar, and verified as to the level of that plane. If the spirit-level remains at level, the gun is properly sighted as to the level of sights. See *Pointing*.

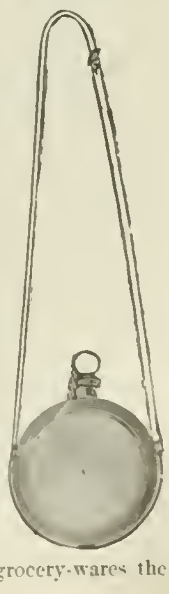
CANONNIERE.—1. A name formerly given to a tent which served to shelter four canonniers, but later the term was applied to all infantry tents which contained seven or eight men. 2. An appellation formerly given to a gun-proof tower; it also designated an opening in the walls of cities, forts, etc., through which the defenders of these places could fire on an enemy without being exposed.

CANONNIERS GARDES-COTES.—Guards instituted in 1702 by Louis XIV. of France for the service of coast-batteries. They are similar to the Artillery Coast Brigade in the British service.

CANTABRI.—A rude race of mountaineers in ancient Spain, of Iberian origin, and who lived in the district now known as Burgos, and on the coasts of the Bay of Biscay, which derived from them its name, *Oceanus Cantabricus*. The most important of their nine towns were Juliobrica (near the source of the Ebro), Vellica, and Concana. The Cantabri are described as like the Scythians and Thracians in hardihood and martial character, sleeping on the bare earth, enduring extreme pain without a murmur, and, like most savages, leaving agricultural toil to their women. Their bravery was evinced in the Cantabrian war, a six years' contest with the Romans, begun under Augustus, and concluded by Agrippa, 25–19 B.C. Tiberius afterwards stationed garrisons in the towns of the conquered Cantabri; but some portion retreated into their fastnesses among the mountains, where they preserved their independence. They are supposed to be the ancestors of the Basques.

CANTABRUM.—A large banner used during the time of the Roman emperors, and borne on festive occasions.

CANTEEN.—1. A vessel used by soldiers to contain whatever beverage may be obtainable on the march or in the field. It is sometimes of tin, sometimes of wood. In the British army, the canteen is a wooden vessel, holding about three pints, painted blue, and inscribed with the number or designation of the regiment, battalion, and company to which the soldier belongs.



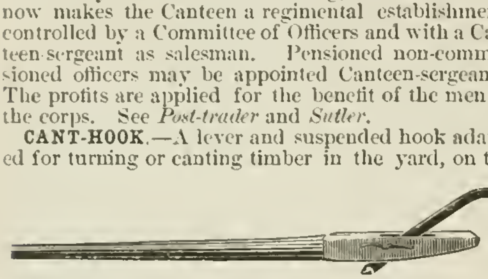
2. A leathern or wooden chest, divided into compartments, and containing the plate and table-equipage for a military officer when on active service.

3. In the French barracks, the canteen is a sort of club-room for the whole regiment. The Cantinier is a non-commissioned officer, who acts merely as an agent for all, selling the liquors and commodities at prime cost.

4. In the British service, a refreshment-house in a barrack, for the use of the soldiers. The chief articles of food are supplied to the troops direct by the government; but wine, malt liquor, and small grocery-wares the

soldier is left to buy for himself; and the Canteen is, or is intended to be, a shop where he can make these purchases economically without the necessity of going beyond the precincts of the barrack. No soldier is obliged to buy anything at the Canteen; he may lay out his small sums elsewhere if he prefer. Formerly the Canteens were under civilians called Canteen-tenants, and spirits were sold. Between the years 1836 and 1845 it was found that among 112 Canteens in the United Kingdom the rent and head-money paid varied from £4 per annum (one at Guernsey) to £1344 per annum (one at Woolwich); they brought in collectively to the government about £70,000 annually. Great intoxication having resulted from the sale of spirits at the Canteens, the War Office prohibited such sale in 1847; as a consequence, the rents had to be lowered to the extent of £20,000 in the following year, the Cantineers finding their profits much reduced. The rent paid was found to be injurious to the soldiers, who were charged higher prices within the barrack than without, and who were thence driven to places where dangerous temptations are at hand. The result of this system being undeniably bad and demoralizing, the War Office now makes the Canteen a regimental establishment, controlled by a Committee of Officers and with a Canteen-sergeant as salesman. Pensioned non-commissioned officers may be appointed Canteen-sergeants. The profits are applied for the benefit of the men of the corps. See *Post-trader* and *Sutler*.

CANT-HOOK.—A lever and suspended hook adapted for turning or canting timber in the yard, on the



Cant-hook.

skids, or on the mill-carriage. The term is also applied to a sling with hooks for raising and tilting casks to empty them.

CANTINIERE.—Women who are authorized to establish themselves in the barracks or follow the troops in time of war, selling them liquors and provisions. The *cantinières*, whether attached to regiments or barracks, are selected from the wives of non-commissioned officers or privates, and wear a uniform. See *Virandière*.

CANTLE.—The hind-bow or protuberance of a saddle. Sometimes written *Cantel*. See *Saddle*.

CANTON.—In Heraldry, the canton occupies a corner of the shield, either dexter or sinister, and in size is the third of the chief. It is one of the nine honorable ordinaries, "and of great esteem."

CANTONMENTS.—When, after long fatigues, some repose must be given to an army, it must be dispersed over a sufficient extent for subsistence. This disposition of the troops is termed *cantoning*, and the camps occupied, *cantonments*. This state supposes that the enemy will not for some time be in a condition to attack. Still, even this assurance should not induce any relaxation of proper military precautions to prevent a surprise, and to permit a concentration on some suitable point either for offensive or defensive movements. The dispositions to be made for this purpose resemble, in their principal features, those for one of advanced-posts. Advanced points are held by some of the troops where there is no relaxation of discipline allowed; other points, in their rear, are occupied as supports to the first; and all are connected with some main central position where the army is to be concentrated in case of need. The communications to the rear, at least of all these detached portions, should be kept in good traveling order, and no obstruction to the free movements of the troops be even for an hour allowed to exist. When cantonments are taken up in winter they are termed *winter quarters*. They differ from the preceding only in being often of greater extent; and therefore, from their weakness, requiring all the additional means of defense at hand.

As cantonments are taken up either during seasons when operations cannot be well carried on, or to give the troops some extraordinary repose after a harassing campaign, more advanced-posts will generally be necessary than under ordinary circumstances; and to fulfill their end they ought to be placed on ground favorable to a strong resistance, in order to give the separated corps time to concentrate against an earnest attack of the enemy. A good disposition of stations for outposts, from which the enemy can be seen at a distance; a line of supports placed on strong ground in the rear; easy communications for concentration on the main body; active and vigilant patrols, kept moving not only along the front, but penetrating on the flanks and rear of the enemy, to get wind of his strategical plans: such are the general precautions demanded of its advanced-posts by an army in station for some time. In the disposition of the main force, to concur with the preceding, one precaution should not be omitted in a stay of any duration; and that is, not to allow any one body to remain long enough in a village, or inhabited place, to become in a degree domesticated. Nothing is more likely than this to injure the *morale* of the best troops. The seductions of otherwise harmless pleasures may lead to fatal habits of remissness in duty.

In India, cantonments are *permanent* places, regular military towns, distinct and at some little distances from the principal cities. If on a large scale, such a cantonment contains barracks for European cavalry, infantry, and artillery; rows of bungalows or houses, each inclosed in a garden, for the officers; rows of huts for the native soldiery; magazines and parade-grounds; public offices and buildings of various kinds; and a bazaar for the accommodation of the native troops. During the revolt in 1857–58 most of the outbreaks began in the cantonments. It was in the cantonment outside Cawnpore that Nana Sahib commenced his treachery. See *Camp*, *Field-service*, and *Winter Quarters*.

CANTONNEE.—When, in Heraldry, a cross is placed between four other objects, as, for example, scallop-shells, it is said to be *cantonnée*. See *Heraldry*.

CANTON'S PHOSPHORUS.—A combustible obtained by heating in a close vessel 3 parts oyster-shells and 1 part sublimed sulphur, when the sulphuret of calcium (CaS) is formed, which takes fire when exposed to or thrown into the air. Frequently spoken of as *pyrophorus*.

CANVAS.—A material made from hemp, and much used for artillery purposes, such as the covering of the seats of gun-carriages, caps for sponge-heads, soldiers' bags, aprons for the vents of guns, and paulins for covering stores; it is also used in the manufacture of tents. The canvas in use in arsenals in India is of two kinds—English and that manufactured in the country. The canvas made in India is used for all purposes where rough material would be required, such as artillery-practice curtains, sand-bags, bags for charcoal, etc. The chief places of manufacture of Indian canvas are in Bengal, and at Cuddalore and Travancore, in the Madras Presidency. Being "under canvas" means being in camp or in the field.

CANVAS-BOAT.—A boat has been invented by Colonel R. C. Buchanan, of the United States Army, which has been used in several expeditions in Oregon and in Washington Territory, and has been highly commended by several experienced officers, who have had the opportunity of giving its merits a practical service-test. It consists of an exceedingly light framework of thin and narrow boards, in lengths suitable for packing, connected by hinges, the different sections folding into so small a compass as to be conveniently carried upon mules. The frame is covered with a sheet of stout cotton canvas, or duck, secured to the gunwales with a cord running diagonally back and forth through eyelet-holes in the upper edge.

When first placed in the water the boat leaks a little, but the canvas soon swells so as to make it sufficiently tight for all practical purposes. The great advantage to be derived from the use of this boat is that it is so compact and portable as to be admirably adapted to the requirements of campaigning in a country where the streams are liable to rise above a fording stage, and where the allowance of transportation is small. It may be put together or taken apart and packed in a very few minutes, and one mule suffices to transport a boat with all its appurtenances, capable of sustaining ten men. Should the canvas become torn, it is easily repaired by putting on a patch, and it does not rot or crack like india-rubber or gutta-percha; moreover, it is not affected by changes of climate or temperature. See *Blanket-boats.*

CANVAS CAPS.—Caps used, after having been water-proofed, for covering the mouths of mortars, and for covering sponge-staves.

CAP.—1. A cover for the head, with or without a visor, but without a brim; worn generally by the military. 2. A sheet of lead laid over the vent of a cannon. 3. A copper capsule containing a fulminate, and placed upon the nipple to explode the charge on the fall of the hammer.

CAP-A-PIE.—This term was applied in the Middle Ages to a knight or soldier armed at all points, or from head to foot, as the words imply, with armor for defense, and with arms for offense.

CAPARISON.—The bridle, saddle, and trappings complete of a horse for military service. *Caparisoned,* in Heraldry, is said of a war-horse completely furnished for the field.

CAP-CORD.—A gilt cord worn on the forage-cap as an ornament. The drawing represents the new pattern cap-cord recently adopted in the United States army. A similar cap-cord is worn by United States Naval Officers.

Cap-cord.

CAPELINE.—A helmet without a visor, nearly in the form of a round head. It was formerly much worn by the infantry.

CAPITAL.—In fortification, a capital is an imaginary line dividing a defense-work into two similar and equal parts. The capital of a bastion is a right line drawn from the point or salient angle to the middle of the gorge or entrance in the rear. The capital of a ravelin is a right line drawn from the re-entering angle of the counterscarp to the salient angle of the ravelin. See *Field-fortification.*

CAPITAL PUNISHMENT.—The law on this subject in England is contained in the 19th of the Articles of War now in force, which prescribes death as the punishment of the following offenses, or such other punishment as by a Court-Martial shall be awarded: (1) Any officer or soldier who shall excite or join in any mutiny or sedition in any forces belonging to Her Majesty's Army, or Royal Marines, or who shall not use his utmost endeavors to suppress it, and knowing of it, shall not give immediate information of it to his Commanding Officer; or (2) who shall hold correspondence with, or give advice or intelligence to, any rebel or enemy of Her Majesty; or (3) who shall treat with any rebel or enemy without Her Majesty's license, or license of the Chief Commander; or (4) shall misbehave himself before the enemy; or (5) shall shamefully abandon or deliver up any garrison, fortress, post, or guard committed to his charge; or (6) shall compel the Governor or Commanding Officer to deliver up or abandon such place; or (7) shall induce others to misbehave before the enemy, or abandon or deliver up their posts; or (8) shall desert Her Majesty's service; or (9) shall leave his post before being regularly relieved, or shall sleep on his post; or (10) shall strike or offer any violence to his Superior Officer, being in the execution of his office, or shall disobey any lawful command of his Superior Officer; or (11) who, being confined in a military prison, shall offer any violence against a visitor or his Superior Military Officer, being in the execution of his office.

By Article 20 it is declared that no judgment of death by a Court-Martial shall pass, unless two thirds at least of the officers present shall concur therein; and by Article 21 it is provided that judgment of death may be commuted for penal servitude for any term not less than four years, or for imprisonment for such term as shall seem meet. It would appear that the employment of a soldier in the service subsequent to his arrest on a capital charge may operate as a remission of the sentence of death. This is illustrated by the following case, mentioned by Mr. Prendergast in his *Law Relating to Officers in the Army.* In 1811 Private John Weblin of the 3d Buffs was sentenced to be shot. The Commander-in-Chief, the Duke of Wellington, in his "remarks" upon the proceedings, took notice that, through some extraordinary inattention, the prisoner had actually been permitted to serve in an engagement with the enemy after he had been put into arrest for his crime. On this ground the Duke pronounced that he was under the *necessity* of *pardoning* the prisoner. In the army, capital punishment is inflicted by the offender being either shot or hanged—the latter being the more disgraceful mode of execution.

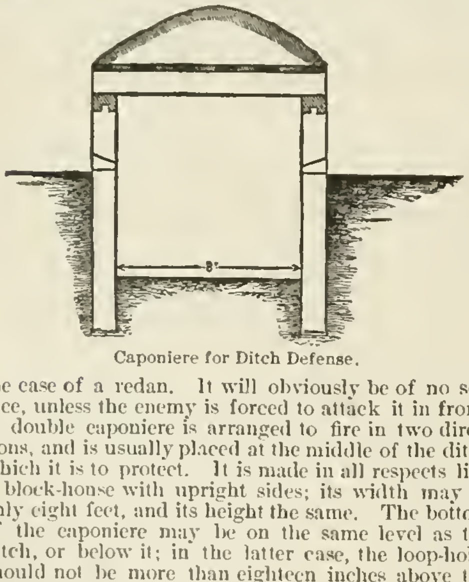
Under the laws of the United States, capital punishment may be inflicted for treason, murder, arson, rape, piracy, robbery of the mails with jeopardy to the lives of persons in charge, rescue of a convict going to execution, burning a vessel of war, and corruptly destroying a private vessel. Until within a few years capital punishment was the rule for the highest crimes in all the States, but it was abolished in Wisconsin and in Maine in 1874, and had been about that time abolished in Iowa; but in the latter State it was restored in 1878, the argument showing from the record that during its abolition crimes of violence had largely increased. Under the present law a year must intervene between the sentence and execution, and the term may be further extended by reprieve. There is much difference of opinion as to the effect of the abolition of the death-penalty, and perhaps no settled conclusion can be reached. The effect of its abolition has not thus far supplied any very strong reasons for the stand of those who would abolish it altogether. Perhaps the most notable suspension of this punishment in all history was during the War of the Rebellion in the United States, when, in the face of the most powerful, open, and dangerous treason, not one person was deliberately executed for that crime, the extreme penalty visited even upon the captured leader of the Rebellion, being the loss of the political (but not the personal) rights of a citizen.

CAPITULATION.—A treaty consisting of several specified conditions. In the military sense of the word, a capitulation is a treaty of surrender to an enemy. When a place can no longer be defended, on account of failure of ammunition or provisions, or the progress made by the besieging party, a white flag is commonly put up, as a sign that the besieged are willing to capitulate. According to the kind and degree of peril in which the fortress is placed, so are the terms which the Governor may reasonably expect from his successful opponent. Sometimes the arms and military stores are left to the besieged, but more frequently they are taken by the besiegers, except articles of private property belonging to the officers and men. The "honors of war," the marching out with drums beating and colors flying, are usually stipulated for, unless the conqueror exacts very severe terms. The mildest form of a capitulation is a *Convention*, agreed to when the conqueror is not strong enough to insist on stringent conditions. See *Armistice*.

CAP OF MAINTENANCE.—A cap of crimson velvet lined with ermine, with two points turned to the back, originally only worn by Dukes, but afterwards assigned to various families of distinction. Those families who are entitled to a cap of maintenance place their crests on it instead of on a wreath. According to Sir John Fearne, the wearing of the cap had a beginning from the Duke or General of an army, who, having gotten victory, caused the chiefest of the subdued enemies whom he led to follow him in his triumph, bearing his hat or cap after him in token of subjection and captivity. Most of the reigning Dukes of Germany, and various families belonging to the peerage both of England and of Scotland, bear their crests on a cap of maintenance. Sometimes called *cap of dignity*.

CAPONIERES—CAPONNIERES.—The surest defense for a ditch is a good flanking arrangement of the work itself; but as this is in many cases impracticable, owing either to the relief or to the plan, flank defenses must be procured by a construction made in the ditch. Several methods may be resorted to for this purpose, termed *caponieres*, *scarp*, and *counterscarp galleries*.

The caponiere is a work made across the ditch, and may be either single or double. A single caponiere is nothing more than a defensive stockade, or palisading, made at the extremity of a ditch, as in



Caponiere for Ditch Defense.

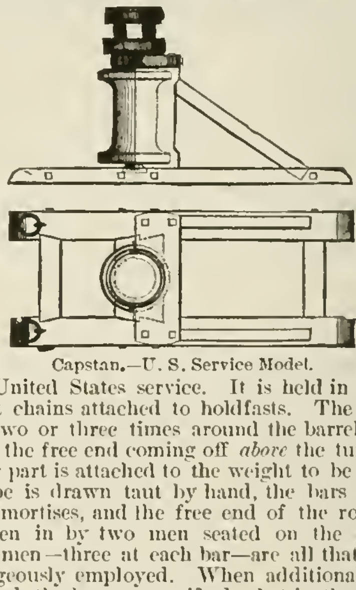
the case of a redan. It will obviously be of no service, unless the enemy is forced to attack it in front. A double caponiere is arranged to fire in two directions, and is usually placed at the middle of the ditch which it is to protect. It is made in all respects like a block-house with upright sides; its width may be only eight feet, and its height the same. The bottom of the caponiere may be on the same level as the ditch, or below it; in the latter case, the loop-holes should not be more than eighteen inches above the level of the ditch, to prevent the enemy from using them against the assailed within. In the former, a small ditch should be made round the caponiere, and the earth from the ditch be thrown against its sides. The plan of the caponiere should be arranged to admit of being flanked by a defensive stockade, placed at the foot of the scarp; for this purpose the end next to the counter-scarp should be in the form of a salient flanked by the stockade. To prevent the enemy from jumping on the caponiere from the crest of the counterscarp, a space of at least twelve feet should be left between the two. Moreover, the top of the caponiere should be covered from the enemy's artillery, either by the counterscarp crest or by a glacis. The communication to the caponiere from the work may be by a timber gallery under the parapet, formed of frames and a sheeting similar to the construction used for a powder-magazine.

CAPOTE.—A heavy coat with a hood, worn by soldiers, sailors, and others when on duty.

CAP-SQUARE.—In artillery, that part of the iron-work of a gun-carriage which folds or laps over the exterior portion of the trunnions of a piece of ordnance, when it is laid in its bed or carriage. The cap-square is secured by a key or some other stronger contrivance. This fastening prevents the gun from jumping out of its trunnion-bed.

CAPSTAN.—A hoisting or hauling machine, consisting of a drum set vertically and revolved by hand-spikes. The capstan differs from the windlass in having an upright axle, the bars being placed in the sockets of the drum-head and revolving horizontally as the men walk around, pushing the bars before them and winding the cable on the whelps. The capstan has many advantages, among which may be enumerated—compactness; facility for allowing a large number of men to work at it simultaneously; continuity of its work, as the bars do not require to be unshipped after making a quarter of a revolution. Frequently, when moving artillery, it becomes necessary to improvise a capstan with a limber. To do so, dismount a siege-limber; place a half-block under the pintle and each axle-arm, close to the shoulder. Drive a stout stake in rear of each axle-arm against the half-blocks. The pole is turned *from the weight*, its axis in the direction of it. Lay the wheel on the pintle, outside down, and secure four handspikes to the spokes and felloes, dividing the circumference into four equal parts. Take a round turn with the fall around the lower part of the nave, the free end coming off below. The man who holds on to the fall sits on the end of the pole. Keep the fall as high as the nave and clear of the ground. The power is multiplied fifteen times.

The drawing represents the capstan as employed



Capstan.—U. S. Service Model.

in the United States service. It is held in position by stout chains attached to holdfasts. The rope is passed two or three times around the barrel of the capstan, the free end coming off *above* the turns; the standing part is attached to the weight to be moved. The rope is drawn taut by hand, the bars inserted into the mortises, and the free end of the rope held and taken in by two men seated on the ground. Twelve men—three at each bar—are all that can be advantageously employed. When additional power is required, the bars are swifted; that is, the ends of the bars are lashed together with ropes, by which additional men are enabled to take hold.

To use the gin as a capstan, put it together on the ground in the usual manner; place the feet of the legs toward the weight, and secure them well with stakes against the cross-bars, feet, and head of the gin; rig the fall as usual, and attach the hook of the lower block to a rope of suitable strength running to the weight to be moved; the windlass is worked in the same manner as when the gin is standing. Or the gin, with its pry-pole in the direction of the weight to be moved, may be raised almost to its usual position for hoisting. A block is hooked to the clevis, and through it the rope is passed from the weight to the windlass; the latter is worked as usual. *See Mechanical Maneuvers.*

CAPSULES.—Copper caps for percussion-locks. Not used at present.

CAPTAIN.—This is perhaps the most general designation given to an officer of land forces; something equivalent to it being found in most European languages. As a word, it simply means a *head* or *leader*, and may be applied to a Chief over any number of men. *Captain-general* is in some countries a very high command. In the time of Queen Elizabeth there was, among other high military officers, a Captain-general of footmen. In the organization of the British army at the present day, there is one Captain to every *company* of infantry, and every *troop* of cavalry. Formerly every battery of artillery had two Captains—a first and a second, the latter being called Captain-lieutenant. Now, the first in command has the title of Major, and the second that of Captain. The first in command of a battery of artillery, even when styled Captain, was considered higher than a Captain of infantry or cavalry, and was privileged to be mentioned by name in military dispatches like Colonels and Majors. The duty of the Captain is to see to the men of his company in everything that relates to discipline, exercises, billeting, pay, settlement of accounts, mess, kit, clothing, arms, ammunition, accouterments, stores, barracks, cooking, etc.; to receive orders concerning these matters from the Major, and to enforce these orders among the men. He is responsible to the Major, and is assisted in his duties by the Lieutenant and Sub-lieutenant. The number of Captains on the peace establishment of the British army, in its several branches, are about 239 Cavalry, 1236 Infantry, 248 Artillery, 115 for Engineers, and 28 for Colonial Corps—1866 in all, in full commission. In the United States army, a Captain is responsible for the camp and garrison equipage and the arms and clothing of his company. The rank is between Lieutenant and Major.

CAPTAIN-GENERAL.—The appellation of a Commander-in-Chief till Marlborough's time, if not later. The rank is sometimes still given on extraordinary occasions. It was borne by the Marquis of Wellesley during his government in India, and is applied to the Governor-general of the Canadas. In the United States, the Governor of a State is Captain-general of the militia.

CAPTAIN-LIEUTENANT.—A rank formerly held in the English army. This position carried the rank of Captain in the Army, similar to what the rank of Lieutenant and Captain does in the Foot-guards at the present day. A Captain-lieutenant did Subaltern's duty in his company, and could hold the post of Adjutant. He was also the Subaltern who commanded the "Colonel's Company" in each regiment of infantry.

CAPTAINRY.—The power or command over a certain district; Chieftainship; Captainship.

CAPTAINSHIP.—The condition, rank, post, or authority of a Captain or Chief Commander. The term also signifies skill in military affairs; as, to show good captainship.

CAPTIVES.—It is laid down by Blackstone that, as in the goods of an enemy, so also in his person, a man may acquire a sort of qualified property in him as a captive, or prisoner of war—at least till the ransom of the captive is paid. In Scotland all legal proceedings against a captive are stopped till his liberation, although in some cases execution against his estate may proceed.

CAPTIVITY.—The state of being a prisoner, or of being in the power of the enemy, by force of the fate of war.

CAPTURE.—Prize taken in time of war. The law on this subject is stated with precision in a paper addressed on behalf of the British Government to the American Ambassador at London in September, 1794: "When two powers are at war, they have a right to make prizes of the ships, goods, and effects of each other, upon the high seas. Whatever is the property of the enemy may be acquired by capture at sea; but the property of a friend cannot be taken, provided he observes his neutrality. Hence the Law of Nations has established that the goods of an enemy on board the ship of a friend may be taken, that the lawful goods of a friend on board the ship of an enemy ought to be restored; that contraband goods going to the enemy, though the property of a friend, may be taken as prize: because supplying the enemy with what enables him better to carry on the war is a departure from neutrality."

During the Russian war in 1854 there appeared in the *London Gazette*, under date the 28th March of that year, a declaration stating, *inter alia*, that Her Majesty would waive the right of seizing enemy's property laden on board a neutral vessel, unless it be contraband of war, and that it was not Her Majesty's intention to issue letters of marque for the commissioning of privateers. The right of seizing enemy's property on board a neutral vessel, whether contraband of war or not, had always before been maintained by England. On the re-establishment of peace with Russia, a treaty was signed, and the following declarations adopted: 1. Privateering is and remains abolished; 2. A neutral flag covers an enemy's goods, with the exception of contraband of war; 3. Neutral goods, with the exception of contraband of war, are not liable to capture under an enemy's flag; 4. Blockades, in order to be binding, must be effectual—that is to say, maintained by force sufficient to prevent effectually access to the coast of the enemy. See *Booty* and *Prize*.

CAPTURED PROPERTY.—A victorious army appropriates all public money, seizes all public movable property until further direction by its government, and sequesters for its own benefit or that of its government all the revenues of real property belonging to the hostile government or nation. The title to such real property remains in abeyance during military occupation, and until the conquest is made complete. A victorious army, by the martial power inherent in the same, may suspend, change, or abolish, as far as the martial power extends, the relations which arise from the services due, according to the existing laws of the invaded country, from one citizen, subject, or native of the same to another. The commander of the army must leave it to the ultimate treaty of peace to settle the permanency of this change. It is no longer considered lawful—on the contrary, it is held to be a serious breach of the law of war—to force the subjects of the enemy into the service of the victorious government, except the latter should proclaim, after a fair and complete conquest of the hostile country or district, that it is resolved to keep the country, district, or place permanently as its own and make it a portion of its own country.

As a general rule, the property belonging to churches, to hospitals or other establishments of an exclusively charitable character, to establishments of education, or foundations for the promotion of knowledge, whether public schools, universities, academies of learning or observatories, museums of the fine arts or of a scientific character, may be taxed or used when the public service may require it. Classical works of art, libraries, scientific collections, or precious instruments, such as astronomical telescopes, as well as hospitals, must be secured against all avoidable injury, even when they are contained in fortified places whilst besieged or bombarded. If such works of art, libraries, collections, or instruments belonging to a hostile nation or government can be removed without injury, the ruler of the conquering State or Nation may order them to be seized and removed for the benefit of the said Nation. The ultimate ownership is to be settled by the ensuing treaty of peace. In no case shall they be sold or given away, if captured by the armies of the United States, nor shall they ever be privately appropriated, or wantonly destroyed or injured.

The United States acknowledge and protect, in hostile countries occupied by them, religion and morality; strictly private property; the persons of the inhabitants, especially those of women; and the sacredness of domestic relations. Offenses to the contrary shall be rigorously punished. This rule does not interfere with the right of the victorious invader to tax the people or their property, to levy forced loans, to billet soldiers, or to appropriate property, especially houses, land, boats or ships, and churches, for temporary and military uses. Private property, unless forfeited by crimes or by offenses of the owner, can be seized only by way of military necessity, for the support or other benefit of the Army or of the United States. If the owner has not fled, the Commanding Officer will cause receipts to be given, which may serve the spoliated owner to obtain indemnity.

The salaries of civil officers of the hostile government who remain in the invaded territory, and continue the work of their office, and can continue it according to the circumstances arising out of the war—such as judges, administrative or police officers, officers of city or communal governments—are paid from the public revenue of the invaded territory, until the military government has reason wholly or partially to discontinue it. Salaries or incomes connected with purely honorary titles are always stopped. There exists no law or body of authoritative rules of action between hostile armies, except that branch of the law of nature and nations which is called the law and usages of war on land. All municipal law of the ground on which the armies stand, or of the countries to which they belong, is silent and of no effect between armies in the field.

Slavery, complicating and confounding the ideas of property (that is, of a *thing*) and of personalty (that is, of *humanity*), exists according to municipal or local law only. The law of nature and nations has never acknowledged it. The digest of the Roman law enacts the early dictum of the pagan jurist, that "so far as the law of nature is concerned all men are equal." Fugitives escaping from a country in which they were slaves, villains, or serfs, into another country, have, for centuries past, been held free and acknowledged free by judicial decisions of European countries, even though the municipal law of the country in which the slave had taken refuge acknowledged slavery within its own dominions. Therefore in a war between the United States and a belligerent which admits of slavery, if a person held in bondage by that belligerent be captured by or come as a fugitive under the protection of the military forces of the United States, such person is immediately entitled to the rights and privileges of a freeman. To return such person into slavery would amount to enslaving a free person, and neither the United States nor any officer under their authority can enslave any human being. Moreover, a person so made free by the law of war is under the shield of the law of nations, and the former owner or State can have, by the law of postliminy no belligerent lien or claim of service.

All wanton violence committed against persons in the invaded country, all destruction of property not commanded by the authorized officer, all robbery, all pillage or sacking, even after taking a place by main force, all rape, wounding, maiming, or killing of such inhabitants, are prohibited under the penalty of death, or such other severe punishment as may seem adequate for the gravity of the offense. A soldier, officer or private, in the act of committing such violence, and disobeying a Superior ordering him to abstain from it, may be lawfully killed on the spot by such Superior. All captures and booty belong, according to the modern law of war, primarily to the government of the captor. Prize-money, whether on sea or land, can now only be claimed under the local law.

Neither officers nor soldiers are allowed to make use of their position or power in the hostile country for private gain, not even for commercial transactions otherwise legitimate. Offenses to the contrary committed by commissioned officers will be punished with cashiering or such other punishment as the nature of the offense may require; if by soldiers, they shall be punished according to the nature of the offense.

Crimes punishable by all penal codes, such as arson, murder, maiming, assaults, highway robbery, theft, burglary, fraud, forgery, and rape, if committed by an American soldier in a hostile country against its inhabitants, are not only punishable as at home, but in all cases in which death is not inflicted the severer punishment shall be preferred.

CAPUCHIN.—A piece of mail generally worn in early days under the great bascinet.

CAPUCHONS.—A society formed in France, from 1181 to 1183, for the suppression of the brigandage of the *Routiers;* they exterminated 7000 brigands in an engagement near Verdun.

CARABINE A TIGE.—A very ancient and celebrated rifle. The tige is a sort of small anvil growing like a stem out of an ordinary flat breeching, so that the powder-charge, instead of resting centrally, is distributed all around the tige. Notwithstanding the great military defects of this stem-principle, the carabine à tige has been recently and extensively employed by the French infantry.

CARABINEERS—CARBINEERS.—Dragoons armed with carbines, who occasionally acted as infantry. They are said to have derived their designation from the Arabs, among whom the *Carabins* or *Karabins* were light horsemen, stationed at outposts to harass the enemy, defend narrow passes, etc.; in action, they took the place of skirmishers. A corps under the same name was raised in France in 1560; but the designation has not been much used in that country since the introduction of Hussars and Lancers. In the English army, Carabineers was at one time a frequent designation for cavalry; but now there is only one regiment, the 6th Dragoon Guards, known by this title; and the distinction between them and other cavalry is little more than nominal.

CARABINS.—Light horsemen, sometimes called *Karabins*, among the Arabs, who were stationed at outposts to harass the enemy, defend narrow passes, etc.; in action they took the place of skirmishers. Troops called *Carabins*, a sort of light cavalry from Spain, are first mentioned in England in 1559.

CARACOLE.—In horsemanship, a sudden half-turn sometimes performed in an attack of cavalry to mislead the enemy as to the point at which the assault is to be made.

CARAVAN.—The name given to the assemblages of troops or travelers which at stated times traverse the deserts of Asia and Africa. Many caravans are entirely for the purposes of trade, the merchants associating themselves for mutual help and protection. A caravan sometimes has as many as 1000 camels, which follow each other in single file, so that it may be a mile or more in length. The most celebrated caravans are those formed by pilgrims going to Mecca, particularly those which annually assemble at Cairo and at Damascus. The latter consist of 30,000 to 50,000 pilgrims, and is under the special protection of the Turkish Sultan. The caravan by which the Persians travel to Mecca starts from Bagdad, and is the vehicle of a very important trade. The great Indian caravan to Mecca, which started from Muscat, has been long given up. Mecca, upon the arrival of the caravans, bringing goods from so many different parts of the world, presents all the appearance of a vast fair. The trade between Tripoli and the interior of Africa is exclusively carried on by caravans, likewise that between Darfur and Egypt. The great trade between Russia and China is also a caravan trade. In the East, caravans in which the camels have a load of 500 to 600 lbs. are called *heavy* caravans; *light* caravans are those in which the camels have only half that weight, so that the daily journeys may be longer. *Heavy* caravans travel from 17 to 18 miles a day; *light*, from 22 to 25. The caravans are generally conducted with great regularity, and assemble at and start from stated places on stated days. The leader of the Mecca caravans is called Emir-el-Hadsch, i.e., Prince of the Pilgrims. In trade-caravans, a leader, who is called Karwan-Baschi, is elected by the merchants from their own number.

Among the Knights of Malta, caravans meant the troops of Knights appointed by the Order to serve in garrisons, and also the cruises of their galleys against the Turks.

CARBINE.—A small-arm with a short barrel, adapted for the use of cavalry, and having a bore of .44 to .50 inch, or thereabout. Carbines appear to have come into notice in the army of Henry II. of France, 1559. The arm was 3½ feet long, and the practice was to fire and fall back behind the rear rank, who fired and followed suit. The troops were light cavalry, and the arm seems to have had a wheel-lock. The term now is applied to a short gun adapted for cavalry, of which many breech-loading varieties have been tried in the United States army with greater or less success. Previous to the general introduction of breech-loaders, the fire-arm in common use for cavalry, as well as engineers and heavy artillery, was a species of carbine denominated *musketoon*, differing from the musket only in length and in the fact that the arm for the cavalry was provided with a sling-bar for more convenient carriage on horseback; those for the engineers and artillery were generally furnished with sword-bayonets. These all appear to have corresponded nearly in caliber and general dimensions with the modern French *carabine*. The ramrod of the muzzle-loading carbine is attached to the barrel by a swivel, which permits it to be handled freely, but at the same time prevents it from falling to the ground. The carbine is secured to the person of the soldier by the sling, which hooks on to a ring moving on a swivel-bar attached to the left side of the carbine, thereby affording a play to the piece in loading and firing. See *Carabineers* and *Springfield Carbine*.

Carbine.

CARBON.—One of the elementary substances largely diffused in nature. It occurs uncombined in the mineral graphite, or black-lead, and in the diamond, which is pure crystallized carbon. It is much more abundant, however, in a state of combination. United with oxygen, it occurs as carbonic acid (CO_2) in the atmosphere, in natural water, in limestone, dolomite, and ironstone. In coal it is found combined with hydrogen and oxygen; and in plants and animals it occurs as one of the elements building up wood, starch, gum, sugar, oil, bone (gelatine), and flesh (fibrine). Indeed, there is no other element which is so characteristic of plant and animal organisms, and it ranks as the only element never absent in substances obtained from the two kingdoms of organic nature. Wood-charcoal, coke, lamp-black, and animal charcoal are artificial varieties, more or less impure, of carbon. The atomic weight or equivalent of carbon is 6 (new system 12); the specific gravity greatly varies; that of the diamond is 3.330 to 3.550 (water being 1.000), and of graphite 1.800. Carbon in its ordinary forms is a good conductor of electricity; in the form of diamond it is a non-conductor. Of heat, the lighter varieties of carbon, such as wood charcoal, are very bad conductors; graphite in mass has very considerable conducting powers. At ordinary temperatures all the varieties of carbon are extremely unalterable: so much so that it is customary to char the ends of piles of wood which are to be driven into the ground, so as by this coating of non-decaying carbon to preserve the interior wood; and with a similar object the interior of casks and other wooden vessels intended to hold water during sea-voyages are charred (coated with carbon), to keep the wood from passing into decay, and thereby to preserve the water *sweet*. Its power of arresting odors and colors likewise varies much. In the simple property even of combustion there is a marked difference. Wood-charcoal takes fire with the greatest readiness, bone-black less so; then follow in order of difficulty of combustion—coke, anthracite, lamp-black, black-lead, and the diamond. Indeed, black-lead is so non-combustible that crucibles to withstand very high heats for prolonged periods without breakage or burning are made of black-lead; and the diamond completely resists all ordinary modes of setting fire to it. In the property of hardness, carbon ranges from the velvet-like lamp-black to diamond, the hardest of gems. In 1879 it was announced that a method of producing pure crystallized carbon, or diamond, had been discovered in Glasgow. See *Charcoal*.

CARBON TOOL-POINT.—An application of the diamond to mechanical purposes. These points are much used in the armory to point, edge, or face tools for drilling, reaming, sawing, planing, turning, shaping, carving, engraving, and dressing flint, grindstones, whet-stones, emery, corundum, tanite, or tripoli-wheels, iridium, nickel, enamel, steel, hardened or otherwise, chilled iron, copper, or other metals.

CARCAIRE.—The spur of the Middle Ages, composed of a shank, a spur-neck, and a rowel.

CARCAS.—The name given to a quiver during the Middle Ages. Now obsolete.

CARCASS.—In military pyrotechny a hollow case of iron, sometimes globular and sometimes ovate, filled with combustibles. It is fired from a mortar. Its chief use is to ignite buildings in the enemy's quarter, and to give sufficient light to aim the shot and shells. Carcasses are said to have been first used by one of the princely ecclesiastics of Germany, the Bishop of Munster, when he fought against the Duke of Luxembourg at Groll, in 1672. The oval carcasses, being uncertain in their flight, are now nearly abandoned. The round carcasses now made are chiefly those here indicated:

Diameter.	Composition.	Weight.
13 inch	18 lbs.	213 lbs.
10 "	7 "	100 "
8 "	3 "	51 "
5 "	19 ozs.	17 "
4⅗ "	7 "	9 "

In the United States service the composition is the same as for port-fires, mixed with a small quantity of finely-chopped tow, and as much white turpentine and spirits of turpentine as will give it a compressible consistency. The composition is compactly pressed into the shell with the drift, so as to fill it entirely; one of the sticks is then inserted into each fuse-hole with the points touching at the center so that when withdrawn corresponding holes shall remain in the composition. In each hole thus formed three strands of quick-match are inserted and held in place by dry port-fire composition, which is pressed around them. About three inches of the quick-match hangs out when the carcass is inserted in the piece; previously to that it is coiled up in the fuse-hole, and closed with a patch of cloth dipped in melted kit. A common shell may be loaded as a carcass by placing the bursting-charge on the bottom of the cavity, and covering it with carcass-composition driven in until the shell is nearly full, and then inserting four or five strands of quick-match, secured by driving more composition. This projectile, after burning as a carcass, explodes as a shell. See *Case shot*, *Compositions*, *Fire-works*, *Projectiles*, and *Shells*.

CARCHERA.—A name given by the Corsicans to their cartridge-belts. Now little used.

CARDUCHI.—A warlike people once inhabiting the mountains of Kurdistan, supposed to have been the ancestors of the Kurds of the present day. The Greeks, in the famous Retreat of the Ten Thousand, had to pass through their country, and were greatly harassed by them.

CARE OF SMALL-ARMS.—To clean the barrel—1. Draw a rag through the slot in the head of the ramrod; moisten or wet it with water (warm, if it can be had), and pass it up and down through the bore from muzzle to chamber, until all the residuum is removed, or so moistened and dissolved that it may be entirely removed with a dry rag. 2. Replace the wet rag by a dry one, and wipe the bore as before, changing the rag until the bore is perfectly clean; take pains to see that the well of the receiver is carefully wiped and cleaned out, and that the surfaces of the cam and breech-screw are free from dirt, dust, and rust. 3. Wipe the outside of all metal parts, the bore, well of the receiver, and surfaces of the cam and breech-screw with a slightly-oiled rag. 4. To clean the exterior of the barrel, lay it flat on a bench or board, to avoid bending it. Since the arms now issued are browned, abrasive substances, such as emery, tripoli, sand-paper, etc., should *never* be used to clean them. If the browned parts become rusty, they should be rubbed down with a scratch-brush, and then oiled. 5. After firing, the bore should always be wiped with a wet rag as soon as practicable; afterwards wipe it dry, and then pass into it a rag moistened with oil.

To clean the lock—wipe every part with a moist rag, and then a dry one; if any part of the interior shows rust, put a drop of oil on the point or end of a piece of soft wood dipped into *flour* of emery; rub out the rust clean and wipe the surface dry; then rub every part with a slightly-oiled rag. For the mountings, and all of the iron and steel parts, use the scouring material described in the contents of box of *cleaning materials*. Remove dirt from the screw-holes by screwing a piece of soft wood into them. Wipe clean with a linen rag, and leave the parts slightly oiled. In cleaning the arms, great care should be observed to preserve the qualities essential to service, rather than to obtain a bright polish. Burnishing the barrel (or other parts) should be strictly avoided, as it tends to crook the barrel, and also to destroy the uniformity of the exterior finish of the arm. It is very important to use no other implements than those before mentioned. By using nails to drive out the wires their holes are enlarged. The mainspring should never be heated for the purpose of either raising or lowering its temper; this destroys the elasticity of the spring, and the lock no longer explodes the cartridge. The notches of the tumbler, the mainspring-swivel, and, in general, all the joints of the lock, should be frequently oiled, after first wiping off the hard grease and the dust.

Browned arms are cleaned by rubbing them hard with an oiled rag until the oil is well incorporated with the browning, or by rubbing them with beeswax on a rag or cork. Rifled arms should not have the ramrod sprung in the bore with unnecessary force. It batters the head of the rod and wears injuriously the grooves. The soldier should let the rod slide down gently, supported by the thumb and finger; and the inspecting officer can satisfy himself of the condition of the bottom of the bore by gently tapping with the rod. The face of the breech can be polished, after washing, by means of a cork fixed on the wiper or ball-screw; the polished surface can be seen if the muzzle is turned to the light.

Habitual care in handling is necessary to keep arms in good, serviceable condition. In ordering arms on parade, let the butt be brought gently to the ground, especially when the exercises take place on pavements or hard roads. This will save the mechanism of the lock from shocks, which are very injurious to it, and which tend to loosen and mar the screws and split the wood-work. In stacking arms, care should be taken not to injure the bayonets by forcibly straining the edges against each other. The stack can be as well secured without such force being used. No cutting, marking, or scraping in any way the wood or iron should be allowed; and no part of the gun should be touched with a file. Take every possible care to prevent water from getting in between the lock, or barrel, and stock. If any should get there, dismount the gun as soon as possible, clean and oil the parts as directed, and see that they are perfectly dry before reassembling them.

The iron and brass parts of swords and sabers are cleaned in the same manner as those of muskets. When the oil on the blade of a sword is dried up, it will leave a spot which may be removed by covering it with oil, and, after a short time, rubbing it smartly with a linen rag. When a leather scabbard has become wet, draw the blade and dry the scabbard slowly without heating it; wipe the blade dry, and pass an oiled rag over it and the scabbard before returning the blade. Oil the blades of arms in store, also the scabbards, especially on the seams. See *Cleaning Materials* and *Small-arms*.

CARIPI.—A kind of cavalry in the Turkish army, which, to the number of 1000, are not slaves, nor bred up in the seraglio, like the rest, but are generally Moors, or renegade Christians, who have obtained the rank of Horse-guards to the Grand Seignior.

CARMEL.—The Knights of the Order of Our Lady of Mount Carmel were instituted by Henry IV. of France, and incorporated with the Order of the Knights of St. Lazarus of Jerusalem. The Order of Mount Carmel consisted of 100 gentlemen, all French, who were to attend the king in his wars, and had considerable revenues assigned to them. The Order was confirmed by bull by Pope Paul V., in 1607. The Great Master was created by the king putting about his neck a tawny ribbon, suspending a cross of gold, with the Cloak of the Order, and granting him power to raise 100 knights. None were admitted but those who had four descents of nobility both by father and mother.

CAROLING.—A custom of the ancients before going to war, which consisted of singing, etc.

CARPENTRY.—The art of framing timber for architectural and other purposes. Technically, the term is restricted to the framing of heavy work, such as the roofs, floorings, partitions, and all the wood-work concerned in maintaining the stability of an edifice, while the minor and ornamental fittings are called joinery; but popularly the workman who does either kind of work is called a carpenter. The present article will be confined to a popular description of the most useful methods of framing timber and smaller wood-work. The preliminary preparation of timber is the work of the sawyer, who, by the saw-mill or pit-saw, divides the trunks of trees into planks, etc.; these are further divided by the carpenter, who uses hand-saws of various kinds, according to the work. For dividing wood into separate pieces in the direction of the fiber, the *ripping-saw* is used; for cross-cutting, or sawing thin pieces in the direction of their length, the common *hand-saw* or the finer-toothed *panel-saw;* for making an incision of a given depth, and for cutting small pieces across the fiber, the *tenon-saw*, the *sash-saw*, or *dovetail-saw* is used. These are thin saws, stiffened by a strong piece of metal at the back to prevent crippling. When a curved cut is to be made, a very narrow saw without a back, called a *compass-saw* or a *keyhole-saw*, is used. The general name for these is *turning-saws;* they have their plates thin and narrow towards the bottom, and each succeeding tooth finer, and the teeth are not bent on contrary sides of the plate for clearing, as in broad saws. The surface of wood is smoothed by planing. According to the work, different kinds of planes are used: the *jack-plane*, which is large and rough, for taking away the rough of the saw; the *trying-plane*, for bringing the surface perfectly level and true, or the *long-plane*, for the same purpose, where the work is of great length, as for the joining edges of long boards to be glued together. The *smoothing-plane*, which is much smaller than these, gives the smooth finished surface. The *spoke-shave*, a sort of plane with a double handle, is used for paring and smoothing rounded work. Ornamental moldings are cut by means of *molding-planes*, which have their cutting edges curved to the required pattern. A good stock of these is one of the most expensive items of the tool-chest. The paring of wood, and the cutting of rectangular or prismatic cavities, notches, etc., are done by means of *chisels*. Those for cutting across the fiber are called *firmers* or *paring-chisels;* those for cutting deep and narrow cavities, *mortise-chisels*, which are made very thick and narrow, and fitted in the handles with a strong flange, to bear heavy blows with the mallet. Chisels for paring concave surfaces are called *gouges*. For boring holes, *brad-awls*, *gimlets*, *center-bits*, and *gouges* are used—the two latter are fixed in a *stock* or revolving handle, and are used for large holes. When it is required to ascertain if an angle be square, or of any given inclination, the *square*, or the *bevel* set to the required angle, is applied to test the work as it proceeds. When parallel edges are required, the *marking-gauge* is used to draw the line to be worked to. When a simple straight line is required for working to, a piece of string is chalked, then stretched tightly over the wood and lifted in the middle, when, by its recoil, it strikes the wood and leaves a straight chalked line. The *straight-edge*, a strip of wood with one of its edges perfectly straight, is applied to detect superficial irregularities. The operation of planing the edge of a board straight is called *shooting*, and such edges are said to be *shot*. When the joiner requires to ascertain whether the surface of a piece of wood is all in one plane, he takes two slips of wood with edges perfectly straight and parallel, and of equal width; these slips, called *winding-sticks*, are placed edge upwards, one at each end, across the board, and the workman looks in the longitudinal direction of the board over the upper edges, and if the two edges be not in the same plane, the board is planed down at the elevated parts until it is *out of wind*. For setting work level, a *spirit-level*, set in a wooden frame, or a *plumb-level* is used. When two pieces of timber have to be united at their ends, as in lengthening the beams for roofing, partitions, etc., the operation is called *scarfing*, and the joint a *scarf*. The methods of scarfing are very numerous. That shown in Fig. 1 will serve to illustrate the principle, together with the use of strengthening bolts and straps. The length of the scarf should be, if bolts are not used—in oak, ash, or elm, six times the depth of the beam; in fir, 12 times the depth of the beam.

Fig. 1.

If bolts and indents are combined, the length of the scarf should be—in oak, ash, or elm, twice the depth of the beam; in fir, four times the depth. In scarfing beams to resist transverse strains, straps driven on tight are better than bolts. The sum of the areas of the bolts should not be less than one fifth the area of the beam, when a longitudinal strain is to be borne. No joint should be used in which shrinking or expansion can tend to tear the timbers. No joint can be made so strong as the timber itself. When two pieces of timber are connected so that the joint runs parallel with the fibers of both, it is called a *longitudinal joint;* but when the place of the joint is at right angles to the fibers of both, an *abutting joint*. A very short tenon is called a *stub-tenon*. When a second minor tenon is made projecting from the principal tenon, it is called a *tusk-tenon*. For lighter joiner's work, other methods of framing are used, and adapted to the work—to boards generally instead of beams; thus, for example, the mortise and tenon joint, made oblong instead of square, is used in framing doors, shutters, drawing-boards, or any other kind of extended superficial work liable to warping. An outside frame or skeleton is made with a panel or panels in the middle, and each piece of the frame has the grain at right angles to the piece into which it is mortised, in order that they shall eventually correct the warping. Dovetailing is extensively used for

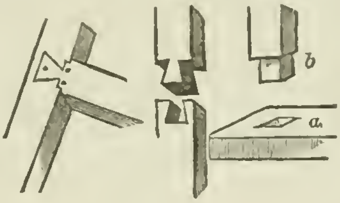


Fig. 2.

connecting boards at right or other angles, as in making boxes, drawers, etc. Common dovetailing is usually glued. Nails or pins and glue are used with the miter and other notched joints. Applications of dovetailing timbers, also the mortise and tenon joint, are shown in Fig. 2. The cavity *a* is the mortise, the projection on *b*, the tenon. The common miter and the lapped miter are shown in Fig. 3. Boards may be united at their edges to form an extended surface, as a flat plank partition, etc., either by simple gluing of the shot edges, by a *rebate*, or by a plowed groove and a plain corresponding projection. The rebate is cut by means of a rebating-plane. The groove, a sort of extended mortise, is cut by a plane with a projecting iron called the *plow*. In all cases where glue is used in joints, it should be applied to both surfaces, which should be rubbed and pressed together until nearly all the glue is forced out, then kept pressed by a cramp or weights. White-lead is used for outside joints. Special departments of this subject are treated under their respective heads.

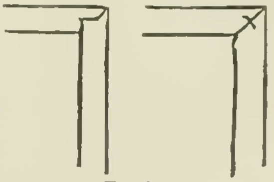

Fig. 3.

CARPET-KNIGHT.—A man who obtains knighthood on a pretense for services in which he never participated.

CARQUOIS.—A quiver of iron, wood, leather, etc., which was worn slung over the right shoulder.

CARRAGO.—A kind of fortification, consisting of a great number of wagons, placed round an army. It was employed by barbarous nations, as, for instance, the Scythians and Goths.

CARREAU.—A bolt or dart, with a large steel head, for a cross-bow. Commonly written *Carre*, *Carrel*, and *Quarreau*.

CARRIAGE-BRIDGE.—A roller-bridge to be moved up a glacis and form a bridge from counterscarp to scarp, for the passage of the attacking column. It has beams and uprights. The latter act as posts, to rest on the bottom of the ditch, and are shiftable to adapt them to the depth of the ditch or fosse.

CARRIAGE DEPARTMENT.—The Royal Carriage Department, at Woolwich, is one of the great national manufacturing establishments maintained for warlike armaments—its duty being the construction of gun-carriages for army and navy, military wagons and vehicles of all kinds, and the joinery of the army generally. The Department was organized as a distinct establishment in 1803, and has been undergoing gradual enlargement ever since. Since the recent introduction of iron carriages for heavy guns, the Department has had a new section added for iron-work. Until 1855 the Board of Ordnance had the direction of this Department, but in that year it passed under the direct control of the Secretary for War, who, since 1869, administers it through the Surveyor-general of the Ordnance. The works, store-rooms, and yards are of vast size, often employing from 2000 to 3000 hands. There are many steam-engines in various parts of the establishment; and the iron and wood cutting and shaping machines are of the highest order of excellence. The internal communications are carried on by locomotives on a tramway of 18-inch gauge. See *Gun-carriages*.

CARRIAGES.—A gun-carriage is designed to support its piece when fired, and also to transport cannon from one point to another. Field, mountain, and siege artillery have also limbers, which form when united with the carriage a four-wheeled vehicle. Sea-coast carriages are divided into *barbette*, *casemate*, and *flank-defense* carriages, depending upon the part of the work in which they are mounted. They are now made of wrought-iron and found to possess lightness, greath strength, and stiffness. The sea-coast carriages are made in a similar manner, and one carriage can be altered to fit another piece by changing the trunnion-plates and transom-straps. The carriage consists of two cheeks of thick sheet-iron, each one of which is strengthened by three flanged iron plates bolted to the cheeks. Along the bottom of each cheek an iron shoe is fixed with the end bent upwards. In front this bent end is bolted to the flange of the front strengthening-plate. In rear the bent portion is longer, and terminated at top by another bend, which serves as a point of application for a lever on a wheel, when running to and from battery. The trunnion-plates fit over the top ends of the strengthening-plates, which meet around the bed, and are fastened to the flanges of the latter by movable bolts and nuts. The *cheeks* are joined together by transoms made of bar-iron. The front of the carriage is mounted on an axletree, with truck-wheels similar to the wooden casemate-carriages. The elevating-screws are of two kinds: one for low angles of elevation, and the second for columbiads where great angles of elevation are required. The elevating arc is made of brass and attached to the upper edge of the right cheek, and may be folded down. It is employed to measure the elevation of the piece.

The very diverse purposes for which military carriages are intended necessitate many varieties of form, as may be seen in the carriages of the field and siege artillery, of the ponton and telegraph equipments, of the transport and ambulance services, etc. The many varieties may be classed under one of two heads, viz.: 1. Those used in the transport of stores; 2. Those which, besides fulfilling the usual functions of a carriage, are especially adapted to facilitate the working of field- and siege-guns. For a description of the carriages of the second class, see the various artillery-carriages. The component parts of the transport-carriages are the following: Axletree (*arms* or *axletree-arms*, *linch-pin*, *body*, *shoulder*, and *point*); axletree-bed; splinter-bar; futchells; sweep-bar; fore-carriage; body (*frame-sides*, *front car-bed*, *hind car-bed*, and *summers*); bolsters; main-pin; stays; knees; sweep-plate and wheel-plate; shaft-irons; scroll-irons; sides, headboard and tailboard; floating raves; and wheels (*nave*, *nave-bands*, *nave-box* or *pipe-box*, *spokes*, *felloes*, and *tire*). In the construction of all carriages the following conditions should be realized: Adaptability of form to the load (including convenience in loading, as well as suitable capacity); strength; stability; durability; ease and convenience of draught; suitability for shipment; facility of repair; and economy of manufacture. The ease of draught is chiefly affected by the following considerations: Weight of carriage and load; height of wheels; mean diameter of pipe-box; degree of smoothness of the surfaces of arm and box, and the quality of the lubricants applied to them; width of tire; position of trace-loops, and inclination of the traces; and the presence or absence of springs. The width and length of carriages should be limited by considerations of convenience in turning and *passing* along narrow roads and other confined spaces. See *Chassis* and *Gun-carriages*.

CARRICK.—An old Gaelic term for a castle or fortress, as well as for a rock in the sea.

CARRICK-BEND.—A knot formed on a bight by putting the end of a rope over its standing part, so as to form a cross: reeve the end of the other rope through the bight, up and over the cross and down through the bight again, on the opposite side from the other end. See *Cordage*.

CARRIER-BLOCK.—A component part of most machine-guns. Directly behind the open barrels a hollow cylinder of metal, called a *carrier-block*, is fastened to the shaft, and in the exterior surface of this carrier-block semi-cylindrical channels are cut, which form trough-like extensions of the cartridge-chambers of the barrels to the rear, and are designed to receive and guide the cartridges while they are being thrust into the barrels, and to guide the empty cases while they are being withdrawn. This block is covered above the frame by the *hopper-plate*, and beneath everything is open. See *Gatling Gun*.

CARRIER-PIGEON.—The term *carrier*, as applied to pigeons, evidently was first employed to signify those breeds that were used to convey or carry messages to their own homes from distant places. In the process of time it has been used by English fanciers to signify a very artificial or high-class breed, the birds of which are never employed for carrying messages, but are valued solely in proportion to the perfection of certain "properties" that they possess. This is an unfortunate circumstance, for by the public at large the term *carrier* is always taken to express the fact that the birds to which it is applied are really those employed to "carry" messages; whereas the long-distance-flying birds, those known more correctly as "homing" birds, or "les pigeons voyagers," are totally distinct. See *Homing Pigeon*.

CARROCCIO.—A very large four-wheeled carriage, which was used by the Crusaders during the Middle Ages. On its platform, which was large enough to hold fifty persons, was erected a tower surmounted with a cross, and a standard, and to it was attached a bell which indicated the passing of the carroccio. Before engaging in battle, an effigy of Christ of life size was placed on the platform, and at its feet an altar; then a mass was held. A number of knights guarded it, and it was drawn by oxen richly caparisoned. Its invention is attributed to the people of Lombardy.

CARRONADES.—Short iron guns invented by Mr. Gascoigne, and named after the Carron Iron-works in Scotland, where they were first made. They are lighter than ordinary guns, and have a chamber for powder, like mortars. They were made standard navy guns in 1779, to be carried on the poop, forecastle, and upper works. Being manageable by a smaller number of hands than guns, and being very useful in close engagements, they were held in much favor during the great war: the seamen called them "smashers." A 68-pounder carronade weighed not much more than half as much as the 42-pounder gun in use in 1779. They range from 68-pounders down to 6-pounders. Some carronades are made shorter with a given bore. Carronades are but little used, except by the English and French. Though valuable at close quarters, they are no match for long guns at a distance; and therefore a ship armed only with carronades would fare badly in a general action. In recent years carronades have to a considerable extent been replaced in the English navy by howitzers, long guns, and shell-guns. See *Ordnance*.

CARROUSEL. — A species of knightly exercise which, down even to the beginning of the eighteenth century, was very common in all the courts of Europe. Carrousel was a kind of imitation of the tournament, and for a time after the discontinuance of the latter seems to have supplied its place. The dresses, for the most part, were those of the knights of former times, and the combatants, or rather competitors, were divided into two parties, usually according to their different nationalities. One of the favorite exercises in France consisted in running at the pasteboard head of a Moor or Turk with a lance, cutting it down with a sword, or firing at it with a pistol. Another of these tests of skill and horsemanship, if not of courage, consisted in carrying off a whole line of rings, which were suspended for the purpose. The carrousel in France was not known earlier than the reign of Henry IV.; but it had existed for some little time previously in Italy. There were brilliant carrousels under Louis XIII., and two celebrated ones were given in honor of Mademoiselle de la Vallière—the one at Paris in 1662, the other at Versailles in 1664. The place where the first of these fêtes was held has ever since been called the Place du Carrousel. A revival of the carrousel was attempted at Berlin in 1750; and in 1828 the Cavalry School at Saumur held one in honor of Madame la Duchesse de Berry. The so-called Eglinton Tournament — an entertainment given some years ago by the chivalrous Earl of Eglinton — was in reality a carrousel.

CARRY ARMS.—A word of command in the Manual of Arms, directing that the musket be taken to the fundamental position, which consists of the piece being held in the right hand; the barrel nearly vertical, and resting in the hollow of the shoulder, the guard to the front: the arm hanging nearly at its full length, near the body, the thumb and forefinger embracing the guard, the remaining fingers closed together and grasping the stock just under the hammer, which rests on the little finger. See *Manual of Arms*, Fig. 1.

CART.—A framework of wood, with sides, front and end boards, placed upon two wheels, and drawn by one or two horses. In the artillery, carts are very generally used. A new-pattern cart was introduced a few years ago into the English service for the carriage of small-arm ammunition in the field. There are about eighteen carts in service of different patterns and for various purposes. See *Hand-cart*.

CARTE.—A movement of the sword in fencing, as tierce and carte. Also a movement in the bayonet-exercise. Frequently written *Quarte*. See *Fencing*.

CARTE-BLANCHE.—In a military sense, a full and absolute power which is lodged in the hands of an officer to act according to the best of his judgment, without waiting for superior instructions or orders. It likewise strictly means a blank paper sent to a person, to fill up with such conditions as he may think proper to insert. In the general acceptation of the term, it implies an authority to act at discretion.

CARTEL.—An agreement between the belligerents for an exchange of prisoners. Sometimes the name is given to a ship, called by the French a *bâtiment parlementaire*, commissioned to convey the exchanged prisoners, or to carry messages to the enemy. A ship, when thus employed, must carry no cargo, ammunition, or implement of war, except one gun for signals.

The following may be taken as a form of the *cartel*, the provisions being liable to modification, according to agreement, by the agents appointed by the proper authorities:

The undersigned, having been commissioned by the authorities they respectively represent to make arrangements for a general exchange of prisoners of war, have agreed to the following articles:

Article 1. It is hereby agreed and stipulated that all prisoners of war held by either party, including those taken on private armed vessels known as privateers, shall be discharged upon the conditions and terms following:

Prisoners to be exchanged man for man and officer for officer; privateers to be placed upon the footing of officers and men of the Navy.

Men and officers of lower grades may be exchanged for officers of a higher grade, and men and officers of different services may be exchanged according to the following scale of equivalents:

A General commanding-in-chief or an Admiral shall be exchanged for officers of equal rank or for sixty privates or common seamen.

A Major General or Flag Officer shall be exchanged for officers of equal rank or for forty privates or common seamen.

A Brigadier General or a Commodore carrying a broad pennant shall be exchanged for officers of equal rank or for twenty privates or common seamen.

A Colonel or a Captain in the Navy shall be exchanged for officers of equal rank or for fifteen privates or common seamen.

A Lieutenant Colonel or a Commander in the Navy shall be exchanged for officers of equal rank or for ten privates or common seamen.

A Major or a Lieutenant Commander shall be exchanged for officers of equal rank or for eight privates or common seamen.

A Captain in the Army or Marines or a Lieutenant or a Master in the Navy shall be exchanged for officers of equal rank or for six privates or common seamen.

Lieutenants in the Army shall be exchanged for officers of equal rank or for four privates or common seamen.

Midshipmen, Warrant Officers in the Navy, Masters of merchant-vessels, and Commanders of privateers shall be exchanged for officers of equal rank or for three privates or common seamen.

Second Captains, Lieutenants, or Mates of merchant-vessels or privateers, and all petty officers of the Navy and all non-commissioned officers in the Army or Marines, shall be severally exchanged for persons of equal rank or for two privates or common seamen; and private soldiers or common seamen shall be exchanged for each other, man for man.

Article 2. Local, State, civil, and militia rank held by persons not in actual military service will not be recognized, the basis of exchange being the grade actually held in the naval and military service of the respective parties.

Article 3. If citizens held by either party on charges of any alleged civil offense are exchanged, it shall only be for citizens. Captured sutlers, teamsters, and all civilians in the actual service of either party, to be exchanged for persons in similar position.

Article 4. The surplus prisoners not exchanged, if paroled, shall not be permitted to take up arms again, nor to serve as military police or constabulary force in any fort, garrison, or field-work held by either of the respective parties, nor as guards of prisons, depots, or stores, nor to discharge any duty usually performed by soldiers, until exchanged under the provisions of this cartel. The exchange is not to be considered complete until the officer or soldier exchanged for has been actually restored to the lines to which he belongs.

ARTICLE 5. Each party, upon the discharge of prisoners of the other party, is authorized to discharge an equal number of their own officers or men from parole, according to the scale of equivalents already agreed upon, furnishing at the same time to the other party a list of their prisoners discharged and of their own officers and men relieved from parole—thus enabling each party to relieve from parole such of their own officers and men as the party may choose. The lists thus mutually furnished will keep both parties advised of the true condition of the exchange of prisoners.

ARTICLE 6. The stipulations and provisions above mentioned to be of binding obligation during the continuance of the war, it matters not which party may have the surplus of prisoners, the great principles involved being—1st. An equitable exchange of prisoners, man for man, officer for officer, or officers of higher grade exchanged for officers of lower grade, or for privates according to the scale of equivalents; 2d. That privateers and officers and men of different services may be exchanged according to the same scale of equivalents; 3d. That all prisoners, of whatever arm of service, are to be exchanged or paroled as soon as it is practicable to transfer them to their own lines; 4th. That no officer, soldier, or employé in the service of either party is to be considered as exchanged and absolved from his parole until his equivalent has actually reached the lines of his friends; 5th. That the parole forbids the performance of field, garrison, police, or guard, or constabulary duty.

ARTICLE 7. For the purpose of carrying into effect the foregoing articles of agreement, each party will appoint two agents, to be called agents for the exchange of prisoners of war, whose duty it shall be to communicate with each other, by correspondence and otherwise, to prepare the lists of prisoners, to attend to the delivery of the prisoners at the places agreed on, and to carry out promptly, effectually, and in good faith all the details and provisions of the said articles of agreement.

ARTICLE 8. In case any misunderstanding shall arise in regard to any clause or stipulation in the foregoing articles, it is mutually agreed that such misunderstanding shall not interrupt the release of prisoners on parole, as herein provided, but shall be made the subject of friendly explanations, in order that the object of this agreement may neither be defeated nor postponed. See *Exchange of Prisoners*, *Parole*, and *Prisoners of War*.

CARTEL-SHIP.—A vessel used in exchanging prisoners or carrying proposals to an enemy. See *Cartel*.

CARTHOUN.—The ancient cannon-royal, carrying a 66-pound ball, with a point-blank range of 185 paces, and an extreme one of about 2000. It was 12 feet long and of 8½ inches diameter of bore.

CARTOUCH.—1. A roll or case of paper, etc., holding a charge for a fire-arm. 2. In gunnery, a case of wood about 3 inches thick at the bottom, bound about with marline, holding about 400 musket-balls, besides 8 or 10 iron balls of a pound each, to be discharged from a howitzer for the defense of a pass, etc. 3. An article of leather to sling over the shoulder of the gunner, who therein carries the ammunition from the tumbril for the service of the artillery when at exercise in the field.

CART-PIECE.—An early battering cannon mounted on a peculiar cart, and thus moved from place to place.

CARTRIDGE.—The requirements of a good service-cartridge are strength, durability, uniform dimensions, and cheapness. Its power should be stored up in as small a space as possible, that a soldier may carry a maximum number of rounds with a minimum effect upon his endurance. It must possess certainty of fire combined with uniform accuracy, range, and penetration. After firing, the shell must be easily extracted from its chamber. To unite all these qualities the greatest care is required in the different processes of manufacture. The materials from which the component parts of the cartridge are made, which are the shell, the primer, the powder, the bullet and lubricant, must be of the best quality. A variation of .001 inch in the thickness of the metal disk from which the shell is drawn, from standard dimensions, produces waste of material and unnecessary wear upon the tools if above the standard, and other complications if below. The priming or explosive compound for igniting the cartridge must be made with such care and of such ingredients as will almost absolutely insure ignition from a blow of calculated strength upon the cup or cap containing it. The component parts of the powder must be sufficiently pure that when incorporated, pressed, and grained, its density may be so nearly constant that a fixed charge will give a nearly constant initial velocity to the bullet, producing a corresponding constant range and accuracy under like conditions of the atmosphere. Electric ballistic machines readily determine the initial velocity, enabling us, by slight variations of the charge, to keep that velocity practically a constant quantity, thus solving the problem of a cartridge with a measured or fixed amount of work stored up in it to be given out with deadly effect when needed. This is the state of perfection to which the cartridge is now made.

The cartridge-cases for ordnance or large guns are chiefly made of serge and flannel, sewn up into the form of a bag, which, supplied with a given weight of powder, is tied round the neck and strengthened by iron hoops. The weight of powder varies from about 300 lbs. for an 81-ton gun, to a few ounces for a mountain-gun.

Cartridges for small-arms which load at the muzzle are usually paper tubes, containing a leaden ball and a few drams of powder. The tubes are made in such a way that the powder has two or three thicknesses of paper around it, while at the mouth of the tube and over the bullet there is only one. The paper over the bullet is lubricated generally with a composition of beeswax and tallow. In loading, the paper at the mouth of the tube has to be twisted or bitten off; the powder is then poured into the barrel, the tube reversed, and the bullet inserted into the muzzle, and the tube broken away. Cartridges for breech-loading small-arms in England are generally formed of a thin sheet of brass coiled into a cylinder, and having an iron case, in the center of which is the percussion arrangement. Besides the cartridge-case of coiled brass, there are others made of solid brass or copper (American invention), and these seem to be gaining favor abroad, the Prussians having adopted such a case for the new Mauser rifle.

For sporting rifles the cartridges are quite numerous and varied. With large-bore rifles the same cartridge-case is generally used as for shot-guns, but loaded with powder and ball (spherical, solid conical, hollow conical, or shell). For small-bore, or what are known as *express* rifles, either a coiled brass cartridge-case, similar in construction to that for the Snider or Martini-Henry rifle, but made to contain a larger charge, or a solid brass case is used. The coiled case can be reloaded twice or thrice, while the solid case can be reloaded as often as twenty times, and on this account the latter is rapidly gaining favor with sportsmen in India and Africa. The express cartridge contains a very heavy charge of powder, with a light hollow conical bullet giving very great velocity, low trajectory, and immense killing power. In the Henry express cartridge the charge of powder is 4 drams, while the bullet weighs only 270 grains.

Cartridges for breech-loading pistols and revolvers are generally small metal cylinders containing a charge of powder and a bullet, and with rim, pin, or central-fire ignition, the diameter varying from .230 of an inch upwards.

In the manufacture of metallic cartridges the United States leads the world. Besides the various patterns described under other headings in this work, the United States Cartridge Company, of Lowell, Mass., make a specialty of the central-fire solid-head reloading cartridges, of which some full-size varieties are shown in the drawings. This Company commenced operations in the year 1869, having for its object the manufacture of the Meigs solid-head metal upset by heading joined, rupture was liable to take place. These difficulties have been entirely overcome by the new method of manufacture; and since its introduction, and during the manufacture and trial of several millions, not one shell has been ruptured by firing, nor has a gun been impeded by any failure. During a remarkable test by the United States Navy Department, of firing 100,000 cartridges consecutively in the Gatling gun, not a single

Central-fire Solid-head Reloading Cartridges.—Rifle.

cartridge, which could not be burst or ruptured by any possible charge of powder, and which could be depended upon at all times for rapid firing in magazine, repeating, and ordinary guns. New and improved machinery, the result of extensive, exhaustive, and costly experiment, was erected. By the usual failure occurred which prevented the operation of the gun for a second, although 64,000 rounds were fired in a single day, without stopping to clean the gun.

This method of manufacture has been fully developed and perfected by this Company, and the cost is but little more than the usual one. This cartridge

Central-fire Solid-head Reloading Cartridges.—Pistol.

method of manufacture, good cartridges were made, yet when fired they frequently failed, bursting near the head, or around the body of the shell near the head, clogging the gun or endangering the user. After long and careful examination, study, and experiment, it was discovered that part of the metal of the shell at or near the head, as hardened by the usual process of drawing, was rendered brittle and completely demoralized by the then known process of heading, and when this hard-drawn metal and the is of the reloading type, and the method of priming has been brought to such great perfection that during the trial above referred to but two primers failed to explode in firing 100,000 rounds. During the experience of this Company very many of the great number of primers which have been introduced have been tested and abandoned, and not until the one now in use was invented was any primer found which could be relied upon under all conditions. In this primer the anvil is firmly secured directly in line with the firing-pin, and the fulminating-compound is fully protected from displacement and injury. The merits claimed for this cartridge are: great strength and non-liability to rupture; adaptability to reloading; ease of extraction; certainty of fire, and water-proof. See *Ammunition, Blank Cartridge, Center-fire Metallic-case Cartridge*, and *Reloading-cartridges*.

CARTRIDGE-BAGS.—Cartridge-bags are made of two shapes: conical, for gomer chambers, and cylindrical, for other ordnance. The cartridge-cloth from which the bags are made is woven expressly for the purpose, being entirely of wool, and of close and uniform texture. It is manufactured in pieces varying in width from sixteen to thirty-six inches; the different widths being adapted for the several lengths of cylinders to save waste in cutting. Cartridge-bags for cylindrical chambers are made of a rectangle to form the cylinder, and a circular piece to form the bottom. The flat patterns are consequently to be made rectangular for the cylindrical part of the bag, and circular for the bottom. The length of the rectangle is equal to the development of the cylinder, together with the allowance for seam; and its width, to the whole length of the bag before sewing, including the allowance for seam and tie. Special patterns are furnished for those of 15-inch, 11-inch, and 9-inch guns. Cartridge-bags for gomer-chambered ordnance are made conical in shape, and out of two pieces. In cutting, the length of the rectangle should be taken in the direction of the length of the stuff, as it does not stretch in that direction, and the material should be chosen, as nearly as possible, of the width required for the length of the bags, to save waste in cutting.

The cartridge-bags for field and mountain service are made as follows: A marker and assistant spread out the cloth on the table in two thicknesses, and make it fast at each end of the table on three or four hooks driven in the ends of the tables, or by means of weights, drawing it sufficiently to take out the folds, and no more. They mark out the rectangles and bottoms with the patterns and ruler, so disposing and combining them as to cut the cloth to the best advantage. The length of the rectangle (development of the cylinder) should be taken in the direction of the length of the stuff, as it does not stretch in that direction. The selvage, if there be any, ought to be at the mouth of the bag. The cutter takes a piece thus marked to another table, and cuts out the rectangles and bottoms with a pair of shears. The bottoms may be cut out with a hollow punch of the proper size. Marks for the seam are traced on the rectangles and bottoms by means of patterns of the proper size. The seam should be at least a half-inch from the edge. The bag is sewed with woolen yarn, with a back-stitch, 12 to the inch. The edges are turned down on the same side of the seam and basted, to prevent the powder from sifting through; the edges of the bottom are basted down upon the sides. Bags may be sewed advantageously by the sewing-machine. Bags for fixed ammunition are sewed to within three inches of the mouth for 12-pounders; all others up to the mouth. A bag is given as a model to sew by.

Cartridge-bags, when filled, should pass through the small shot-gauge of their caliber; those used for patterns should be thus verified. The empty bags should be measured by laying the bag, flattened out, between two marks on a table, showing the width of the pattern-bag; a variation of .1 inch greater or less is allowed. Those sewed with too large stitches are rejected.

Bags for practice or blank cartridges may be formed by sewing together two rectangular pieces with semicircular ends; the cloth is marked for cutting and sewing, with stamps made of 1-inch boards of the dimensions of the cutting-stamp, with a strip of tin or copper fastened to the edge of the board, and projecting about ¼ inch perpendicular to the side; another strip, parallel to the first, is inserted in a groove ½ inch from it; the edges of these strips are made rough to retain chalk or paint used in marking. A handle is placed in the middle of the face opposite to the marking-strips. Width of cutting-stamp for 12-pounder, 7.6 inches; length, including semicircular ends, for 12-pounder, 10.5 inches.

Cartridge-bags are preserved from moths by being packed with pounded camphor and black pepper, or dipped in water with arsenic dissolved in it, or a solution of sulphate of copper, 1 pound of sulphate to 25 pounds of water; or they may be sealed up in bundles of fifty in cases made of cartridge-paper, carefully closed with strips of thin paper pasted over the seams. Each bundle is marked with the number and kind of bags. They may be preserved from moisture by being enveloped in water-proof paper.

The charge of powder for siege and garrison guns is inclosed in a cartridge-bag made of merino, raw silk, serge, cotton, or paper, or of paper with woolen bottoms. Bags made of woolen or silk materials are preferable, as they are not so liable to leave fire in the guns, and are more durable; but they are much more costly. *Merino or cotton bags* are cut in two pieces, in the form of a rectangle, with semicircular ends, and sewed together to form the bag, as described in making bags for field-service.

The paper for *paper bags* is cut into rectangles to form the cylindrical part of the bag, the length of the rectangle being the development of the cylinder, allowing .5 inch on each side for the lap, and into circles for the bottoms. The sides of the rectangle are lapped and sewed with woolen yarn; one end of the bag is slit with longitudinal cuts, 1 inch long, .75 inch apart, and these strips are pasted on the paper bottom over a cylindrical form; or a circular piece of merino is sewed in the end of the paper bag, forming the bottom. To close a paper bag after being filled, the open end is folded down about .75 inch wide, and this fold is rolled on itself down to the powder, and the part which projects beyond the cylinder is turned in on the top of it. Two turns are taken with strong twine around the cartridge in the direction of its length, 90° apart, and then tied.

For mortars, cartridge-bags may be made in the same way as for guns, their dimensions corresponding to those of the chamber of the mortar. But as the charge is generally poured loose into the chamber, the bag being used only for carrying it to the mortar, a gun cartridge-bag of any convenient size may be used for mortar-service.

For ricochet firing, or other occasions when very small charges are required, a cartridge-bag for a piece of an inferior caliber may be used. Or else, after the charge is poured into the bag, place on it another bag filled with hay, pressing it with the hands to reduce the diameter; after having shaken this bag down and rolled and flattened the empty part of the two bags, tie them with woolen yarn, like a bundle of musket-cartridges, placing the knot on top.

For proving ordnance, cartridge-bags may be made of cotton cloth. They should be of the full diameter of the bore or chamber.

For hot-shot, cartridge-bags should be made double by putting one bag within another. The charge ought not to exceed three fourths the service-charge, for in consequence of the expansion of the shot the windage is reduced, and a greater strain will be exerted on the metal of the gun. The expansion of the gas will also be increased by the heat generated within the bore; and, moreover, very great penetration is not required, the object to be attained being that the shot shall merely lodge in the timber See *Ammunition*.

CARTRIDGE-BELT.—A belt for carrying small-arm cartridges. A form extensively used in the Western United States, called the *prairie-belt*, has a number of leather or canvas loops sewed on the outside in which the cartridges are stuck.

CARTRIDGE-BLOCK.—A contrivance for more readily supplying ammunition when firing rapidly or when it is not convenient to go to the cartridge-box for cartridges, in certain situations. Cartridge-blocks are usually made detachable, and are made fast to the piece when desirable. See *Benton*, *Hare*, and *Metcalfe Cartridge-blocks*.

CARTRIDGE-BOX.—A leathern case, with cells for cartridges, which are protected by a flap of leather. This box is either suspended by a leathern strap, which passes over the left shoulder and under the right arm of the wearer, or is attached to the waist-belt, as in the United States service.

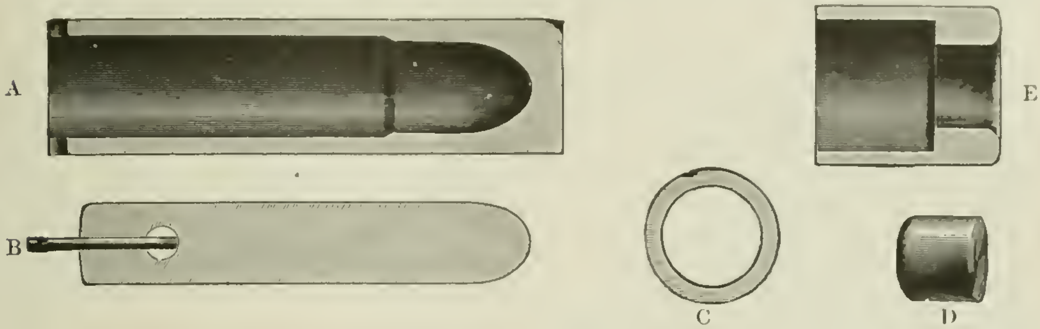
CARTRIDGE-GAUGES.—Gun-metal rings of the required size, with a handle to each gauge, on which is stamped the nature and size of the cartridge. There are two kinds: one for testing the diameter of the filled cartridge, the other for showing the length of the cartridge.

CARTRIDGE-LOADER.—An apparatus for loading cartridge-shells. The drawing represents a complete cartridge-loader, combining in one compact and portable machine all the various implements employed in loading paper or metallic shells, viz.: powder and shot reservoir and gauges, rammer, wad-starter, shell-cutter, and crimper.

This machine loads very quickly, and during the operation of loading the cartridges the powder is inclosed in a covered reservoir. The cartridges are loaded uniformly, and the wads squarely placed, thus improving the shooting of the gun. An adjustable shelf adapts the cartridge-receiver to loading shells of any length. The machine can be carried in a gun-case, occupying smaller space than the paraphernalia in general use. No practice is required to make it perfect in its use, and there are no complicated parts liable to get out of order. All the parts are in one, and the loss by the separation of any, and danger of breakage, are thus reduced to a minimum.

The accuracy with which the powder is measured will be best understood when it is stated that fifty charges being cut off in one tray of the most sensitive scale, and fifty in the other, no difference can be detected in the balance, the equipoise being perfectly preserved. The machine is not simply a combination of old parts, but embodies several new inventions. The device for cutting shells disposes of the rings which form upon all other knives to the inconvenience of the operator; and by the lever employed in crimping no lateral motion is imparted to the shell, and a shell only an inch in length can be closed or turned over if desired. See *Reloading Implements*.

CARTRIDGE-LOADING IMPLEMENTS.—The implements used in reloading cartridge-shells. These are variously constructed. A tool for *recapping* and *reloading*, of very light weight, manufactured by the United States Cartridge Company, has been used with much success both in our army and abroad. Its parts are shown in the drawing. A is the crimping-die and ball-seater, cut open; B is the cap-extractor;



Recapping and Reloading Tool.

C is the collar; D is the capping-punch; and E is the safety-block, cut open.

To cap the shell, place the collar upon it and insert the shell into the long die or ball-seater and crimper. Put the cap in the pocket by hand, then place the safety-block down over the shell and die. Put the capping-punch through the hole in the safety-block, the solid end resting upon the cap, and force the cap home by striking upon the end of the punch with the hammer. The convex surface on the capping-punch is for the purpose of forcing the cap *below* the surface of the head of the shell.

To load the shell, remove the safety-block and take the collar from the shell; fill the shell with the required amount of powder, drop a ball into the ball-seater, and place it over the shell. Then insert the head of the shell into the safety-block, taking care to remove the capping-punch from the hole in the block to prevent the premature discharge of the cartridge, and force the ball home by striking upon the end of the ball-seater with the hammer. At the same time the ball is driven home the end of the shell is crimped, and upon removal from the tools the cartridge is ready for use.

After firing the cartridge, to remove the exploded cap, place the head of the shell in the safety-block and insert the cap-extractor in the shell, the small pin will pass through the vent-hole in the shell, and a light blow will remove the cap. Should the loaded cartridge stick in the ball-seater, it can be easily started by inserting the pin in the end of the cap-extractor in the slot in the end of the ball-seater under the flange of the shell. As the collar is only necessary in recapping those shells that are crimped upon the ball, none are used with tools for shells that do not require crimping.

With all reloading tools for straight tapered shells a reducing-die is generally employed to restore the shell to its original size and shape. None are made for straight or bottle-necked cartridges. Moisten the shell slightly with oil, to prevent it from sticking in the die; enter the shell at the large end of the die; place the safety-block over the head of the shell, and drive the shell down into the die by striking on the end of the block with the hammer.

To extract the shell from the die, hold the die firmly in the hand with the head of the shell down; insert the hollow end of the extractor in the mouth of the shell, and strike several quick blows on the rounded end. To reduce the shell easily it will be necessary to let the end of the die rest upon a firm foundation. See *Reloading Cartridges*.

CARTRIDGE-PAPER.—A strong paper of which cartridges are made. It comes of various sizes and thicknesses, according to the kind of cartridge to be made, ranging from a quality similar to bank-note paper, employed for small-arm cartridges, to that used for cannon-cartridges, which is about the thickness of thin pasteboard, but rougher and more flexible. The latter is, however, now seldom or never used. The different qualities are in the United States service numbered from 1 to 6, the latter being the coarsest and thickest.

CARTRIDGE-PRIMER.—The percussion-cap used in loading metallic cartridge-cases, and set in a recess in the head of the shell. When the firing-pin strikes the outside end of the cap, the fulminate is exploded by being driven against a perforated cone called the anvil, which is usually a part of the shell. In the Winchester primer, recently invented, the anvil is a part of the primer itself, being inserted upon the fulminate. A shoulder in the recess holds the anvil when the cap is struck. The Frankford Arsenal cartridge-primer is designed and manufactured as a component of the solid-head reloading cartridge, which has a pocket, formed in the exterior of the base of the shell, to receive and securely hold the primer. It is essentially a revival of the percussion-cap, which served for many years as an adjunct to muzzle-loading small-arms, and now, modified in its

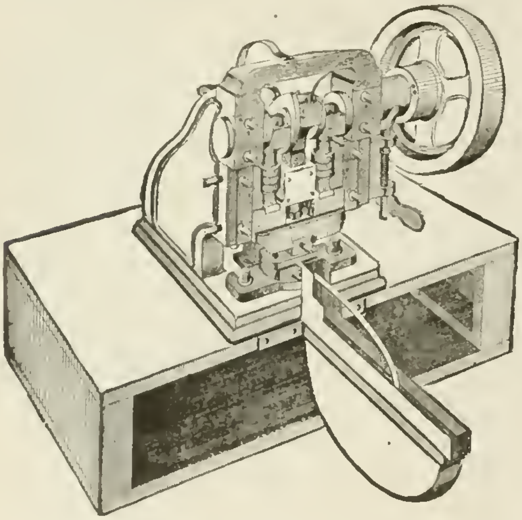


Fig. 1.

form, construction, and application, fills an equally important purpose in the modern breech-loader, being an integral part of the cartridge, instead of a detached auxiliary to the arm. It consists of a copper cap containing a pellet of fulminating-composition, protected by a disk of tinfoil, and a copper anvil, so formed as to permit the flame from the fulminating-composition to pass, through a vent in the pocket of the cartridge-shell, to the powder-charge, and at the same time afford resistance to the blow of the firing-pin of the arm, which explodes the fulminate. The primer-cap is formed, charged, and dried before the anvil is inserted. When the two are assembled the complete primer is ready for insertion in the pocket of the shell, prior to loading the latter with powder and bullet. The materials entering into its composition are as follows:

Materials.	Components.
Sheet cartridge copper......	Primer-cap.
Fulminating composition....	Primer-cap.
Tinfoil....................	Primer-cap.
Cartridge copper wire.......	Primer-anvil.

The sheet cartridge-copper is received from the manufacturers in the form of a ribbon, about 50 feet long, from .36 to .37 inch wide, and from .025 to .027 inch thick, coiled for automatic feeding to the machine which forms the caps. The blanks for the caps are cut from the sheet-metal ribbon as disks and formed into caps by a double-action press represented in Fig. 1, the disk being cut by a die and hollow punch, and pushed through the die to form a cap by another punch following it down through the hollow one. This machine is automatic, requiring attention only when a ribbon is cut up and is to be replaced with another. The skeleton or scrap ribbon is also cut into short pieces by the machine, to facilitate its packing and return as scrap to the manufacturer. The metal ribbon having been oiled to facilitate the formation of the caps, they must be washed in an alkaline solution to remove every trace of oil, which, if present, would destroy the fulminate. After washing and drying, the caps are varnished on the interior surface of the base, to protect the fulminate from injurious chemical action with the metal, and to assist in attaching and sealing it in place. A solution of gum shellac in alcohol, four pounds of the former to one gallon of the latter, constitutes the varnish used. The varnishing-machine (Fig. 2) consists of an iron bed-plate and two uprights, upon which a cross-

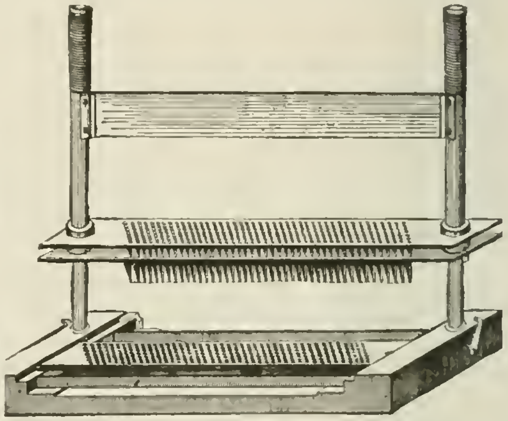

Fig. 2.

head, carrying a gang of wire pins, moves vertically over a vessel containing the varnish. Just above the varnish-pan the bed-plate is grooved to receive and adjust accurately, under the gang-pins, a plate containing the caps, in receptacles arranged in rows corresponding to the pins. The plate is filled by shaking it, with a handful of caps placed over the receptacles, with a horizontal motion. The caps settle into the receptacles, open end up generally, and the surplus caps are shaken off. The filled plate is inspected, and any caps requiring it are reversed by the aid of a forceps. The caps remain in the plate until they are charged, inspected, and ready for removal to the drying-room. A plate holds 326 caps, and a tally is kept of each plateful, to keep account of the number of caps completed. In varnishing, the ends of the pins are made to dip into the varnish by lowering the cross-head to a stop. When it is lifted each pin carries a drop of varnish. The plate of caps is pushed into the groove in the bed-plate, the cross-head is lowered until the pins touch the caps, and then raised, leaving a drop of varnish in each cap. The plate of caps is withdrawn and laid for a few minutes upon the heater, which consists of an iron plate heated by steam-pipes under it to a temperature of about 200° Fahrenheit, the object being to dry the varnish. The plate of caps is removed to the cooler, which is an iron plate cooled by contact with water on its under surface. By the reduction of their temperature the caps may be safely charged without further delay. The fulminate composition consists of—

Moist fulminate of mercury..	6	pounds.
Powdered chlorate of potash.	1.75	"
Ground glass crystals.......	1.66	"
Mucilage............	14	fluid ounces.

The preparation of the fulminate of mercury is prepared as usual, except that aquafortis of the same specific gravity is used instead of nitric acid, the former being the commercial nitric acid and less expensive. The ground glass is sifted between bolting-cloths of 100 and 160 meshes per linear inch, to remove coarser and finer particles. Owing to its liability to sour in warm weather, the mucilage should be made only in such quantities as can be used before it spoils. The moist fulminate is well drained of its water, spread upon a board, and rolled out into a thin sheet, like pastry. The dry chlorate of potash and glass-dust are spread evenly over and thoroughly incorporated with it, by means of a wooden rolling-pin and a spatula, using care not to allow any of it to become scattered and dry. The mucilage is next added, and the whole mass well stirred and mixed, after which it is placed in a delf bowl and the latter covered with a damp cloth. If too moist, it is left spread out a short time until it has the consistency of a stiff paste. The charging-machine consists of a rectangular iron bed-plate, 18 by 20 inches. At one edge is a groove to receive the plate of caps from the cooler. Near the inner edge of this groove a plate, perforated with holes corresponding to the caps, is hinged to the bed-plate, to measure and convey the charges to the caps. The tinfoil is procured in strips about 150 feet long, 2.25 inches wide, and from .003 to .0035 inch thick. It is cut into strips about 4 feet long for convenience in handling and feeding to the machine. This short strip is laid flat upon a table, and its upper surface is coated with shellac varnish, after which it is laid aside to dry. A number of strips having been thus prepared, one at a time is taken and again coated with a thinner shellac varnish immediately before feeding it to the foiling-machine. The last coat of varnish softens and combines with the first and facilitates the attachment of the edge of the tinfoil disk to the varnished surface of the bottom of the cap around the charge. The foiling-machine is a single-action press arranged to receive and move horizontally the plate of caps under a gang of punches and dies. The strip of foil is fed between these tools, and by them cut into disks. The caps are next shaken out of the plates into trays having woven brass-wire bottoms, in which they are removed to the drying-room (Fig. 3), where they remain for six or eight weeks. The room is kept at a temperature of about 100° Fahrenheit, and by suitable ventilation its atmosphere is kept in motion and gradually renewed. This process is necessary to dry and harden the charge. At first sight it would seem to impair the sealing between the tinfoil disk and the base of the cap, for that is the only avenue of escape for the moisture of the charge; but it is probable that the temperature slowly dries the charge and keeps the varnish soft enough to renew the sealing at such points where it may be temporarily opened by the escaping moisture. A comparison of the water-proof quality of caps dried in this slow manner and more rapidly, at higher temperature, shows a decided advantage for the former method. Although they are not absolutely water-proof, they are sufficiently so for the ordinary vicissitudes of service, and the risks of serious accidents attending the use of dry fulminate, for the sake of hermetical sealing, are obviated. The primer-anvil is made from cartridge copper wire, which is procured in coils about 50 feet long, for automatic feeding to the machine which forms the anvil. The anvils are cut from this wire by a punch and die operated by a single-action press (Fig. 4), after which they are washed to free them from oil, dried, and churned in clean hard sawdust to brighten them and remove any burr formed in the operation of cutting them from the wire. This machine is automatic, requiring attention only when a new coil of wire is needed to supply it, and it cuts the skeleton wire or scrap into small pieces for convenience in packing and shipment to the manufacturers. The anvils and caps are assembled by means of a lever hand-press. They are shaken into receptacles in plates prepared for each. These fit together by dowel-pins, and a plate having pins corresponding to the anvils forces them, by aid of the press, securely into the caps. The complete primers are now ready for insertion into the pocket of the shell, or for being packed, for issue separately, in tin seamless boxes containing 500 primers each. After its insertion in the shell a drop of varnish is put upon the primer, *in situ*, by a machine similar to that for varnishing the caps. This varnish flows around the junction of the primer and pocket, and renders the cartridge practically waterproof. See *Center-primed Metallic-case Cartridge*, *Charging-machine*, and *Foiling-machine*.

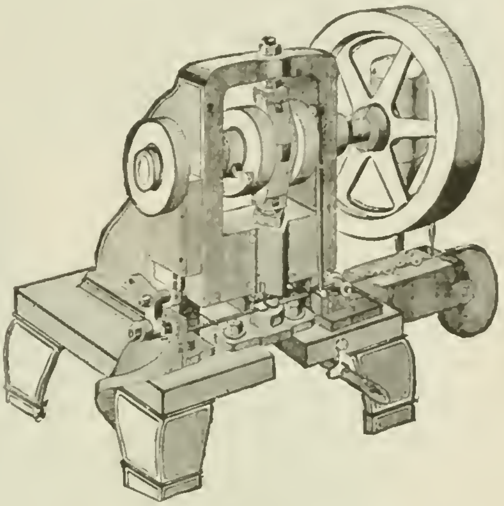

Fig. 4.

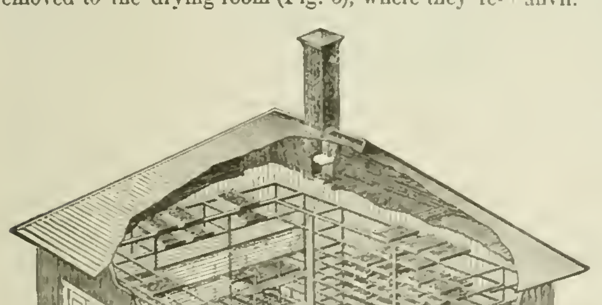

Fig. 3.

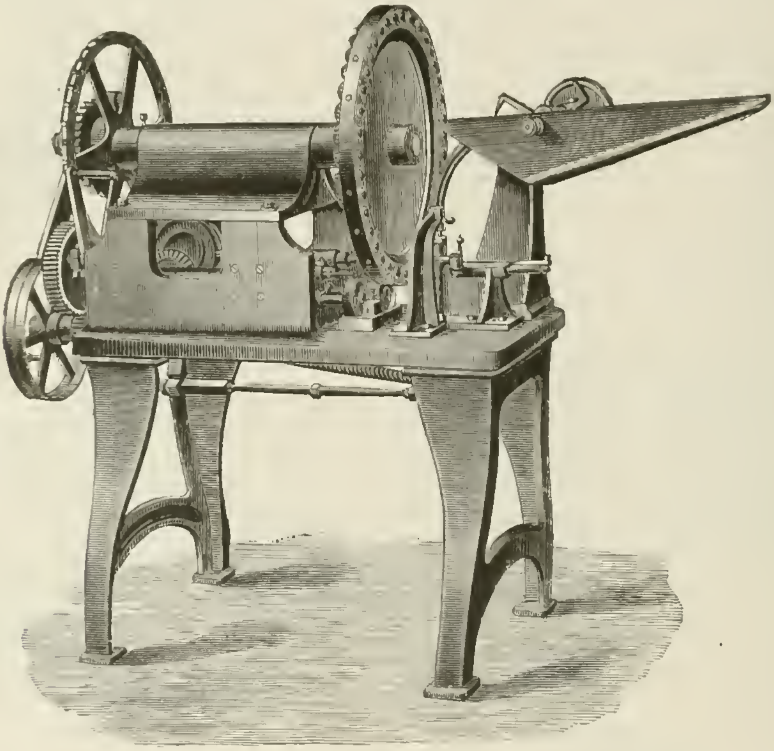
CARTRIDGE-RETRACTOR.—That part of a breech-loading fire-arm which catches the empty cartridge-case by its flange and draws it rearwardly from the bore of the gun.

CARTRIDGE-VARNISHING MACHINE.—The design of this machine is to coat the interior of metallic rifle-shells with air impermeable elastic varnish that will prevent chemical action between the salts of the gunpowder and the material of the shells. The result is to insure the preservation of the shells, and of the quality of the cartridges, for an indefinite period. The operation is also adapted to the preparation of once-discharged shells, making them available for recharging. The shells are placed in a hopper, several hundred at a time, and fed singly, 40 passing through the different stages of the process at once, at the rate of 2000 or more per hour. Besides revolving around the central spindle, the shells are rotated in the chucks which hold them, to prevent the accumulation of the varnish in any one spot, and to insure its being spread evenly. This rotary motion "sets" the varnish, which should afterwards be hardened and thoroughly dried, by means of a cheap sheet-iron furnace, that may be readily heated by steam-pipes, or in any other convenient manner. One operator may attend two or three machines, as all the motions of the machine are entirely automatic, including an effective stop-motion, that acts promptly at any obstruction. To insure uniform results, the temperature of the room in which the machine is used should be kept, as nearly as possible, at 70° Fahr., and the air should be dry and free from dust. The machine may be adapted to shells of any caliber. It weighs 1800 pounds.



Cartridge-varnishing Machine.

CARTRIDGE-WIRE.—1. The priming-wire whereby the cartridge is connected to the conducting-wire of the voltaic battery. 2. The needle whereby the cartridge-envelope is pierced, in order that the priming may connect with the powder.

CASCABEL—CASCABLE.—The projection in rear of the breech. It is composed of the knob and the neck; the latter unites the knob to the base of the breech. In heavy guns of recent model the cascabel is quite rudimentary, while in mortars it is entirely wanting. The object of the cascabel is to facilitate handling the piece when mounting, dismounting, and transporting it. The *cascabels* of ships' guns have *breeching-loops* in place of knobs, intended for the *breeching*, whose ends pass to ring-bolts on each side of the port, and whose duty is to limit the recoil.

CASCABEL-BLOCK.—A device employed in the inspection of cannon. It consists of a wooden cylinder of the proper diameter of the breeching-hole, the size of which it is used to verify. The opening between the jaws may be ascertained by measuring the iron block which is fitted to go between them, or by a template. See *Inspection of Ordnance.*

CASCABEL-PLATE.—In machine guns, a plate closing the rear end of the breech-casing, and serving to incase and protect the revolving-gear. See *Gatling Gun.*

CASCANS.—In fortification, holes in the form of wells, serving as entrances to galleries, or giving vent to the enemy's mines.

CASCHETTO.—An Italian casque of the sixteenth century, in iron beaten work, chased and also damascened.

CASE.—1. The charge-holder of a submarine mine. Whatever may be its form, the following conditions are essential:

1st. It must be water-tight, to prevent damage to the charge by leakage.

2d. It must be sufficiently strong to bear handling without danger of becoming leaky by straining, and must be able to sustain the external pressure due to the depth of water at which it is to be placed.

3d. When gunpowder, or gun-cotton fired with an ordinary fuse, is used, it must be sufficiently strong to hold the charge together, as it were, for an instant at the moment of ignition, so that its full effect may be obtained by as thorough a combustion as possible of the charge.

4th. In the case of a buoyant mine, it must be capable of being arranged with a large excess of flotation, so that when moored it may remain as stationary as possible at the required point.

5th. It should be of such form as to be capable of being handled and moored conveniently.

6th. It should be of such form as to secure the thorough ignition of the charge with the smallest possible number of fuses.

7th. It should be easy of construction and not too costly.

First, with reference to the form of the case. This generally is either conical, spherical, or cylindrical. The former is the best for self-acting buoyant mines. The apex (Fig. 1) of the cone forms a convenient point to which the mooring-cable may be attached, while the base, terminating by a curved portion, serves as an air-chamber, giving the necessary buoyancy to keep the mooring-cables taut, and to hold the mine in a comparatively stationary position in a current or tide-way. The nipples containing the fulminating composition are placed on the rim uniting the base with the conical surface. In this position they are most likely to be struck by a passing vessel. There should be four or more of these nipples, depending upon the size of the case. For all other cases, except the one just mentioned of a floating mine, intended for small charges to be exploded by mechanical means, the cylindrical form is best, and the one most frequently adopted for both ground and buoyant mines containing heavy charges. Fig. 2 represents the form so successfully used by the Confederates, 1861–65. Fig. 3 represents that of the Austrians. For large ground-mines the best form of case seems to be that of the turtle-mine. A heavy charge may be contained in it; it forms its own anchor, and it would withstand an explosion of an adjacent mine without sustaining any injury. This is the best form for resisting strong currents. The difficulty and cost of making spherical cases have heretofore debarred their adoption on a large scale, but recently General Abbott, U. S. Engineers, has simplified the process of manufacture and made them practicable. This process consists in pressing circular disks of steel into hemispherical segments, which are united by flanges, as represented in Fig. 4. As regards the material of which the cases may be most advantageously constructed, several substances have been tried and used, such as wood, iron, and vulcanized India rubber. For actual war-service, regularly-constructed torpedoes or mines would generally be turned over to the posts ready for use; but it might become necessary to improvise cases out of such materials as would be available. Tight barrels and hogsheads, when properly strengthened, are a good substitute for even the most improved form of case. The barrel or cask is simply an external shield for the protection of the charge, which is contained in a water-tight envelope, and may be an India-rubber bag or a tin or zinc can. The strengthening of the cask is to guard against collapsing when submerged in deep water. Under ordinary circumstances the depth of the water will not be so great as to require strengthening of good casks beyond stout hoops of iron. As the charge must generally remain a considerable time—perhaps many months—under water before explosion, it is most essential to have the case, whatever it may be, completely water-tight; and with this view the cask is coated, both inside and outside, with a composition of pitch and tar. The envelope containing the charge within the cask should be firmly fixed, so that no independent motion may disturb the connections of the electrical apparatus. See *Submarine Mines.*

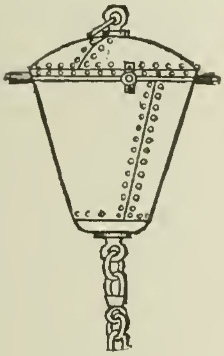


FIG. 1.

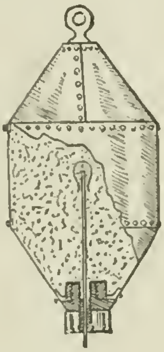

FIG. 2.

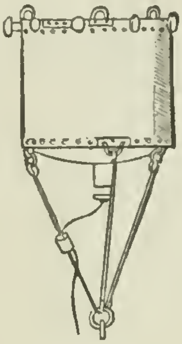

FIG. 3.

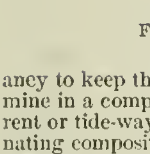

FIG. 4.

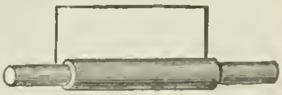
2. To give a portable form to compositions, they are inclosed in cases, cast in molds, or attached to cotton yarn, rope, etc. Cases are generally paper tubes, made by covering one side of a sheet of paper with paste or gum-arabic, then wrapping it around a *former*, and rolling it under a flat surface until all the layers adhere to each other.



The quality of the paper, and the thickness of the sides of the case, should depend upon the pressure of the gases evolved in the burning. To fill a case, it is first cut to the proper length, and placed in a mold; the composition is then poured in, a ladleful at a time, and each ladleful is packed by striking a certain number of blows on a drift with a mallet of a given weight. The height of each ladleful of composition should be about equal to a single diameter of the bore of the case. Small drifts, receiving heavy blows, should be made of steel, and tipped with bronze; large drifts may be made of wood or bronze, depending on the force of the blow. In driving highly inflammable compositions, as that of the rocket, care should be taken to settle the drift, so as to exclude the air before striking with the mallet, as the heat generated by the sudden condensation of air might be sufficient to ignite the composition. Preliminary tests of all new materials should be made by burning one or more specimens of the composition, and the proportions of the ingredients corrected, if necessary. The length of the flame from a given composition depends on the size of the vent and the extent of the burning surface. The vent is made small by *choking* the end of the case with stout twine; and the burning surface is increased by driving the composition around a spindle, which on being withdrawn leaves a conical-shaped cavity. A vent may be also formed by driving in moist plaster of Paris or clay, and boring a hole in it with a gimlet. If the end of the case is to be closed up entirely, the boring is omitted. See *Compositions* and *Fuse.*

CASE-HARDENING.—A process by which the external surface of wrought-iron is converted into steel to enable it to resist the wear and tear of friction and to receive a fine polish. It produces the external hardness of steel without its brittleness. Case-hardening consists in heating the wrought-iron to a cherry-red in a close vessel in contact with animal-charcoal, and then plunging the heated iron into cold water or sperm-oil. Bone-dust is usually employed at the armory, although old shoes, leather scraps, hoofs and horns of animals, and soot may be used. The bones are first pulverized and then charred. The work to be case-hardened is packed as follows: First, a layer of animal charcoal or bone-dust is placed over the bottom of the iron retort, and then rows of the iron pieces to be case-hardened are placed side by side, but not in contact, until the stratum of bone-dust is covered. Enough bone-dust is now put in to cover the metal parts, and then another layer of components put in as before. Continue to put in these alternate layers until the retort is full; and lastly, pour a quantity of the finest bone-dust on the top of the retort, and pack it down well to exclude the air. The retorts thus packed are transferred to an oven or reverberatory furnace and brought to the proper heat, when they are removed and plunged into cold water or sperm-oil, where they are left until cold. The process is called *case-hardening in oil* or *case-hardening in water*, according as sperm-oil or water be used for the cooling medium. If plunged in oil the metal is uniformly *blackened* on the exterior, provided the air does not strike it and produce a film of oxide, which will "scale" off and leave a marred surface. When water is used the "steeled" surface will often exhibit fine colors, and will be harder than that chilled in oil. The iron will be more liable to crack ("check"), especially at sharp angles, and to warp by sudden and unequal contraction when immersed in water than it would in oil. In packing, the small parts are frequently strung together on wires for convenience in handling. See *Fabrication of Fire-arms*.

CASEMATE.—Various modes have, from time to time, been proposed for arranging defensive casemates for the exterior defense of land-fronts. The difficulty in covering the masonry from the batteries of the assailant has been the chief objection to these structures, and is the more prominent as the fire of artillery becomes more accurate, as such casemates would soon be ruined or rendered untenable by embrasure shots. The structure for this purpose which has been most applied within late years is what is termed the *Haxo casemate;* the details having been first proposed by General Haxo, one of the first authorities of the French school of engineers. These casemates consist of a series of arched bomb-proof chambers closed in front by a thin mask wall which, except around the embrasures through it, is covered from the assailant's artillery by the parapet. To present but a small surface of masonry to fire, the arches, which are horizontal and perpendicular to the mask wall for the greater portion of their length, descend toward the front, leaving where they join the mask wall just sufficient height within for the service of the gun. To effect this the anterior portion of the arch must be conoidal in shape. The piers of the arches are pierced with wide arched openings, which serve the double purpose of a communication between the casemates and to give the gun a wider traverse for firing. Embrasures are pierced in the parapet in prolongation of those of the mask wall, and it is proposed to cover the small portion of the masonry necessarily exposed by this arrangement by placing several thicknesses of heavy timber in front of it to receive the shot, or to case it with wrought-iron. When the casemates serve simply for the cover of the cannon, the arches are covered with from 4 to 6 feet thickness of earth, and are left open to the rear for the more prompt escape of the smoke, and a ditch is sometimes made just in rear of the casemates to catch bombs and limit the effects of their explosion. When the arches are made longer than for the service of the guns alone, the earthen covering is sometimes arranged with a parapet to cover cannon in the barbette, or for small-arms.

In the casemated batteries for sea-coast and harbor defenses, the scarp or mask walls of the chambers for the guns, being exposed to the fire of ships alone, are not covered, as on land-fronts, by an earthen mask; these walls being built of sufficient thickness and strength to withstand the fire of the heaviest guns within the range that ships can venture to attack, and being far less vulnerable than the wooden or iron sides of vessels thus far brought into general use. These batteries in our own and European works consist of a series of arched bomb-proof chambers which serve for the service of the guns alone; or else they receive such dimensions that the portions of the chambers immediately in rear of the mask wall are appropriated to the service of the battery, and the rear portions are converted into quarters, store-rooms, and other necessary purposes for the garrison. In the earlier sea-coast casemated defenses constructed in our service, the gun-chambers have received dimensions to admit of two guns in each chamber. The chambers are usually formed of segmental brick arches of 120°, which rest upon stone piers built back perpendicular to the mask wall. When the casemates serve also as quarters for the garrison, the rear, towards the parade, is closed by a brick or stone parade-wall, which forms the front wall of the quarters. A brick partition-wall separates the quarters from the gun-gallery. Arched recesses and flues are made in the piers for chimneys, and the parade-wall, the sides of the piers, and soffit of the arch are suitably finished to give a dry and well-ventilated dwelling. In most of our earlier casemated works there is but one tier of casemated guns; this tier being surmounted by a barbette battery covered either by an earthen or stone parapet on the water-fronts. Casemates adapted to two guns in each room present a more vulnerable mark in the portion of the mask wall between the piers; expose more men to danger from embrasure shots; present a greater opening in rear to the assailant's fire when not closed by a parade-wall; offer less resistance to the shock of shells; and are more difficult to construct without settling than rooms for single guns. These advantages in favor of casemates for single guns are the more marked where, for the purpose of obtaining a heavy fire in some fixed direction, it is desirable to resort to a castellated structure consisting of several tiers of casemates. See *Covered Defenses* and *Mortar Casemates*.

CASEMATED RETRENCHMENTS.— Fortifications proposed by Carnot. They consist of a wall 36 feet high and 9 feet thick, erected at the gorge of the bastions, and provided with two rows of loop-holes, the upper for musketry, the lower for small mortars of a peculiar description. Behind this wall is a ditch 20 feet wide, and on the rear of it stands a casemated battery.

CASEMATE-GIN.—The garrison and casemate gins differ from the siege-gin in having two cross-bars of iron instead of the three wooden cross-bars, and in having the pry-pole inserted between the legs, which are kept together by the clevis-bolt. The upper block (generally treble) is hooked to the clevis. The casemate-gin is made shorter than the garrison-gin, so that it may be hoisted in casemates. With the guns now usually mounted in casemates it is essential to use a bail for slinging, in order to gain the necessary distance from the head of the gin for the working of the tackle. The gin is put together across the piece, or on the ground near it, and raised by moving up the legs and pry-pole towards each other. The pry-pole has cleats nailed to it to enable a man to mount to the head of the gin to hook on the block and to reeve the fall.

To reeve the fall, fasten one end of a trace-rope to the upper block by passing it through the *shell* of the block. An expert man ascends the pry-pole to the head, and passes the free end of the rope through the clevis, from whence it is carried down to the windlass, where a couple of turns are taken. By heaving on the windlass, the block is raised and the hook passed through the clevis, with its point *towards* the pole. The upper block may be hooked to the clevis and raised with the gin; the fall may also be rove and the whole raised together. The extra weight thus given makes the gin more difficult to lift. The gin is lowered by gradually drawing out the pry-pole until the men can get near enough toward the head to support it; it is then lowered upon the piece or on the ground, as the case may be. See *Gin* and *Mechanical Maneuvers.*

CASEMATE-GUN.—A gun mounted in a casemated battery. Casemated batteries are generally used on the sea-faces of works, and in defending the entrance of harbors, in which case they consist of a bomb-proof arch, open to the rear. Iron plating and shields of various thickness are used in the protection of the embrasures.

CASEMATES NOUVELLES.—Arched batteries which are constructed under all the openings of revetments or ramparts. The different forts of Cherbourg are defended by these casemates; the works erected around Dover Castle come likewise under this description; the works at Fort Columbus, New York, are erected on the same principle.

CASEMATE-TRUCK.—This machine is intended for moving pieces and their carriages in the galleries of casemate-batteries, or through posterns. It consists—old pattern, of a stout frame of wood; new pattern, of wrought-iron, mounted on three low wheels. Two of the wheels are placed at the sides, like those of a cart; the third is placed in a fork at the middle of the front end; the fork turns around its vertical axis as the direction of the truck changes. The fork and wheel are removed by raising the end of the truck and allowing the fork to drop from its socket. A tongue, likewise removable, is attached for the purpose of guiding the truck. To better understand the use of this construction, we will notice the manner of placing a casemate chassis on the truck.

The chassis is on the ground, the truck near it, with its front wheel and tongue removed. The chassis, either side down, is raised, by successive purchases, with handspikes, and blocked up to a height sufficient to allow the truck to go under it. The truck is then run under the chassis and turned so that

its axis is parallel to that of the chassis, and is so placed that the center of gravity of the chassis is, as near as possible, over the axle of the truck. The blocking is then removed and the chassis allowed to rest on the truck. The tongue of the truck is replaced. The truck is moved to the designated casemate, and the chassis lowered from the truck as it was placed thereon. If it is upside down, it is turned over and placed properly on the traverse-circles. The tongue of the chassis is then bolted to the front transom and secured by the pintle in the throat of the embrasure. The chassis may be lowered from the truck by means of the gin.

To remove the chassis from the casemate, the tongue of the chassis is unbolted from the front transom and the chassis raised, either by prying and blocking or with the gin; the truck is then placed under it as before. It is generally preferable to remove the front wheel from the truck and to pry up but one end of the chassis; the truck is then worked under it from the side, and, after the chassis is lowered upon the truck, the raised end is borne down until the front wheel of the truck can be replaced. See *Mechanical Maneuvers.*

CASERNES.—In fortification, buildings for the soldiers of the garrison to live in; generally erected between the houses of fortified towns and the rampart. In a general acceptation, casernes signify barracks.

CASE-SHOT.—An assemblage of bullets or small balls inclosed in a cylindrical case or canister. The diameter of this canister is a little less than the bore of the gun from which it is to be discharged. According to the size of the canister, the balls vary from 1 pound to ½ ounce each, from 30 to 280 in number, and from 3½ pounds to 85 pounds in total weight. The canister bursts immediately on leaving the gun, and the balls spread out into an irregular sort of cone. Within a range of 500 yards they work great execution among troops. They are generally used at 200 or 300 yards.

In a more modern and effective kind, called *Spherical Case*, the bullets are inclosed, along with a charge of powder, in an iron shell, instead of a tin canister. It is often called *Shrapnel*, from the name of its inventor. A spherical case-shot for a 68-pound carronade, or for an 8-inch howitzer, contains 337 balls; for a 24-pounder gun, 128; and for an 18-pounder, 90. It is exploded by a fuse the length of which depends on the distance of the point where the destructive effect is to be wrought. Its effect is something like that of a prolonged musket-fire. The Shrapnel shell is not of much use against the hull of a ship, but is very destructive against masses of men on shore, or on the decks of a ship, with a greater range than that of ordinary canister. Artillerymen prefer just such an amount of charge as will burst the sphere, without scattering the balls very widely. See *Canister-shot*, *Grape-shot*, *Projectiles*, *Shells*, *Shrapnel*, and *Spherical Case-shot.*

CASHIERING.—A punishment for officers in the army and navy. It is a severe form of dismissal from the service, and implies that the officer, by some disgraceful conduct, has deserved not only dismissal, but disqualification for ever again entering the service. Sometimes there are words added implying still deeper ignominy and degradation. On some rare occasions, when a Court-Martial has awarded cashiering, the Commander-in-Chief has mitigated the punishment to simple dismissal. "Scandalous and infamous conduct," and "Conduct unbecoming the character of an officer and a gentleman," mark two degrees of offense which may lead, the one to cashiering, the other to dismissal.

CASING.—1. The middle wall of a blast-furnace. Beginning from the inside, we find the *lining*, *stuffing*, *casing*, and *mantle*. 2. A wooden tunnel for powder-hose in blasting. 3. The cast-iron case of converted guns.

CASK.—A round wooden vessel of more length than breadth, bulging out in the middle, and closed up at either end. In military operations casks are used to form bridges across rivers when no pontons can be had. They should be about 4 feet 3 inches long, and diameter at head and bulge 2 feet 2 inches and 2 feet 9 inches respectively, which is the size of the water-butts of the navy; but any barrels available will answer. Casks filled with earth may also be used as gabions on an emergency, and also in the erection of barricades when it is necessary to build a revetment.

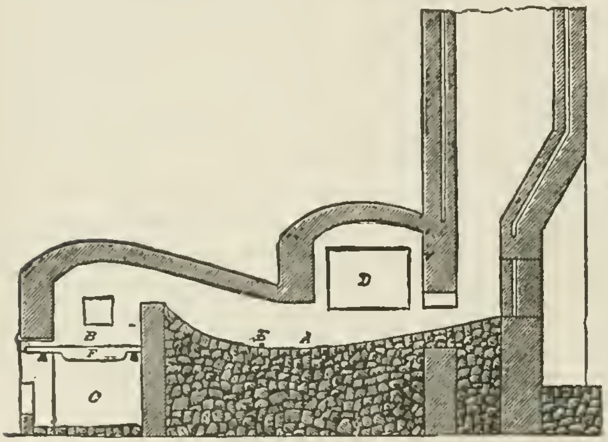
CASQUE.—The French name for helmet, and which in ancient armor was the name by which that head-piece was known. Also written *Cask.*

CASSE-TETE.—A mace or war-club, made of very hard wood, used formerly in savage warfare.

CASSINE.—A small house, especially in the open country; applied also to a house standing alone, where soldiers may lie hid, or may take a position.

CASTELLAN.—A Governor or Constable of a castle. The office and the rank of the Castellan were various in various countries. In France and Flanders the title Castellan belonged to the holders of certain demesnes, and was next in order of rank to that of a Bailiff. In Germany the Castellan had the jurisdiction of a Burg-graf during the Ages of Chivalry. In Poland, the title of Castellan, with its appendages, remained in later times, and, after the sixteenth century, the Castellans, with the Waiwodes and Bishops, formed the Senate or Superior Legislative Chamber.

CASTING.—The operation next after *molding*, in the fabrication of cast guns. The metal for the gun is melted in reverberatory air-furnaces, of the construction shown in the drawing, two or three being sometimes required for casting the heavier guns. In these furnaces the draught is produced by high chimneys instead of a blast, which is used in the cupola-furnace. The metal for what is termed a "heat" is all placed in the metal-chamber, A, before the fire is lighted. The fuel, bituminous coal, is placed on grate-bars, F, in the fuel-chamber, B, and, when ignited, the flame passes through the metal-chamber on its way to the chimney. The iron is melted by this flame without coming in contact with solid carbon at all, unlike the cupola-furnace, where the fuel and iron are mixed together. D is the charging-door, and C the ash-pit. The furnace is prepared for charging by covering the bed of the metal-chamber with a layer of sand evenly distributed and firmly packed. Boards



Reverberatory Air-furnace.

are laid down, upon which the pigs of iron are piled. If a number of guns are to be cast from the same grades of iron, it is very important that the beds of the furnaces should be prepared in every instance as with the standard gun, as the treatment of a given charge of iron may be varied by the manner of dressing the bed of the furnace. The different grades of iron to be used for the heat are weighed and piled in proper proportions in the metal-chamber. Care should be taken to have the furnace perfectly dry throughout. When it has been out of use long enough to become damp, it should be dried by a fire in the fire-chamber before being charged. When two or more furnaces are used in casting a gun, the tap-holes, E, are connected by troughs with a reservoir called a mixing-basin, in which the different charges are thoroughly mixed before entering the mold. The furnaces being charged and everything in readiness, the fires are started and regulated so that the iron in all will be melted or "down," as near as practicable, at the same time. The length of time required to obtain complete fusion depends in great measure upon the state of the atmosphere and quantity of metal in the charge; it may vary from 5 to 12 hours. When the charge is nearly down, wooden poles or iron rods are inserted in holes provided for that purpose in the walls of the furnaces, and the melted metal frequently stirred or puddled to bring the unmelted lumps in contact with the flame. As soon as the charge of a furnace is ascertained to be fairly down, specimens are taken out to determine whether the iron is sufficiently decarbonized or "high" to be in a proper condition for casting. These specimens are cast in green sand-molds and broken as soon as they become cold. The condition of the iron is indicated by the appearance of the fracture, and varies so much with different brands used that its determination is largely a matter of experience. If the first specimens show insufficient decarbonization, the iron is kept in fusion still longer and the puddling process is continued. When it is found that the decarbonization has gone far enough, the puddling is stopped. As the density and tensile strength of the iron depend in a great measure upon the highness to which it is brought, a correct decision is very important. As soon as the melted metal in all the furnaces is found to be in proper condition for casting, the furnaces are tapped simultaneously and the metal conducted by troughs to the mixing-basin, where the several charges are thoroughly mixed. It then flows on through other troughs connecting with the side-gates of the mold, and, passing down, enters the mold-cavity by the branches. These branches connect with the side-gates at regular intervals, and are so constructed that the metal enters in a horizontal direction toward the axis of the mold-cavity. The surface of the metal, as it enters, is stirred to prevent the scoria from lodging; care should be taken not to give it a "swirl," which throws the lightest metal in around the core, where the heaviest and best should be. When the mold is filled, the tap-holes of the furnaces are closed, and the surface of the metal in the sinking-head is covered with a layer of charcoal to prevent its chilling. For two or three hours after the casting, more metal is added at short intervals of time, to feed the shrinkage, by pouring from a ladle at the top of the mold as the surface sinks. See *Rodman Gun.*

CASTING-LADLE.—An iron vessel with handles for conveying molten metal from the cupola and pouring it into the mold. The term is also applied to a ladle used in the manufacture of steel, made of wrought-iron lined with fire-clay, having a small hole in the botton for running out the melted steel into the ingot-molds placed below. This hole is closed by an iron rod coated with fire-clay, and is raised or lowered by a hand-lever. The ladle is mounted on trunnions on the arm of a hydraulic crane, which allows it to be brought over the molds in the pit.

CASTING OUT.—The rejection of horses deemed unfit for further cavalry use. Usually written *Casting.*

CAST-IRON.—By refining, etc., a portion of the carbon and other impurities may be removed, but so long as the proportion of the carbon is not less than 2 per cent the metal will possess the characteristic properties of cast-iron mentioned below. The presence of silicon, sulphur, and phosphorus modifies the strength, brittleness, etc., of cast-iron very much, that of sulphur in particular increasing its tenacity, which is always, however, comparatively low. We may say that cast-iron contains from 2 per cent to 5 per cent by weight of carbon, which exists in two states, either chemically combined with the iron or mechanically mixed with it. In the trade, cast-iron is distinguished by numbers from one to eight, the lower numbers being given to those descriptions in which the surface when broken presents a gray or mottled appearance, and in which the larger part of the carbon is in the state of graphite—that is, uncombined with the iron. The higher numbers represent white or bright iron, and in these the carbon is almost entirely in the combined state. Cast-iron is easily fused, and can be readily cast into a homogeneous mass of any size or shape we choose, but it is brittle and cannot be worked under the hammer either hot or cold. If, indeed, we heat a mass of cast-iron to a red heat and hammer it, it will crumble to pieces—a fact taken advantage of in the breaking up of obsolete smooth-bore cast-iron guns.

The following table shows the mean mechanical properties of American cast-iron employed in rifle-guns of large caliber, as determined by the tests of a trial cylinder, 60 inches long with an elliptical base 24 inches by 19.5 inches.

Original Dimensions of Specimens.	Nature of Property.		
	Density		7.2771
Area, 1,001 square inches	Tenacity per square inch		33,875
	Hardness		18.46
	Hardness of copper		3.33
Length, 30 inches; diameter, 1.385 inch; area, 1.5065 inch.	Pulling stress per square inch:		
	Elastic limit	pounds	9,750
	Ultimate resistance	do.	31,000
	Ratio of elastic limit to ultimate resistance	per cent	31.45
	Extension per inch at elastic limit	inch	0.00051
	Ultimate extension per inch	do.	0.00337
	Ultimate restoration per inch	do.	0.00199
	Ultimate set per inch	do.	0.00163
	Reduction in area at point of rupture	per cent	0.215
	Ultimate resistance per square inch fractured area	pounds	31,065
	Appearance of fracture: bright gray medium-sized crystals.		
Length, 10 inches; diameter, 1.385 inch; area, 1.5065 inch.	Thrusting stress per square inch:		
	Elastic limit	pounds	8,200
	Compression per inch at elastic limit	inch	0.00093
	Compression per inch under 43,000 pounds	do.	0.00619
	Restoration per inch under 43,000 pounds	do.	0.00344
	Set per inch under 43,000 pounds	do.	0.00275
	Increase in area of cross-section after 43,000 pounds	per cent	0.371
Length, 2 inches; diameter, .8 inch	Absolute resistance to crushing force	pounds	114,143
	Bending stress:		
Length, 20 inches; breadth, 1.075 inch; depth, 1.075 inch	Transverse resistance	do.	11,556
	Bursting stress:		
Cylinder: length, 5 inches; exterior diameter, 3 inches; interior diameter, 1 inch.	Ultimate resistance	do.	63,184

See *Gray Cast-iron*, *Manganese*, *Mottled Cast-iron*, *Phosphorus*, *Silicon*, and *White Cast-iron*.

CAST-IRON GUNS.—It is in the smelting-furnace that the character of the iron is fixed. Iron of good character and high susceptibility may be spoiled by treatment at the foundry; but this, with ordinary experience and intelligence, ought but rarely to occur. But from iron that leaves the smelting-furnace with bad qualities it is impracticable, with our present knowledge, to make good and reliable guns. The smelting of iron is a purely chemical process, and should be conducted with the same regularity and precision as any other important chemical process. Though, with every precaution, perfect uniformity in the quality of the iron produced from day to day cannot be expected, in consequence of the many disturbing causes which tend to affect its character, yet a near approximation to it is practicable. All the stock for a "blast" of gun-iron should be carefully prepared and housed before beginning to "blow." The ore should all be roasted and well mixed so as to be as nearly uniform, as to size of lumps and all other qualities, as possible. The charcoal should all be made as nearly as possible from the same kind of wood, and well mixed together after charring. All the stock should be carefully weighed and supplied to the furnace at regular intervals of time. The pressure, temperature, and hygrometrical condition of the "blast" should be kept as nearly constant as possible. The temperature of the blast may be kept very nearly constant without using what is termed a "hot blast," by warming it just enough to bring it above the highest summer temperature. The quantity of moisture may, it is believed, be kept nearly constant by passing the blast some distance over water heated to the proper temperature. And this may be readily done by passing the blast through a long horizontal tube, like a cylindrical steam-boiler, partly filled with water, and kept at a constant temperature by the waste heat from the furnace. The temperature of the water should be such as to saturate the blast with moisture, and thus render it hygrometrically independent of atmospheric changes.

Supposing a standard of quality to have been determined, with the stock all prepared for a given number of guns, and having determined by comparison with the *standard* the quality of iron required, a further approximation to identity in quality of the metal in the guns may be made by casting each run of metal from the smelting-furnace into a number of pigs of equal size, something greater than the number of guns to be made, and piling them in separate piles—each run of metal furnishing one pig to each pile. Each pile should contain iron enough for one gun and one test-cylinder, and be kept separate and distinct from all others in transportation, and be repiled in the foundry-yard in the same order as at the smelting-furnace; one gun being made from each pile, after the treatment which the iron should receive at the foundry shall have been determined by experiments made on the iron in the surplus piles. The pigs should be cast in molds prepared from a pattern, so as to be as smooth and free from adhering sand as possible. The quality of the iron is much modified, and ordinarily improved, by remelting and long continuance in fusion. But all kinds of iron are not affected in like manner by the process. The difference between the iron as it exists when presented for use, and as it exists in the body of the finished gun, is very great, and has been found to be, in certain cases, more than twenty pounds per cubic foot in density, and in tenacity as 1 to 2.8. This shows how unreliable the tests of the pig-iron are, as means for determining the quality of iron and its suitableness for making cannon. It is found that, though some kinds of iron are susceptible of very great improvement by different methods of treatment at the foundries, other kinds are at their maximum strength in the crude pigs. The cause of this difference in the susceptibility for change and improvement will doubtless be found in the qualities of ores used, and in the process of melting them.

In examining the effects of the different treatment of iron at the foundry, such samples should be chosen as will best exhibit the following particulars and characteristics, viz.: 1st. The properties which distinguish the different grades of iron made from the same ores at the same furnace. 2d. The changes in the mechanical properties of iron produced by repeated meltings of one of these grades, separately, showing the changes effected at each melting. 3d. The changes produced by repeated meltings of the different grades of iron mixed. 4th. The changes produced in iron of the same melting and quality by casting it into masses of different bulk, and by different methods of cooling. The softest kinds of iron will endure a greater number of meltings with advantage than the higher grades. It appears from experiments with Greenwood iron, that when it is in its best condition for casting into proof-bars of small bulk, it is then in a state which requires an additional fusion to bring it up to its best condition for casting into the massive bulk of cannon. In selecting and preparing for cannon, we may proceed by repeated fusion, or by varying the proportions of the different grades and different fusions until the maximum tenacity is attained. An increase of density is a consequence which invariably follows the rapid cooling of cast-iron, and, as a general rule, the tenacity is increased by the same means. The density and tenacity usually vary in the same order. It appears that the tenacity generally increases quite uniformly with the density, until the latter ascends to some given point; after which an increased density is accompanied by a diminished tenacity. The turning-point of density at which the best qualities of gun-iron attain their maximum tenacity appears to be about 7.30. At this point of density, or near it, whether in proof-bars or gun-heads, the tenacity is greatest. As the density of iron is increased its liquidity when melted is diminished. This causes it to congeal quickly, and to form cavities in the interior of the castings. If in preparing iron for guns it is carried *too high*, either by long continuance in fusion or by using a large portion of a hard grade of iron, the casting will be lost.

The following table exhibits the various qualities of cannon-metals:

Metals.		Density.	Tenacity.	Transverse str'gth.	Compressive str'gth.	Hardness.
Cast-iron	least....	6.900	9,000	5,000	84,529	4.57
	greatest	7.400	45,970	11,500	174,120	33.51
Wro'ght-iron	least...	7.704	38,027	6,500	40,000	10.45
	greatest	7.858	74,592	....	127,720	13.14
Bronze.......	least....	7.978	17,698	....	....	4.57
	greatest	8.953	56,786	....	....	5.94
Cast-steel....	least...	7.729	....	....	198,944	.....
	greatest	7.862	128,000	23,000	391,985	......

A prominent feature of this table is that which shows the great difference between the lower and higher grades of the same metal. In cast-iron the density differs as 6.9 to 7.4, a difference equal to 31 pounds per cubic foot; in tenacity it differs as 45,970 to 9000 pounds per square inch, or as 5 to 1; and in hardness as 7 to 1. The bronze varies in tenacity from 56,786 to 17,698, more than 3 to 1; and in density it is as 8.953 to 7.978, equal to 61 pounds in the cubic foot.

While the cannon are making, the inspecting officer examines and tests the metal before it is used, observes its melting and casting, and tests the metal in the first gun made before the second is cast. If the first proves unsatisfactory, such changes are made, either in the material or in the treatment, as will tend to produce the desired result. This practice of ascertaining the quality of the material used, and of the casting made from day to day, as the work proceeds, enables the founder to distinguish the material, to select those of the best quality, and to treat them in the best manner. If these tests are satisfactory, the inspecting officer is assured of the good quality of the guns before any proof by firing is made. And this supersedes the necessity of using excessive proof-charges in the final proof, which may do serious and fatal injury to guns without bursting them or leaving any visible marks of injury. The testing instrument furnishes to the founder a convenient and accurate method of comparing the qualities of iron. It therefore enables him to select his materials before casting with greater certainty and safety. He can also by these means determine the comparative utility of different methods of melting and casting the gun. As the quality of the iron is essentially changed by the different ways of treating it while in the melted state, and by the different means adopted for cooling it after it is cast into the mold, the testing instrument enables one to ascertain the effect produced by these processes in all their several stages of progress, and to decide upon that which is found most suitable for making the guns of the best quality.

Of the various circumstances which affect the strength of cannon-metal, the most important appear to be those which connect themselves with crystallization. The size of the crystals of a particular metal depends on the rate of cooling of the heated mass; the most rapid cooling giving the smallest crystals. The size of the crystals or coarseness of grain in castings of iron depends for any given *make* of iron and given mass of castings upon—first—the high temperature of the fluid iron above that just necessary to its fusion, which influences—second—the time that the molten mass takes to cool down and assume again the solid state. The lower the temperature at which the fluid iron is poured into the mold, and the more rapidly the mass can be cooled down to solidification, the closer will be the grain of the metal, the smaller its crystals, the fewer and least injurious the planes of weakness, and the greater the specific gravity of the castings. Slow cooling develops a coarse, uneven grain, with large but thoroughly irregular and confused crystallization: cast-iron with such a grain is never strong or cohesive, though soft and extensible. The more rapidly a casting once consolidated can be cooled, without introducing injurious effects, the finer, closer, and more even will be its grain on fracture, and with any given metal the greater will be its strength. The rate of cooling cannot be accelerated beyond a moderate limit. If this limit be exceeded, as by casting in a cold, thick, highly-conducting metallic mold, the iron is "chilled," its constitution changed, and the carbon, not having time to crystallize out, remains combined or diffused through the mass. It should not be so fast as to cause unequal contraction, nor must it be so fast in large castings, such as guns requiring to be "fed" from a *feeding* or *sinking head* with fresh portions of hot fluid metal during consolidation to fill up the internal cavities or porosity due to contraction and crystallization, that this filling cannot be accomplished. The larger the mass of the casting, with any given quality of iron, generally the coarser is the grain—that is, the larger are the crystals that develop themselves in the mass. The same metal that shall produce a fracture bright gray, mottled, and without a crystal visible, in a small bar, will in a large casting produce a dark, confusedly crystalline surface of fracture as coarse as granite rock. A certain amount of contraction, on becoming solid from the liquid state, occurs in all castings. For iron this is variable and depends upon the mass of the castings, being greatest for small and least for large castings, of the same make of iron, and poured at the same temperature. There are two conditions that principally affect the degree of contraction, namely, the extent to which the fluid metal as entering the mold has been expanded by elevation of temperature, and the state of final aggregation of the particles, depending upon the size of the mass. Sudden changes of form or of dimensions in the parts of cast guns, besides the injury they do to the crystalline structure of the mass, introduce violent strains, due to the unequal contraction of the adjoining parts whose final contraction has been different. The enormous time required by a large casting for cooling is not generally known. A solid casting sufficiently large for a 15-inch gun weighs about 35 tons; it is red hot three days after having been cast, and only becomes cold enough to handle after a fortnight. The cooling of a casting must be uniform so far as uniformity is possible. This is impossible strictly in any casting; the approach to it is most difficult in heavy solid castings, and hence the great advantage of the practice of hollow casting upon a suitably made core admitting of internal cooling by artificial means. The contraction of cast-iron in becoming solid introduces strains into the mass by consolidation of one portion of the casting before another. When a large gun is cast solid and the metal cools in the ordinary way, the external portions solidify long before the interior has ceased to be liquid, and the process of solidification is propagated, as it were, in parallel layers from the outside to the center of the mass. When the first layer or thickness of solid crust has formed on the exterior it forms a complete arch all round, so that the contraction between fluidity and solidification of each subsequent layer is accommodated by portions of matter withdrawn radially from the interior towards the still cooling exterior—that is to say, from a smaller towards a larger circumference. The final effect of this propagated to the center of the mass is twofold: first, to produce a violent state of internal tension in the particles of the metal in radial lines from the axis of the gun inward as a cylinder, tending to tear away the external portions of the mass from the internal nucleus; second, to produce about the center or along the axis a line of weakness, and one in which the texture of the metal is soft, porous, and of extremely low specific gravity. The effect of this unequal contraction may be so great as to crack the interior metal of cast-iron cannon, even before it has been subjected to the force of gunpowder, and large masses of iron which have been cooled very rapidly by casting them in iron molds have been known to split open longitudinally from no other cause than the enormous strains to which they are subjected.

Guns have long been cast in a vertical position and with a certain amount of head of metal above the topmost part of the gun itself. From this head the casting is fed with fresh portions of fluid metal during consolidation; it also affords a gathering-place for all scoria or other foreign matter. But the great value of increased head of metal is in adding to the density of castings and so also to their strength. Fineness of grain, smallness of crystal, density, increased cohesion, and elasticity are all induced by casting under largely increased statical heads of fluid metal.

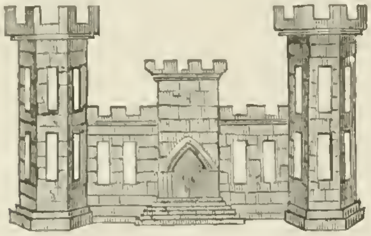
In the practical treatment of iron in fusion while preparing it for casting into cannon, it may be safely continued in fusion, with increasing improvement of its quality, so long as sufficient liquidity is retained to insure an exemption from cavities in the interior of the casting. The point at which such cavities of a fatal character will form will be reached before arriving at the point of density for maximum tenacity. A convenient method for determining the condition of the iron while in fusion, and whether it has arrived at the proper condition before casting or should be longer continued in fusion, is found in dipping from the melted pool of iron and casting into small bars, about 10 inches long, and from 1 to 2 inches square at one end and tapering to a point at the other end. The first one is taken from the furnace, and cast soon after the iron is all melted, and others are cast at such intervals afterwards as may be judged proper. They are cast vertically, point downwards, in sand-molds, and cooled rapidly. Proof-bars are cast at different times while the metal is in fusion. They are broken in different places, and the condition of the iron is judged by the appearance of the several fractures. These fractures will exhibit various aspects, from white at the small end to dark gray at the large end: and the bars cast at the latter periods of the fusion will exhibit the white at a greater distance from the small end, and the mottle, bright and lighter shades, will be found advancing towards the large end. This method, although much less reliable than that of an actual measure of density and strength, is convenient because of its ready application at short intervals, while the iron is in fusion, and a practiced eye will soon be able to mark the progress of the changing quality of the iron, and to determine the proper time for casting the gun. In process of time, a gradual adjustment of the internal strains produced in cooling cast pieces takes place; like many other substances, iron possesses the property of accommodating itself to this.

The principal improvement in the fabrication of cast-iron guns is General Rodman's process of cooling them as far as possible from the interior, and for this purpose casting them hollow. The design is to remedy the various defects of the old process; principally to obviate the tendency of solid castings to burst by their own initial strains, by reversing the process of cooling and shrinking described above. Since there would then be no force opposed to the contraction of the inner layers of metal, except the trifling cohesion of the liquid or pasty mass that they shrink away from, they would not be left in tension, and therefore they could not exert any power to pull the exterior layers into compression. The method employed is to carry off the internal heat by passing a stream of water through a hollow core, inserted in the center of the mold-cavity before casting, and to surround the flask with a mass of burning coals to prevent too rapid radiation from the exterior. Extensive trials have been made to test the merits of this plan, and the results show that cast-iron cannon made by it are not only stronger but are less liable to enlargement of the bore from continual firing, the surface of the bore being the hardest and densest part of the casting, and best calculated to resist pressure and abrasion.

Before proceeding to manufacture cannon in quantity, a *trial-gun* may be made and exposed to extreme proof with *service*-charges. After undergoing this proof in a satisfactory manner, the trial-gun should serve as a standard, and the proportions of the several kinds of metal used, and the methods employed in the manufacture, should be followed in all respects in the fabrication of other guns.

With the trial-gun should be cast a *sample-gun*, or a cylinder of equal diameter, and at least half the length of the gun, from which test specimens should be cut and tested. The sample-gun or cylinder should be of the same diameter as the guns to be made, and should be made under the same circumstances which are to attend the preparation of the iron for, and the casting and cooling of, the guns themselves. The object of the sample is to obtain specimens which have not been subjected to previous strain and vibration, as would be the case if taken from the fragments of the broken trial-gun. For it is impossible to reason back to what would have been either the capacity for work, or work due to elasticity of an unstrained specimen, by knowing to what extent these properties were possessed by that specimen after it had been subjected to both strains and vibrations of unknown intensity and number. And although it is interesting to know to what extent these properties are possessed by the fragments of a worn-out gun, yet it would be of far greater practical utility and importance to know the value of these properties in the new, untried guns. Specimens thus obtained would afford reliable results, and in connection with the powder-proof, with service-charges of guns cast at the same heat, these results would become standards. See *Crystallization*, *Fifteen-inch Gun*, *Ordnance*, and *Rodman Gun*.

CASTLE.—1. The insignia of the United States Engineer Corps, as represented in the drawing. 2. A building constructed for the purpose of repelling attack. The *castella*, left by the Romans in Britain and elsewhere, were constructed on the general model of their stationary encampments (*castra stativa*); and though they may have suggested the castles of the Middle Ages, they differed from them in being designed for military purposes only, and not also as places of permanent residence. Even Burgh Castle, in Suffolk, the ancient Garamenium, and Richborough Castle, in Kent, the ancient Rutupiæ, were encampments or fortresses, rather than castles. Besides these monuments of the military occupation of the island by the Romans, traces are found in various parts of the country of encampments or castles, which are ascribed to its aboriginal or early inhabitants. These are generally situated on the tops of hills; as, for example, the Herefordshire Beacon, on the Malvern Hills; Moel Arthur, in Flintshire; Chem Castle, in Cornwall; the Maiden Castle, in Dorsetshire; the Caterthuns, near Brechin, in Forfarshire; the Barmkin of Echt, in Aberdeenshire. It is probable that the Saxons adapted the Roman castles to a certain extent to their modes of defense, and traces of Saxon and even Norman workmanship are found in structures which are believed to have been originally Roman. One very frequent change consisted in raising a mound of earth on one side of the walls on which the keep or citadel was erected. The Decuman and Prætorian gates were also, as at Portchester, converted into the fortified entrances peculiar to the castellated structures of the Middle Ages. But of castles designed for residence as well as defense there are few or none which are of higher antiquity than the Conquest. They were part of the organization of the feudal system—castle-guard being one of the duties which the tenants were bound to pay in return for their lands; and till that system



Insignia of U. S. Engineer Corps.

was developed by the Normans, the residences of persons of importance were probably guarded only by their domestic retainers, or, in extraordinary circumstances, perhaps by the national militia.

The Norman castle was generally surrounded by a moat or ditch; and in order that the ditch might be readily filled with water, the site chosen was usually either on the banks of a river, or on a peninsula running into a lake. In the latter case the ditch was of course merely a deep cut made through the neck of land, by means of which the castle and its surroundings were converted into an island. On the inner side of the ditch mounds were constructed, which were surmounted with walls and towers, both of which, but particularly the latter, were supplied with battlements and bastions. The entrance-gates were also protected by towers, which were usually of great strength. The communication was by a bridge, sometimes of stone, but usually of wood, which was made to draw up and down; and the entrance, in addition to thick folding-doors, was protected by a portcullis, which was dropped down through grooves in the masonry at the sides. The gateway, in castles of the larger sort, was further defended by a barbican. On passing the external wall, you entered the bailey, which sometimes consisted of several courts, and contained the barracks, magazines, a well, a chapel, and sometimes even a monastery. The only portion of the castle which was always spoken of as distinguished from the bailey was the keep or citadel, which corresponded to the prætorium of the Roman fortification. The keep was a species of internal castle, more strongly defended than any other portion of the fortress, and placed in the most advantageous position, so as to afford a last chance to the garrison when driven from the external works. As the keep had the same design as the castle itself, it contained most of its appliances, even to a chapel, when large and complete. The keep was also called the dungeon or donjon. An excellent example of a keep is seen at Rochester Castle. The best known is probably that at Windsor, which forms so prominent an object in the surrounding landscape. The protection which the walls of his castle afforded to the retainers of a baron in a state of society in which life and property were extremely insecure naturally led to the construction of houses around the moat, and to this custom a very large number of the towns, both in England and on the Continent of Europe, owe their origin. See *Fortification*, *Keep*, and *Safety-redoubt*.

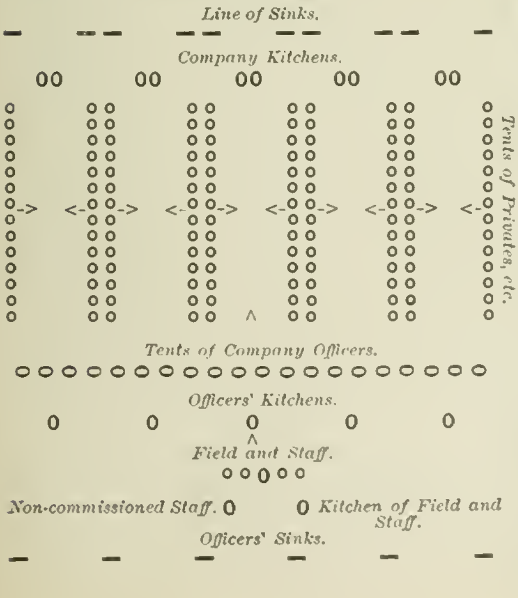
CASTLES.—In Heraldry, castles are often given as charges in the shields of persons who have reduced them, or who have been the first to mount their walls in an assault.

CASTRAMETATION.—The art of laying out camps and of placing the troops so that the different arms of the service shall afford support to each other in the best manner. A locality well sheltered and secured, and affording fuel, grass, and fresh water, should be selected for the camp. If it is expected to remain in the camp for any great length of time, its sanitary condition must be carefully observed. All ponds, swamps, lands recently stripped of their timber, and muddy rivers must be kept at a distance. In a malarious district it is well to habitually sleep between two fires. The flood-level of the nearest water should also be carefully noticed—weeds and stray bits of driftwood washed into the branches of adjacent trees or bushes will serve as a guide. Many streams are subject to sudden and terrific rises, and frequently without any apparent cause. When camping for the night on a fordable stream, with the intention of crossing, make it an invariable rule to cross it before going into camp. A sudden rise or appearance of the enemy might seriously interfere with the crossing next morning. Wind-storms are a common annoyance in the camp. When there is time to prepare for their coming, the tent-pegs should be secured and sufficient guy-ropes attached to the tent. If the soil is loose and sandy, rocks or other hard material should be placed under the tent-poles to prevent their working into the soil, and leaving the tent slack and unsteady; the pegs should also be inclined towards the tent, and driven in the direction of the prolongation of the tent-cords (if they are inclined from the tent they will soon be jerked loose). When the pegs will not hold at all, fasten the tent-cords to brush or rocks buried in the soil. A few trees add very much to the comfort of a camp, and when they are so situated as to permit the guy or ridge ropes to be made fast to them or their branches, the wind-storm need not be dreaded.

So far as may be prudent, the camp should be protected by bluffs and thickets, and the backs of the tents should be braced from towards the wind. It is not proper to camp beneath certain trees, whose branches are liable to suddenly fall off. In a hostile country the security of the command will depend very much upon the judicious selection of a camp as regards its capability of defense. If on the bank of a stream, a concave bend, where the water is very deep, should be selected. In such a position the defending party can cross his fire in case of an attack from the other bank, or can herd the stock in the concavity of the bend in order to avoid a stampede. When the camp is remote from a stream or river, a portion of it should rest on the highest hill or bluff within range. As a rule the tents should be pitched on that side of the camp most exposed to attack. When the packs and aparejos are removed in camp, they should be arranged so as to form a fortification in case of need. Immediately upon going into camp, pickets should be posted in strong positions, and sufficiently close to the camp to give timely alarm in case of the enemy's approach. The picket should be posted, during daylight, on some eminence near the camp, where he can keep a lookout in all directions. During the night he should be posted several hundred yards farther in advance of the point subject to attack and on *low ground*, in order that he may be screened from observation, and at the same time see to the best advantage, as low objects will then appear high and stand in bold relief against the sky; moreover, in timber it is easy to see a great distance between the trunks of the trees, while their tops and branches hide all objects beyond. If the picket discovers the enemy and is not seen himself, he should quickly withdraw and report the facts in order that no time may be lost in preparing for action. But if the picket is discovered by the enemy, he should first discharge his piece and then retreat. To save time and avoid all false alarms, a well-defined system of night and day signals should be devised, before going into the hostile country, and thoroughly understood by every picket. In this way they could very readily and promptly communicate their discoveries to the camp.

No rules can be laid down for laying out camps that will be universal. The proper exercise of the art of encamping is to so place the troops that they can quickly form line of battle on the position they are to occupy. In the United States, troops on campaign are provided with the shelter-tent, the pieces of which are carried by the occupants. In the presence of the enemy the troops bivouac in line of battle; if safety permits, the tents may be pitched immediately in rear of the line of stacks, the tents of the Company Officers in rear of their companies, the tents of the Field and Staff in rear of the center of the line of Company Officers. When not in the presence of the enemy, each battalion usually camps in column of divisions. The tents of each division are arranged in two lines facing each other; those of the right company face to the rear, those of the left company face to the front. The Company Officers' tents are arranged in line parallel to the flank of the column, facing the division-streets; the tent of the Captain of the right company of each division is to the right (or left) of the line passing through the center of the street, according as the officers are on the right (or left) flank of the column, his Lieutenants are on his right (or left); the Captain of the left company is on the left (or right) of the Captain of the right company, the Lieutenants of his company on his left (or right). The First Sergeant's tent is on the flank of the company towards the officers' tents. The tents of the Field and Staff, when practicable, are in line parallel to those of the Company Officers; the Colonel is opposite the center of the column, Lieutenant-colonel and Major are on his right, the Adjutant is on the left of the Colonel; the other Staff Officers are on the left of the Adjutant. The tents of the Non-commissioned Staff are in rear of the tents of the Staff; they may be assigned to tents in the divisions.

Camp of a Regiment of Infantry in Column of Divisions.



The kitchens of the men are in line on the flank opposite the Company Officers; the sinks for the men are outside of the line of kitchens. The kitchens of the officers are in rear of their tents; the sinks for the officers are in rear of the line of tents of the Field and Staff. The positions of the color-line, guard-tents, sutlers' store, officers' horses, and baggage-wagons are prescribed by the Colonel. The width of the division-streets, and the street in front of the Company Officers, varies with the nature of the ground and the strength of the battalion. When the companies are large, the camp may be formed according to the above principles, in column of companies, the tents of each company being in one line, or in two lines facing each other.

A battalion of Cavalry being in line with the usual intervals, to encamp, the men dismount, and, without forming rank, unsaddle and place their arms and equipments in line ten yards in front of the horses; the blanket is placed on the equipment, moist side up. The picket-line is stretched between posts about six feet high, or is stretched on the ground, the ends being firmly secured; the horses are tied to the picket-line by the halter at intervals of a yard; if the picket-line be on the ground, they may be fastened to it by a strap about two and a half feet long, the strap being provided with a collar which is buckled around the pastern of the left fore-foot. The tents of the men are pitched in line about fifteen yards in front of the picket-line, the intervals between companies being left free; the tent of the First Sergeant is on the right; the arms and equipments are kept in the tents of the men. The kitchens of the men are in line in front of their tents; the sinks in front of the line of kitchens. The tents of the Company Officers are in line about thirty yards in rear of the picket-line, the Captain on the right; their kitchens are in rear of their tents.

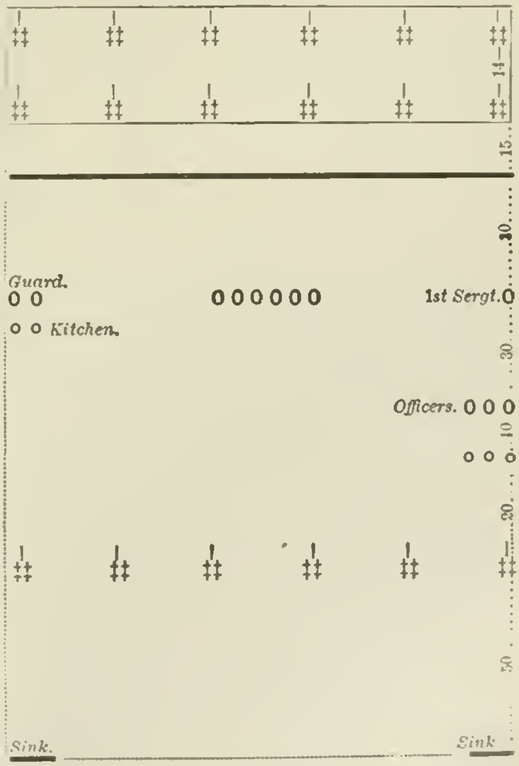


Fig. 1.

When Artillery camp, the pieces and caissons are parked at fourteen yards' interval, as shown in Fig. 1. The harness of the team of each carriage is on a rack on the right, and close to the carriage, so that the paulin can cover the harness. Horse-equipments are kept on the racks or in the tents. The picket-line is fifteen yards in rear of the caissons; it is stretched between posts about six feet high, the ends being firmly secured; the horses are tied to the picket-line by the halter at intervals of a yard. The men's tents are pitched in line about thirty yards in rear of the picket-line; the First Sergeant's tent covers the carriages of the right section; the left guard-tent covers the carriages of the left section; the tents of each section are in the order of their pieces in park, and are closed on the center, or to the right, so as to have a vacant space between the guard-tents and the tents of the left section. The men's kitchens are in line ten yards in rear of the guard-tents, which may be faced to the right so that No. 1 can overlook the kitchen. The officers' tents are in line thirty yards in rear of the battery-tents; the Captain's tent is on the right, covering that of the First Sergeant. The officers' kitchens are ten yards in rear of their tents. The battery-wagon, baggage-wagons, and forge are in line thirty yards in rear of the officers' tents; the battery-wagon covers the Captain's tent; tho forge covers the left guard-tent. The sinks are fifty yards in rear of the wagons; the officers' sink on the right, the men's sinks on the left.

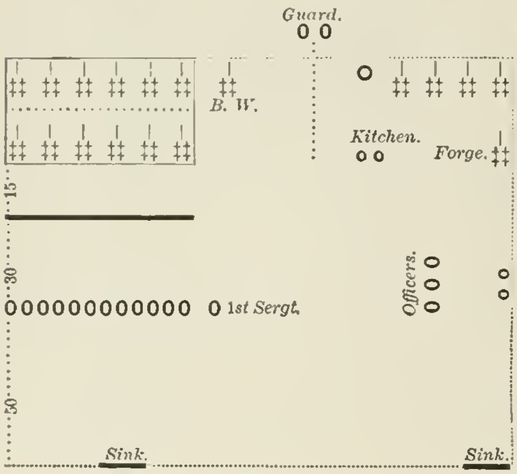

Fig. 2.

The preceding order may be modified as shown in Fig. 2, if circumstances require it. The battery-wagon and baggage-wagons may be in line with the pieces, the interval between the battery-wagon and nearest piece being fourteen yards, that between the battery-wagon and left baggage-wagon about thirty yards; the guard-tents half-way between the battery-wagon and baggage-wagons, facing to the rear; the forage-pile between the guard-tents and the baggage-wagons; the forge in line with the caissons and covering the right baggage-wagon; the men's kitchens in line with the caissons, and covering the left baggage-wagon; the officer's tents on a line perpendicular to the men's tents, facing them, and on the prolongation of one of the baggage-wagons; the officers' kitchen in rear of the officers' tents, and on the prolongation of the forge. In a *horse-battery*, if but one picket-line be used, it may be turned equally to the front around the flanks of the park; the battery-wagon, forge, and baggage-wagons may be divided equally and placed on the flanks of the men's tents, facing inward, and so as to be on the prolongation of the bent portions of the picket-line. The picket-line may also be in one straight line, in which case the baggage-wagons should be equally divided upon lines to the rear of its extremities. The horses are sometimes picketed in two lines, in which case the second line is fourteen yards in rear of the first, and the wagons are placed in line thirty yards in rear of the men's tents. See *Camp*.

CASTRIOTTO SYSTEM OF FORTIFICATION.—In this system the bastions are replaced by round towers, and the enceinte is covered by detached bastions. Vauban borrowed his second and third systems from Castriotto. He recommended demi-revetments and also hollow revetments. See *Fortification*.

CAST-STEEL.—This term until lately was confined to steel made by melting blister-steel, obtained by the old cementation process. Through this simple operation of melting it in crucibles, which was invented by an Englishman named Huntsman about the middle of last century, steel was first readily made perfectly homogeneous, and fitted for the production of the finer kinds of tools and cutting instruments. The crucibles are made of fire-clay, mixed with a small proportion of the material of old ones and coke. They are very carefully prepared and annealed, but notwithstanding this the heat of the furnace is so high that they can only be three times used. Each crucible contains from 30 to 40 lbs. of steel, which is poured, when melted, into cast-iron ingot-molds previously smoked. The name "cast-steel," however, can no longer be confined to steel so made, because Bessemer steel, although produced by a quite different process, is truly a cast-steel. In Sheffield the finer kinds of cast-steel are now sometimes called "crucible-steel;" but since puddled steel, which, like the Bessemer, cannot be used for fine cutlery, is also cast in crucibles, such a term is not sufficiently distinctive. See *Bessemer Steel, Crucible-steel, Puddled Steel*, and *Steel*.

CAST-STEEL GUNS.—In the fabrication of these guns, the best quality steel is cast into ingots 4 feet long and 15 inches square; the ingots are heated and hammered down till they are about 7 inches square, and long enough for two guns. The ends are hammered round, and a square block is left in the middle for the breech-mechanism, and two smaller blocks for the trunnions, presenting the shape shown in the drawing. The ingot is cut in halves at A, thus form-

ing the blocks for two guns. The gun-block is bored to a diameter of 2.5 inches, heated to a red heat and immersed in an oil-bath to temper it. After being tempered, it is turned and bored to a diameter of 2.92 inches and finally rifled, the grooves being .04 inch deep. The rimbases are planed to the proper dimensions, and the trunnions are screwed into them. Toward the bottom of the bore, and immediately in rear of the full rifling, is found the "shot-chamber." When the shot-chamber is reached, however, the ribs are cut away by a slope toward the rear, having an inclination of .04 of an inch, the depth of the rib, in 2 inches of length. This incline is called the compression-slope, it receives the belt of the projectile (when loaded), and centers the latter while in the loading position and as it is being driven into the bore. To the rear of this compression-slope the chamber continues on at a somewhat quicker inclination, connecting the shot-chamber with the powder-chamber. The latter is also a truncated cone, and has a diameter at the forward end of 3.2 inches, and at the rear end of 3.25 inches where the ring-recess is placed. The ring-recess is a short cylinder .39 of an inch long. It contains the Broadwell ring, or gas-check. Immediately in rear of the ring-recess is the screw-box. It has a female screw chased upon its surface, the thread having the same profile and pitch as that upon the breech-plug. Three blanks are planed longitudinally through the thread, each one removing one sixth of the surface. One blank is at the lowest side of the screw-box, and the other two equidistant from the first around the interior surface.

BALISTA, CATAPULTS, AND OTHER MODES OF ROMAN WARFARE. 1. Legionary. 2. Triarius. 3. Velitor[illegible] 4. Slinger. 5. Centurion. 6. Tribune of war. 7. Lictors. 8. Consul 9. Roman cavalry. 10. Plan of battle of the cohorts. 11. Roman encampment for five legions. 12. Plan of companies drawn [illegible]vable tower. 14. Balista (stone-thrower). 15. Battering-ram. 16. Battle-chariot. 17, 18 Catapults.

The plug, which is a cylindrical piece of steel, has a thread cut upon it. One half of the bearing surface of the plug-thread is cut away, in the same manner as has already been described for the screw-box, and the area thus to be removed is distributed into three longitudinal blanks, cut at equal intervals around the engaging surface. Thus there are on the plug, and also in the screw-box, three sections of screw-threads, separated by blanks, running parallel to an element of the bore, forming a slotted screw. In order to lock or secure the plug into the rear of the bore, it is only necessary to match its threaded sections to the blanks of the screw-box, and to push the plug at once home. A turn to the right of one sixth of the circle then engages, at the same time, all the threads of the plug with those of the screw-box; after which the plug is ready to oppose the effort of the charge. In rear of the threaded sections the plug is plain, where it works circumferentially in the collar, and it is terminated at the rear end by a flange, having its forward side furnished with locking-faces, the use of which will be explained elsewhere. The rear end of the plug is deeply recessed, in order to obtain lightness; the forward end is terminated by a flat face, which is recessed in the center to receive the boss of the nose-plate. The plug is also pierced with an axial hole one inch in diameter. The nose-plate is made of steel, and is somewhat less in diameter than the body of the plug. It presents the appearance of a low truncated cone, terminated by two short cylinders. On its rear surface it has a "boss," from which projects the stem, which passes through the hole in the axis of the plug. A nut runs upon this stem, and, bearing against the forward face of the hollow, brings the nose-plate to a firm bearing against the forward face of the plug. The forward face of the nose-plate bears against the gas-check ring when the breech is locked. The vent passes entirely through the axis of the nose-plate and stem, the rear orifice being found in the center of the after-end of the stem, and the forward one in the center of the nose-plate.

At the latter point the nose-plate is recessed, and a gas-check is fitted over the orifice of the vent. This vent-check, as it is called, consists of a disk of mild steel, secured over the interior orifice of the vent by four steel screws, which pierce through the disk perpendicular to its flat surface and near its edge. The screws are equidistant from one another, and their heads are not set down hard upon the disk, but allow it to rise about .05 of an inch. The pressure of primer-gas through the vent pushes the disk forward and admits flame to the charge; then the pressure of gas arising from the combustion of the charge forces the disk firmly back upon the orifice of the vent, and prevents all leakage in that direction. The shanks of the four securing-screws act as guides to the disk during its motion. The outer orifice of the vent is found at the rear end of the axis of the stem; but as this is not a convenient place from which to fire the primer, a secondary or offset vent is drilled nearly through a short cylinder of steel, the lower end of which is made to pass vertically down through the nose-plate stem near its rear end. The lower end of the vent in this cylinder is turned at right angles and comes out in the axis of the main vent. The Broadwell gas-check ring is made of copper or steel and fits into the ring-recess. The front of the ring bears against the forward face of the recess, and the face projects .01 of an inch to the rear of the recess wall. The ring is cylindrical on its exterior, fits the recess neatly, and its face is furnished with two circular grooves. The forward side (or curve) of the ring is furnished with an expansion-groove and rib, and the forward face of the nose-plate bears squarely against the face of the ring when the breech-mechanism is locked. See *Ordnance*.

CASUALTIES.—In the military service, a word which includes all losses in numerical strength of officers by death, dismissal, or resignation, and of enlisted men by death, desertion, or discharge; also all losses in fighting strength caused by wounds.

CASUS BELLI.—A phrase used with reference to any event, or complication between sovereign powers, which gives rise to a declaration of war.

CAT—CAT-CASTLE.—In the military engineering of the Middle Ages, a kind of movable tower to cover the sappers as they advanced to a besieged place. The garrison sometimes poured down burning pitch and boiling oil from the walls upon the *cat;* but occasionally this stratagem was disastrous, for the besiegers availed themselves of the blazing tower to burn the wooden gates of the town or fortress.

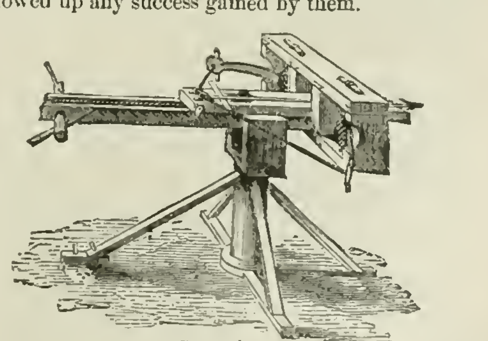
CATAFALCO.—In ancient military architecture, a scaffold of timber, decorated with sculpture, paintings, etc., for supporting the coffin of a deceased hero during the funeral solemnity.

CATALAN FURNACE.—A blast-furnace for reducing iron-ores, extensively used in the North of Spain, particularly in the province of Catalonia, from whence it derives its name, and whence it was probably introduced into Southwestern Europe. It consists of a four-sided cavity or hearth, which is always placed within a building and separated from the main wall thereof by a thinner interior wall, which in part constitutes one side of the furnace. The blast-pipe comes through the wall, and enters the fire through a tuyere which slants downward. The bottom is formed of a refractory stone, which is renewable. The furnace has no chimneys. The blast is produced by means of a fall of water, usually from 22 to 27 feet high, through a rectangular tube, into a rectangular cistern below, to whose upper part the blast-pipe is connected, the water escaping through a pipe below. This apparatus is exterior to the building, and is said to afford a continuous blast of great regularity; the air, when it passes into the furnace, is, however, saturated with moisture. This apparatus is called a *trompe*.

CATAPHRACT.—The old Roman term for a horseman in complete armor. Now obsolete.

CATAPHRACTA.—In the ancient military art, a piece of heavy defensive armor, formed of cloth or leather, fortified with iron scales or links, wherewith sometimes only the breast, sometimes the whole body, and sometimes the horse also, was covered.

CATAPHRACTI.—The cavalry of the Greeks consisted of two kinds. 1. The *Cataphracti*, or heavy cavalry, in which both rider and horse were well covered with defensive armor; the former armed with the lance, and a saber slung from a shoulder-belt. 2. A light cavalry of an irregular character, who were without defensive armor, consisting of archers and lancers, who also carried a sword, javelin, and a small buckler. The position of the cavalry, in line of battle, was on the wings. The duties of this arm were mainly to charge that of the enemy. The Cataphracti, for this purpose, were drawn up on each wing, with a portion of the light cavalry on each of their flanks. The charge was made by the former, and the latter followed up any success gained by them.



Catapult.

CATAPULT—CATAPULTA.—A warlike machine used in ancient times for projecting stones, long darts, or javelins. There were different kinds and sizes of catapultæ to which various names were given. The smaller kinds were in the form of a cross bow; the larger were supported by a frame which sustained two arms moving horizontally, having for a motive force two skeins of catgut. The catapulta was less powerful than the balista, but more uniform in its range. Catapultæ have occasionally been used in modern warfare. There was one erected at Gibraltar by General Melville, for the purpose of throwing stones a short distance over the edge of the rock in a particular place where the Spaniards used to frequent, and where they could not be annoyed by shot or shell.

CATCHPOLE. — A German implement of war, of the fifteenth and sixteenth centuries. It was shaped like the *war-fork*, with sharp points projecting to the rear, was about 14 inches long, and fixed on to a long shaft. This terrible weapon was intended to catch the adversary by the throat and unhorse him.

CATENARY.—The curve formed by a flexible homogeneous cord hanging freely between two points of support, and acted on by no other force than gravity. If the cord is not homogeneous, and the density varies in any regular way, the cord hangs in a curve slightly different in shape from that of the ordinary catenary. The catenary possesses several remarkable properties, one of which is that its center of gravity is lower than that of any curve of equal perimeter, and with the same fixed points for its extremities. Where the cord is such that the weight of any part of it is proportioned to its horizontal projection, the curve is a parabola. The latter curve and the ordinary catenary are of importance chiefly in the theory of suspension-bridges.

CATERVA.—In ancient military writings, a term used in speaking of the Gaulish or Celtiberian armies, denoting a body of 6000 armed men. The word is also used to denote a party of soldiers in disarray; in opposition to *cohort* or *turma*, which signify in good order.

CATGUT.—The material employed in the fabrication of the strings of violins, harps, guitars, and other musical instruments; as also in the cords used by clockmakers, in the bows of archers, and in whipcord. It is generally prepared from the intestines of the sheep, rarely from those of the horse, ass, or mule, and *not* those of the cat. The first stage in the operation is the thorough cleansing of the intestines from adherent feculent and fatty matters; after which they are steeped in water for several days, so as to loosen the external membrane, which can then be removed by scraping with a blunt knife. The material which is thus scraped off is employed for the cords of battledoors and rackets, and also as thread in sewing the ends of intestines together. The scraped intestines are then steeped in water, and scraped again, when the large intestines are cut and placed in tubs with salt, to preserve them for the sausage-maker; and the smaller intestines are steeped in water, thereafter treated with a dilute solution of alkali (4 oz. potash, 4 oz. carbonate of potash, and 3 to 4 gallons of water, with occasionally a little alum), and are lastly drawn through a perforated brass thimble, and assorted into their respective sizes. In order to destroy any adherent animal matter, which would lead to putrefaction and the consequent development of offensive odors, it is customary to subject the catgut to the fumes of burning sulphur—sulphurous acid, which acts as an antiseptic and arrests decomposition. The best strings are used for musical instruments; and those which come from Italy, and are known as *Roman strings*, are the strongest. They are remarkable for their clearness and transparency. Cord for clockmakers is made from the smallest of the intestines, and occasionally from larger ones, which have been split longitudinally into several lengths. Whip-cord is fabricated from catgut, which has been twisted in a manner somewhat similar to single-corded ropes. The catgut obtained from the intestines of horses, asses, and mules is principally made in France, and is employed instead of leather belts for driving machinery.

CATHARINE-WHEEL — CATHERINE-WHEEL.— 1. A form of fire-work having a spiral tube which rotates as the fire issues from the aperture. Catharine is the name of several saints of the Roman Catholic Church. The simple designation of *Saint Catharine*, however, is givin to a virgin, said to have been of royal descent, in Alexandria, who, publicly confessing the Gospel at a sacrificial feast appointed by the Emperor Maximinus, was put to death in 307 A.D., after being tortured on a wheel. Hence the name Catharine-wheel. 2. The Catharine-wheel is frequently used as a charge in coats of arms, when it is represented with teeth.

CAT-O'-NINE-TAILS.—A whip with nine knotted cords. It is occasionally used in the British service for the punishment of soldiers convicted of heinous crimes.

CATOPTRICS.—That subdivision of geometrical optics which treats of the phenomena of light incident upon the surfaces of bodies, and reflected therefrom. All bodies reflect more or less light, even those through which it is most readily transmissible; light falling on such media, for instance, at a certain angle, is totally reflected. Rough surfaces scatter or disperse a large portion of what falls on them, through which it is that their peculiarities of figure, color, etc., are seen by eyes in a variety of positions; they are not said to *reflect* light, but there is no doubt they do, though in such a way, owing to their inequalities, as never to present the phenomena of reflection. The surfaces with which catoptrics, accordingly, deals are the smooth and polished. It tracks the course of *rays* and *pencils* of light after reflection from such surfaces, and determines the positions, and traces the forms, of images of objects as seen in mirrors of different kinds.

A ray of light is the smallest conceivable portion of a stream of light, and is represented by the line of its path, which is always a straight line. A pencil of light is an assemblage of rays constituting either a cylindrical or conical stream. A stream of light is called a converging pencil when the rays converge to the vertex of the cone, called a focus; and a diverging pencil when they diverge from the vertex. The axis of the cone in each case is called the axis of the pencil. When the stream consists of parallel rays, the pencil is called cylindrical, and the axis of the cylinder is the axis of the pencil. In nature, all pencils of light are primarily diverging—every point of a luminous body throwing off light in a conical stream; converging rays, however, are continually produced in optical instruments, and when light diverges from a very distant body, such as a fixed star, the rays from it falling on any small body, such as a reflector in a telescope, may, without error, be regarded as forming a cylindrical pencil. When a ray falls upon any surface, the angle which it makes with the normal to the surface at the point of incidence is called *the angle of incidence;* and that which the reflected ray makes with the normal is called *the angle of reflection.*

Two facts of observation form the groundwork of catoptrics. They are expressed in what are called the laws of reflection of light: 1. In the reflection of light, the incident ray, the normal to the surface at the point of incidence, and the reflected ray lie all in one plane. 2. The angle of reflection is equal to the angle of incidence. These laws are simple facts of observation and experiment, and they are easily verified experimentally. Rays of all colors and qualities follow these laws, so that white light, after reflection, remains undecomposed. The laws, too, hold, whatever be the nature, geometrically, of the surface. If the surface be a plane, the normal is the perpendicular to the plane at the point of incidence; if it be curved, then the normal is the perpendicular to the tangent plane at that point. From these laws and geometrical considerations may be deduced all the propositions of catoptrics. In the present work only those can be noticed whose truth can in a manner be exhibited to the eye without having rigid mathematical proof. They are arranged under the heads *plane surfaces* and *curved surfaces*.

Plane Surfaces.—1. When a pencil of parallel rays falls upon a plane mirror, the reflected pencil consists of parallel rays. A glance at Fig. 1, where PA and QB are two of the incident rays and are reflected in the directions AR and BS respectively, will make the truth of this pretty clear to the eye. The reader may satisfy himself of its truth practically by taking a number of rods parallel to one another and inclined to the floor, and then turning them over till they shall again be equally inclined to the floor, when he will again find them all parallel. 2. If a diverging or converging pencil is incident on a plane mirror, the focus of the reflected pencil is situated on the opposite side of the mirror to that of the incident pencil, and at an equal distance from it. Suppose the pencil to be diverging from the focus Q, Fig. 2, on the mirror of the surface of which CB is a section. Draw QNq perpendicular to CB and make qN=QN; then q is the focus of the reflected rays. For let QA, QB, QC be any of the incident rays in the plane of the figure; draw the line AM perpendicular to CB, and draw AR, making the angle MAR equal to the angle of incidence, MAQ. Then AR is the reflected ray. Join qA. Now it can be proved geometrically, and indeed is apparent at a glance, that qA and AR are in the same straight line; in other words, the reflected ray AR proceeds as if from q. In the same way it may be shown that the direction of any other reflected ray, as BS, is as if it proceeded from q: in other words, q is the focus of reflected rays; it is, however, only their *virtual* focus. If a pencil of rays converged to q, it is evident that they would be reflected to Q as their real focus, so that a separate proof for the case of a converging pencil is unnecessary. The reader who has followed the above will have no difficulty in understanding how the position and form of the image of an object placed before a plane mirror—as in Fig. 3, where the object is the arrow AB, in the plane of the paper, to which the plane of the mirror is perpendicular—should be of the same form and magnitude as the object (as *ab* in the figure), and at an equal distance from the mirror, on the opposite side of it, but with its different parts inverted with regard to a given direction. The highest point, *a*, for instance, in the image, corresponds with the lowest point, A, in the object. He will also understand how, in the ordinary use of a looking-glass, the right hand of the image corresponds to the left hand of the object.

When two plane mirrors are placed with their reflecting surfaces towards each other, and parallel, they form the experiment called the endless gallery. Let the arrow, Q, Fig. 4, be placed vertically between the parallel mirrors, CD, BA, with their silvered faces turned to one another; Q will produce in the mirror CD the image q^1. This image will act as a new object to produce with the mirror BA the image q^2, which, again, will produce with the mirror CD another image, and so on. Another series of images, such as q', q'', etc., will similarly be produced at the same time, the first of the series being q', the image of Q in the mirror BA. By an eye placed between the mirrors, the succession of images will be seen as described; and if the mirrors were perfectly plane and parallel, and reflected all the light incident on them, the number of the images of both series would be infinite. If, instead of being parallel, the mirrors are inclined at an angle, the form and position of the image of an object may be found in precisely the same way as in the former case, the image formed with the first mirror being regarded as a new (virtual) object, whose image, with regard to the second, has to be determined.

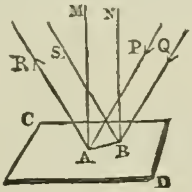


FIG. 1.

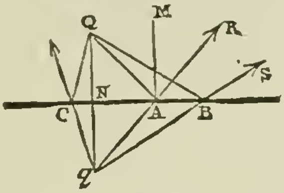

FIG. 2.

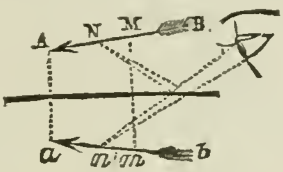

FIG. 3.

3. The two propositions already established are of extensive application, as has partly been shown. They include the explanation of all phenomena of light related to plane mirrors. The third proposition is one also of considerable utility, though not fundamental. It is: When a ray of light has been reflected at each of two mirrors inclined at a given angle to each other, in a plane perpendicular to their intersection, the reflected ray will deviate from its original course by an angle double the angle of inclination of the mirrors. Let A and B, Fig. 5, be sections of the mirrors in a plane perpendicular to their intersection, and let their directions be produced till they meet in C. Let SA, in the plane of A and B, be the ray incident on the first mirror at A, and let AB be the line in which it is thence reflected to B. After reflection at B it will pass in the line BD, meeting SA, its original path, produced in D. The angle ADB evidently measures its deviation from its original course, and this angle is readily shown to be double of the angle at C, which is that of the inclination of the mirrors. It is on this proposition that the important instruments called the Quadrant and Sextant depend.

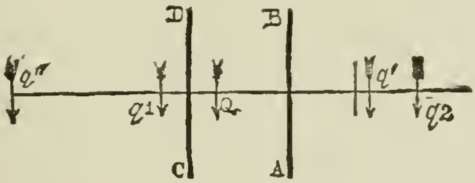

FIG. 4.

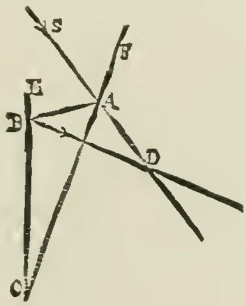

FIG. 5.

Curved Surfaces.—As when a pencil of light is reflected by a curved mirror each ray follows the ordinary law of reflection, in every case in which we can draw the normals for the different points of the surface we can determine the direction in which the various rays of the pencil are reflected, as in the case of plane mirrors. It so happens that normals can be easily drawn only in the case of the sphere, and of a few "surfaces of revolution," as they are called. These are the paraboloid, the ellipsoid, and the hyperboloid of revolution. The paraboloid of revolution is of importance in optics, as it is used in some specula for telescopes. The three surfaces last named are, however, all of them interesting as being for pencils of light incident in certain ways what are called surfaces of accurate reflection—i.e., they reflect all the rays of the incident pencil to a single point or focus. We shall explain to what this property is owing in the case of the parabolic reflector, and state generally the facts regarding the other two.

1. The concave parabolic reflector is a surface of accurate reflection for pencils of rays parallel to the axis or central line of figure of the paraboloid. This results from the property of the surface, that the normal at any point of it passes through the axis, and bisects the angle between a line through that point, parallel to the axis, and a line joining the point to the focus of the generating parabola. Referring to Fig. 6, suppose a ray incident on the surface at P, in the line SP, parallel to the axis AFG. Then if F be the focus of the generating parabola, join PF. PF is the direction of the reflected ray. For PG, the normal at P, by the property of the surface, bisects the angle FPS, and therefore ∠ (angle) FPG = ∠GPS. But SPG is the angle of incidence, and SP, PG, and FP are in one plane, and therefore, by the laws of reflection, FP is the reflected ray. In the same way, all rays whatever, parallel to the axis, must pass through F after reflection. If F were a luminous point, the rays from it, after reflection on the mirror, would all proceed in a cylindrical pencil parallel to the axis. This reflector, with a bright light in its focus, is accordingly of common use in light-houses.

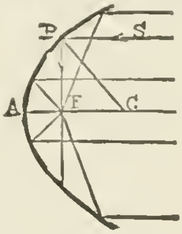

FIG. 6.

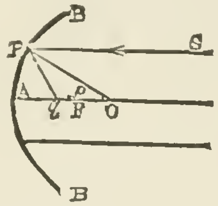

FIG. 7.

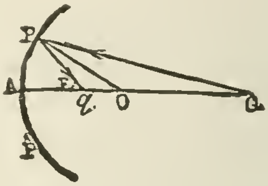

FIG. 8.

2. In the concave ellipsoid mirror there are two points—viz., the foci of the generating ellipse, such that rays diverging from either will be accurately reflected to the other. This results from the property of the figure, that the normal at any point bisects the angle included between lines drawn to that point from the foci.

3. Owing to a property of the surface similar to that of the ellipsoid, a pencil of rays converging to the exterior focus of a hyperbolic reflector will be accurately reflected to the focus of the generating hyperbola.

The converse of the above three propositions holds in the case of the mirrors being convex.

Though the sphere is not a surface of accurate reflection, except for rays diverging from the center, and which on reflection are returned thereto, the spherical reflector is of great practical importance, because it can be made with greater facility and at less expense than the parabolic reflector. It is necessary, then, to investigate the phenomena of light reflected from it.

It is usual to treat of two cases, the one the more frequent in practice, the other the more general and comprehensive in theory. First, then, to find the focus of reflected rays when a small pencil of parallel rays is incident directly on a concave spherical mirror. Let BAB, Fig. 7, be a section of the mirror, O its center of curvature, and A the center of its aperture. AO is the axis of the mirror, and therefore of the incident pencil, because it is incident directly on the mirror; a pencil being called oblique when its axis is at an angle to the axis of the mirror. As the ray incident in the line OA will be reflected back in the same line—OA being the normal at A—the focus of reflected rays must be in OA. Let SP be one of the rays; it will be reflected so that ∠ qPO = ∠ SPO. But ∠ POq = ∠ OPS by parallel lines. Therefore ∠ qPO = ∠ qOP, and Pq and Oq are equal. If, now, the incident pencil be very small—i.e., if P be very near A—then the line Pq will very nearly coincide with the line OA, and Pq and Oq will each of them become very nearly the half of OA. Let F be the middle point of OA—the point, namely, to which q tends as the pencil diminishes. The F is called the principal focus of the mirror, and AF the principal focal length, which is thus = ½ radius of the mirror. It will be observed that when AP is not small, q lies between A and F. Fq is called the aberration of the ray. When AP is large, the reflected rays will continually intersect, and form a luminous curve with a cusp at F. This curve is called the caustic. We shall now proceed to the more general case of a small pencil of diverging rays, incident directly on a concave spherical mirror. Let PAP', Fig. 8, be a section of the mirror, A the center of its aperture, O of its curvature, and let F be its principal focus. Then, if Q be the focus of incident rays (as if proceeding from a candle there situated), q, the focus of the reflected rays, lies on QOA, since the pencil is incident directly, and the ray QOA, being incident in the line of the normal OA, is reflected back in the same line. Let PQ be any other ray of the pencil. It will be reflected in Pq, so that ∠ qPO = ∠OPQ; and on the supposition that PA is very small, so that QP becomes nearly equal to QA, and qP to qA, it can be shown, by Euclid, vi. 3, that $\frac{QO}{QA} = \frac{qO}{qA}$ very nearly. From this equation is deduced the formula $qA = \frac{QA \times AF}{QA - AF}$, which enables us to find qA when QA and AF are known. Thus, let the radius of curvature be 12 inches, and the distance of the source of the rays, or QA, 30 inches, the focal length $qA = \frac{30 \times 6}{30 - 6} = 7\frac{1}{2}$ inches. If the rays had diverged upon q, it is clear they would have been reflected to Q. The points Q and q, accordingly, are called conjugate foci.

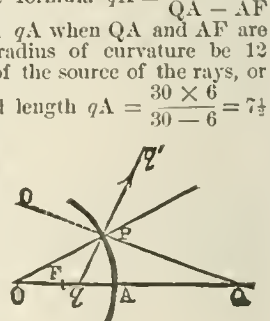

FIG. 9.

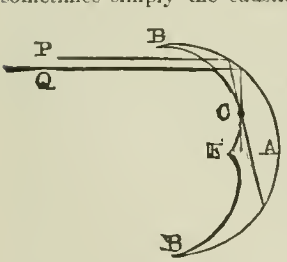
If the mirror be convex, as in Fig. 9, instead of concave, and a pencil of diverging rays be incident directly on it from Q, we should find, proceeding in exactly the same way as in the former case, the equation $Aq = \frac{QA \times AF}{QA + AF}$; or, taking the same numbers as before, $qA = \frac{30 \times 6}{30 + 6} = 5$ inches.

By considering Fig. 8 it is easy to see how the relative positions of the two conjugate foci, as they are called, Q and q, vary as the distance, AQ, of the origin of the rays is changed. As Q is advanced towards O, q also approaches O, since the angles QPO and qPO always remain equal; and when the source of the light is in the center, O, of the sphere, the reflected rays are all returned upon the source. As Q, again, recedes from O, q moves towards F, which it does not quite reach until the distance of Q is infinite, so that the incident rays may be considered as parallel, as in Fig. 7. If Q is placed between O and F, then q will be to the right of O; and when Q coincides with F, the reflected rays will have no focus, but will be parallel. If Q is between F and A, the reflected rays will diverge, and will have their virtual focus to the left of A. The correctness of these deductions may easily be verified. The positions of the conjugates are traced in precisely the same way for the convex mirror, and the reader who is interested will find no difficulty in tracing them for himself.

CAT'S-PAW.—The name given to a particular turn made in the bight of a rope, to which a tackle is fastened. See *Cordage*.

CAULKING.—The operation of driving oakum or untwisted rope into the seams of a structure to render them water tight. The quantity thus driven in depends on the thickness of the planking; it varies from 1 to 13 double threads of oakum, with 1 or 2 single threads of spun-yarn. The caulker first *raims* or *reems* the seam—that is, drives a caulking-iron into it, to widen the seam as much as possible and close any rents or fissures in the wood; he then drives in a little spun-yarn or white oakum with a mallet and a kind of chisel, and afterwards a much larger quantity of black or coarse oakum. The fibers are driven in until they form a densely hard mass, which not only keeps out water, but strengthens the planking. The seam is finally coated with hot pitch or resin.

CAUSTIC.—In optics, *caustic* is the name given to the curved line formed by the ultimate intersections of a system of rays reflected or refracted from a reflecting or refracting surface, when the reflection or refraction is inaccurate. When the caustic curve is formed by reflection, it is called the catacaustic—sometimes simply the caustic; when formed by refraction, it is called the diacaustic curve. In mathematical language, a curve formed by the ultimate intersections of a system of lines drawn according to a given law is called the *envelope*, and is such that the lines are all tangents to it. As in a system of rays reflected or refracted by the same surface *all* follow the same law, it follows that the caustic is the envelope of reflected or refracted rays. An example of the catacaustic is given in the annexed figure for the case of rays falling directly on a concave spherical mirror, BAB', from a point so distant as to be practically parallel. The curve may be said to be made up of an infinite number of points, such as C, where two very near rays, such as P, Q, intersect after reflection. This catacaustic is an epicycloid. The curve varies, of course, with the nature of the reflecting surface. In the case represented in the figure, the cusp point is at F, the principal focus. No such simple example can be given of the diacaustic curve as that above given of the catacaustic. It is only in the simplest cases that the curve takes a recognizable form. In the case of refraction at a plane surface, it is shown that the diacaustic curve is the evolute either of the hyperbola or ellipse, according as the refractive index of the medium is greater or less than unity. The reader may see a catacaustic on the surface of tea in a teacup about half full, by holding the circular rim to the sun's light. The space within the caustic curve is all brighter than that without, as it clearly should be, as *all* the light reflected affects that space, while no point without the curve is affected by more than the light reflected from half of the surface.



CAUTION.—An explanation given previous to the word of command, by which soldiers are called to attention, that they may execute any given movement with unanimity and correctness.

CAVALCADE.—In military history this term implies a pompous procession of horsemen, equipages, etc., by way of parade, to grace a triumph, public entry, and the like

CAVALIER.—1. A term originally signifying any horse-soldier; but in English history, the name given to the party which adhered to King Charles I., in opposition to the Roundheads, or friends of the Parliament.

2. In fortification, a cavalier is a defense-work constructed on the terre-plein, or level ground of a bastion. It rises to a height varying from 8 to 12 feet above the rampart, and has a parapet about 6 feet high. Its uses are to command any rising ground held by the enemy, within cannon-shot, and to guard the curtain, or plain wall between two bastions, from being enfiladed. For these purposes it mounts heavy ordnance. It may be either curved or bounded by straight sides. In modern permanent fortifications, cavaliers are placed either upon the curtains or within the bastions. The latter is the more usual position selected for them. Their plan in this position is usually that of a lunette, the faces and the flanks of which are parallel to those of the enveloping bastion. They receive a considerable command over the parapet of the enceinte, and in some cases are arranged with a tier of casemated fire, above which is an open battery. This arrangement enables the cavaliers to give a plunging fire upon the enemy's works on the glacis of the bastion covered-way. Cuts are made across the bastion-faces, isolating the cavalier from the salient portion of the bastion. They are arranged with parapets. These parapets and the faces of the cavalier in front of them form an interior intrenchment by means of which the breach that might be made in the bastion salient is defended.

CAVALLI BREECH-LOADER.—This apparatus is very simple, and is adapted to the use of a cup or ring gas-check. The sliding block is similar to that of the *wedge breech loader*. The wedge has two handles; the charge is passed through the larger one, the chain preventing too great a movement. The wedge slides on three steel pins, to prevent excessive friction. In case it is stuck by fouling, it may be pried to one side by inserting a handspike in the mortise.

CAVALLI GUN.—A gun invented in 1846 by General Cavalli of the Sardinian service. The chase does not differ essentially from the usual form of cannon; but at the breech of the piece, instead of being round, the four sides are planed off so as to present from the rear an appearance of a square with the corners rounded off. It is bored throughout its length, and rifled with two flat grooves with rounded edges. The rear of the chamber is enlarged, and these grooves being continued through it, although shallower than in the chase, are deep enough to receive the wings or projections on the shot, and hold it up till it reaches its seat in the gun. Crossing the bore at right angles, with its front face perpendicular to the axis of the piece, a wedge-shaped opening with a rectangular cross-section is cut. It is for a 32-pounder 9.4 inches deep, 5.4 inches wide at the large end, and 3.7 inches at the small end. This opening receives the quoin or wedge, made of hardened iron or steel, destined to close the breech in rear of the charge. See *Cavalli Breech-loader*. This gun was designed more particularly for casemate-batteries, or positions where it could be protected by blindages and covers of different kinds. In this gun the mechanical contrivances for securing the breech are very superior to the rude processes of earlier times; but it is very doubtful whether they are sufficiently strong to insure safety when high charges are used in long-continued firing.

CAVALOT.—A very ancient cannon, carrying a ball weighing one pound. Long since obsolete.

CAVALRY.—The earliest records of cavalry as a distinct military organization date far back in the history of Egypt. Diodorus of Sicily states that Osymandias, who lived long before the Trojan War, led 20,000 mounted men against the rebels in Bactriana. Josephus states that the host of Israelites which escaped from Egypt included 50,000 horsemen and 600 chariots of war. Herodotus often alludes to cavalry; and Xenophon relates that in the first Messenian war, 743 B.C., Lycurgus formed his cavalry in divisions. In the year 371 B.C. Epaminondas had a cavalry force of 5000 men, and we know that cavalry contributed greatly to the victories of Philip and Alexander of Macedon. It had an important part in the battle of the Granicus, 334 B.C.; and at the battle of Arbela, 331 B.C., Alexander, who led the Macedonian cavalry of 7000 men, dashed into a gap of the Persian army, and by this brilliant feat utterly routed the enemy. After the death of Alexander, the cavalry of Greece and Macedon greatly degenerated. The Roman cavalry was very inferior to that of Hamilcar and Hannibal, and most of the victories of these two Generals were won by cavalry over the splendid infantry of the Romans. Publius Scipio's defeat at the Ticinus, 218 B.C., was due to the superiority of the Carthaginian horse; and the bitter experience at the Trebia and the battle of Cannæ, 216 B.C., taught the Romans the value of cavalry, by which Scipio finally defeated Hannibal at Zama, 202 B.C. Vegetius states that the Roman cavalry was organized into ten troops or squadrons, forming a regiment of 726 horses, generally attached to some special legion. It is a singular fact that saddles were not in use until the time of Constantine, and stirrups were introduced by the Franks in the fifth century. During the Middle Ages cavalry may be said to have constituted almost the only efficient arm of battle. This was owing to the unwillingness of the nobility in all countries of western Europe to intrust any military power to the serfs; the upper classes went into battle mounted, and both riders and horses had heavy defensive armor. The feudal cavalry consisted of mail-clad knights with their men-at-arms. Their weapons were lances, battle-axes, and swords. The infantry was looked down upon during the Middle Ages, being composed principally of serfs and such as had not the means to keep a horse; but with the invention of gunpowder, the introduction of muskets, and the use of field-artillery a complete change took place; the infantry gradually rose in reputation, and the number of this class of troops was augmented. It seems that light cavalry did not exist as a distinct body, with General Officers and a Staff, before the time of Louis XII. Montluc, however, mentions a General of 12,000 light horse in the time of that monarch; and we hear of Henry II., in 1552, taking a troop of 3000 cavalry in his expedition to Germany. In 1554 Marshal De Brissac formed a corps of mounted infantry, called Dragoons, trained to fight either on horseback or on foot. Maurice of Nassau, who saw the importance of giving more mobility to this arm, was the first to organize cavalry regiments, each regiment being composed of four squadrons, formed in five ranks, and numbering about 1000 horses. Gustavus Adolphus was a great cavalry General, and used his Cuirassiers and Dragoons to good avantage. His tactics were much admired, and were adopted by many European Nations. The French, especially, distinguished themselves after his death in the employment of cavalry. Turenne, Condé, Montecuculi, and Marlborough were considered excellent cavalry leaders in the wars of Louis XIII. and Louis XIV. Cromwell was indebted to his abilities as a cavalry officer for the victories of Marston Moor and Naseby. Defensive armor for cavalry had been abolished in his time, and the cavalry troops were taught to use the carbine. Charges of cavalry were seldom made in battle except by the French; though Charles XII. always made use of cavalry charges at full speed with great effect. Marshal Saxe made many improvements in this arm, and used guns in connection with cavalry at the battle of Fontenoy, although regular horse-artillery was not introduced till 1762. It was not until the wars of Frederick the Great, however, that the full importance of cavalry was developed; he saw the necessity of training these troops to use swords instead of fire-arms, and endeavored to make them perfect riders. No firing whatever was allowed in the battle during the first charge; he claimed that the only two things required to beat the enemy were to charge him with the greatest possible speed and force, and then to outflank him. The brilliant victories he obtained from the adoption of these tactics under the able leadership of Seydlitz have probably never been excelled. At the battle of Hohenfriedberg the Prussian cavalry of 10 squadrons broke 21 battalions, routed the entire left wing of the Austrian infantry, and captured 66 standards, 5 guns, and 4000 prisoners. At the battle of Zorndorf, after the Russians had compelled the Prussian infantry to retreat, Seydlitz, with 36 squadrons rode down the Russian cavalry, and then completely routed their infantry. Frederick had learned to appreciate the true principles of mounted warfare through long experience and the occasional disasters which he had met in the first and second Silesian wars; and it was due to the efficient reforms which he instituted in the Prussian cavalry that he was able to win the battles of Rossbach, Striegan, Kesselsdorf, Leuthen, and others. One of the first improvements made in the French army by Napoleon was the reorganization of the cavalry. He increased the Cuirassiers from one regiment to twelve, and reintroduced the use of the lance and defensive armor. Some of his splendid victories were due to this force, especially at Marengo and Austerlitz; and it was owing to the loss of the French cavalry in the Russian campaign of 1812 that some of his finest achievements in 1813 proved useless: he was well aware of this, and made the statement that had he possessed cavalry at the battles of Lutzen and Bautzen the war would then have been brought to an end. In modern warfare it may be mentioned that cavalry was conspicuous at the battle of Solferino; but in 1866, the first great European war since Waterloo, neither the Austrian nor the Prussian cavalry won great distinction, although the manner in which the Austrian cavalry covered the retreat of their army at the battle of Königgrätz was a noble example of courage and devotion. In the Franco-German war of 1870, however, the excellence of the Prussian cavalry was the chief means of Von Moltke's ability to carry out his strategic plans. The French cavalry were more remarkable for bravery than efficiency. Great progress was made in the cavalry of the United States during the War of the Rebellion; a large number of men of both armies were good riders, and understood the management of horses. They were at first, however, quite ignorant of military tactics, and were used as scouts, as orderlies, and for outpost service. General Sheridan, acting under instructions from General Grant, made the first successful organization of cavalry, which was called the Cavalry Corps of the Army of the Potomac, comprising three divisions of 5000 mounted men each. Their weapons were repeating carbines and sabers. It was with this force that General Sheridan defeated the Confederate cavalry at Yellow Tavern, near Richmond; and it contributed largely to the defeat of Early at the battle of the Opequan, near Winchester; and later, at the battles near Petersburg and at Five Forks, the cavalry took an important part. General Wilson, whom General Sherman put in command of a force called the Cavalry Corps of the Military Division of the Mississippi, did good work in the way of organization towards the close of the war; he had 12,000 mounted cavalry and 3000 who fought on foot at the battle of Nashville, not including a detachment of 3000 men in Kentucky.

Cavalry is usually placed in the rear of the infantry, on ground favorable to its maneuvers, and where it will be masked from fire until the moment arrives to bring it into action; here, if acting on the defensive, the cavalry watches its opportunity to support the other troops, driving back the enemy, by prompt and vigorous charges, when these are hard pressed; or, if on the offensive, biding its time, to rush upon the assailant, and complete his destruction, when his ranks commence to waver or show signs of disorganization from the assaults of the other arms. Its habitual formation for the attack is in a line of two ranks, with a reserve, or support, to its rear. The supports are indispensably requisite to guard against those chances of danger to which cavalry is particularly exposed, if attacked in turn, when in a state of partial disorganization, after a successful charge; or when threatened by an offensive movement against its flanks. The supports offer a safeguard against either of these dangers; for, if the front line is brought up by the enemy, after a successful charge, it can retire and rally in the rear of the supports; and if the enemy makes a movement against the flanks, the supports, placed behind them and in column, can form and anticipate the enemy's charge. For the foregoing reasons, cavalry should not give way to a headlong pursuit after a successful charge, unless its supports are at hand; and in cases where a charge is made without supports, a portion only should engage in pursuit, the rest being rallied to form a support. Cavalry is seldom called on to use fire-arms. When on outpost service, or acting on the defensive on ground unfavorable to charging, a portion of the force may be dispersed as flankers, to hold the enemy in check by their fire. In this case their movements are regulated in the same way as other skirmishers. The defensive qualities of cavalry lie in the offensive. A body of cavalry which waits to receive a charge of cavalry, or is exposed to a fire of infantry or artillery, must either retire or be destroyed. This essential quality of cavalry renders its services invaluable in retreats where the enemy pursues with vigor. In such cases it should be held in constant readiness to take advantage of every spot favorable to its action, and, by short and energetic charges, force the enemy to move with circumspection. So long as infantry maintains its position firmly, particularly if the ground is at all unfavorable to the movements of cavalry, the chances are against a successful attack by the latter. Cavalry should therefore either wait patiently until a way is prepared for its action, by a fire of artillery on the enemy's infantry; or until the infantry has become crippled and exhausted by being kept in action for some time; or else, watching its opportunity, make a charge whilst the infantry is in motion, so as to surprise it before it can form to receive the attack. Cavalry should direct its charge on that point of the enemy's infantry where it will itself be exposed to the least column of fire. If the infantry is in line, the charge should be made on one of its flanks; if in square, on one of the angles of the square; and when several squares are formed, so as to afford mutual support by their fire, selecting the squares on the flanks as most vulnerable, from their position. The formation usually recommended for charging against squares is that of three squadrons in line at double distance; the leading squadron being followed by the others, either directly in its rear, or else the squadrons may be formed in echelon, successively overlapping each other by about the front of a platoon. The angle of the square is charged by each squadron in succession, if the charge of the one preceding it fails; the repulsed squadrons each wheeling to the right or left on retiring, to leave the way clear for its successor. A fourth squadron in column follows those in line, to surround the square and make prisoners if it should be broken by the charge. To draw the fire of the infantry before charging, a few skillful flankers may be thrown forward to open a fire on the square. Stratagem may also be tried, by moving along the front of the infantry, at some 400 paces, and then charging, if it is tempted to throw away its fire at this distance. In an attack where several squares are in line, if one fires to second another it should be instantly charged. In attacks against artillery, the detachment of cavalry should be divided into three bodies; one fourth of the detachment being charged with carrying the guns, one half to attack the supports of the battery, and the remaining fourth acting as a reserve, to cover the parties in advance from an offensive movement against their flanks or rear. The party to secure the guns make their attack in dispersed order, and endeavor to gain the flanks of the battery. When the battery has a fair sweep over the ground along which they must advance, they should, by maneuvering and false attacks, try to confuse the artillerists, and draw their fire before making their charge. The attack against the support of the battery will be directed in the usual manner, the party maneuvering to gain their flanks. See *Dragoon* and *Horse-guards*.

CAVALRY DEPOT.—A depot formed at Canterbury, to which all the depot troops of cavalry regiments abroad are attached.

CAVALRY FORGE.—A recent Board of Officers recommended for the cavalry service, to supply a want long felt, the adoption of a traveling forge-cart, to be issued to each company of cavalry, for the purpose of carrying the blacksmith's bellows, fire-box, anvil, coal, blacksmith's tools, horseshoes, nails, and iron; also for the purpose of carrying the extra ammunition, saddler's tools, and supply of leather for repairs of horse-equipments. The cart was to be an open one, without cover or tail-board, and of such size as to give a stowage of 21.9 cubic feet for tools, coal, and materials, packed in boxes, and arranged for draught by two horses or mules, one in shafts and the other by his side or in front. After the necessary strength to withstand the wear and tear of service, and the desired efficiency to do the required work, the next most important requisite for a forge for the cavalry is light weight, to enable it to move with rapidity. Of late years the smith's bellows for blowing his fire has been gradually giving place, both in portable and stationary forges, to the rotary fan-blower, which has the advantage of giving a much better and steadier blast and occupying less space. These qualities fit it in an eminent degree for use in traveling forges and specially urge its claims for favorable consideration; but it was found on visiting shops where both systems were used that the bellows were preferred by the workmen, and this arose on account of the monotonous and tiresome mode of working the fan-blower, which was done by a crank. This motion does not admit of the same change of position as that for blowing the bellows, but calls in play always the same muscles, and admits of little change or relief. It was clear that in order to make the introduction of the fan-blower a success other means of giving motion to it must be devised. It was observed that sewing-machines and hand-lathes were successfully worked by Hall's treadle, which communicates motion always in the same direction by simply pressing the foot on the treadle, no matter in what position the fly-wheel may be: it has no dead-centers. It was believed that if the blower were arranged to be driven by a lever worked by the hand, so as to enable the man to change his position and shift the work from one hand to the other, the sole objection to the blower would disappear and a better and more constant blast be obtained; the space occupied by it being less, the size and weight of the cart could be diminished. A better disposition of the fire-pan was desirable, so as to obviate the necessity of breaking and forming the connection of the blast-pipe with the fire-pan whenever the forge was to be prepared for the march or for work. This was effected by making this connection permanent, and causing the fire-pan and blower to slide in and out of the body of the cart when required, or not, for use, like a table drawer. It was also deemed advisable to provide the body with a light wooden cover, the better to protect the contents of the boxes from rain and dust.

The drawing represents a side and end view of the cavalry forge, as designed by Colonel Laidley, United States Army, in position and ready for use. When it is packed for traveling, the materials, tools, and implements are all under lock and key and not liable to be lost or stolen. The time required to prepare the forge for work or for transportation is not more than a minute, and the latter can be performed though the fire-pan may be greatly heated. The blast is strong enough to raise the tuyere-plate, weighing four pounds, from its seat, and a baggage-wagon axle may be brought to a welding heat in its fire. It has been found to meet all the requirements of the service, and has furnished the conveniences for keeping shod for five months a wagon-train of 750 horses and mules. It is believed that the advantages gained by having the boxes removable from the body is not commensurate with the expense and additional weight that it necessitates, and it would be better to make them permanent fixtures to the cart.

When using the forge, to prevent the cart from tipping over chock the wheels in front and rear, and let down both props by pulling the handle-rings in front and rear. Unlock and take the key out of the end of the tail-rod; withdraw it. Let down the forge-door and take out the shoeing-box. Grasp the hasp of the forge door with the right hand, insert the middle finger of the left hand in the handle of the locking-bolt; draw out the forge, pulling both hands toward the body; as soon as the forge has moved, let go with the left hand, continuing the action with the right till the locking-bolt stops it. Raise the fulcrum to a vertical position. Unlock and turn the anvil-hasp; seize the anvil-block with both hands; draw it out till the anvil rests near the end of the slide; take the anvil-plate from the fire-pan, screw it on the end of the block, and place the anvil four feet in rear of the cart and six inches to the left of the left wheel; withdraw the brake-handle from its pocket, hook the end in the link, and enter the handle in the slot in the fulcrum on the right, if the smith have a helper; on the left if he have none. Bear down on the handle gently at first, raise it a foot and bear down somewhat harder, increasing the pressure as the fan gains speed, continuing this pumping motion, and varying the rapidity of the stroke according to the amount of blast required. To remove the forge from the cart, place two trestles parallel to each other, 16 inches apart; raise them to a height of 2 feet 8 inches. Two men, one on each side of the forge, take hold of it; one pulls the handle of the stop-bolt, and both draw the forge to the rear and place it lengthwise on the trestles. Take out the smith's chest and coal-box in the same way and place them in convenient places. The saddler's chest may be taken out or left in the cart after the others have been removed.

The following are the principal dimensions and weights:

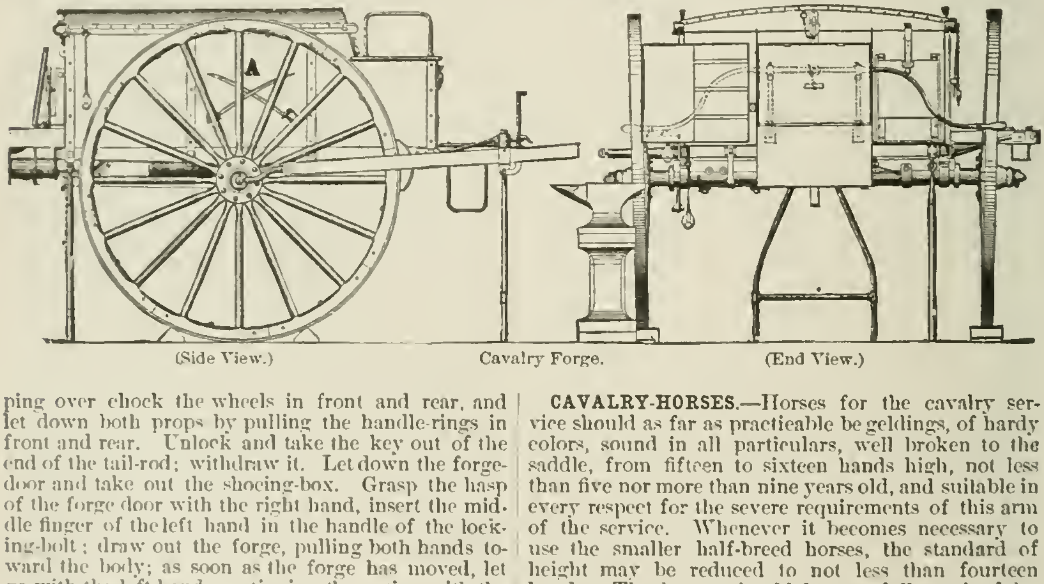
Dimensions.

Width of track of wheels...........	62	inches.
Whole length of axle...............	83½	"
Width of body......................	47	"
Length of body.....................	66	"
Length of cart, including shafts......	154	"
Height of wheel....................	57	"

Weights.

One wheel	108	pounds.
Shafts (both)	47	"
Anvil-block and base...............	106	"
Forge, hood, etc	145	"
Tool-box, empty................ ...	55	"
Coal-box, empty................ ...	63	"
Coal-box, filled with coal...........	228	"
Saddler's box.................. ...	44	"
Whiffletree	4	"
Tuyere.............................	4	"
Anvil-base.........................	7½	"
Cart (complete), empty.............	1075	"

See *Blower* and *Traveling Forges.*



(Side View.) Cavalry Forge. (End View.)

CAVALRY-HORSES.—Horses for the cavalry service should as far as practicable be geldings, of hardy colors, sound in all particulars, well broken to the saddle, from fifteen to sixteen hands high, not less than five nor more than nine years old, and suitable in every respect for the severe requirements of this arm of the service. Whenever it becomes necessary to use the smaller half-breed horses, the standard of height may be reduced to not less than fourteen hands. The horses should be carefully trained by the best horsemen, under the supervision of an officer or non-commissioned officer. Extreme gentleness and patience must be used, and loud talking and shouting avoided. By careful treatment at first, most horses soon become perfectly gentle and tractable. Mere force, without skill or coolness, only serves to confirm bad habits. Approach the horse on the near side, speak to him gently, place the right hand on his haunch, and step into the stall beside him. Take hold of the halter-strap; pat the horse and speak to him gently until he permits his legs to be rubbed and his feet to be lifted. As soon as the horse becomes quiet in handling, he is bridled with the watering-bridle, great care being taken not to frighten or hurt him. The blanket is then folded and placed on the horse; if the horse show any fear of the blanket, lay the blanket over the left arm, and go into the stall, show the blanket to the horse and permit him to smell it, patting him on the neck until he is quiet and allows the blanket to be placed on his back; then place the surcingle gently over the blanket and buckle it. The horse is now led out of the stable, and is patted and coaxed until he becomes perfectly quiet and stands still while the man goes about on both sides, rubs him, takes up his feet, etc., and at length permits the man to get on his back. After mounting, the man pats the horse for a few moments, without attempting to make him move, and then dismounts. This is repeated several times, until the horse submits without fear. It must be remembered that the efficiency of cavalry depends almost entirely upon the *condition of the horses,* which alone makes them able to get over long distances in short spaces of time. The horses must, therefore, be nursed with great care, in order that they may endure the utmost fatigue when emergencies demand it. Reveille, ordinarily, should not be sounded on the march before daylight, as horses rest better from midnight until dawn than at other times. The average march for cavalry is from fifteen to twenty miles per day. The walk is the habitual gait, but, when the ground is good, the trot may be used occasionally for short distances. Long marches or expeditions should be begun moderately, particularly with horses new to the service. Ten or fifteen miles a day is enough for the first marches, which may be increased to twenty-five miles when necessary, after the horses are inured to their work. The march is usually in column of fours; when practicable, it may be in double column of fours; in small commands it is often in column of twos. In small commands, not in campaign, distances of forty to fifty yards may be taken between the companies, so that checks will not extend from one to another and cause unnecessary halts. A halt of from five to ten minutes is made at the end of every hour, for the purpose of adjusting equipments, tightening girths, etc. The companies are dismounted in column at the command of their Captains; if there be grass, each Captain first obliques his company a short distance from the road to let the horses feed, as horses must always be encouraged to graze as much as possible on the march. When troops march for the greater part of the day, a halt of from twenty to forty-five minutes is usually made about noon. On long marches, officers and men, except the sick, should be required to dismount and lead from twenty to forty minutes every second or third hour; to save their backs, horses should be led over steep ground, and particularly down hill. See *Horse* and *Horsemanship.*

CAVALRY-PARRIES.—Important movements in bayonet-exercise, executed as follows: The Instructor commands—1. *High tierce,* 2. PARRY. Turn the piece, barrel to the left; support it with the right elbow against the hip, the barrel between the thumb and forefinger of the left hand; the left forearm above and about eight inches in front of the head; the piece about eight inches to the right of the head, covering the head and right shoulder. 1. *High quarte,* 2. PARRY. Carry the piece to the left of the left shoulder, the barrel to the right and nearly vertical, the right hand at the small of the stock, the left elbow at the height of the shoulder and touching the right wrist, the fingers on the stock. 1. *High prime,* 2. PARRY. Raise the piece with both hands, about eight inches in front and four inches above the head, the barrel downward and supported between the thumb and forefinger of the left hand midway between the upper and lower bands. The positions are shown in Figs. 1, 2, and 3. The *thrusts* and *lunges* are executed after each cavalry-parry, the bayonet elevated. In the thrust from *high tierce* and *prime* the barrel is downward; in *high quarte* the barrel is upward. The high double parries are executed as follows: 1. *High tierce,* 2. QUARTE. 1. *High quarte,* 2. TIERCE. 1. *High prime,* 2. SECONDE. 1. *Seconde,* 2. HIGH PRIME. The *seconde* is the same for cavalry as for infantry. See *Bayonet-exercise* and *Parry.*

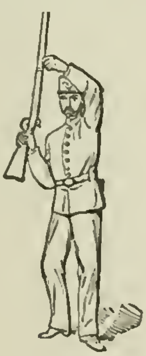


FIG. 1.

FIG. 2.

FIG. 3.

CAVALRY TACTICS.—Authorities differ concerning the proportion that ought to be observed between cavalry and infantry in an army. In France and Austria the ratio is about 1 to 5; in Prussia and Bavaria, 1 to 4; in Russia, 1 to 6; in England, 1 to 8; and in the United States, 2 to 5.

So far as concerns actual duties, heavy cavalry charge the enemy's cavalry and infantry, attack the guns, and cover a retreat; while the light cavalry make reconnaissances, carry dispatches and messages, maintain outposts, supply pickets, scour the country for forage, aid the commissariat, pursue the enemy, and strive to screen the movements of the infantry by their rapid maneuvers on the front and flanks of their army. At the battle of Balaklava the heavy-cavalry charge was within the reasonable duties of the troops, but that of the light cavalry was not; the former succeeded, the latter failed. A cavalry-horse will walk 4 miles in an hour on general service, trot 8 miles in maneuvering, and gallop 11 miles in making a charge. The cavalry usually attack in line against cavalry, in echelon against artillery, and in column against infantry. When an attack is about to be made, the cavalry usually group into three bodies—the attacking, the supporting, and the reserve. Close combat and hand-to-hand struggle are the province of cavalry; infantry and artillery may fight at a distance, but cavalry cannot. It is rare that two bodies of cavalry stand to fight each other; the weaker of the two, or the less resolute, usually turns and gallops off. The work to be done by the horse is to pursue, to overwhelm, to cut down. They cannot wait to receive an attack like infantry; they must either pursue or retreat; and on this account it has been said, "Rest is incompatible with cavalry." The infantry and artillery more frequently win the victory; but the cavalry prepare the way for doing this, capture prisoners and trophies, pursue the flying enemy, rapidly succor a menaced point, and cover the retreat of infantry and artillery, if retreat be necessary. Cavalry is necessary to finish off work mainly done by others; and without its aid signal success is seldom obtained on the field. Many of the brilliant achievements of the British in 1857 and the following year, in India, were rendered almost nugatory by the paucity of cavalry, while, as a contrast, the German victories of 1870 were enhanced by the splendid services of their Uhlans and other light cavalry. See *Cavalry* and *Tactics*.

CAVEATING.—In fencing, a motion whereby a person in an instant brings his sword, which was presented to one side of his adversary, to the opposite side. See *Fencing*.

CAVESSON.—A sort of nose-band, of leather or iron, which is put on the nose of a horse to assist in breaking or training him. It resembles the *twitch* or *barnacles*, being a grip by which the nose is wrung and twisted, to subdue the refractory spirit of the animal. Otherwise spelt *causson* or *cavezon*.

CAVIN.—In military affairs, *cavin* implies a natural hollow sufficiently large to lodge a body of troops and facilitate their approach to a place. If it be within musket-shot, it is a place of arms ready made, and serves for opening the trenches, free from the enemy's shot.

CAXON.—A chest of ores, calcined, ground, and washed, ready for the refining-furnace. From the Spanish *caxon*, *cajon*, a large chest.

CELERES.—A body-guard of 300 young men of the best Roman families, organized, according to tradition, by Romulus. Next to the king, their leader was the highest officer of the State. This position was held by Brutus when he expelled the Tarquins.

CELLS.—Places of solitary confinement in which soldiers are placed, as punishment for certain crimes. In England and elsewhere this confinement is limited to 168 hours.

CELLULOID.—A remarkable modern invention, apparently capable of wide usefulness in the arsenal and laboratory, wherever India-rubber and various kinds of cloth are now employed. Celluloid is produced by mixing gum camphor with a pulp of guncotton, and subjecting the combination to a high degree of pressure and heat. The result is a hard product of extraordinary toughness and elasticity. It can be made plastic again and molded into any required form. Any color can be given to it by the use of coloring matter during the process of manufacture. It is extensively used as a substitute for ivory, which it resembles so closely that it is sometimes difficult to detect the difference.

CELT.—The name by which certain remarkable war-weapons of the early inhabitants of western Europe are known among archæologists. Celts are either of *stone* or of *bronze*.

Stone celts vary in length from about 1 inch to 22 inches; but the most common size is from 6 to 8 inches in length, and from 2 to 3½ inches in breadth. They are made of almost every kind of stone, and show considerable diversity of shape, almost all, however, having more or less resemblance to the mussel-shell. The ruder celts are generally of slate, shale, schist, or grit; the finer, of flint, porphyry, greenstone, syenite, or agate. Many of the finer celts are beautifully shaped and highly polished. A remarkable example of this class, the property of Sir Coutts Lindsay, found near St. Andrews, in Scotland, is described by Sir David Brewster in the *Philosophical Journal* for 1823. Recently a class of celts found in the later geological strata have excited much interest as well among archæologists as among geologists. They are obviously of the same type with the more common celts, but of ruder construction, as if fashioned by a more barbarous people. The stone celt was fastened into a handle of horn, bone, or wood. A celt of serpentine, with a handle of deerhorn, was found in one of the Swiss lakes in July, 1859, and a stone celt, with a wooden handle, in the County of Tyrone, in Ireland.

Bronze celts vary in length from about 1 inch to 8 or 10 inches, the most common length being about 6 inches. They are sometimes ornamented with rudely incised lines or circles, and have occasionally been found wrapped up in linen, or inclosed in bronze cases or sheaths. They show much greater diversity of shape than the stone celt. As many as four classes have been distinguished by archæologists: 1st. The simple wedge-shaped celt, most nearly resembling the common form of the stone celt. 2d. The wedge-shaped celt, with sides more or less overlapping, and a stop-ridge or elevation between the blade and the part which received the handle. 3d. The wedge-shaped celt, with sides greatly overlapping, with or without the stop-ridge, but with a loop or ear upon, and parallel to, its lower surface. 4th. The socketed celt, or the celt with a hollow to receive the handle, and generally with a loop or ear upon its lower surface.

Both stone and bronze celts were probably used for several purposes, serving for chisels, adzes, and axes, as well as for weapons of war, like the stone hatchets of the South Sea Islanders and other savage or barbarous tribes. Examples of stone and bronze celts of all classes (together with the molds in which bronze celts were cast) may be seen in the British Museum at London, in the National Museum of the Antiquaries of Scotland at Edinburgh, and in the Museum of the Royal Irish Academy at Dublin. The last collection has more than 500 examples of stone celts, about one half of which were found in deepening the bed of the Shannon or its tributaries, between the years 1843 and 1848. A bushel of bronze celts has more than once been discovered at one spot.

CELTIBERI.—A powerful people of ancient Spain, supposed to have sprung from a blending of the Iberians or Spanish aborigines with Celtic invaders from Gaul. The Celtiberi inhabited a large inland district of the peninsula, corresponding to the southwest half of Aragon, nearly the whole of Cuença and Soria, and a great part of Burgos, but the name Celtiberia had often a wider signification, including the country as far south as the sources of the Guadalquivir. The Celtiberi were divided into four tribes, and were unquestionably one of the bravest and noblest peoples in the peninsula. Their cavalry and infantry were equally excellent. For many years they withstood the efforts of the Romans to subdue them, and it was not till after the campaigns of Sertorius that they began to adopt the Roman language, dress, and manners.

CEMENT.—A cement is a substance used to make the surfaces of solid bodies adhere to one another; it is applied in a liquid or viscous state, and hardens after the surfaces are brought together. When fused metals or alloys are used in this manner, they are called solders. There is a great variety of cements derived from animal, vegetable, and mineral substances. The animal cements are chiefly composed of gelatine and albumen as their bases. Joiners' glue is an example. The binding materials of vegetable cements are gums, resins, and wax. The mineral cements are chiefly of lime and its compounds. In many cements, animal, vegetable, and mineral substances are combined. The simplest of the mineral cements is plaster of Paris, which is used for uniting slabs of marble, alabaster, and many similar purposes. It is mixed with water to the consistence of thick cream, and then applied. This hardens rapidly, but is not very strong. Its hardening depends upon the true chemical combination of the water with anhydrous sulphate of lime, of which plaster of Paris is composed, and the formation thereby of a solid hydrate. The plaster of Paris may be mixed with thin glue, with diluted white of egg, or a solution of size or gum, instead of water, and is strengthened thereby. Keene's marble cement is prepared by steeping plaster of Paris in a concentrated solution of alum, then recalcining and powdering. This powder is mixed with water in the same manner as plaster of Paris.

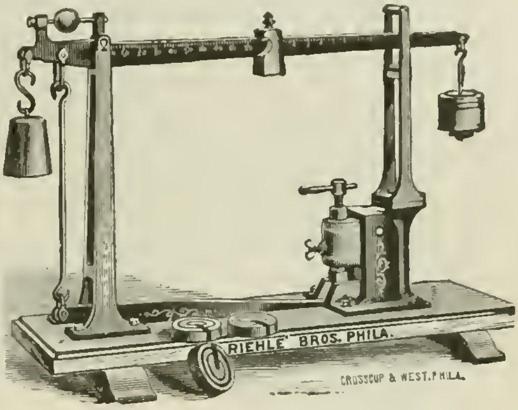
It is used as a stucco for internal decorations, takes a high polish, and when colored forms beautiful imitations of mosaic, marbles, scagliola, etc. A mixture of paper-pulp, size, and plaster of Paris in equal proportions forms a useful cement, and is also used as a sort of papier-mâché for casting into architectural ornaments, etc. Common mortar is one of the most important of the lime cements. It is composed of slaked lime, or a mixture of this with sand; its hardening depends upon the slow formation of carbonate of lime by the absorption of carbonic acid from the atmosphere, and a partial combination with the silica of the sand. Cow-hair is sometimes mixed with it, to bind it when laid in masses. In order to obtain a fine smooth paste, which is required for good mortar, the lime should be slaked rapidly by adding about three parts of water to one of lime; if the quantity of water is too small, a coarser or semi-crystalline hydrate of lime is produced by the slaking. Ordinary mortar, when exposed to the continuous action of water, softens and disintegrates, and some of the lime dissolves away. Lime which contains 20 or 30 per cent of clay, or finely divided silica, produces a mortar which is not liable to this softening, but possesses the property of hardening under water; such lime is called *hydraulic*, and the mortar made from it, hydraulic cement or mortar. Puzzolana, a porous lava found at Puzzuoli, near Naples, has been long celebrated for its property of forming a hydraulic cement when mixed with ordinary lime. It is mainly composed of silicates of alumina, lime, and soda. Portland cement, so named from its resemblance to Portland stone when dry, is made from clay found in the valley of the Medway, which is intimately mixed with the neighboring chalk, and then burned. Roman cement is similar to the Portland, but of a darker color; it contains a larger proportion of clay, and solidifies more rapidly. These cements should be mixed with a sufficient quantity of water to form a moderately thick paste; the surfaces to which they are applied should be well wetted, and the cement kept slightly moist until it hardens. The solidification of hydraulic cements depends upon the combination of the lime with the silica and alumina, forming first a hydrated compound, and finally a true silicate. They expand slightly in solidifying. See *Cement-tester.*

CEMENTATION.—The process of infusing a solid body with the constituents of another body in which it is buried, by the application of heat. The production of steel by cementation consists essentially in the exposure of bars of malleable iron, in close contact with charcoal, to a high and long-continued heat, the air being excluded. A decided peculiarity of the converted bars is the blistering of the external surface, whence the term *blister-steel* is derived. When the blisters are small and regularly distributed, the steel is of good quality; but when large, and only occurring along particular lines, they may be considered as indicative of defective composition or want of homogeneity in the iron employed. See *Blistered Steel.*

CEMENT-TESTER.—A machine for ascertaining the strength of cement, mortar, or other similar material by compression. The drawing shows an improved machine of this class with the following dimensions: Extreme height, 2 feet 4 inches; extreme length, 3 feet 6 inches; extreme width, 1 foot 5 inches; weight, 110 pounds. Adaptation—Crushing specimen, 1-inch cube or less; motion of screw, $1\frac{1}{2}$ inch; capacity, 1500 pounds.

The beam is of brass, with sliding poise and graduated from 1 pound up to the capacity of 1500 pounds The levers being carefully sealed to the United States standard, the results of the tests are positively correct. The specimen (1-inch cube) is shown in position at butt end of main lever just below the thumb-screw. The following simple directions will show how to operate the machine:

After the specimen is properly adjusted in place, force the screw down with the hand-lever until you have got enough pressure on to make the lever nearly touch the top of the stand; the weight on the beam is then carefully increased and the specimen will, in most cases, break before the beam reaches the bottom



of the stand or gate. If, however, it should not, the beam is again raised by applying pressure with the screw and moving the poise on beam until the specimen breaks or the desired test is applied. See *Testing-machine.*

CENOTAPH.—A monument which does not contain the remains of the deceased. They were originally erected for those whose bones could not be found; e.g., for those who had perished in battle. Latterly the name was applied to tombs built by a man during his lifetime, for himself or for the members of his family.

CENTER.—One of the points on the lathe-spindles on which the work is placed. The *front* or *live center* is on the spindle of the *head-stock.* The *back* or *dead center* is on the *tail-stock.* The *centers* of a planer are on stocks temporarily attached to the bed of the planer, so that the object may be turned on its axis in the course of the work thereon. See *Lathe.*

CENTER-FIRE METALLIC-CASE CARTRIDGE.—The successful invention of the self-primed metallic-case cartridge has greatly simplified the construction of breech-loading small-arms. Prior to its introduction and use, the prevention of the escape of flame through the joint of the breech was of difficult if not impossible accomplishment, and complicated arrangements of the breech-mechanism had to be resorted to, with, at best, unsatisfactory results. The metallic cartridge overcomes this difficulty, being itself a perfect gas-check renewed at every round, prevents foulness and wear of the mechanism, and exercises the most vital functions in the life of the arm. So important an element is it that it may be said that with a perfect cartridge the most indifferent breech arrangement can be used with safety and efficiency.

Its advantages, other than that already indicated, are many: its completeness and simplicity, being self-primed, and used as a whole in loading; its strength and safety, withstanding the roughest usage and thoroughly protecting the powder and fulminate; its accuracy, because of the coincidence of the axis of the bore and bullet; and, added to these, the absolute impossibility of using more than one cartridge at a time.

That adopted by the Ordnance Department is known as the *center-fire.* The superiority of this system over the rim-fire is so marked as will undoubtedly lead to its universal adoption. By concentrating the percussion-composition in the center of the head the quantity used is reduced to a minimum,—to less than one fourth of what is required to prime the entire circumference in the rim-fire,—and this smaller quantity is so much better protected as not to be at all liable to accidental explosions. The central portion of the head has more elasticity than the rim, and is better able to resist the strain upon it from the sudden action of the fulminate, besides having the additional advantage of permitting the reinforcing of the rim, thus strengthening the weakest portion of the cartridge-case.

The United States regulation center-fire cartridge, caliber .45, consists of the following parts, viz.: the

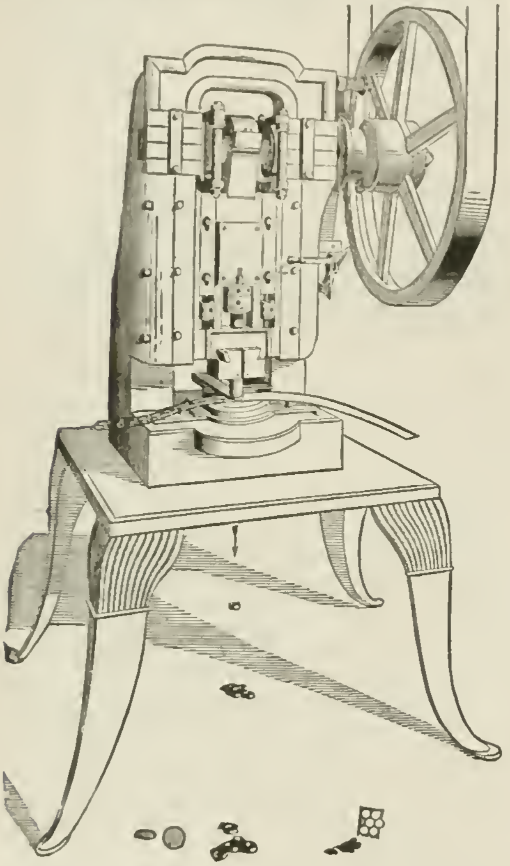


Fig. 1.

case, the *cup-anvil*, ½ grain of *percussion-composition*, 70 grains of *musket-powder*, and a lubricated *leaden bullet* weighing 450 grains. The case is the copper tube which forms the receptacle for the powder-charge, the percussion-composition, and the leaden bullet. Its exterior conformation is designed to facilitate its ready extraction from the chamber of the gun after firing. Besides the rim at the closed end, which is intended primarily to assist extraction, the case is tapered from the rear to a point where it seizes the bullet, whence it merges into a right cylinder. The cup-anvil is a small metallic cup, of sufficient rigidity to resist the blow of the hammer communicated by the firing-pin, and of such form as to insure the passage of the flame to the powder-charge upon the explosion of the percussion-composition. It is provided with a circular recess or cavity into which the percussion-composition is deposited. Two little vents, at the extremities of a diameter of this recess, direct the flame to the charge. The cup, when charged with the composition, is placed within the copper case, pressed snugly against its closed end, and crimped firmly into position. Cups were formerly made of sheet-iron tin-plate, but they are now made of copper. The bullet enters more than half its length into the case, in order that the lubricant in its grooves may be entirely covered and protected. To render the cartridge water-proof, the edge of the case is crimped hard against the bullet.

The sheet-copper for making the cases is No. 22, wire gauge, obtained in strips 35¼ inches long, 3.3 inches wide, and .03 inch thick. The ends of these strips are cut at an angle to avoid waste, and each strip gives material for 40 cases. One pound of copper will make 40 cases, ⅓ scrap. In the selection of sheets for making the cases, such only should be chosen as appear to have been rolled in a careful manner. They must be free from the slightest seams, blisters, or flaws, and of an even thickness throughout, well annealed, and trimmed to the foregoing dimensions. The best copper ores are mined on the shores of Lake Superior. The Minnesota mines and the most approved brands of Detroit smelting should be selected in preparing metal for cartridge purposes. It is not pure as received from the mills, being alloyed with 5 per cent of spelter.

The first operation in drawing the tubes is performed by the double-action press, shown in Fig. 1. The strips of copper are prepared for the press by straightening their ends and edges, if necessary, with a hand-mallet, and oiling both surfaces. The strips are then fed to the press by hand, a small stop on the die-plate regulating the length of feed. The first

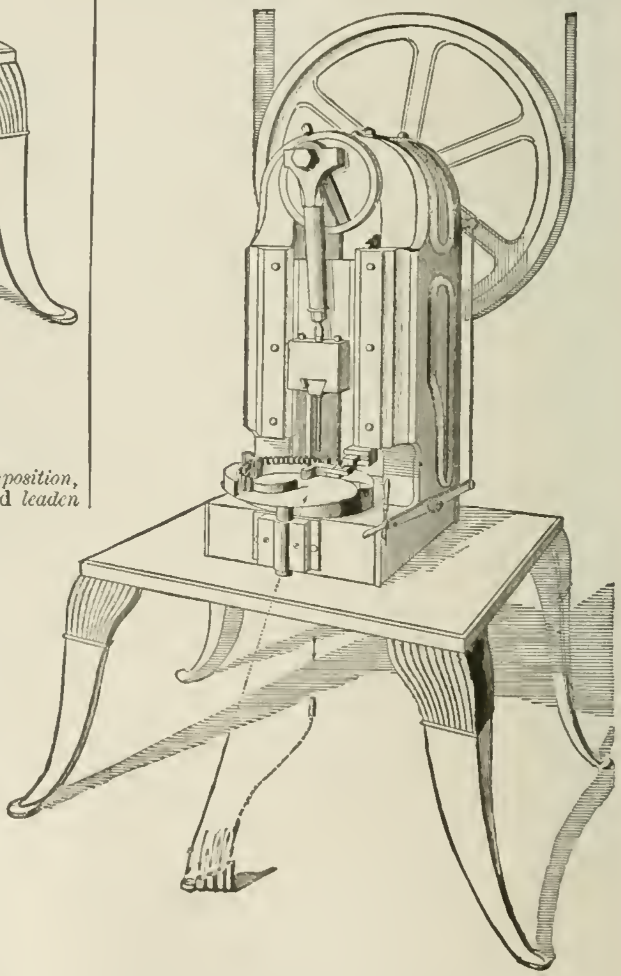

Fig. 2.

shape given to the future cartridge-case is that of a flat circular disk, 1.63 inch in diameter, cut from the copper strips fed under the double punch of this press. This punch is essentially a punch within a punch, the exterior one cutting the disk clear from the strip, while the interior one descends and forces it through a tapered die, giving it a shallow, cup shape, about 1 inch in diameter and .5 inch deep. After passing through and beyond the tapered die, the cup expands slightly and is stripped from the interior punch as the latter ascends. Two rows of disks are cut from each strip, one disk at a time. They are cut and cupped at the rate of 65 a minute. Experience has proved that a width of strip giving only two rows of disks is better than a width giving three or more rows, the former being rolled to a more uniform thickness and subject to less percentage of waste.

In order to draw the cups to the dimensions required for the finished cases, they are subjected to the action of four additional punches and dies of decreasing sizes, so as to gradually elongate the cups while reducing their diameters. These draws are made by single-action presses, having each a single punch and die, as shown in Fig. 2. The first press elongates the cup from .92 to .95 of an inch, and reduces its diameter to (according to the maximum thickness of copper and wear of tools) about .7 of an inch. The second press elongates it from 1.15 to 1.2 inch, and reduces the diameter to about .65 of an inch, thus lengthening out the cup into a tube. These tubes at this stage are annealed after a process

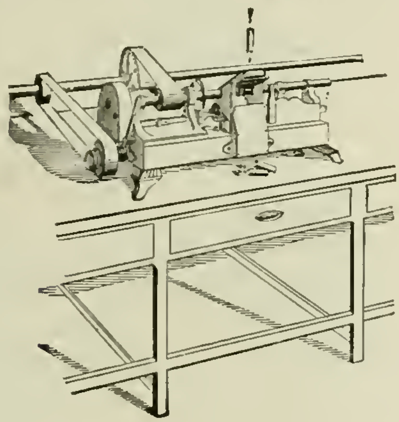

FIG. 3.

to be presently described. The third press elongates the tube from 1.75 to 1.8 inch, and reduces its diameter to .55 of an inch. The fourth press brings the tubes to the required exterior diameter of .501 minimum and .503 maximum of an inch, the extreme permissible variation of which is .002 of an inch; but they are left of unequal lengths and with ragged edges. These presses are fed at the rate of 65 tubes a minute, by placing them upright on a revolving horizontal plate provided with guides and stops.

The tubes are annealed after the second draw, as stated above, to restore to the metal its ductility, the previous operations having rendered it hard and brittle. The number of annealings required during the entire process of manufacture will depend on the quality of the metal used; with the best copper, only one is necessary. The annealing is done by placing the tubes in a perforated iron cylinder, heating them red-hot in a charcoal-fire, revolving the cylinder meanwhile to equalize the heat, then plunging them into a solution of one part of sulphuric acid and fifteen parts water, and, afterwards, thoroughly washing in several changes of water to remove all trace of acid. The acid solution (pickle) is intended to cleanse the metal from any scale, or oxide, occasioned by the annealing. They should be kept in a slightly acid bath until ready for use, when they are washed and oiled.

The finishing draw having left the tubes of unequal lengths and ragged edges, it is necessary, in order to facilitate the subsequent steps of manufacture, and to insure uniformity in the finished cartridges, to remove the ragged edges and reduce the tubes to a uniform length. This is done by means of the trimming-machine represented in Fig. 3. The tubes are placed in the trough of this machine, whence they are taken up by a revolving mandrel, against which, and just inside of a shoulder upon the same, the edge of a circular cutter is pressed. The tube, when brought to position by the mandrel, is cut clean and even by the cutter, a stripper removing the tube and scrap after each operation. To allow for the metal that is used for forming the head or rim, the tubes are cut a little longer (about .13 inch) than the headed case. The tubes are trimmed by this machine at the rate of 80 a minute.

In all the operations previous to and succeeding the annealing, lard-oil of the best quality is the lubricant used. But as the smallest particle of oil will impair the efficiency of the percussion-composition, it is of the last importance that all vestiges of it be removed from the interior of the tube before the percussion-

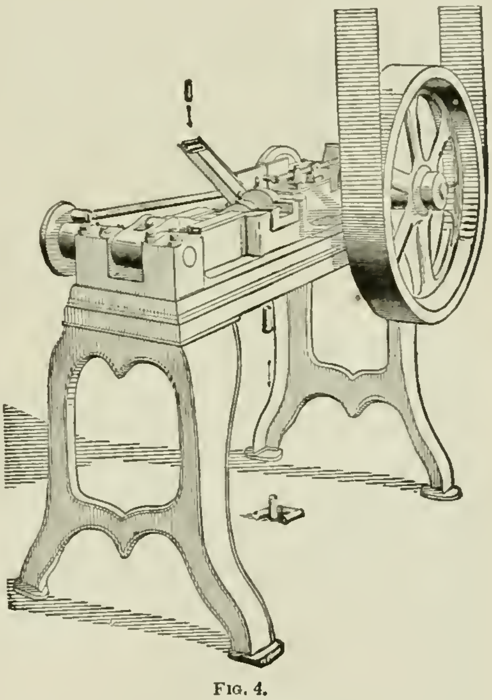

FIG. 4.

composition is inserted, The flattening of the closed end of the tube by the next operation would, if the oil were not previously removed, retain a greater or less quanity of it in the interior fold of the rim, from which no subsequent process could entirely remove it, and from which it would be liable to exude in the finished cartridge, to the destruction of the percussion-composition. The present unheaded condition of the tube, therefore, affords the most favorable opportunity for removing the oil, which is done by washing the tubes in a solution of $1\frac{1}{2}$ pound potash, $1\frac{1}{2}$ pound soda, and 5 gallons of water, temperature 120°, for seven minutes, and afterwards rinsing them thoroughly in clean warm water, using a revolving wire barrel partially immersed in it.

The head or rim of the cartridge-case is next formed by the heading-machine. This machine, shown in Fig. 4, consists of a horizontal die, countersunk at one end for sizing (diameter and thickness) the head, a feed-punch to insert the tubes into the die, and a heading-punch to flatten the closed end of the tubes into the countersink. The bumper may be reversed, and the die left without countersink. This plan has been recommended. The tubes, which are a little longer than the headed case, are fed into the inclined trough of the heading-machine, whence they are taken up on the feed-punch. A shoulder on this punch, at a distance from its extremity equal to the inner depth of the headed case, prevents it from extending to the full depth of the tube, and a surplus

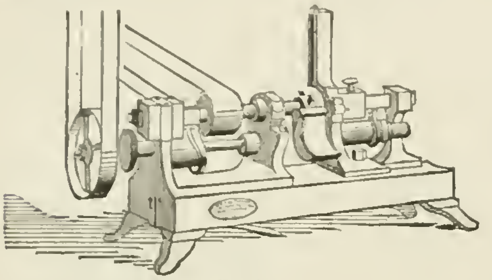

Fig. 5.

of metal is thereby left at the closed end of the tube for the formation of the head. The feed-punch inserts the tube into the die, and holds it there, while the heading-punch moves forward by a powerful cam, and presses and folds the unsupported projecting portion of the tube into the countersink of the die or recess of bumper, as the case may be, forming and accurately sizing and shaping the head or rim. The headed case being left in the die as the feed-punch recedes, is pushed out by the succeeding tube and thrown by a flipper into the receptacle below. No oil is used in this operation, the moisture of the tubes from the recent washing sufficing as a lubricant. The machine is fed at the rate of 65 per minute. The cases are now finished; but to be certain that the oil is entirely removed from them, they are again washed in the alkaline solution and dried thoroughly in a drying-room, at a temperature of about 125° Fahrenheit.

The cup-anvil is made of copper, by a double-action press, similar to the one for cutting and cupping the disks for the copper cases. Copper sheet-metal strips, 25 inches long, 2.5 inches wide, and .045 inch thick are used. One pound will make 176 cups, ½ scrap. The sheet-metal for cups must be free from all defects, with a bright, smooth surface, and uniform in thickness throughout, and annealed. The cups are cut and formed by this machine at the rate of 45 a minute. The cup-anvils, as they come from the double-action press, are of the right diameter, but too long, and with ragged edges. The cups are reduced to a uniform height by cutting off the ragged edges in the cup-trimming machine, shown in Fig.

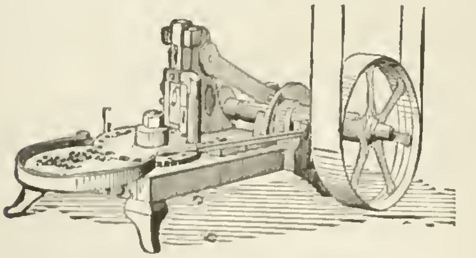

Fig. 6.

5, which consists of a revolving rose cutter, made of a number of small cutters that can be changed and sharpened at pleasure. The cups are fed to the cutters through a vertical trough, and are trimmed at the rate of 30 a minute. The vents are punched in the trimmed cups by the cup-venting machine shown in Fig. 6, which is provided with a two-pointed punch and corresponding dies. The cups are fed by hand on a revolving circular plate, at the rate of 70 per minute. The circular depression in the bottom of the cup, which serves as the receptacle for the percussion composition, is next made. The cups are fed through a vertical trough at the rate of 90 per minute. The trough has a flat pan at the top, into which the cups in quantities are emptied, and where they are arranged so as to present the proper end to the punch. The cups thus completed are well washed in an alkaline solution, to remove all traces of oil, and then thoroughly dried.

The percussion-composition consists of fulminate of mercury, 35 parts; chlorate of potash, 16 parts; glass-dust, 45 parts; gum-arabic, 2 parts; gum-tragacanth, 2 parts, by weight. These are mixed without danger by using the fulminate in a moist state, the water having been entirely drained from it. The chlorate of potash being well triturated, and the glass-dust properly prepared, the ingredients are put into a china bowl and thoroughly mixed, using a small steel spatula for the purpose. The dissolved gums will contain sufficient water to reduce the composition to a thick paste, it being used in the machine of this consistency.

Glass-dust for the percussion-composition is prepared for use in the following manner: Broken French plate-glass only is used. The glass is washed clean and dried; it is then broken into small pieces,

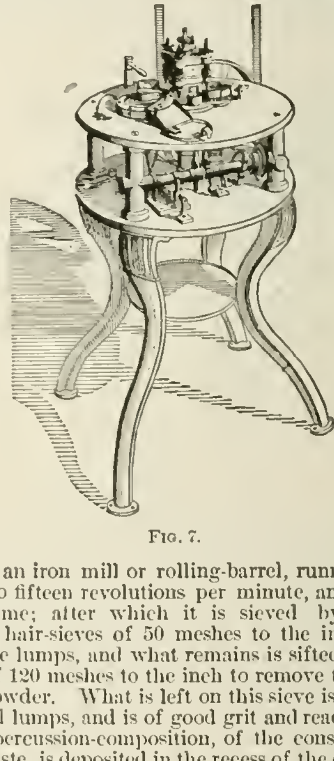

Fig. 7.

put into an iron mill or rolling-barrel, running from twelve to fifteen revolutions per minute, and ground for a time; after which it is sieved by shaking through hair-sieves of 50 meshes to the inch to remove the lumps, and what remains is sifted on hair-sieves of 120 meshes to the inch to remove the impalpable powder. What is left on this sieve is free from dust and lumps, and is of good grit and ready for use.

The percussion-composition, of the consistency of thick paste, is deposited in the recess of the cup by the priming-machine, a very ingenious piece of mechanism (shown in Fig. 7), which performs this important operation with the greatest accuracy and certainty, and with perfect safety. Its principal parts are, first, the central revolving spindle, with four tubular feeders at its head, which deposit the percussion-composition in the cups; second, the magazine on the right; and, third, the circular plate on the left, on which the unprimed cups are fed to the machine. The four tubular composition-feeders at the head of the spindle consist each of a small depending stem, down which a closely-fitting tube is made to slide, the lower edge projecting a little below the end of the stem. By the revolving motion of the spindle these tubular feeders are brought successively over the magazine and over the cups to be primed. At the moment a feeder is presented over the magazine, which is a shallow dish containing the percussion-composition, the magazine rises until its metal bottom is in contact with the tube, a slight shaking motion of the magazine during its progress serving to deposit compactly into the open projecting end of the tube a sufficient quantity of composition for the priming of a single cup. The magazine then recedes, while the revolving spindle

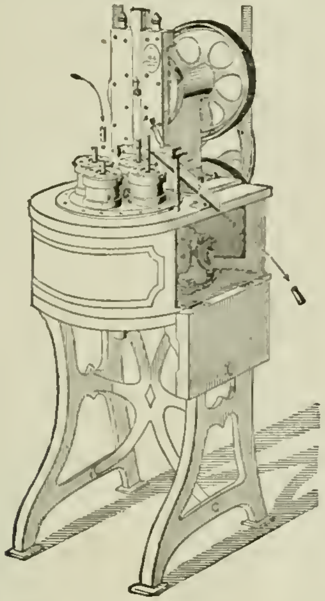

FIG. 8.

carries the charged feeder to the circular plate on the left, which presents the cups for priming. The motion of this plate is from left to right, while that of the spindle is from right to left, whereby the feeders and cups are made to meet and leave each other in opposite directions. The plate is provided with eight upright movable stems, on the ends of which the unprimed cups are fed. As the cups and feeders are brought, by the revolutions of the plate and spindle, in a vertical line with each other, the cups are raised by their stems so as to receive the percussion-composition exactly in their circular recesses from the tubes of the feeders. The tube, at the moment of contact with the cup, slides up its depending stem and frees the composition from its end, which is pressed by the upward motion of the cup snugly into the circular recess. The feeders and cups in parting leave each other horizontally in opposite directions, so that the percussion-composition is sheared off evenly and smoothly with the bottom surface of the cup. A specific quantity of composition is thus deposited in the recess of each cup at each operation. The principal difficulty heretofore encountered in perfecting a machine of this kind is entirely overcome by the use of this peculiar feeder. This machine primes at the rate of 38 per minute.

The tapering is performed in two operations: first, by forcing the shell through dies made in three cylindrical sections of graduated dimensions; second, while the composition is still moist in the circular recesses of the cups, the latter are put into the headed cases and crimped into position, the cases being tapered and reduced at the same time. The first operation prevents the case from wrinkling or folding; the second completes the tapering. The tapering-machine, shown in Fig. 8, consists of four vertical tapered dies, with stems projecting from their centers, on which the cases and cups are fed, the crimpers working from the sides of the dies, and the descending punch which forces the cases into the dies. The primed cups are placed on the ends of the stems projecting from the dies, and the cases are placed over them. By the revolution of the horizontal plate on which the dies are placed, each die is in succession brought under the descending punch, which forces the cases into the dies and presses their heads hard against the primed cups, while the crimpers move forward from the side and bite the cups snugly and firmly into place. The central stem rises out of the die as the latter leaves the punch, and the case is removed by a spring extractor. The section of the case which is to envelop the bullet is not tapered by the machine, but reduced to the form of a right cylinder whose inner diameter is the same as that of the bullet. This gives the bullet a securer hold in the case and helps to make the cartridge water-proof.

The United States elongated service-bullets are made by compression by means of machinery adapted to this purpose. They are uniform in size and weight, smoother and more homogeneous, more accurate, and give better results than cast and swaged bullets. The alloy for bullets should be pure soft lead of commerce, of specific gravity about 11.35, which is increased by pressure to about 11.45, and which melts at 600° Fahrenheit and volatilizes at red heat, and in proportion of 16 parts of lead to 1 of tin. The lead is first melted and skimmed of dross—amounting to 5 per cent in good lead—and cast in iron molds into cylindrical bars, .50 of an inch in diameter and 20 inches long. These bars are passed through rolls which reduce them to .38 of an inch in

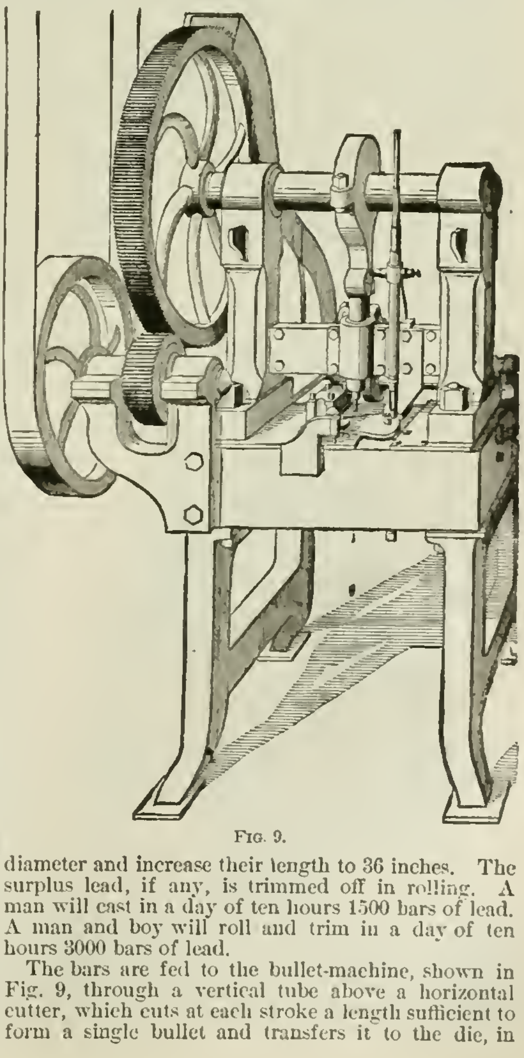

FIG. 9.

diameter and increase their length to 36 inches. The surplus lead, if any, is trimmed off in rolling. A man will cast in a day of ten hours 1500 bars of lead. A man and boy will roll and trim in a day of ten hours 3000 bars of lead.

The bars are fed to the bullet-machine, shown in Fig. 9, through a vertical tube above a horizontal cutter, which cuts at each stroke a length sufficient to form a single bullet and transfers it to the die, in which, by means of a vertical punch, the bullet is formed with its grooves. The surplus lead is forced out at the junction of the dies in the direction of the longer axis of the bullet, and at the junction of the punch and dies at its head. A bullet-machine will

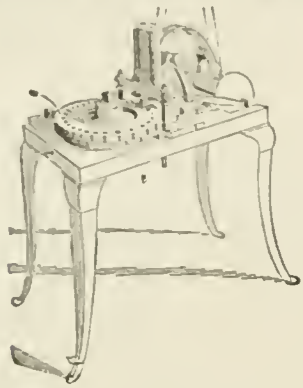

Fig. 10.

make in a day of ten hours about 25,000 to 27,000 bullets. Best lard-oil is used on the lead bars to lubricate the dies.

The operation of trimming the bullets is performed by the bullet-trimming machine shown in Fig. 10. The bullets are fed by hand into a revolving perforated circular plate, whence they are forced by a punch through trimmers which open from the point to the base of the bullet, and which conform to its shape, a cutter at the same time passing over the base. After this they are forced by the punch through the

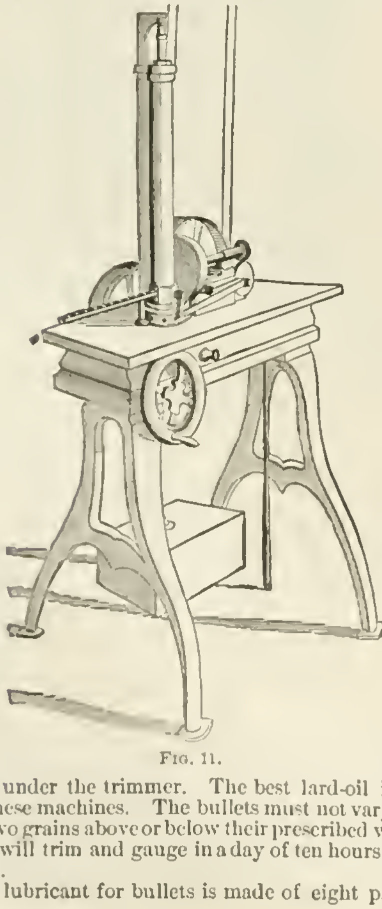

Fig. 11.

gauge under the trimmer. The best lard-oil is used with these machines. The bullets must not vary more than two grains above or below their prescribed weight. A boy will trim and gauge in a day of ten hours 15,000 bullets.

The lubricant for bullets is made of eight parts of bayberry tallow and one part of graphite, by weight. The latter must be of the best quality and free from grit. The bullets should be lubricated by machinery whenever possible, as the grooves are more surely and completely filled and more closely packed by mechanical pressure. Experiment has shown that one of the best lubricants for use with the gun, and in the lubricating machine, is Japan wax. It gives a very small per cent of fouling and works freely in the machine. It is generally cheaper than the above lubricant and has been in use several years.

The lubrication of the bullet is done by the lubricating-machine shown in Fig. 11. The lubricant is molded into cylinders of about 10 inches in length. These cylinders are fed to the machine through a vertical tube, pressure being applied to keep the supply constant. The bullets are placed by hand in a perforated revolving vertical plate and forced by a punch through a sizing-die fixed in the bottom of the tube, which is pierced with small holes. The lubricant is forced through these holes into the grooves of the bullet, filling them completely. In cold weather an arrangement for slightly warming the lubricant should be provided. A boy will lubricate in a day of ten hours 15,000 bullets.

The cases are now loaded with powder and bullets by means of the loading-machine, shown in Fig. 12, which consists of a revolving circular plate with holes or receivers, and a hopper and powder-measure. The cases and bullets are fed on revolving plates, 35 a minute; the former are lifted into the receivers, passed well under the hopper and measure for a charge of powder, and then under the bullet-feeder for a lubricated bullet. In order to insure a full charge in each cartridge, the machine is provided with a bell, which gives notice to the operative of any failure in this particular. The edge of the case is then crimped on the bullet in a very simple manner. The receivers are smaller at the top where the bullet enters than at the bottom where the case is received, the diameter of the former being only equal to that of the interior of the open end of the latter. After the bullet has been pressed into the case, the cartridge is lifted so that the edge of the case is forced into the conical surface of the receiver between its larger and smaller diameters. The powder is placed in a pasteboard hopper, about two feet above the machine, and is fed to the cases through a paper tube one inch in diameter; the hopper and tube stand inside of a large conical shield of boiler-iron.

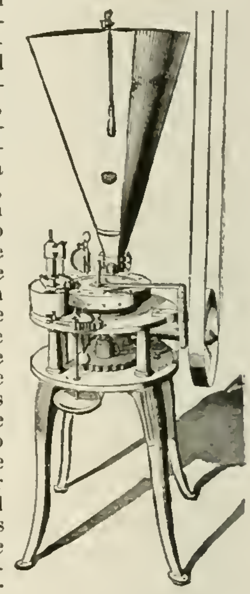

Fig. 12.

During the process of manufacture, accidents are only possible with the loading-machine; and every precaution is taken to provide against their occurrence. As the machine is now made and arranged, the explosion of one cartridge may communicate fire to the few charged cases near it without danger. The entire charge of powder in the hopper may be thus exploded without the possibility of injury, either to the operative or to the machine, as the hopper and tube offer but a slight resistance to the action of the gases that expand their forces in every direction without affecting the stability of the protecting shield. This has been proved by experimentally exploding full charges of two and a half pounds in the hopper itself. But the explosion of a cartridge in the operation of loading is of very rare occurrence. Out of the many millions loaded at Frankford Arsenal in the past ten years, a trifling number only have exploded prematurely, resulting in no damage whatever. After loading, the cartridges are wiped clean and put up in paper packages and packed in wooden boxes for storage or issue.

The cartridges are put up in paper boxes holding 20 rounds. Each box is arranged for two rows of 10, the rear row being higher than the front, each alternate cartridge having its rim below that of the other, for facility in loading and close packing. The frames and skeleton divisions of the boxes are made of straw-boards, the shapes of each part being cut with punches and dies, and such as reqnire it being creased for folding. The frame of the box is covered with stout paper bearing a printed description of the contents, and projecting far enough over to paste down the lid securely. For convenience in opening the box, a piece of strong twine is fastened at one end of the box and pasted along the inside of the seam of the lid, the loose end projecting a few inches.

The cartridges are packed, for storage or transportation, in wooden boxes, containing fifty packages each. These ammunition-boxes are painted, and the description of contents is stencil-marked on the ends, the date of fabrication branded on the sides, and the place of fabrication on the interior of the lid. See *Cartridge*.

CENTERING.—1. In consequence of windage, which is necessary for all muzzle-loading guns, the axis of the projectile does not always coincide with that of the bore; in firing, this leads to inaccuracy of fire. In order to secure accuracy of fire, it is essential that the axis of the projectile should correspond with that of the bore of the gun, for otherwise the axis of rotation will be variable and the deflection of the projectile uncertain. Should the axis of the projectile on leaving the bore be unsteady, the projectile will have the wabbling motion so frequently observed in experimental practice. A projectile is said to be centered when the grooves of the rifling are so constructed as to bring the axis of the projectile in line with that of the bore when the piece is fired. Centering may embody the compressing or expanding systems in any required degree. While the projectile is rotated by the solid projections formed upon it, and fitting into the grooves of the gun, the exterior of these projections, or of the whole projectile, may be covered with a soft substance which may, in the case of a breech-loader, be larger than the bore, and thus be compressed while passing out of the gun; or which may be expanded, by the pressure of the powder, to fill the gun. When the projectile is well centered, windage cannot affect its straight passage through the bore.

2. The framework upon which an arch or vault of stone, brick, or iron is supported during its construction. The simplest form of centering is that used by masons and bricklayers for the arches of common windows and doors. This is merely a deal board of the required shape, upon the curved edge of which the bricks or stones of the arch are supported until they are keyed in. In building bridges or other structures where arches of great span are to be constructed, the centering is usually made of framed timbers, or timbers and iron combined. The arrangement of the timbers should be such that the strain upon each shall be mainly a thrust in the direction of its length, for if the strain were transverse, a comparatively slight force would snap it, and if a longitudinal pull, the whole structure would be no stronger than the joints holding the pieces of timber together. In arches of great span, such as that of the Waterloo Bridge, London, a longitudinal pulling strain is almost inevitable in some parts, as a beam of great length would bend to some extent under a thrusting strain. In such cases great skill and care are demanded in the designing and construction of the joints. As an arch is built from the piers towards the keystone, the weight upon the haunches during construction tends to push the crown upwards, and therefore the problem of designing a framed centering involves the resistance of this tendency, as well as the supporting of the weight of the materials. The centering of the Waterloo Bridge, designed by Rennie, presents a fine example of the fulfillment of these requirements. It will be easily seen that a weight upon two parts equidistant from the center will be resisted by direct thrust upon the beams passing obliquely downwards from these parts; one of each pair of these oblique beams thrusts outwards, and is directly supported by the abutments; the other thrusts inwards towards the center, the yielding of which is prevented by the longitudinal pull of the lower and longer oblique beams. In this and other modern structures cast-iron shoes have been successfully used for the tying-joints subject to the longitudinal pulling strain. The flexible centering, so called from its yielding at the joints, and varying its form with the load put upon it, is now abandoned. It was chiefly used by French engineers. That of Perronet for the bridge of Neuilly is a celebrated example. Occasionally, when a very great span is required, and the navigation will permit, piers are built, or piles are driven, to support the centering, and the design is much simplified thereby.

Among the bridges of antiquity, that built by Trajan over the Danube is considered to have been the most magnificent; it was erected on 30 piers, of 150 feet in height, and the opening from one pier to another was 170 feet wide; the piers of this fine bridge are still to be seen on the Danube, between Servia and Moldavia, a little above Nicopolis. In the United States there are, as yet, comparatively few stone bridges of great size; the magnitude of our rivers, the heavy expense, as well as the amount of time required for the erection of such structures, being ill adapted to the pressing wants of the country; but the wrought-iron and suspension-bridges built of late years in this country rank among the most remarkable in existence. In suspension-bridges the flooring or main body of the bridge is supported by strong iron chains or rods, hanging in the form of an inverted arch from one point of support to another. The points of support are the tops of strong pillars or small towers erected for the purpose.

CENTERING-MACHINE.—A form of machine used in gun-construction for centering shafts, bolts, etc. The purposes are various, but especially to make such a depression at the exact center that the object may be placed in a lathe for turning, Fig. 1 shows

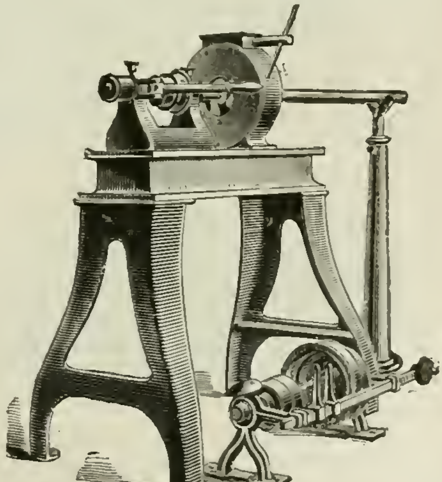

Fig. 1.

the Hyde centering-machine, which is provided with a chuck (enlarged in Fig. 2), especially designed for centering purposes. The jaws, which are very wide and heavy, are firmly supported on both sides. A steel stud ¾ of an inch in diameter passes through the jaw and each side of the case. The jaws are faced with best quality tool-steel and thoroughly hardened. In holding stocks of different sizes, the chuck is so constructed that the line of contact of the jaws moves from a point near their ends towards the fulcrum-studs, as the work to be held increases in diameter,

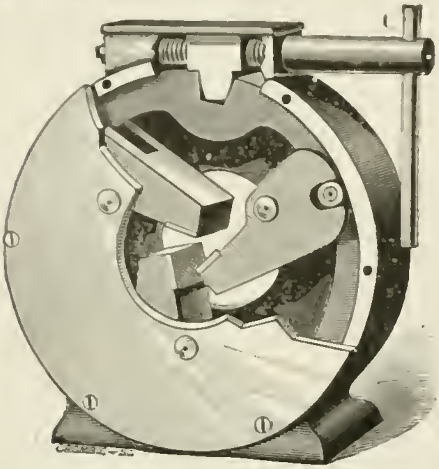

Fig 2.

thereby giving greater leverage and holding power for heavy work and distributing the wear over the whole surface of the jaws. Another important point in securing the continued accuracy of this chuck lies in the fact that the wear of the screw does not in any way affect the accuracy of the jaws. The drill-spindle slides through the cone and is operated by a lever having a toothed segment connected through a pinion with a rack cut on the box which slides in the headstock. This gives a quicker and much more desirable feed to the drill than the ordinary screw-feed. Both bearings of the live spindle are large and long and made of the best hard bronze metal. The machine will center all sizes of round stock from ¼ of an inch to 4½ inches, and is provided with an adjustable stand for supporting long bars.

Fig. 3 shows the Pratt and Whitney 8 inch Double Cutting-off and Centering Machine, used for axles and shafts of any length and diameter to 8 inches. The shafts revolve in self-centering jaws, adjustable by rack and pinion to any position on the bed, and are driven by cone and double gearing giving three changes of speed, any of which may be quickened as the cutting tools approach the center of the shaft, the number of speeds being thus increased to six. Tool-slides may be adjusted by rack and pinion to any length of shaft, and operated separately or together, each having three changes of power-feed; also rapid hand-movement quickly changed from hand to power feed. The centering-heads, with revolving spindles driven by a separate countershaft, slide on the tool-carriages.

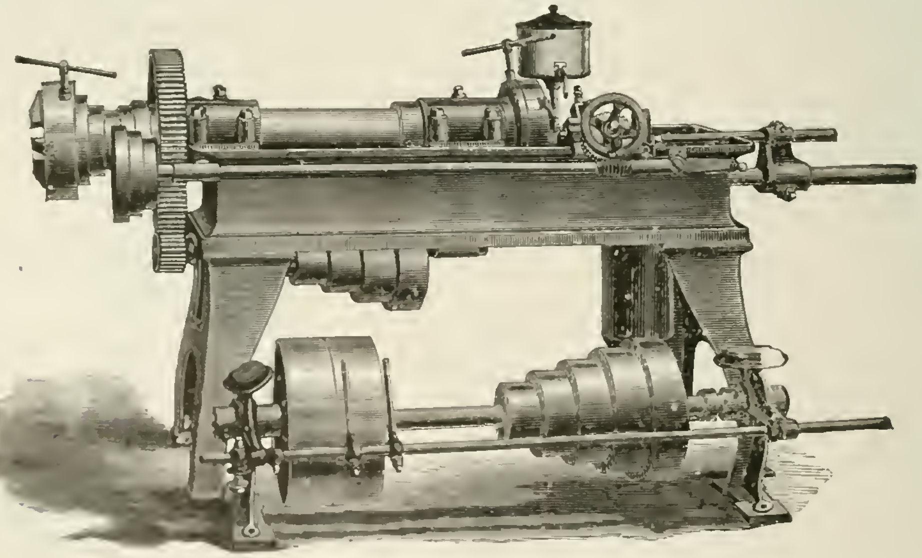

Fig. 3.

CENTER OF AN ARMY.—The body of troops occupying the place in the line between the wings.

CENTER OF FIGURE.—The point on which a plane figure or plane surface would balance, supposing their areas to have weight. This point is so situated that all straight lines passing through it, and terminated by the superficies of the figure or surface, are bisected in it.

CENTER OF GRAVITY.—That point in a body, or system of bodies rigidly connected, upon which the body or system acted upon only by the force of gravity will balance itself in all positions. Though the action of gravity enters this definition, many of the properties of the point are independent of that force, and might be enunciated and proved without conceiving it to exist. By some, accordingly, the point has been called the *center of magnitude*, and by others the *center of parallel forces.* Such a point exists in every body and system, and only one such point. Every body may be supposed to be made up of a multitude of minute particles connected by cohesion, and, so far as its balance under gravity is concerned, each of these may be supposed to be removed, and its place occupied by a force proportioned to its weight. Instead of the body, on these suppositions, we should then have a system of parallel forces, the lines from the various particles to the earth's center being regarded as parallel. But a system of parallel forces has a single resultant acting through a fixed point, whose position is independent of the position in space of the points of application of the component forces, provided their relative positions in the system continue unchanged. This point is the center of gravity; and if it be supported, it is clear that the body will balance itself upon it in all positions. The same reasoning obviously applies to any system of bodies rigidly connected. It is usual to demonstrate this and the general rule for finding the center of gravity by proving it first in the case of two heavy particles forming a body or system, and then extending the proof to the case of any number of particles. Let P and Q, Fig. 1, be two heavy particles. Join P and

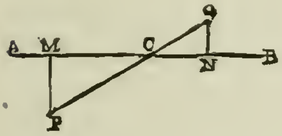

FIG. 1.

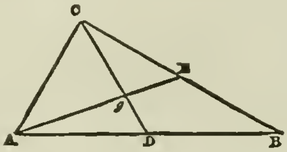

FIG. 2.

Q, and divide the line PQ in C, so that weight of P : weight of Q : : CQ : CP. Then C will be the center of gravity of P and Q. Draw ACB horizontal, and PM, QN vertical, meeting AB in M and N. Then if P and Q represent the weights of P and Q, we have P : Q : : CQ : CP. But CQ : CP : : CN : CM by similar triangles. Therefore P : Q : : CN : CM, and P . CM = Q . CN. P and Q, therefore, are balanced about C. This is true in all positions of P and Q, for no assumption was made as to their positions. C, therefore, is their center of gravity. Also, we may conceive P and Q to be removed, and in their stead a particle at C equal to them taken together in weight. If, now, the system contained three, it is clear how we should proceed to find its center of gravity; having found the center of gravity of two, we should consider the system as formed of two—viz., the equivalent of the first two at their center of gravity, and the third, when the case would fall under that already treated; and so on, extending the rule to a system containing any number of particles. Apart from this rule, however, it is possible, in the case of most regular homogeneous bodies, to fix upon their centers of gravity from general considerations. The center of gravity of a straight line, for instance, must clearly be in its middle point. So the center of gravity of a uniform homogeneous cylinder must be in the middle point of its axis. It must be in the axis, for the cylinder clearly is equally balanced about its axis. It must also be somewhere in its middle circular section, for it will balance itself on a knife-edge under that section. It must, therefore, be in the point where that section cuts the axis, or in the middle of the axis. The center of gravity of a uniform material plane triangle may be found from similar considerations. The triangle ABC, Fig. 2, may be supposed to be made up of uniform material lines parallel to its base, AB; each of these will balance upon its middle point. The whole triangle, therefore, will balance upon the line CD, which bisects the base AB and all lines parallel to it. In the same way the triangle will balance upon the line AE, bisecting BC. But if a figure balances itself upon a line, its center of gravity must lie in that line. The center of gravity of the triangle is therefore in CD, and also in AE. It must therefore be at g where these lines intersect, g being the only point they have in common. Now, by geometry, we know that g divides CD, so that $Cg = \frac{2}{3}CD$. Hence the rule for finding the center of gravity of a triangle: Draw a line from the vertex, bisecting the base, and measure off Cg, two thirds of the line. g is the center of gravity. By a similar method the center of gravity of a great number of figures may be determined. The above method applies only where the figure of the body is regular and its mass homogeneous. But many bodies, besides being irregular, are formed by the agglomeration of particles of different specific gravities. Of these, the center of gravity can be found only by experiment, though not always satisfactorily. Let the body be suspended by a string, and allowed to find its position of equilibrium. The equilibrium being due to the tension of the string counterbalancing gravity, it follows that the tension is in the same line with that on which gravity acts on the body. But the tension acts on the line of the string, which therefore passes through the center of gravity. Mark its direction through the body. Suspending it then by another point, we should ascertain a second line in which lies the center of gravity. The center of gravity, then, must be where these lines intersect.

The determination of the center of gravity is a matter of great importance in cannon, both for mechanical maneuvers and for ordinary handling. In all the large guns in the United States, and in many in Europe, the axis of the trunnions passes through the center of gravity of the gun. Such guns have no preponderance, and need no support when firing except the trunnions. This innovation was introduced by the genius of Rodman, and brought many advantages in the handling of heavy guns. In projectiles the center of gravity is also a thing of moment. Spherical projectiles, in which this point does not coincide with the center of figure, are said to be eccentric and are subject to certain deviations. Regarding the gun as a solid of revolution whose axis coincides with that of the bore, the position of the center of gravity is determined from the principle that the sum of the moments of the weights of the several parts is equal to the moment of the weight of the entire piece. For convenience, the plane of reference is usually taken either at the knob of the cascabel and perpendicular to the axis of the bore, or as coincident with the front face of the piece. The general formula expressing the above relation is

$$W\,x = w^{i}\,x^{i} + w^{ii}\,x^{ii} + w^{iii}\,x^{iii} + w^{iv}\,x^{iv} + \text{etc.},$$

or

$$x = \frac{w^{i}\,x^{i} + w^{ii}\,x^{ii} + w^{iii}\,x^{iii} + w^{iv}\,x^{iv}}{W}, \ldots (A)$$

in which W = the weight of the entire piece; x = the distance of its center of gravity from the plane of reference; w^{i}, w^{ii}, w^{iii}, etc. = the elementary weights; those corresponding to cavities (as the bore, chamber, etc.) being regarded as negative; x^{i}, x^{ii}, x^{iii}, etc. = the distances of their respective centers of gravity from the plane of reference. Should the gun be homogeneous throughout, the unit of weight may be canceled from the second member of equation (A), in which case it will be necessary to operate with the volumes simply, instead of the weights. In guns of a curved exterior, like those of the Rodman model, it is customary to divide the gun up by a system of parallel planes, at right angles to the axis, and in numbers such that the elementary volumes thus formed shall closely approximate some regular geometrical figure, usually the conic frustum, of which the volume and the position of the center of gravity admit of ready calculation. When the gun is to be without preponderance, i.e., when the axis of the trunnions is to pass through the center of gravity, the weights of the trunnions and rimbases may be omitted, since they will be symmetrically disposed about that axis. Where it is desired that the gun shall have a certain preponderance, the position of the axis of the trunnions in front of the center of gravity of the gun is determined as follows: The weight of the piece is supported by the elevating device and the trunnions. The pressure on the elevating device and its distance from the center of gravity are known; therefore the distance which the trunnions should be placed in front of the center of gravity to support the remainder of the weight will become known from the proportion $p : (W - p) : : Y \; l$, in which p represents the preponderance; l, the distance of the point of attachment of the elevating device from the center of gravity; $(W - p)$, the weight to be sustained by the trunnions; and Y, the distance of their axis from the center of gravity. See *Centrobaric Method* and *Distorted Section*.

CENTER OF GYRATION.—The point at which, if the whole mass of a body rotating round an axis or point of suspension were collected, a given force applied would produce the same angular velocity as it would if applied at the same point to the body itself. The center of gyration bears a strong analogy to the center of oscillation. The cases differ only in this, that in the latter the operating forces are supposed to act at every point of the moving body, while in the former there is only one force acting upon one point. The center of gyration is found by the following rule: Divide the moment of inertia of the rotating mass by the mass of the body, and extract the square root of the quotient. The result is the distance of the point from the axis of rotation. The moment of inertia, it may be stated, is the sum of the products of the weight of each point of the mass by the square of the perpendicular distance of that point from the axis.

CENTER OF IMPACT.—The *mean point of impact*, or the mean of all the hits, when a projectile strikes a target a number of times. It is a point of the mean trajectory. See *Point of Impact*.

CENTER OF OSCILLATION.—Referring to the article PENDULUM, it will be seen that the time of a pendulum's vibration increases with its length, being always proportioned to the square root of its length. This is strictly true only of the simple pendulum, in which the pendulous body is supposed to have no determinate magnitude, and to be connected with the point of suspension by an inflexible wire without weight. If, however, the vibrating body have a determinate magnitude, then the time of vibration will vary, not with the square root of its length, but with the square root of the distance from the axis of suspension of a point in the body called its center of oscillation.

If each part of the vibrating body were separately connected with the axis of suspension by a fine thread, and entirely disconnected from the rest of the body, it would form an independent simple pendulum, and oscillate as such—the time of each vibration being as the square root of the length of its thread. It follows that those particles of the body which are nearest to the axis of suspension would, as simple pendulums, vibrate more rapidly than those more remote. Being connected, however, as parts of the solid body, they vibrate all in the same time. But this connection does not affect their *tendencies* to vibrate as simple pendulums, and the motion of the body which they compose is a compromise of these tendencies of its particles. Those nearest the axis are retarded by the more remote, while the more remote are urged on by the nearer. Among these particles there is always one to be found in which the accelerating and retarding effects of the rest are mutually neutralized, and which vibrates in the same time as it would if it were unconnected with the other parts of the body, and simply connected by a fine thread to the axis of suspension. The point in the body occupied by this particle is its center of oscillation. By this center of oscillation the calculations respecting the vibration of a solid body are rendered as simple as those of a molecule of inconsiderable magnitude. All the properties which belong to a simple pendulum may be transferred to a vibrating body of any magnitude and figure, by considering it as equivalent to a single particle of matter vibrating at its center of oscillation.

The determination of the position of the center of oscillation of a body usually requires the aid of the calculus. It is always further from the axis of suspension than the center of gravity is, and always in the line joining the center of gravity and the point of suspension, when the body is suspended from a point. The rule for finding it in such a case is: If S be the point of suspension, and O the center of oscillation, $SO = \frac{\Sigma(md^2)}{M \cdot Sg}$; or it is the quotient obtained by dividing the moment of inertia of the body by the product of its mass into the distance of its center of gravity from the point of suspension. See *Pendulum*.

CENTER OF PERCUSSION.—The center of percussion of a body or a system of bodies revolving about a point or axis is that point in it which striking an immovable object, the whole mass shall not incline to either side, but rest, as it were, in equilibrio, without acting on the center or axis of suspension. If the body be moving freely, then the center of percussion is that point in it at which its whole impetus is supposed to be concentrated. In this case, if the body struck with its center of percussion an immovable obstacle, and if it were perfectly rigid and inelastic, it would come to perfect repose; whereas, if it struck the obstacle with any other point a rotatory motion would be produced in it. When the body is moving freely, and there is no rotatory motion, the center of percussion coincides with the center of gravity. If the body be moving round a point or axis of suspension, the center of percussion coincides with the center of oscillation. The more complicated case of a body rotating round an axis within it would require, for its explanation, analytical formulæ which cannot conveniently be translated into ordinary language. There are many positions which the axis may have in which there will be no center of percussion—i e., there will be no direction in which an impulse could be applied without producing a shock upon the axis. One case of this sort is that of the axis being a principal axis through the center of gravity.

CENTER OF PRESSURE.—The center of pressure of any surface immersed in a fluid is the point in which the resultant of the pressures of the fluid on the several points meets the surface. When the bottom of a vessel containing fluid, or when a plane immersed in fluid, is horizontal, a pressure on every point of it is the same, being that due to the weight of the column of fluid standing above the bottom or plane. In either case the pressures at the different points obviously form a system of equal parallel forces, whose center will be the center of gravity of the bottom or plane, their resultant passing through this point being the sum of all their forces. But when the plane is inclined at any angle to the surface of the fluid, the pressure is not the same at all points, but is obviously greater at the lower than at the upper points, for the lower have to support taller columns of the fluid. The resultant of these forces, then, will not pass through the center of gravity of the surface, but through a point below it. This point is the center of pressure, and evidently will lie below the center of gravity for all fluids in which the pressure increases with the depth. If the surface pressed upon form part of the containing vessel, and be supposed movable, it will be kept at rest by a pressure equal to the sum of the fluid pressures applied at the center of pressure, and acting in the opposite direction. In the case of a vessel with a parallelogram for one side, the center of pressure is at the distance of one third of the height from the bottom. In the case of a triangular vessel whose base is at the bottom, it is one fourth of the height only.

CENTER OF THE BASTION.—In fortification, the intersection made by two demi-gorges.

CENTER-PINTLE CARRIAGE.—One in which the chassis is attached to the pintle at its middle, and revolves around it through the entire circumference of the circle. The traverse-circles are consequently continuous. By this arrangement a much greater horizontal field of fire is secured.

CENTESIMATION.—In ancient military history, a mild kind of military punishment in cases of desertion, mutiny, and the like, when only every one hundredth man was executed.

CENTRAL FORCES.—Those forces which cause a moving body to tend towards some point or center, called the center of force or motion. The doctrine of central forces has for its starting-point the first law of motion—viz., that a body not acted on by any external force will remain at rest, or move uniformly in a straight line. It follows from this law that if a body in motion either changes its velocity or direction, some external force is acting upon it. The doctrine of central forces considers the paths which bodies will describe round centers of force, and the varying velocity with which they will pass along in these paths. It investigates the law of the force round which a body describes a known curve, and solves the inverse problem, and many others, the general statement of which could convey no clear idea to the unmathematical reader. As gravity is a force which acts on all bodies from the earth's center, it affords the simplest general illustration of the action of a central force. If a stone be slung from a string, gravity deflects it from the linear path which it would otherwise pursue, and makes it describe a curved line which we know would, in vacuo, be a parabola. Again, the moon is held in her orbit round the earth by the action of gravity, which is constantly preventing her from going off in the line of the tangent to her path at any instant, which she would do, according to the first law of motion, if not deflected therefrom by any external force. To that property of matter by which it maintains its state of rest or motion, unless acted upon by other matter, has been given the name *inertia*.

We will now explain how, through the action of a central force, a body is made to describe a curved path. Suppose it to have moved for a finite time, and conceive the time divided into very small equal parts; and instead of the central force acting constantly, conceive a series of sudden impulses to be given to the body in the direction of the center, at the end of each of the equal intervals, and then observe what, on these suppositions, will happen. Let S, Fig. 1, be the center, and let the original motion be

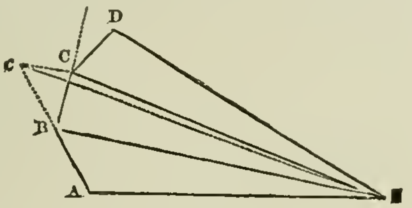

FIG. 1.

from A, on the line AB, which does not pass through S. In the first interval the body will move with a uniform velocity, say from A to B. In the second, if acted on by no force, it would move on in AB produced to *c*, B*c* being = AB. But when it arrives at B it receives the first sudden impulse towards S. By the composition of velocities, it will move now with a new but still uniform velocity in BC instead of B*c*, BC being the diagonal of the parallelogram of which the sides represent its impressed and original velocity. Having reached C at the end of the second interval, it receives the second impulse towards S. It will now move in CD instead of in BC produced. If, then, we suppose the periods of time to be indefinitely diminished in length, and increased in number, the broken line ABCD will become ultimately a continuous curve and the series of impulses a continuous force. This completes the explanation.

Going back, however, on our suppositions, we may here establish Newton's leading law of central forces. That the body must always move in the same plane results from the absence of any force to remove it from the plane in which at any time it may be moving. The triangles ASB and BSC are clearly in the same plane, as the latter is on that in which lie the lines B*c* and BS. Also, since the triangles ASB, BS*c* are equal, being on equal bases, AB, B*c*, and triangle BSC = triangle BS*c*, as they are between the same parallels, *c*C and BS, it follows that ASB = BSC. So BSC = CSD; and so on. In other words, the areas, described in equal times by the line (called the radius vector) joining the center of force and the body, are equal. As this is true in the limit, we arrive, by the composition of the small equal areas, at the law that the areas described by the lines drawn from the moving body to the fixed center of force are all in one plane, and proportional to the times of describing them. Very few of the laws of central forces are capable of being proved like the preceding, without drawing largely on Newton's lemmas, with which we shall not suppose the reader to be acquainted.

We have shown that a body continually drawn to a center, if it has an original motion in a line that does not pass through the center, will describe a curve. At each point in the curve it tends, through its inertia, to recede from the curve, and proceed in the tangent to it at that point. It always *tends* to move in a straight line in the direction in which it may at any time be moving, and that line, by the definitions of a tangent and of curvature, is the tangent to the curve at the point. At the point A, Fig. 2, it will endeavor to proceed in AD: if nothing hindered it, it would actually proceed in that line, so as, in the time in which it describes the arc of the curve AE, to reach the point D, and thus recede the length DE from the curve; but being continually drawn out of its direction into a curve by a force to a center, it falls below the point D by the distance DE. The force which draws it through this distance is called the centripetal force, and that which would make it recede in the same time through the distance DE from the curve is called the centrifugal force. It may be remarked that the centrifugal force is not, like the centripetal, an impressed or external force acting on the body. It is simply the assertion of the body's inertia under the circumstances produced by the centripetal force.

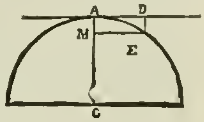

FIG. 2.

Many familiar illustrations will occur to the reader of the action of what is called the centrifugal force. A ball fastened to the end of a string, and whirled round, will, if the motion is made sufficiently rapid, at last break the string and fly off. A glass of water may be whirled so rapidly that, even when the mouth is pressed downwards, the water will still be retained in it, by the centrifugal force pressing it up against the bottom of the glass. The centrifugal action will be found to increase with the velocity. In all cases of a body moving in a circle, the force, it can be proved, varies as the square of the velocity of the body at the moment, and in the inverse ratio of the radius. As in this case the velocity varies as the radius inversely, it follows that the force is as the inverse cube of the radius. As in the case of circular motion the body always is at the same distance from the center, it follows that the centrifugal and centripetal forces are equal at all points of a circular orbit. The general law for all orbits is, that the centrifugal force varies as the inverse cube of the distance from the center. As the attractive force of gravitation varies as the inverse square of the distance, it may hence be shown that the centrifugal force gives perfect security, notwithstanding the constant attraction of the sun, that the planets, so far as that attraction is concerned, will never fall into the sun. See *Falling Bodies*, *Force*, and *Gravity*.

CENTRALIZATION.—In military affairs, a system of organization or of administration by means of which all matters appertaining to the army are directed by one center. The legitimate application of the term is to a state of change from local to central management, and therefore the opposite of localization. The system, when adopted in the administration of an army, is very dangerous, as it takes away the independence of action of the different officers under the Commander-in-Chief, and leads to favoritism; and should the mainspring of the machine break down, all the works come to a standstill. In England, the administrative military authority, although centralized in the Crown, has been placed under the control of Parliament, and there is nothing done under the orders of the War Office for which the Secretary of State for that Department may not at any time be called to account by Parliament.

CENTRICAL RIFLING.—The solid projectile, fitted to the rifling of the gun so as to center itself, has been improved by the *centrical* system, so called because of the peculiar mode of centering its simple iron projectile, which, instead of inclining towards the bottom of the bore in its passage out, is centered on its rounded bearings, without jar by the first pressure of the elastic fluid. This is effected by the peculiar curves of the shoulders of the three grooves, which incline towards the center of the bore, and thus form three rails for the projectiles to slide out upon without being compressed or strained. In case of large calibers with heavy projectiles, a shallow shoulder is taken out for the shot to turn against in loading. It is readily seen how rounding the groove prevents the violent shock of the projectile when its bearing-edges strike the rifling. The projection, *a*, bears and remains

upon the side, *d*, of the groove going in, and so leaves the windage, *c*, on the other side. In going out, the projectile will have acquired considerable velocity before it strikes the side, *c'*, so that the blow will be violent, and the commencement of the rotation instantaneous. The projection not only slides up the rounded groove without a blow, but lifts the projectile into the center of the bore, thus centering it. See *Scott Rifling*.

CENTRIFUGAL GUN.—A form of machine-gun, in which balls are driven tangentially from a chambered disk rotating at great speed.

CENTROBARIC METHOD.—The method ordinarily used to determine by calculation the center of gravity of a projected gun. The principle used is that the volume generated by any surface in revolving about a fixed axis is measured by the product of the surface into the path described by its center of gravity. The moments of the weights of the several parts are referred to an axis usually taken tangent to the knob of the cascabel. The sum of these moments, divided by the weight of the piece, gives the distance of the center of gravity from the assumed axis. In homogeneous guns the volumes of the several parts can be used instead of the weights.

CENTURION.—A Roman infantry officer who originally commanded a hundred men, but afterwards an indefinite number. They were of two grades, and were chosen by the Tribunes. Their duties were to drill the soldiers and appoint them tasks; and they had power to punish for minor offenses.

CENTURY.—In an ancient military sense, the hundred soldiers, who were employed in working the battering-ram.

CERCELEE.—In Heraldry, a cross circling or curling at the ends, like a ram's horn. Also written *Recercle*. See *Heraldry*.

CERCLE.—A form observed under the old government of France, by which it was directed that every evening at a specific hour the Sergeants and Corporals of brigade should assemble to receive orders, the former standing in front of the latter. Subsequent to the grand cercle, a smaller one was made in each regiment, when general or regimental orders were again repeated to the Sergeants of each regiment, and from them communicated to the officers of the several companies.

CEREMONIES.—Stated military performances, such as Parades, Reviews, Inspections, Escorts of Color, Escorts of Honor, Funeral Honors, Guard-mountings, etc. In the United States army, at all Parades and Inspections of a battalion, the Field and Staff are dismounted; they are also dismounted at Review, unless the Reviewing-officer be mounted.

CERTIFICATE OF DEPOSIT.—Every person who has moneys of the United States in his hands or possession pays the same to the Treasurer, an Assistant Treasurer, or some public depositary of the United States, and takes his receipt for the same, in duplicate, and forwards one of them forthwith to the Secretary of the Treasury. The face of each Certificate should show, in writing, to what appropriation the deposit belongs, provided the depositor has such information as may be necessary to enable the depositary to state the same in preparing the Certificate for issue. The place, date, and amount of deposit, and the number of the Certificate, together with the appropriation, if specified, are noted on the account-current or other proper return upon which the depositor desires to be credited for the money.

As the Certificates of Deposit constitute an important check upon the transactions of the different Government depositaries, and are required at the Treasury Department at the earliest possible moment for verification with the accounts of said depositaries, the following regulations concerning their future disposition are prescribed, which, as they are based upon express provisions of law, are expected to be strictly complied with:

1. The originals of all Certificates of Deposit for the deposit of any and all public moneys of every character and description, *except as stated in the next succeeding paragraph*, should be forwarded to the Secretary of the Treasury immediately upon their issue by the depositors (not the depositaries), who, before transmitting them, should see that their amounts correspond with the amounts actually deposited by them.

2. Those issued to disbursing-officers for disbursing funds deposited to their own official credit, subject to the payment of their checks, and more properly called disbursing-officers' receipts, should be retained in their own possession; those issued for the transfer of funds from one Government depository to another should be forwarded to the Treasurer of the United States.

3. Certificates of Deposit issued to military officers, either on account of repayments, sales of public property, or otherwise, should be *in duplicate;* the duplicates to be retained by the depositors.

4. In no case are Certificates of Deposit required to be filed with accounts rendered by Government officers to the accounting officers of the Treasury Department, nor does such a disposition of any Certificates of Deposit secure to the officers transmitting them proper credits in their accounts. Credits are only given officers in the settlement of their accounts upon warrants, which warrants are issued by the Secretary of the Treasury, and based upon the original Certificates of Deposit. In taking credit in their accounts-current, however, for deposits made, officers should state specifically the date of the deposit, and the designation and location of the depository in which the deposit was made, as well as the source, etc. All original Certificates of Deposit in favor of military officers, the amounts of which are required to be listed and recorded in the offices of any of the Heads of the Bureaus of the War Department, will immediately upon their receipt—a record having first been made of them for verification with the proper depositary accounts—be forwarded to the Head of the respective Department to which the deposits pertain for designation of the proper appropriations.

CERTIFICATE OF DISABILITY.—Whenever a non-commissioned officer or soldier becomes unfit for the military service in consequence of wounds, disease, or infirmity, his Captain forwards to the Commander of the Department or of the army in the field, through the Commander of the regiment or post, a statement of his case, with a certificate of his disability, in duplicate, signed by the Senior Surgeon of the hospital, regiment, or post, according to the form prescribed. If the recommendation for the discharge of the invalid be approved, the authority therefor is indorsed on the Certificate of Disability, which is sent back to be completed and signed by the Commanding Officer, who then sends the same direct to the Adjutant General's Office. But under no circumstances is the certificate given into the hands of the soldier. In deciding upon applications for pension, reference is made to the Certificate of Disability for proper proof that the soldier is entitled under the law. Therefore, when it is a *probable* case for *pension*, *special care* must be taken to state the *degree* of disability—as ½, ⅓, etc.; to describe particularly the disability, wound, or disease; the extent to which it deprives the soldier of the use of any limb or faculty, or affects his health, strength, activity, constitution, or capacity to labor or earn his subsistence. The Surgeon adds from his knowledge of the facts and circumstances, and from the evidence in the case, his professional opinion of the cause or origin of the disability, and whether *in the line of duty* or not.

CERTIFICATE OF MERIT.—A certificate given by the President to enlisted men in the United States army, upon the recommendation of Commanding Officers. The certificates are awarded only for acts of extraordinary gallantry in presence of the enemy, which acts must be specific and certified to by an eye-witness, preferably the immediate Commanding Officer of the soldier. Good standing and undoubted courage in a soldier will also be required to entitle him to a Certificate of Merit. Recommendations for the Certificate of Merit must each be in behalf of only one person, and must contain a full description of the merits of the case. They must be forwarded through the regular channel, and indorsed with approval and recommendation by each Commander, especially the Regimental Commander. The extra pay granted on Certificate of Merit commences at the date of the act of gallantry for which the certificate is granted. This extra pay is two dollars per month while the soldier remains continuously in service. Certificates of Merit are not granted to persons not in the military service of the United States at the date of application for them. Should a soldier die before receiving a certificate conferred upon him, it will be deposited in the office of the Second Auditor of the Treasury for the benefit of his heirs. In case the soldier is discharged before the certificate is issued, it will be retained in the office of the Adjutant General until called for, when proof of the identity of the applicant will be required.

CERUSE.—The basis of white oil-paint and a *carbonate of lead*. It has several other names—krems, Nottingham white, flake-white, etc. Like all other preparations of lead, ceruse is liable to be acted upon by exhalations from sewers, or by anything which contains sulphuretted hydrogen, in which case it is changed to a dull and leaden hue. Neither will it bear to be mixed with any pigment containing sulphur, such as vermilion. It is supposed that the white oxide of zinc might be substituted for ceruse as a white pigment with advantage.

CERVELIERE.—A small bascinet anciently worn under the *heaume*. Now obsolete.

CESSATION OF ARMS.—An armistice or truce agreed to by the Commanders of Armies, to give them time for a capitulation, or for other purposes.

CESTUS.—The covering for the hands worn by Roman pugilists. It was originally nothing more than a leathern thong or bandage used to strengthen the fist; but in after years it was well covered with knots and nails, and loaded with lead and iron, etc., to increase the force of the blow. It was not uncommon for a pugilist armed with the cestus to dash out the brains or break the limbs of his antagonist. The Roman pugilist (*cestuarius*) was often represented in sculpture. This word is often and more correctly written *Cæstus*, from the Latin *cædere*, to slay.

CHAFF-CUTTER.—An implement now much used at cavalry posts and in the field for cutting hay and straw into half-inch lengths. The advantage of this consists not so much in facilitating mastication or digestion as in preventing animals from wasting their food. No small amount of mechanical ingenuity has been applied to the construction of chaff-cutters, the simplest and oldest kinds of which are mere hand-machines with a single large knife, the hay or straw being pushed forward in a trough or box, whilst others are driven by horse, steam, or water power, and are not a little complicated. See *Forage*.

CHAFFEE MAGAZINE-GUN.—This gun belongs to that system in which a fixed chamber is closed by a movable breech-block, sliding and rotating, and operated by a lever from below. On the inner surface of the receiver are two circular guides which enter grooves in the breech-block and over which the breech-block slides. The block is a single piece hollowed out to receive the hammer and the mainspring. At the front of the block is the firing-pin, limited in its motion by a screw. The breech-block is operated by a lever. The front of the lever is hinged to the front of the breech-block; its middle is hinged to two arms which are in turn hinged to the sides of the receiver. The hammer is cocked when the breech-block lever is thrown open by the pressure of the lever-hook on the face of the hammer, which forces the latter back until the nose of the sear—which is a part of the trigger—enters a notch. Reverse motion of the lever closes the block which is locked by a projection on the lever, entering a recess in the block and in the sides of the receiver. The extractor is not rigidly connected with the breech-block, but has a longitudinal motion along its side. It does not begin to draw the shell until the breech-block has moved to the rear nearly an inch, when a shoulder on the extractor strikes a corresponding one on the block, after which both move together. The object of the extractor projecting so far in front of the block is to support the cartridges as they leave the magazine on their way to the chamber. A shoulder on the bottom of the carrier serves as an ejector. Its effect is to rotate the empty shells through the opening in the bottom of the receiver to the ground. The magazine is in the butt-stock. The shape of the inner surface of the carrier at its front is such that the point of the cartridge as it leaves it is opposite the center of the chamber. An inclined rear surface of the carrier prevents the rear of the cartridge from rising while on its way to the chamber. When the lever is thrown open a spring at the front of the carrier causes its rear to descend opposite the mouth of the magazine. In this position it serves as a cartridge-stop, preventing the escape of other cartridges. There is no cut-off to the magazine, nor can there be, each motion of the lever being accompanied with a corresponding motion of the ratchet. As a single-loader, the piece is loaded through the carrier, the rear of which is opened by depressing the front; this should be done before the lever is opened. The trigger is locked by a set-screw when the piece is carried at full-cock. As a magazine-gun, three motions are necessary to operate, viz., opened, closed, fired. As a single-loader, four motions are necessary, viz., loaded, opened, closed, fired. The gun carries six cartridges in the magazine, one in the carrier, and one in the chamber. See *Magazine-gun*.

CHAFFEE-REECE MAGAZINE-GUN.—This arm, an improvement on the Chaffee magazine-gun, belongs to that system of bolt-guns in which a fixed chamber is closed by a movable breech-bolt sliding and rotating. The magazine is in the butt-stock. The cartridges are held in the magazine by two ratchet-bars, one fixed and the other sliding, and operated when the bolt is drawn back and closed. The magazine having been loaded, the bolt is thrown open and each tooth of the sliding-bar passes behind the head of the cartridge next in its rear. The closing of the bolt moves the ratchet forward, bringing each cartridge its own length further to the front. The cartridges are firmly held in position, so that they are not and cannot be in contact with each other, which is positive prevention from accidental explosions.

The frequent accidents and loss of life from premature explosions by magazine-arms induced many gun-mechanics, and among the number Mr. Chaffee, to undertake to invent a magazine-arm that should be free from that objection, and after several years in study and hard work, and a large outlay of money, he produced this arm, which, upon a test-trial, before a Board of Army Officers, has demonstrated the fact that he has succeeded in doing it. This arm can be used as a single-shooter until occasion requires the delivery of shots more frequently than would be possible if the arm had to be loaded after each discharge, when, by the turn of a button, seven extra charges will be available which can be delivered in four seconds or less. This makes a body of men with this arm a very formidable foe.

The employment of the Chaffee-Reece arm in the service will reduce to a considerable extent the necessity for machine-guns, which are considered most valuable in destroying a body of men closely packed; but men these days avoid bunching on the field, especially when machine-guns are liable to be trained to cover them. Troops armed with this gun have each a machine-gun, and are more capable of repelling a boarding party from a ship, or an assaulting column upon a military work, as they can be so disposed as to defend the entire space, instead of one or two points.

Much time and expense are devoted to the education of officers of a well-organized army, and they have lived in vain if they know no better than to put dangerous arms in the hands of troops, who, having confidence in the knowledge of, and trusting all such questions to, the officers, as they, the soldiers, are obliged to do, move forward at their command with the risk of disaster from the fire of the enemy, but with no expectation that they are really in more danger from the arms with which they are fighting than from those in the hands of the opposing army.

The art of war is now reduced to a science by all well-regulated governments, and perhaps there is no branch of the service by which troops are asked to take so much risk as to use an arm which is liable to explode prematurely and either kill or maim for life the soldier whose services are necessary for the success of the cause, and in upholding the flag under which he takes service with confidence that he will be armed with a gun with which to kill the enemy, and not himself or his comrades. See *Chaffee Magazine-gun.*

CHAIN.—A device consisting of several associated links, joined endways, so as to string out in line. The varieties of chains are numerous, and their names are derived from their material, structure, or purpose. In mechanical maneuvers, and in the general work of the foundry and construction-shops, chains are indispensable. Chain-cables are made of links the length of each of which is generally about six diameters of the iron of which it is made, and the breadth about three and a half diameters. In government contracts, chain-cables are required to be made in 12½-fathom lengths, with one swivel in the middle of every alternate length, and one joining-shackle in each length. The stay-pins, to strengthen the links, are of cast-iron. The bar or rod from which each link is made has the two ends cut diagonally; it is bent into the form of a nearly complete oval ring; and then the two ends are joined and welded, the stay-pin being at the same time introduced at the proper place. Besides the ordinary links, there are end-links, joining-shackles, splicing-tails, mooring-swivels, and bending-swivels. The sizes of chain-cables are denoted by the thickness of the rod-iron selected for the links. The following table gives certain ascertained quantities concerning the cables in ordinary use :

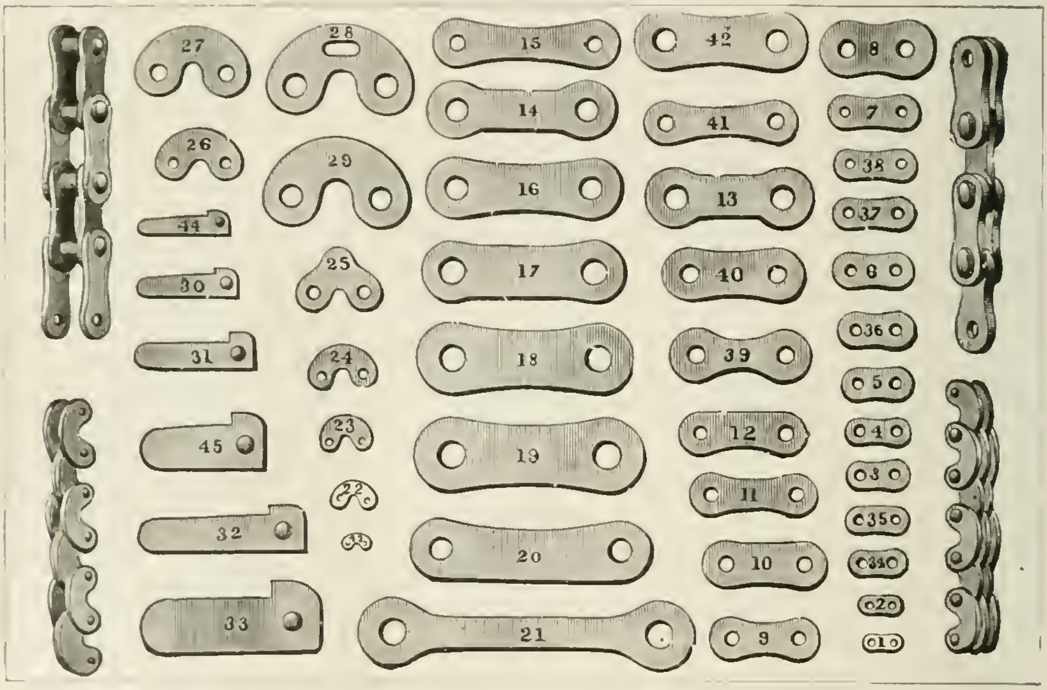

Fig. 1.

Diameter of Link.	Weight per foot.	Breaking Strain.	Diameter of Link.	Weight per foot.	Breaking Strain.
Inches.	Pounds.	Pounds.	Inches.	Pounds.	Pounds.
3/16	.35	1,731	1	9.3	49,280

15/16	8 16	43,277	3	84.0	398,944

Chains with flat links are made in the fly-press. The links are cut out, and the holes are afterward punched as in washers, one at a time, every blank being so held that its circular extremity touches the stops on the bed or die, which insure the centrality of the blank and punch. The two holes are thus made equidistant in all the links, and are afterwards strung together by inserting keys or rivets through the holes. Sometimes the succession of the links of the chain is one and two links alternately; or three and two; or four and three, up to eight and nine links, which is sometimes used. Chains intended to catch on pins or projections on the periphery of a wheel are made two and two, leaving an opening which slips over the cog. A full assortment of punched chain-links and keys is shown in Fig. 1. These links are made with special machinery by Messrs. Hoopes & Townsend, Philadelphia, and have been tested for ordnance purposes with the following results:

Nos. 30, 31, 32, 33, 44, and 45 are keys for 1/2, 5/8, 3/4, 1 1/4, 1 3/8, and 1 inch bolts respectively.

The *roller detachable chain-belting*, made by the Lechner Manufacturing Company, is now generally used throughout the United States for driving elevators, drags, heavy and light shafting, conveyors, hoists, log-haul-ups, traction-engines, racking-carriages on lifting-cranes, roller-trains in rolling-mills, live rolls, etc. Fig. 2 shows a roller detachable chain-link one half actual size, with a working strain of 3500 pounds. The method of detaching the links, shown in Fig. 3, is very simple, and is as follows: Bring the links to right angles with each other, by a slight tap on the roller; change the position of the pin from the narrow to the larger portion of the slot, when it (the pin) can be driven through and out, and the chain detached. This belting has many superior qualities. 1st. The action of the roller upon the sprocket-wheels and links greatly reduces friction and the usual wear upon both, by rolling when coming in contact with the sprockets until seated, when it rests quietly till released by leaving the wheel, causing no scrape whatever. Again, when the chain is used for conveyors, in its movement on a plane or incline, it rolls upon the rollers, and thus requires much less power to drive the conveyor, than is the case where chains are dragged upon their flat surface. It also admits of a lighter chain to do the same

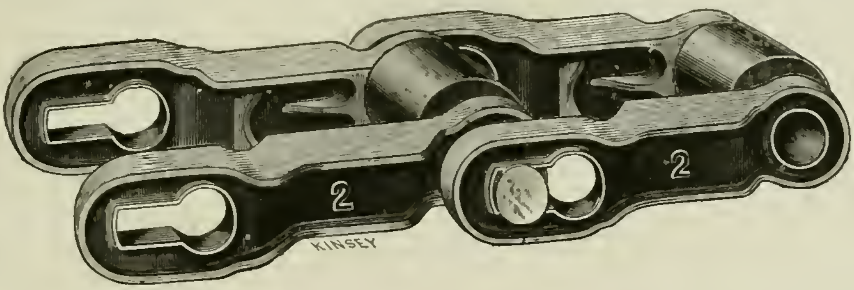

FIG. 2.

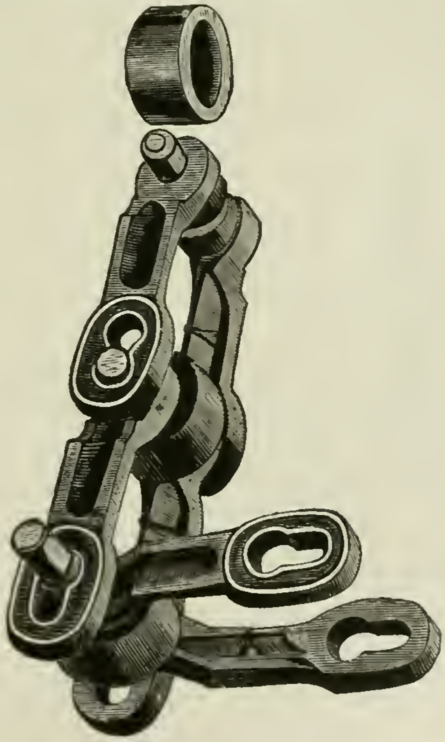

FIG. 3.

work, its strength not being exhausted in dragging its own weight. 2d. The formation of the links is such that the greatest strength to weight of metal is obtained, there being absolutely no weak point. 3d. By an examination of the links and pin after detaching, it will be discovered that the wearing surface, or bearing, covers the entire portion of the pin between the end grooves or notches, there being no wear upon the ends of pin or outside links, for the reason that the pin is held rigidly, not moving in the square slot. The pins and links are also greatly strengthened by the tubular bearing, or that portion of the link upon which the roller is mounted, and which, taken together, makes the strain upon the pin a shearing strain upon the ends, thus giving it greater strength than it would otherwise have. 4th. Fully ten per cent of power is lost by the slipping of leather and rubber belts, and the friction resulting therefrom rapidly generates heat, which hardens the face of the one and rots the fabric of the other, and is one of the most prevalent causes of fire in mills, warehouses, etc. 5th. When space is of importance, roller-chain of from 2 to 4 inches in width will be the equivalent of a 12 to 30 inch leather or rubber belt, and the sprocket-wheels for the chain will cost from one fourth to one half less than pulleys for leather or rubber belting.

CHAIN-BALL.—To arrest the motion of rotation of an oblong projectile thrown under high angles and with a moderate velocity, it has been proposed to attach a light body to its posterior portion by means of a cord or chain, which will offer a resistance to the flight of the projectile and cause it to move with its point foremost. See *Chain-shot.*

CHAIN-MAIL.—A kind of armor much used in the twelfth and thirteenth centuries. It was formed of hammered iron links connected one to another into a dress or form of a garment. Its advantage was in its lightness and flexibility, compared with the sheets of steel or brass of other metal armor, but it was not so good a protection from the spear or lance. Frequently spoken of as *chain-armor.*

CHAIN-SHOT.—A nearly obsolete kind of ammunition, chiefly used in naval warfare, consisting of two balls connected by a short chain. The object of the chain is to destroy the rigging, etc., which otherwise might escape. As grape-shot has been found to serve the same end, the making of chain-shot has been discontinued. See *Bar-shot, Projectiles,* and *Solid Shot.*

CHALK.—A white calcareous substance, prepared by precipitating a solution of chloride of calcium with carbonate of soda and washing; the precipitated chalk of the pharmacopœia is thus formed. Chalk is well known in Europe as an extensive secondary formation. In the arts it is commonly known as *whiting*, after separating the grosser impurities of the chalk. It is used very generally for artillery purposes in arsenal workshops, for marking the center and line of metal on ordnance, to mark the position of gun-carriages and mortar-beds on their platforms, and in a variety of uses.

CHALLENGE.—1. The act of a sentinel in questioning or demanding the countersign from those who appear at or near his post, at certain times. In the British service, the sentinel challenges in these words: "*Who comes there?*" At the same time he comes to the *charge bayonet* to prevent any sudden rush upon his post. If the reply of the approaching person is satisfactory, the sentry allows him to pass in these words: "*Pass, friend; all's well!*" A similar challenge is made to any patrol visiting the guards of a garrison or camp during the night, such as the Grand or Visiting Rounds.

In the United States army, after retreat (or the hour appointed by the Commanding Officer), until broad daylight, a sentinel challenges every person who approaches him, taking, at the same time, the position of *charge bayonet.* He suffers no person to come nearer than within reach of his bayonet, until the person has given the countersign, or is passed by an Officer or Non-commissioned Officer of the Guard. A sentinel, in challenging, calls out, "*Who comes there?*" If answered, "*Friend, with the countersign,*" and he be instructed to pass persons with the countersign, he replies, "*Advance, friend, with the countersign!*" If answered, "*Friends,*" he replies, "*Halt, friends! Advance one with the countersign!*" If answered, "*Relief,*" "*Patrol,*" or "*Grand Rounds,*" he replies, "*Halt! Advance, Sergeant* (or *Corporal*), *with the countersign!*" and satisfies himself that the party is what it represents itself to be. If he have no authority to pass persons with the countersign, if the wrong countersign be given, or if the persons have not the countersign, he causes them to stand, and calls, "*Corporal of the Guard!*" When any person approaches a post of the guard at night, the sentinel before the post, after challenging, causes him to halt until examined by a Non-commissioned Officer of the Guard. If it be the Officer of the Day, or any other Officer entitled to inspect the guard and to make the Rounds, the Non-commissioned Officer will call, "*Turn out the guard!*" when the guard is paraded, arms at a carry, and the Officer of the Guard, if he think necessary, may demand the countersign and parole.

2. The custom of calling another to answer for an offense by combat. In 1844 several new Articles of War were issued by the Commander of the Forces in England, with a view to the abatement of dueling in the army. They were as follows: 1. Every officer who shall send a challenge, or who shall accept a challenge, to fight a duel with another officer, or who, being privy to an intention to fight a duel, shall not take active measures to prevent such duel, or who shall upbraid another for refusing or not giving a challenge, or who shall reject or advise the rejection of a reasonable proposition made for the honorable adjustment of a difference, shall be liable, if convicted before a General Court-Martial, to be cashiered, or suffer such other punishment as the Court may award. 2. In the event of an officer being brought to a Court-Martial for having acted as a second in a duel, if it appear that such officer exerted himself strenuously to bring about an honorable adjustment of the difference, but failed through the unwillingness of the adverse parties, then such officer is to suffer such punishment as the Court shall award. 3. Approbation is expressed of the conduct of those who, having had the misfortune to give offense to or injure or insult others, shall frankly explain, apologize, or offer redress for the same, or who, having received offense, shall cordially accept frank explanations or apologies for the same; or, if such apologies are refused to be made or accepted, shall submit the matter to the Commanding Officer; and, lastly, all officers and soldiers are acquitted of disgrace or disadvantage who, being willing to make or accept such redress, refuse to accept challenges, as they will only have acted as is suitable to the character of honorable men, and have done their duty as good soldiers who subject themselves to discipline. Partly in consequence of these regulations, but still more as a result of the increasing reason and humanity of English society, the practice of dueling has become almost as entirely obsolete in the British army as it has in the country generally. The 26th, 27th, and 28th Articles of War prescribe the punishment for dueling in the United States army. See *Duel* and *Ordeal.*

3. In a legal sense, and as applied to military matters, the right the accused has of objecting to the President or any other Member of a Court-Martial. If he objects to the President, his objection, unless disallowed by two thirds at least of the other members, must be referred for decision to the authority by whom the President was appointed. When any Member is challenged, the accused must state his cause of challenge, of which the Court, after due deliberation, determines the relevancy or validity, and decides accordingly. See *Court-Martial.*

CHAMADE.—A signal made for a parley by beat of drum. See *Parley*.

CHAMBER.—1. A gun is said to be chambered when the seat of the charge is not of the same diameter as the bore. The object of chambering is to obtain increased projectile force. Formerly the chamber was in all cases smaller than the bore, the shape commonly cylindrical or conical. Chambers were placed in light pieces firing comparatively small charges of quick-burning powder. It was considered that the length of space occupied by the charge should be nearly equal to its diameter, in order that the inflammation of the charge should be nearly complete before the gas commenced to escape through the windage, or the projectile had sensibly moved from its place; in the second place, this form of cartridge gave less surface for the absorption of heat by the surrounding metal. It also gave to the cartridge in some cases a more manageable form in loading. In pieces firing heavy charges the seat of the charge was simply the bore prolonged. The termination was in some cases a plane bottom connected with the sides by a curved surface, and in others the bottom of the bore was hemispherical or semi-ellipsoidal. The latter was thought to be more favorable to the strength of the piece. It was necessary that there should be no angles formed by the junction of the bottom and sides of the bore, as these would become receptacles for the residne and burning fragments of the cartridge-bag. There is also a well-known tendency for rupture to commence at an angle, and for this reason, too, the curved termination was necessary.

Chambers are now of larger diameter than the bore proper, and are so made to enable the use of larger charges, aud also to give a certain amount of air-space about the cartridge. They were originally adopted as a necessity in breech-loading guns firing lead-coated projectiles. The tendency at present is to use very large charges of slow-burning powder. If, however, too great a length of cartridge is employed, experience shows that at times abnormal pressures are exerted upon the bore and projectile; the gas rushes from the point of ignition to the end of the powder-chamber and there, being suddenly arrested, produces a zone of high pressure within which the powder burns abnormally fast; then a back-rush takes place and a violent wave-action is set up, resulting in local strains of great severity without materially affecting the velocity of the shot. This difficulty is obviated by an increase in the diameter of the cartridge. The air-space about the cartridge also prevents the dynamic action of the gases described above. It diminishes the mean density of the inflamed products during the first instants of combustion and relieves the piece of the great strain usually brought upon it before the projectile has commenced to move. The maintenance of a due proportion between the bulk of the powder-charge and the space allowed for its combustion is of the highest importance both in the development of energy and the diminution of strain upon the gun. The velocity and energy are increased in less proportion than the increase of charge, but the gas-pressure is not increased in amount, although prolonged in duration, by the heavier charge, if the proportion of space to weight of powder remains the same. The proper dimensions of the chamber in relation to the caliber and length depend very much upon the nature of the powder employed. With some large-grained powders, especially the prismatic variety, it is thought that the charge can completely fill the chamber, the air-space in the interstices and perforations being sufficient to produce the desired effect. Beyond a certain limit the further boring out of the chamber would begin to weaken the breech. In many heavy guns the chamber has a diameter, for a considerable length, of one or two inches greater than the bore. The length should not be more than 3½ or 4 times its diameter if it can possibly be avoided.

The construction with reference to length of bore, etc., will be governed by the purposes for which the piece is intended. I. For armor-piercing the projectile required is a long pointed bolt, nearly solid. It must strike with great velocity, and therefore must be propelled by very large charges. Hence a gun for this purpose should have a large chamber and a comparatively small bore of great length. II. For breaching fortifications *curved* fire is necessary; the escarps of modern fortresses are usually covered from view by screens of earth or masonry, so that the projectiles must pass over the crest of the screen and drop sufficiently to strike the wall about half-way down—that is to say, at an angle of 15° or 20°. For a shell to drop at this angle at the end of a moderate range the velocity at starting must be low. Hence in pieces used for breaching no enlarged powder-chamber is wanted; the shell must be of a shape to hold the most powder for a given weight, and therefore rather short and thick. This gives a large and comparatively short bore. III. For producing destructive effect among troops Shrapnel is principally employed. For this high remaining velocities are required at the point of rupture. The gun must therefore take a large powder-charge. The interior capacity of the envelope should be as great as practicable. For a given weight a comparatively short projectile of large diameter will best fulfill this condition. Thus the proportions of the field-gun will be intermediate between those of the armor-piercing and the shell gun.

2. The chamber of a mine is a cavity formed to receive the charge of powder. When the chamber is made at the end of a gallery, the center of the chamber is placed on a level with the floor of the gallery. It is usually better to place the chamber at the end of a small branch return on one side. When the charge is not to be exploded immediately, or the ground is much saturated with moisture, it should be placed in a well-pitched wooden case, a good cask, or in a wooden case covered with tarpaulin, or any like expedient adopted that may be at hand; the best receptacle is a water-tight tin case. In dry ground, and when the charge is to be soon exploded, canvas bags will answer. If the case to contain the powder is cubical and not more than 2 feet on the edge, it may be introduced into the chamber ready made; if of greater dimensions, it must be put together in the chamber, the pieces to form the sides being arranged like the cases of branches. An opening is made in the cover near the side, about 4 inches square, for the introduction of the charge, and a similar one in the side near the center to receive the hose through.

CHAMBER-GAUGE.—An instrument used in the inspection of cannon. The head of this gauge should be made of close-grained, well-seasoned wood, and of the exact dimensions of the chamber. Two planes crossing each other at a right angle, coinciding with the vertical and horizontal central sections, have been found better than a solid block. The edge should be beveled. A socket in its center connects it with the measuring-staff. Being pushed to the bottom of the bore, if the length coincides with that obtained by the point it is obvious that the chamber is large enough, provided the cylindrical part has not been bored too deep, in which case a shoulder would be formed at the junction. The edges of the gauge should be chalked before insertion. When withdrawn, if the chalk-marks are visible all around the chamber it is evident the chamber is not too large. An examination of the *chamber-reamer* will be very satisfactory, and if found correct in size and shape the impossibility of making the chamber too large will be apparent. See *Inspection of Ordnance*.

CHAMBERS HOOPED GUN.—To obviate the danger of crystallizing the iron by welding it in large masses, this cannon is formed of pieces of a moderate thickness only, commencing with a tube the interior of which is the bore of the gun. The outside of this tube is turned to receive a series of rings, which have an interior diameter, such that they will not when cold pass on or over the tube, but when heated will readily slip on and come to the required position. When these rings are shrunk upon the barrel, the piece is placed in a lathe and the exteriors of the rings are turned so as to receive another tier of rings, which are placed by heating and shrinking on, so as to break joints with the first tier. When a greater number of courses of rings is necessary, they are placed on the preceding series in the same manner as the second series is placed upon the first; that is, so as to break joints with each other. The last series of rings is turned off to the regular form of the finished cannon. The trunnions are forged with one of the outside rings, which, for the purpose of strengthening the connection, may be made thicker than the other exterior rings. See *Ordnance*.

CHAMFER.—A small channel or furrow cut in wood, stone, etc. It may be also explained as an edge, or arris, taken off equally on the two sides which form it, leaving what is called a chamfer or a chamfered edge. If the arris be taken off more on one side than the other, it is said to be splayed or beveled.

CHAMFRON.—The frontlet of an armed horse, usually having a spike between the eyes. Also written *Chamfrain* and *Chamfront*.

CHAMPION.—In the judicial combats of the Middle Ages it was allowed to women, children, and aged persons, except in cases of high treason or of parricide, to appear in the lists by a representative. Such a hired combatant was called Champion. Those who followed this profession were generally of the lowest class, and were held disreputable; for besides the perils of the combat, they were liable to be executed as well as their clients. They were obliged to wear a peculiar dress of leather, and peculiar armor, which was also held disreputable. They were not allowed to fight on horseback, and appeared in the lists with their hair and nails cut short. Champions are mentioned as early as in the time of Charlemagne; and Otto I. employed them in deciding the succession to the Empire. At a later period, in the Age of Chivalry, the word Champion came to have a more dignified acceptation, and signified a knight who entered the lists on behalf of an injured lady, of a child, or of any one incapable of self-defense In England, the Crown even had its Champion, who, mounted on horseback and armed to the teeth, challenged, at every Coronation at Westminster, all who should deny the King to be the lawful Sovereign of the three realms. This practice is understood to have been first introduced under Richard II., and it continues to make a part of the Ceremonial of an English Coronation to this day. The name of Champion was also given to the knight who during a tournament had charge to see that no injury or insult should be offered to the assembled ladies.

CHANDELIER.—In military engineering, a wooden frame filled with fascines, to form a traverse in sapping.

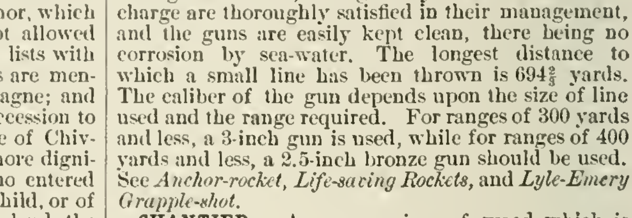
CHANDLER ANCHOR-SHOT.—This shot was originally intended for the use of ships on shore (aground), where the surf is too heavy for boats to land without the assistance of a line. It can also be used at Life-saving Stations to throw lines over beached vessels, or vessels in distress. As an implement of war, it will be useful in waters where torpedoes are supposed to be located. A ship can anchor near the supposed torpedoes, throw the shot two or three hundred yards towards them, and haul it home, breaking such wires as it may encounter. It is very simple, and its simplicity insures its successful working, while its cost is very little more than that of an ordinary shot. It is merely a shot with hinged anchor-flukes projecting from its sides and folding back into slots, so as not to interfere with the entrance of the shot into the gun. To the rear of the shot a chain or wire rope is attached, and carried to the front through another slot, in a very simple and substantial manner. In using it the shot is to be inserted into the muzzle of the gun far enough to bring the ends of the arms inside the muzzle, the chain or wire rope attached to the rear of the shot brought out through the slot, the strap taken off, and the shot pushed gently home. The springs under the arms, always bearing or pushing them outwards, will extend the arms as soon as the shot leaves the muzzle of the gun or mortar, and a perfect anchor will be projected. If in its flight the arms are brought in contact with anything, they will close until the obstacle is passed, and where the shot lands its holding power will be equal to any kedge-anchor of the same weight. It appears to be a most useful invention. One of these shots made for an eleven-inch gun would have power enough to carry a two-inch rope ashore; and after the shot was once ashore and well hooked, all the boats of the ship could be hauled ashore without any other line. The flukes of this anchor-shot are three in number, placed equidistantly around the circumference of the shot

In the U. S. Life-saving Service, no claims of very great originality are made, as the apparatus is a direct evolution from the system of Captain Manby, which dates back to the beginning of the present century. The advances which have been made during the past few years are the result of careful study and conscientious experiment. The data recorded are of value for future reference. Several hundred guns have been made, and every station supplied, at a great economy in the cost of manufacture; the guns being made at the West Point foundry, by contract. During the many heavy storms on our coast they have been used with great success, saving many lives. The men in charge are thoroughly satisfied in their management, and the guns are easily kept clean, there being no corrosion by sea-water. The longest distance to which a small line has been thrown is 694⅔ yards. The caliber of the gun depends upon the size of line used and the range required. For ranges of 300 yards and less, a 3-inch gun is used, while for ranges of 400 yards and less, a 2.5-inch bronze gun should be used. See *Anchor-rocket*, *Life-saving Rockets*, and *Lyle-Emery Grapple-shot*.

CHANTIER.—A square piece of wood which is used for the purpose of raising anything. It serves to place barrels of gunpowder in a proper manner, and frequently to try pieces of ordnance instead of frames.

CHAPE.—1. The catch or piece by which an object is attached—to a belt, for instance; as the piece of leather known specifically as the *frog*, to which a bayonet-scabbard is attached; or a piece used to fasten a buckle to a strap or other piece of leather. 2. The hook of a scabbard. 3. The metallic part put on the end of a scabbard to prevent the point of the sword or bayonet from piercing through it.

CHAPEAU BRAS.—A military hat which can be flattened and put under the arm. In the United States army the chapeau is worn by General Officers, Officers of the General Staff, and Staff Corps, except the Signal Corps. It is worn with the front peak turned slightly to the left, showing the gilt ornaments upon the right side. See *Helmet*.



Chapeau Bras.

CHAPEL-DE-FER.—An iron cap, furnished with a broad and slightly curved rim. It was the head-piece of soldiery in the reign of William Rufus and in subsequent reigns.

CHAPERON.—A hood or cap worn by Knights of the Garter. Such a hood was at one time in general use, but was lately appropriated to doctors and licentiates in colleges. A person who acts as a guide and protector to a lady at public places is called a chaperon, probably from this particular piece of dress having been used on such occasions. The name was also applied to devices which were placed on the heads of horses at pompous funerals.

CHAPLAIN.—A clergyman with a military commission, giving him the spiritual charge of soldiers. The title was originally applied to the ecclesiastic who accompanied an army and carried the relics of the patron saint. It has now come to signify a clergyman not having charge of a parish, but employed to officiate at Court, in the household of a nobleman, or in an army, garrison, ship, etc. Such officials began early to be appointed in the palace of the Byzantine emperors. The practice afterwards extended to the Western Empire, and to the Courts of petty princes, and even of knights, and continued to subsist after the Reformation. Forty-eight clergymen of the Church of England hold office as Chaplains of the Queen in England, four of whom are in attendance each month. Six clergymen of the Church of Scotland have a similar title in Scotland; but their only duty is to conduct prayer at the elections of Scottish representative peers. A statute of Henry VIII. limits the right of nominating private chaplains in England: thus, an archbishop may have eight, a duke six, a baron three; and chaplains so appointed have certain privileges, and may hold two benefices with cure of soul.

In England, an Army Chaplain is a clergyman whose services are retained especially by the government for the soldiery of the army. There have been such Chaplains for many generations, and the office was at one time regarded as a salable perquisite; but the system was reorganized and improved in 1796. In recent years, Roman Catholic and Presbyterian Chaplains have also been appointed, a practice which indicates the progress of toleration. The Chaplains belong, not to *regiments*, but to the Staff of the army, so as to be generally available. At home they are attached to the military stations; but in the field they are located at headquarters, at the hospitals, and with the divisions. The officers at the stations usually arrange for the men to attend divine service at the nearest parish church; but this still leaves the Chaplains many duties to fulfill. Where, as sometimes happens, there is no regular church or chapel near at hand, the Chaplain reads and preaches to as many men as can conveniently group themselves around him at one time, and thus serves many different congregations at different times of the Sunday. He visits the sick at the hospitals, and examines and encourages the regimental schools. Among the wooden huts at Aldershott Camp a church has been built, which is rendered available for Chaplains of different religious denominations in succession. When the system of Army Chaplains was remodeled in 1796, a *Chaplain General* was appointed; this office was abolished by the Duke of Wellington soon after the termination of the great war, but revived by Mr. Sidney Herbert in 1846. The Chaplain General, who receives £1000 per annum, has duties partaking somewhat of those of an archdeacon. He assists the War Office in selecting Chaplains, and in regulating the religious matters of the army, so far as Church of England matters are concerned. His office forms one of the eight departments under the new organization of the War Office. There are 78 Chaplains on the Staff, besides officiating clergymen (not belonging to the army) and chapel-clerks. The commissioned Chaplains receive from 10*s.* to 22*s.* 6*d.* per day, besides allowances; and there are always some on half-pay; while the officiating clergymen receive head-money for the troops attending their ministrations. The whole expenditure for Chaplains, and other charges connected with divine service, figures in the army estimates at near £50,000 annually.

In the United States army there are thirty Post and four Regimental Chaplains; and there is usually a Chaplain in every regiment of militia, though they are not always ordained clergymen. The authorized Post Chaplains are assigned to the several Military Geographical Departments by the Lieutenant General of the Army, in conformity with the spirit of the law governing their appointment. Division and Department Commanders from time to time assign or transfer to posts within their commands, for the best interests of the service, the several Chaplains ordered to report to them. On their action being made known to the Adjutant General of the Army, the Secretary of War designates the posts as Chaplain posts, in conformity with law. Chaplains enter in an appropriate book an accurate record of all marriages, baptismal, and funeral services performed by them, both for persons in the military service and for civilians, at or near the posts where they are stationed, with such particulars relative to each case as may become of importance. This book is one of the post records, and is subject to examination by inspecting officers. An appropriate set of quarters, equal to the allowance of a Captain, is set apart permanently for the Chaplain at posts where Chaplains are employed. He is not disturbed in them further than by a reduction of his allowance, and only then when the quarters of the garrison are insufficient. He is not entirely displaced from them, nor is he allowed to choose quarters elsewhere.

CHAPLAIN GENERAL.—As the name implies, the chief of the Military Chaplains in the British army. The appointment of such an officer was first made by the lake Duke of York when Commander-in-Chief. The recommendation of Chaplains to the several garrisons is made by him to the Minister of War.

CHAPLET.—A garland or head-band of leaves and flowers. In Heraldry, a chaplet is always composed of four roses, the other parts being leaves.

CHAPPE.—A barrel containing another barrel which holds gunpowder. It likewise means a composition of earth, horse-dung, and wad that covers the mouth of a cannon or mortar.

CHARCOAL.—Charcoal is the fiber that remains after wood has been charred, and, as an ingredient in gunpowder, is next in importance to saltpeter. When anything like uniformity in the quality of the gunpowder is required, great care has to be exercised in its preparation, for the chemical composition of charcoal—i.e., the percentage of carbon contained therein—will affect the quality of the gunpowder to a considerable degree; therefore extreme care has to be exercised in charring the wood, seeing that gunpowder contains no less than fifteen per cent of charcoal. Much depends upon the quality and condition of the wood employed, and it is found that if the sap be thoroughly dried up in the wood previous to use it greatly assists in securing a first-class charcoal; this end can be attained by desiccating newly-cut timber in a hot chamber for ten or twelve days, although it is questionable whether the charcoal thus obtained is as good as that produced from wood that has been kept for a number of years to season by natural means. Small wood, perfectly clean, free from all bark, and quite dry, are the essential requisites for making good charcoal. The kind of wood commonly used is that of the willow species—the common white Dutch willow, the poplar, and the alder are generally preferred; other woods are, however, frequently used, and for a first-class strong powder the black dogwood is said to be the best, but its great costliness prevents its being largely adopted. Burning the wood in retorts is the method usually employed for procuring a light and equal quality of charcoal for gunpowder; pit-burned charcoal is, however, preferred for fuse and pyrotechnic compositions, etc., on account of certain qualities it possesses rendering it peculiarly adapted for such purposes. The method of burning in retorts is as follows: Small wood of about ten years' growth is preferred for powder-making. Alder and willow of this age will be probably four or five inches in diameter, dog-wood about one. The wood must be straight, perfectly sound, and entirely free from bark, and must be felled in the spring. Great stress is laid on the cleanliness of the wood. Any traces of bark adhering to it are not to be tolerated. If the wood is cut in the spring when the sap is rising, the bark is

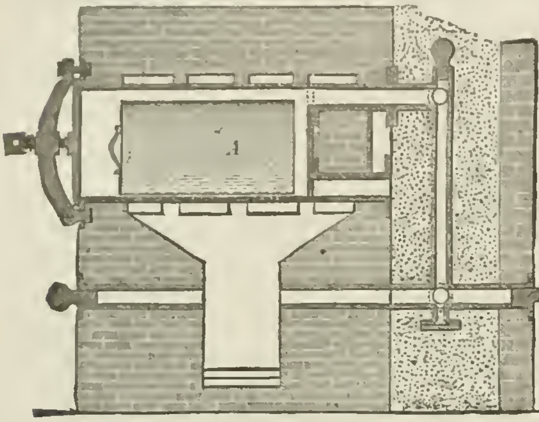


Fig. 1.—Charcoal Converter.

easily removed and the wood is left perfectly clean. Wood cut at any other season of the year is just as good, only in this case the removal of the bark is a much more difficult matter.

The wood is converted into charcoal in iron retorts or cylinders set into brick-work. Fig. 1 represents a longitudinal section of a cylinder, showing how the second cylinder, or slip, A, containing the wood, is placed in its interior, and the arrangement of pipes by which the gaseous matter evolved from the wood is conducted into the fire. Each cylinder is made of cast-iron, having two pipes passing out at the inner end of it. When set, the lower one of these is closed with brick-work, the upper one only being used, and the lower one being only intended for use should the cylinder be turned round and reset. To the uppermost pipe is attached a branch-pipe leading to a horizontal pipe extending behind the whole set of cylinders, from one end of which another pipe descends perpendicularly, joining another leading directly into the former. Each cylinder has a false bottom of brick-work, in front of which is bolted on a piece of wrought-iron plate having a cylinder-hole corresponding to the uppermost pipe of the cylinder. The cylinders are closed with tight fitting iron doors secured by a powerful screw, much in the same way as the ends of gas-retorts are fastened.

For convenience of handling the wood is placed in small cylinders of sheet-iron, A, termed *slips*, which are placed on small iron traveling-carriages, on which they can be run up directly to the mouth of the cylinders and shot in. The back end of each slip is provided with a handle to facilitate withdrawal. As already stated, a good and uniformly pure charcoal is very essential in manufacturing gunpowder, and if properly made will have a jet-black appearance, the fractures show a velvet-like surface, and appear the same in both large and small pieces. It should not scratch soft polished metal, and if treated with distilled water there should be no appearance of alkali. From 20 to 25 per cent of charcoal is obtained from the willow and alder, and from 25 to 30 per cent is yielded by the black dogwood; the latter is very dense, tough, and of slow growth, its usual size being about 1 inch in thickness. When charred it has a yellowish-looking surface, and is slightly metallic in appearance in certain shades of light. The kind of wood from which the charcoal has been made is known by the pith; that of dogwood is circular and large for the size of the wood; that of the willow is also circular, but somewhat smaller; whilst in the case of alder it forms a figure of three equidistant radial lines. They can all be easily distinguished from each other. Charcoal is very porous, and quickly absorbs moisture on being exposed to the atmosphere; therefore a great store is never kept, but is used as soon as possible after being made. Previous to this, however, it is very carefully examined and picked, as thick pieces which have not been properly charred are sometimes found. To test charcoal and ascertain if any alkali be present, finely powder a small quantity and boil it in distilled water; filter the solution, and test with litmus-paper reddened by weak acid. Should the charcoal contain alkali, the paper will be partially or wholly restored to its original color.

Charcoal after standing a fortnight is ground in an apparatus somewhat similar to a coffee-mill on a large scale. The mill consists of a cone secured on a vertical spindle provided with teeth running spirally over its entire outer surface; the cone revolves in a cylinder provided with teeth on its inner surface; these teeth are spiral also, but incline in the opposite direction to those on the cone. The revolving cone is adjustable in a vertical direction to increase or diminish the space between its teeth and those of the fixed cylinder; thus a coarse or fine charcoal is produced at will. The adjustment is effected by means of two hand-wheels working on a fine screw-thread cut upon the small vertical cone-spindle, which spindle can be moved upward or downward by means of the hand-wheels through the large hollow shaft upon which the bevel driving-wheel is keyed. Motion is communicated from this shaft to the small one by means of a feather upon the surface of the latter, which fits and works in a groove cut in the inside of the hollow shaft. The small hand-wheel is used for locking and securing the larger one in any required position. The hopper above receives the charcoal. On the under side of the cone, and revolving with it, are a couple of arms, that carry the ground charcoal to the discharge-spout on one side of the fixed cylinder and conduct it to a sifting-reel. This reel is simply a skeleton-cylinder of wood, covered with copper-wire cloth, having fine meshes thirty-two to the inch. The sifting-reel is driven by a pair of bevel-wheels set at a slight angle to allow the charcoal to run readily along the interior: as it revolves it causes the particles of charcoal to be continually rolling over each other and covering new surfaces of the reel; the fine particles pass through the meshes of the wire cloth and fall into a receiving-bin, whilst the larger ones are thrown out at the lower end of the reel to another bin, whence they are taken and returned to the hopper. The reel and bins are inclosed entirely in a wooden framework and covering, so as to prevent the dust, which is very light, from spreading over the house. Doors are provided in this wooden covering, by means of which the ground charcoal can be removed. After being ground the charcoal stands for about eight or ten days before using it; owing to the readiness with which it absorbs oxygen when in the pulverized state it is apt to become heated, and spontaneous combustion to ensue. The danger from this cause is much lessened when it is stored in small quantities

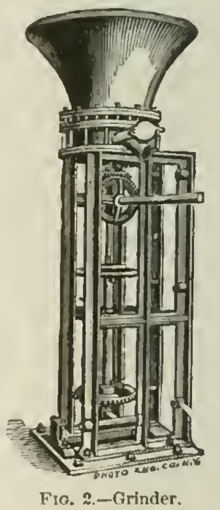

Fig. 2.—Grinder.

and in separate iron cylinders or bins. See *Gunpowder*, *Pit-burned Charcoal*, *Saltpeter*, and *Sulphur*.

CHARGE.—1. The position of a weapon fitted for attack; as, to bring a weapon to the charge.

2. In Heraldry, the figures represented on a shield are called charges, and a shield with figures upon it is said to be charged. The charges in a shield ought to be few in number, and strongly marked, both as regards their character and the mode of their representation. The family shield, belonging to the head of the house, almost always is simpler, i.e., has fewer charges, than the shields of collaterals, or even of junior members. See *Heraldry*.

3. In military pyrotechny, a sufficient combustible material for one firing or one discharge. It is applicable to all kinds of firings, fire-works, and explosions; but the name is generally given to the quantity of gunpowder requisite for firing off a gun, etc. In cannon this varies greatly, from $\frac{1}{4}$ to $\frac{1}{10}$ of the weight of the shot; some of the rifled ordnance now coming into use are remarkable for the smallness of the charge with which they are fired. The quota of charges will be mentioned in connection with the various kinds of fire-arms described in the Encyclopedia. In breaching a wall, a greater charge is necessary than in attacking a ship or a column of troops, even with the same kind of gun and projectile. The charge has to be duly proportioned to the strength of the piece and the capacity of the bore to burn it with profit. The strength of a heavy gun, as reckoned on the principle of all the metal being sound and so placed as to call its resistance well into play, should not be less than about four times the strain expected. If the projectile start as in a muzzle-loader, without offering much resistance beyond that due to inertia, it is necessary to employ a powder which shall burn quickly enough to give off a large proportion of its gas before the shot has proceeded far down the bore; otherwise the velocity at the muzzle will be low. In this case a large amount of air-space is required. In the case of compression-projectiles, however, there is a high resistance to initial motion, and a much slower powder can be used, since the combustion proceeds as in a closed vessel until sufficient pressure is developed to overcome the resistance of the band. This enables the use of a larger quantity of slower-burning powder in the chamber, and we have instead of a space filled with air a space filled with powder giving off gas, which comes into play as the projectile travels down the bore.

4. The statement of the crime for which an officer or soldier is brought before a Court-Martial. As to the perspicuity and precision of charges: If the description of the offense is sufficiently clear to inform the accused of the military offense for which he is to be tried, and to enable him to prepare his defence, it is sufficient. A copy of charges, as well as a list of witnesses for the prosecution, should be given to the prisoner in all cases as soon as possible. Antecedent to arraignment, charges may be framed and altered by the party who brings forward the prosecution, or by the officer ordering the Court, both in regard to substance and in other respects; but the Court, where the deviation was material, would probably deem it sufficient cause for delaying proceedings upon application of the prisoner. As the witnesses may be at a distance, the sooner a copy is given the better.

5. In military warfare, a charge is a sudden and impetuous attack on the enemy, by horse or foot, or both. Its object usually is to drive the enemy from a particular position; but if made with a much stronger force, it may result in his actual destruction. Charges are generally made silently. Those of Frederick the Great always began the "hurrah" at fifty paces from the enemy. If at the moment of the shock the infantry is not disturbed, but their bayonets and fire have on the contrary saved them from the impulsive force of the charge, the fall of the front ranks of the cavalry will have interposed a rampart behind which infantry cannot fail to be victorious. But if the cavalry has practiced the stratagem of beginning operations by drawing the fire of infantry upon skirmishers, and the Commander of the cavalry ready for the charge has pushed forward curtains of light cavalry in a single rank, who succeed, by means of clouds of dust, in making an unskillful infantry believe that to be an attack which in reality is only a feint, the infantry may fire its balls at random; the thinness of the curtain of light cavalry will render the infantry's fire of little effect; the infantry will be eager to reload, and this may be done in agitation and disorder. The proper moment is then at hand, and the heavy cavalry in mass, concealed by the dust of their skirmishers, may charge, break, and saber the infantry. The light cavalry finish the fugitives. The passage of defiles in retreat ought to be secured by a charge of cavalry. Coolness, silence, immobility, contempt of hurrahs, and a reserved fire until within suitable range, are the principal means of resisting a charge of cavalry. The file-closers must prevent firing, not ordered; watch the execution of the fire by ranks; see that it does not commence at too great a distance, then enjoin upon the soldiers to aim at the breast; to act only upon signals of the drum, or at the command of officers on horseback, who occupy the center of the square, and who from that height alone can judge whether the charge of cavalry is a mere feint or a real attack. This necessary impassibility of infantry is obtained by discipline and experience, and is only perfected upon battle-fields. Without *sang froid*, and also promptness in maneuvering upon any ground, infantry will not be able to exhibit the whole strength of its arm against the best cavalry. Charges by infantry are made in order of battle, in column of attack, and in close columns in mass. Charges in order of battle are executed as follows: If the combat is between infantry and infantry, the troops receiving the charge fire at the moment at which it is almost joined with the enemy. The troops making the charge fire at one hundred or one hundred and twenty paces from the enemy; without waiting to reload, they march forward at the quick step; at two thirds the distance take charging step, and if the ground permits they subsequently take a running step, keeping up the touch of the elbow, and throw themselves upon the enemy with hurrahs. Frederick the Great says that it is "better for a line to falter in a charge than to lose the touch of the elbow," so necessary is it that the charge should be *en muraille*. In modern wars the charge in column has been used, but not exclusively, and sometimes with fatal results. But whatever may be the form of the charge, success must not make the victor at once pursue his enemy. He must, on the contrary, halt, rally his men, form line if the charge was made in column, reload, fire upon the fugitives, and continue thus to gain ground, by a regulated fire, until at last the cavalry which seconds him comes to his aid. It must be considered that there may be a second line of the enemy, fresh troops, masked batteries, flank fires, or squadrons of cavalry ready to oppose an unforeseen resistance. It may be that the attacking party has experienced some disadvantage, not far from the point where the infantry has just triumphed in the charge. Such circumstances may cause the infantry to pay dearly for its temporary success, a temporary success sometimes owing to stratagem on the part of the enemy.

CHARGE BAYONET.—A command in the Manual of Arms, executed as follows: The Instructor commands—1. *Charge*, 2. BAYONET. Execute the first motion of *about face*, the left knee slightly bent, drop the piece into the left hand, at the lower band, the elbow against the body, the point of the bayonet at the height of the chin, the right hand grasping the small of the stock and supporting it firmly against the right hip, the body inclining slightly forward. 1. *Carry*, 2. ARMS. Resume the carry with the right hand, at the same time facing to the front.

(Two.) Drop the left hand by the side. See *Manual of Arms*, Fig. 7.

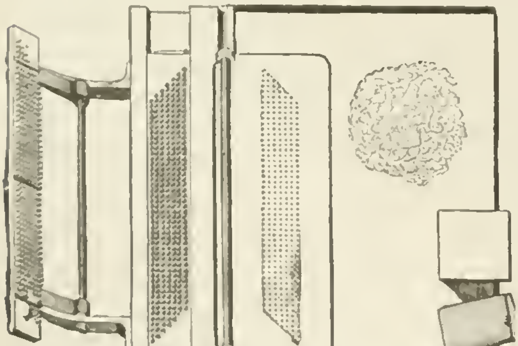
CHARGER.—1. A name sometimes given to a war-horse accustomed to the din of battles, and reliable under circumstances of confusion and danger. In the Middle Ages, when armor was used and gunpowder unknown, the military horses were *barbed* or *bardel* when ridden by men-at-arms—that is, they were nearly covered with armor. The face, the head, and the ears were covered with a mask called a *chanfron*, to prevent fright when charging the enemy; and an iron spike projected from the middle of the forehead. The neck was defended by small plates called *crinières*; the breast by a *poitrinal*; and the buttocks and haunches by *croupières*. These various pieces of armor were mostly made of metal, but sometimes of tough leather. The horse was occasionally covered with chain-mail; and in other instances with a *gambeson* of stuffed and quilted cloth. The man-at-arms generally rode another horse when not charging, to relieve the charger from his great burden. The barbed or *bardé* horse received its name from an old French word implying covered, clothed, or armed. A war-horse is still called a charger, though not armed as in ancient times.

2. A device for dropping into the bore of a fowling-piece from a shot-belt or pouch a gauged quantity of shot. By forcing down the plunger, the communication with the pouch is closed, and the charge is allowed to pass to the tube, which conducts it to the gun. The piston-head is adjustable, to vary the capacity of the charge-chamber.

CHARGER - PITS.—Shelter-pits to cover the charges of mounted officers when exposed to the enemy's fire. They may be excavated parallel to and 20 paces in rear of lines of shelter-trenches.

CHARGING-HOLE.—Formerly the French made their shells for sea-coast service with an additional eye, at an angle of 45 with the other, called a *charging-hole*, the object being to have the fuse already fitted in, ready for use, and allow the charge to be poured in just before the shell is wanted. This arrangement, however, has the disadvantage of requiring the fuses to be cut beforehand and without knowing at what distance they are to be used.

CHARGING-MACHINE.—A machine employed in the fabrication of cartridge-primers. The one used at Frankford Arsenal, and represented in the drawing, consists of a rectangular iron bed-plate 18 × 20 inches. At one edge is a groove to receive the plate of caps from the cooler. Near the inner edge of



this groove a plate perforated with holes corresponding to the caps is hinged to the bed-plate, to measure and convey the charges to the caps. A heap of the fulminate is placed upon the bed-plate, convenient to the charge-plate. A piece of stout paper is laid upon the bed-plate, under the charge-plate. A portion of the fulminate is taken from the heap, pressed into the holes in the charge-plate, and the surplus scraped off with a wooden tool and returned to the heap. The paper is drawn a little from under the charge-plate, while pressing upon the latter, to "set" the charges in the holes. The charge-plate is rotated on its hinge until it rests over the caps. A block of iron containing pins corresponding to the holes in the charge-plate is hinged to the bed-plate at the outer side of the groove containing the plate of caps. When not in use it rests against inclined supports. This block is next rotated on its hinge until it presses the charges through the holes in the charge-plate into the cap. The block and charge-plate are swung back and the plate of caps withdrawn and carried to the foiling-machine. The charge, of cylindrical form, occupies about one third the diameter in the center of the bottom of the cap, and it is desirable to avoid spreading or disturbing it, in order that the tinfoil disk may touch and adhere to the cap all around it. See *Cartridge-primer* and *Center-primed Metallic-case Cartridge*.

CHARIOT.—In ancient times, a kind of carriage used either for pleasure or in war. According to the Greeks, it was invented by Minerva; while Virgil ascribes the honor to Erichthonius, a mythical king of Athens, who is said to have appeared at the Panathenaic festival founded by him, in a car drawn by four horses. The ancient chariot had only two wheels, which revolved upon the axle, as in modern carriages. The pole was fixed at its lower extremity to the axle, and at the other end was attached to the yoke, either by a pin or by ropes. The Greeks and Romans seem never to have used more than one pole, but the Lydians had carriages with two or three. In general, the chariot was drawn by two horses. Such was the Roman *biga*, but we also read of a *triga*, or three-horse chariot, and a *quadriga*, or four-horse one. The last was that in which the Roman Generals rode during their triumphal entrance into the city, and was often adorned with splendid art. The war-chariot held two persons—the soldier himself and the driver, the latter of whom usually occupied the front; but the chariots used by the Romans in their public games held only the charioteer. The oldest war-chariots of which we read are those of Pharaoh (Exodus xiv. 7). All the Eastern Nations used them, while we learn from Cæsar that the Britons also were familiar with their use.

CHARLIER SYSTEM OF HORSESHOEING.—The reform in farriery caused by the revolution which followed the introduction of the Goodenough system has been fertile in new plans and expedients to avoid the clumsy old methods, and to evade the patents with which Mr. Goodenough protected his machine-made shoe in all the patent-granting world. In this country the Goodenough shoe is furnished at a lower price than the hand-made shoe, and it is infinitely superior to the common machine shoe, which is at best but a rough clump of bent iron, requiring as much labor upon the anvil to adapt it to the hoof as would be expended in making a well-shaped shoe from the iron bar. But in England and France, where labor is cheaper than it is in the United States, the evasion of the Goodenough patents has been eagerly sought. In France, Mr. Charlier, wishing to patent his own plans, which were very ingenious, and to adapt the Goodenough teaching to the smooth asphaltum pavements of Paris, invented the shoe bearing his name. Mr. Charlier recognizes the fact that the old system of heavy shoeing is irrational and destructive; that all the diseases of the hoof, and many of the other difficulties to which the horse is subject, come directly from it. He desires to abrogate entirely the use of the three-calked shoes and wide-webbed shoes, and to secure the full bearing of the frog of the hoof upon the ground. Mr. Charlier's method of shoeing is to dress the horse's foot, so that standing upon it he rests equally upon the shell and frog; then a groove is cut around the outer circle of the hoof, about as deep as the thickness of a light horseshoe, and an iron band is let into this groove and secured by nails. In effect, a light and very narrow shoe is sunk into the crust of the hoof. All shock of concussion comes upon the frog and the outer wall of the hoof, though with a full frog bearing such concussion would be light and immaterial. This, then, appears to be a natural and simple method of saving the hoof from breaking at the edge and from wearing too low at the toe, which is the only object of horseshoeing. But in practice we come upon difficulties that often destroy the best spun theories. The idea of Mr. Charlier is to provide an iron rim, or ferrule, to the hoof such as saves the point of a walking-stick from wear. But the shoe cannot have the strength of a ferrule because it is not put on to *encircle* the hoof, but only reaches to the heels. It is not applied to a dead or inert substance, but to a living, growing process, and, however well fitted to its groove, in a few days it has of necessity changed its place. So soon as the least displacement exists it is liable to twist and spread. Another serious difficulty is found in the lack of skill among horseshoers to apply it properly. In France two men are required, one to hold the foot, another to gauge, and then, with special tools, to cut the groove for the shoe. When a shoe is lost, or displaced on the road, a serious embarrassment is felt, because the groove-cut hoof is unsuitable to travel on, and only the instructed smith is competent to do the work of fitting. The expense, in this country of dear labor, is no insignificant argument against the Charlier shoe. See *Horseshoeing*.

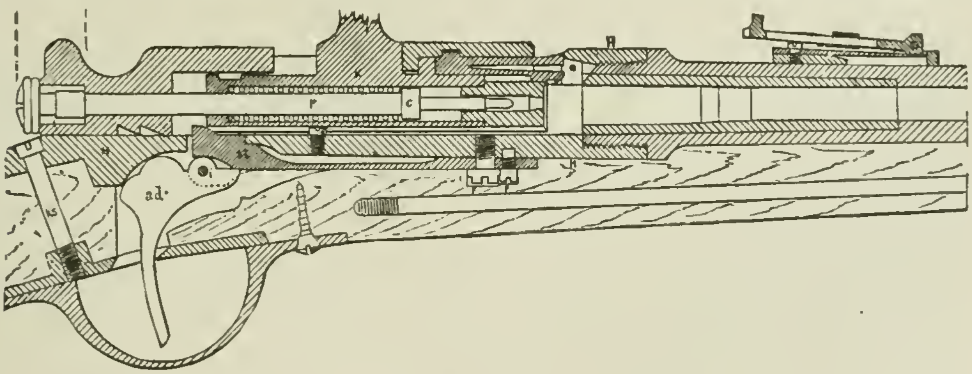
CHASE.—In gunnery, the conical part of the gun in front of the reinforce. In a smooth-bore gun it is comprised between the front of the second reinforce-ring and the muzzle astragal and fillets; or, perhaps, to put it in more comprehensive terms, the greater portion of the gun between the muzzle and the trunnion. The term is applicable to rifled guns as well.

CHASE-RING.—In gunnery, a band at the front end of the chase. See *Cannon*.

CHASING.—The art of working raised or half-raised figures in gold, silver, bronze, or other metal. It was called *cælatura* by the Romans; and the term is expressly limited by Quintilian to working in metal. The same art when exercised on wood, ivory, marble, precious stones, or glass was called *sculptura*. Iron was sometimes though rarely used, silver having been always the favorite metal for this purpose. Closely connected with, but still distinguished from, chasing is the art of stamping with the punch, which the Romans designated by *excudere*. The Greek *toreutike* is usually supposed to correspond to chasing, but the point is by no means free from dispute. The art was known at a very early period, as may be inferred from the shield of Achilles, the ark of Cypselus, and other productions of the kind.

CHASSELOUP BASTION SYSTEM.—This method of fortification is a combination of Bousmard's and Montalembert's systems. It gives 580 yards to the front, and takes a perpendicular of $\frac{1}{4}$. The faces of the bastions are bent lines; the salient part, 70 yards long, is traced on the front line, and the long branch is 160 yards in extent. The flanks are perpendicular to the line of defense, and defend the long branches, whilst the short ones, already secure against ricochet by their direction, are flanked by a caponiere, which occupies the place of the early ravelin. The flanks are parallel to the perpendicular. The main ditch is 20 yards wide at the salient, and its counter-scarp is directed on the shoulder-angle of the caponiere. The tenaille is similar to that of Bousmard, and the casemates are constructed for three guns. The reduits are casemated polygonal redoubts. Although the revetments are quite high, both the ravelin and the reduit are liable to be taken by the gorge.

CHASSEPOT RIFLE.—The Chassepot rifle was introduced into the French service shortly after the Austro-Prussian War of 1866. In its principal features it resembled the Prussian needle-gun, inasmuch as the breech was closed with a sliding bolt, and it fired a self-primed paper-case cartridge which was ignited by a needle impelled by a spiral spring. Unlike the needle-gun, however, it was provided with a gas-check, which was of the form of a thick India-rubber disk or packing, attached to the end of the breech-bolt, and it possessed the modern improvements of reduced caliber and rapid twist of the rifle-grooves for obtaining great range and accuracy of fire. The range of the Chassepot rifle was, and is now, comparatively greater than the accuracy of the flight of its projectile, a fact that undoubtedly arises from the great weight of the powder-charge in proportion to that of the projectile and a want of proper adjustment of the twist, etc., of the rifling to the velocity of flight. In the French service a low trajectory has ever been considered of greater importance than accuracy of flight, especially in line-firing. The Chassepot was the principal arm used by the French army during the German War. Since that time efforts have been made to adapt it to fire the modern metallic-case cartridge. The plan of alteration to this end adopted by the French authorities is that submitted by Captain Gras of the French Artillery Committee. In consequence of the great opposition offered to the altered arms by officers of the army who have had them in their commands, it is understood but little progress was at first made in the manufacture of new rifles or altering the old Chassepot rifles to the Gras system. The Gras system of alteration consists, 1st, in reaming out the old paper-cartridge chamber and inserting in its place a bushing of steel in which a chamber is formed of suitable shape for the metallic cartridge; 2d, replacing the India-rubber gas-check and its attachments by a nose-piece, to which a cartridge-shell extractor-hook is attached; 3d, replacing the firing-needle with a stout firing-pin or bolt; 4th, removing the friction-roller in the base of the thumb-piece and replacing it with the firing-pin nut; 5th, changing



Chassepot Rifle.

the form of the locking-notches and the side groove of the body of the breech-bolt.

The breech-frame or receiver, H, is secured at its front end by screwing on to the barrel, and at the rear end by the tang-screw *ks*, which penetrates through the guard plate on the under side of the stock. The breech-bolt, K, is composed of a body in the form of a stout tube, with a handle attached to one side, for the purpose of working it. The hollow of the body contains the firing-pin and its spiral spring, and has a nose-piece to which the cartridge-shell extractor is attached. A slot is cut in the upper surface of the receiver through its entire length. The handle works in the rear portion of this slot, while the forward portion is enlarged by cutting down the right wall of the receiver to furnish a shoulder for the base of the handle to rest against when the bolt is locked and the piece is ready for firing. On the side and bottom of the body of the breech-bolt are two long grooves of rectangular cross-section. The object of the spiral direction of the side groove at its rear end is to force the handle into the cut of the receiver before the face of the nose-piece presses against the cartridge-head, and thereby prevent the bolt from flying backward in case of a premature explosion of the cartridge. The groove on the under side of the body is for the nose of the sear to play in without pressing on and impeding the motion of the bolt. The firing-pin, *p*, is made of steel. The body of the pin, which is enveloped by the spiral mainspring shown by the rows of small circles above and below it, is circular in cross-section. The collar, *c*, offers a shoulder for the mainspring to press against. The portion of the pin immediately in front of the collar is oval in cross-section, corresponding to the hole in the nose-piece, through which this portion of the pin passes. This form of the pin prevents it from turning in the nose-piece when the bolt is locked and unlocked, and regulates the motion of the thumb-piece relatively to the breech-bolt. The nose-piece is attached to the front end of the breech-bolt by means of a projection. A cylindrical projection on the nose-piece also fits into a corresponding recess in the forward end of the bolt. A continuation of the groove on the side of the bolt receives the point of a screw which serves as a stop to the bolt when pulled backward, and also to prevent the nose-piece from turning in the receiver when the bolt is locked. The under side of the nose-piece has a continuation of the groove in the bolt for the nose of the sear. A cut extends through the upper portion of the nose-piece to receive and hold the extractor-hook, which is composed of two branches, the lower one of which has a hook which takes hold of the rim of the cartridge. Its body has a certain elasticity which allows it to pass over the rim of the cartridge, while its hold on the rim is secured by the inclined surface of the cut *e* made in the receiver, into which the extractor fits. It also serves to keep the extractor in place in the nose-piece. The nut which secures the thumb-piece to the firing-pin has a milled head and a T-shaped groove in it, which fits on to the head of the firing-pin. The pressure of the mainspring on the pin prevents the nut from coming off by keeping it in its recess in the thumb-piece. The nose of the thumb-piece fits into a corresponding notch of the rear end of the body of the breech-bolt when the firing-pin is pushed forward against the cartridge-head and the bolt is locked. There is also a slight notch in which the nose rests to give the handle steadiness when in the vertical position. When the firing-pin is drawn back to the full-cock position the lower corner of the thumb-piece rests against the nose of the sear. At half-cock the nose of the sear rests in a notch, holding the point of the firing-pin at a safe distance from the priming of the cartridge. Another notch receives the nose of the sear when the point of the firing-pin impinges on the head of the cartridge. The upper portion of the thumb-piece is cut away and its surface checked to give a good hold to the thumb and fingers in manipulation. The sear, *st*, is attached to the under side of the receiver by two small screws. The smaller screw acts as a keeper to the larger. The body of the sear is a flat spring, so set as to cause the sear to protrude through a cut in the receiver and engage the notches of the thumb-piece. The trigger, *ad*, is a lever of the first order, and is attached to the sear by a joint-pin, *i*. Pressure on the finger-piece of the trigger depresses the nose of the sear, the rounded part of the trigger acting as a fulcrum against the under side of the receiver. The cartridge-case adopted for the altered Chassepot rifle is drawn out of sheet-brass in the usual way; the head is strengthened after the Hotchkiss plan, and it has the outside primer of Berdan. The bullet is solid and without cannelures, and weighs 386 grains; the powder-charge is 81 grains, and there is a lubricating-wad of the usual form between the powder and the projectile. The length of the bore, including the chamber, is 32.28 inches; the length of the complete arm, without saber-bayonet, is 50.8 inches, and with the bayonet it is about 72.0 inches. The weight with the bayonet is 10.3 pounds; without the bayonet, 8.9 pounds. The grooves are four in number, and of a width equal to that of the lands; the depth of the grooves is 0.0118 inch; the twist is one turn in 21.6 inches, and is from right to left instead of from left to right, according to the usual practice. The pull on the trigger is thought to disturb the aim by carrying the muzzle of the arm slightly to the right; the object of grooving the barrel to the left is to correct this disturbance by the drift which follows the direction of the twist. The initial velocity is stated to be 420 meters (about 1377 feet), and the effective range extends to 1700 yards, about one mile. The rapidity of fire is 15 times per minute. See *Mauser Rifle* and *Small-arms*.

CHASSEURS.—A name used for two important forces in the French army. The mounted Chasseurs (*Chasseurs-à-cheval*) are a body of light cavalry, designed for service in advance or on the flanks of the army, and correspond most nearly to the Light Horse of the British service. The name is first used in this sense in 1741, and has been retained while the force it denotes has undergone many alterations in organization and equipment. In 1831 a body of cavalry was raised for service in Africa, mounted on Arab horses, and with a distinct uniform. These have since become famous as the *Chasseurs d'Afrique*. After the reorganization of the French army in 1873 the effective army contained 14 regiments (subsequently increased to 20) of Chasseurs-à-cheval, besides 4 regiments of Chasseurs d'Afrique.—The infantry Chasseurs (*Chasseurs-à-pied*) are a light-infantry force in many respects corresponding with the cavalry Chasseurs, and like them intended for detached service (like the Rifle Corps in the English army). The French are believed to have adopted the idea of such a force of Sharp-shooters from the *Jäger* (the German word corresponding to Chasseurs, or *hunters*) in the German armies. First used in the Thirty Years' War, the Jäger derived their name from the fact that they were chiefly drafted from amongst mountaineers and inhabitants of forest regions. They have always been regarded as a valuable contingent in the Prussian and Austrian armies, or even constitute the entire force of light infantry. In the German army there are 26 battalions (near 15,000 men) of this force; in the Austrian service, upwards of 20,000 officers and men. In France the equipment of the Chasseurs differed little from that of the other infantry; it was not until the formation, in 1838, of the *Chasseurs de Vincennes* that the experiment of a specially armed force of Sharp-shooters was fairly tried. The fame of the Chasseurs de Vincennes for rapidity and precision of movement, as well as for the accuracy of their fire, soon vindicated the importance of this branch of the infantry; and at present there are 30 battalions of Chasseurs-à-pied in the French army.

CHASSEURS D'AFRIQUE.—The four regiments of cavalry, mounted on Arab horses, and raised for the purpose of warfare in Algeria. They took part, however, in the Franco-Prussian War of 1870–71, and also in the Crimea, where one of the regiments, the "Fourth," distinguished itself by supporting the charge of the light cavalry at Balaklava.

CHASSIS.—The chassis is the movable railway on which the top-carriage moves to and from battery. It is composed of two wrought-iron rails inclined three degrees to the horizon, and united by transoms, as in the top-carriage. In addition to the transoms, there are several diagonal braces, to give stiffness to the chassis. For the 10-inch gun and all smaller carriages the chassis-rails are single beams of rolled iron, 15 inches deep; for all calibers above, the rails are *built up* of long rectangular pieces of boiler-plate and T-iron, in a manner similar to that of the cheeks of the top-carriage. The chassis is supported by *traverse-wheels*, which allow of its having a horizontal motion, for the purpose of giving the piece a proper direction when aiming. The traverse-wheels roll on circular bars of iron resting on a bed of masonry or wood. The *pintle* is an upright journal, around which the chassis traverses. It is a stout cylinder of wrought-iron, inserted in and firmly fastened to a block of stone called the *pintle-block*. The *center-pintle carriage* is one in which the chassis is attached to the pintle at its middle, and revolves around it through the entire circumference of the circle. The traverse-circles are consequently continuous. By this arrangement a much greater horizontal field of fire is secured. The *front-pintle carriage* is one in which the chassis is attached to the pintle by its front transom; the traverse-circles are segments of circles. The *pintle-key* is a stout key of iron passing through the pintle, to prevent the chassis from jumping off when the piece is discharged. The pintle is surrounded by a plate firmly bolted to the block; this plate is called the *pintle-plate*, or *friction-plate*. The hurters and *counter-hurters* are flat pieces of iron bolted, the first to the front and the latter to the rear part of the chassis rails, to check the motion of the top-carriage when the piece is run *in battery*, and when it recoils upon being fired. In carriages of improved model the hurters and counter-hurters are stout buffers of gutta-percha, which, absorbing the shock, prevent racking of the carriage. The *guides* are stout claws of iron bolted to the cheeks of the top-carriage, and, catching under the flanges of the chassis-rails, prevent the carriage from slipping or jumping off. Through the chassis, immediately over the pintle, runs an eccentric axle, carrying upon each end a truck-wheel. This axle and wheels are for the purpose of throwing the chassis *in gear*, thus raising the pintle-transom from the friction-plate and allowing the carriage to be traversed with freedom. It is prescribed that the chassis shall be *out of gear* when the piece is fired. This, however, is not necessary, and the omission of it when firing saves much time and labor. The lighter class of carriages are without the arrangement just described. In the improved pattern of carriages the axle and truck-wheels above mentioned are replaced by two stout rollers attached to bolsters on the front end of the chassis. These rollers move upon the friction-plate, and give firm support and easy motion to the chassis. Casemate-carriages differ from barbette-carriages in being much lower, but their mode of construction is essentially the same. The pintle is placed immediately under the throat of the embrasure, and the chassis is connected to it by a bar of iron called the *tongue*. For the 10-inch smooth-bore and all below that caliber, recoil is checked simply by the inclination of the chassis-rails and the sliding friction thereon of the top-carriage. To increase this friction, the chassis-rails should be sanded with sand free from pebbles. See *Gun-carriages*.

CHAUCI.—An important tribe of ancient Germany, who dwelt between the Elbe and the Ems. Tacitus records that they were conspicuous for their love of peace and justice, being powerful but not ambitious, ready to resist aggression, but never provoking war They finally merged into the wider designation of Saxons.

CHAUFRON.—Masked armor which covered the face, the head, and the ears of military horses during the Middle Ages, to prevent the horses taking fright when charging the enemy.

CHAUSSES.—In the armor of the Middle Ages, defense-pieces for the legs. Some were made of padded and quilted cloth, with metal studs; some of chain-mail; some of riveted plates; and some of banded mail. It was not unusual to fasten them by lacing behind the leg. See *Armor*.

CHAUVINISME.—"Chauvin" was the name of the principal character in a French comedy which was played with immense success at the time of the Restoration. He represented a bragging veteran of the Empire, who was continually talking of his achievements at Austerlitz and Jena, and his determination to take a brilliant revenge for Waterloo. Since then a *Chauviniste* has come to mean a man who has extravagant and narrow-minded notions of patriotism, and corresponding enmity towards foreign peoples.

CHECK-HOOK.—A device in hoisting and lowering apparatus, designed to stop the motion of the wheel over which the rope runs if the machinery becomes unmanageable. On the pulley are hooks which fly out by the centrifugal force when the speed becomes excessive, and engage stop-pins which arrest the rotation of the pulley and the descent of the cage. 2. A hook on a saddle for the attachment of the bearing-rein.

CHECK-NUT.—A nut of frequent occurrence in the construction of artillery-carriages, the elevating-gears, etc. See *Lock-nut*.

CHECK-REIN.—The branch-rein which connects the driving-rein of one horse to the bit of the other. In double lines the left rein passes to the near-side bit-ring of the near horse, and a *check*-line proceeds from the said left rein to the near bit-ring of the *off* horse. The right driving-rein passes directly to the off bit-ring of the off horse, and has a *check-rein* which connects with the off bit-ring of the near horse. The horses of the Egyptian chariots had check-reins.

CHECK-ROPES.—Strong ropes employed to diminish recoil by increasing the frictional resistances. They are usually made fast to the lunette and felloes of the wheels just in rear of the working spokes. They prevent the wheels from turning in recoil, and thus increase the friction.

CHECKY.—In Heraldry, when the field or any charge is composed of small squares of different tinctures, generally metal and color, it is said to be checky. See *Heraldry*.

CHEEKS.—The sides of a gun-carriage in which the trunnions of the gun sit. The term "cheeks" is also applied in fortification to the interior facing of an embrasure. See *Embrasure* and *Gun-carriages*.

CHELONE.—In military antiquity, the form of battle adopted by the Greeks in besieging fortified towns. It served to protect the besiegers in their approach to the walls. This invention was formed by the soldiers placing their shields over their heads, in a sloping position, similar to the tiles of a house. The first rank stood erect, the second stooped a little, the third still more, and the last rank knelt. They were thus protected from the missile weapons of the foe, as they advanced or stood under the walls of an enemy. The chelone was similar to the *testudo* of the Romans.

CHELSEA HOSPITAL.—An edifice built on the banks of the Thames, which was originally begun by James I., and intended as a college for a certain number of learned divines. The unfinished buildings were afterwards completed, and finally converted by Charles II. into a hospital for non-commissioned officers and privates who were wounded or maimed in the service, and has remained to the present day a refuge for worn-out or wounded soldiers, who are termed "In-pensioners."

CHEMIN DES RONDES.—In fortification, a berm usually 4 to 12 feet broad at the foot of the exterior slope of the parapet. It is sometimes protected by a quickset hedge (in India a cactus hedge), but in more modern works by a low wall, built on the top of the revetment, through which (the wall being loop-holed) and over which the defenders can fire and throw hand-grenades into the ditch.

CHEMISE.—In mediæval fortification, an additional escarp or counter guard wall, covering the lower part of the escarp.

CHENAPPAN.—An old musket, invented in the latter part of the sixteenth century. The name *chenappan* was also given in France to robbers who used this new weapon, as also to the Spanish bandits of the Pyrenees who were enrolled under Louis XIII. The name was also applied to the Barbets of the Alps, the last remnants of the unhappy Vaudois, who were forced by religious intolerance to become marauders.

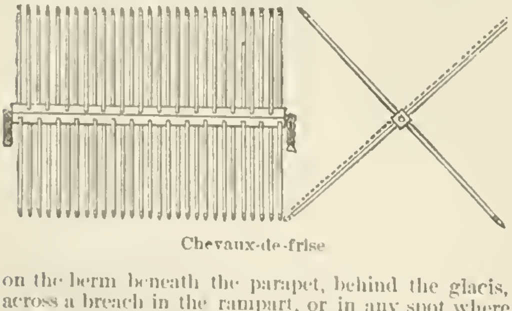
CHESSES.—The planking or flooring-boards of a ponton-bridge. In cylindrical pontons the boards are fastened to the baulks by means of cleats, but in the present-pattern pontons without cleats. Each chess consists of three planks. Half-chesses, consisting of a single plank, are used for that part of the floor which is immediately over the saddle of the ponton.

CHEST.—A technical name for the money and negotiable securities carried with an army, and intended to defray the current expenses. In the English military system this Department is managed by the Commissariat.

CHEVALET.—A sort of bell-tent formerly used in the French service when an army encamped. It resembled in some degrees the Indian wigwam.

CHEVALIER.—A horseman or knight. A member of certain orders of knighthood. In Heraldry, a horseman armed at all points.

CHEVAUX-DE-FRISE.—In fortification, a hastily-constructed substitute for a regular abatis, to stay the progress of an advancing enemy. It may be constructed in any way of wood or iron, provided it presents an array of sharp or ragged points towards the enemy. Sometimes it is made of barrels or centers of timber, with spears springing out from all sides, in such a way as to constitute both a support and a defense. Among the *matériel* of an army under the care of the Engineers are sometimes comprised chevaux-de-frise formed of cylindrical iron barrels, about 6 feet long, each having 12 holes to receive as many spears; the spears can be packed away in the barrel when not in use. Each such piece constitutes a *cheval;* and many such, ranged end to end, form *chevaux*, to be used in ditches around a fortification,



Chevaux-de-frise

on the berm beneath the parapet, behind the glacis, across a breach in the rampart, or in any spot where a check to the storming-party is needed. At Badajoz, during the Peninsular War, great service was rendered by a chevaux-de-frise formed of sword-blades fixed into beams of wood. The name is said to have been derived from "Friesland horse," and to have been first applied by the French during the wars of the seventeenth century. The drawing shows the common form of cheval-de-frise, consisting of a horizontal piece of scantling of a square or hexagonal form, termed the *body*, about 9 feet long, which is perforated by holes 2 inches in diameter and 5 inches apart; round staffs, 10 feet long and 2 inches in diameter, termed *lances*, shod with iron points, and inserted into the body, so as to project equally from it. At one end of the body a ring and chain are attached, at the other a hook and chain, for the purpose of attaching several together, forming a chevaux-de-frise. The square is the best form for the body; it requires only 5-inch scantling, whereas the hexagon will require 12 inch timber. See *Accessory Means of Defense.*

CHEVET.—A small wedge which is used in raising a mortar. It is placed between the frame and swell of the mortar.

CHEVRETTE.—An engine for raising guns or mortars into their carriages; also used in mechanical maneuvers.

CHEVRON.—1. In Heraldry, an ordinary representing the rafters of a house, and supposed to betoken the accomplishment of some memorable work, or the completion of some business of importance, generally the foundation of his own family by the bearer. The chevron is formed of two lines placed pyramidically, i.e., joined together at the top, and descending to the extremities of the shield in the form

Chevron. Chevronel. Per Chevron.

of a pair of compasses. *Chevronel*, a diminutive—half the size—of the chevron. *Per chevron*, or *party per chevron*, is where the shield is divided by a line in the form of the chevron.

2. The rank of non-commissioned officers is marked by chevrons upon both sleeves of the uniform coat and overcoat, above the elbow. The chevrons are of cloth of the same color as the facings of the uniform coat, and divided into bars a half-inch wide by black silk stitching, except for Engineers, which is white stitching and piped with white, points down; and Infantry, which is dark blue, according to patterns in the Quartermaster General's Office, as follows:

For a Sergeant Major, three bars and an arc; for a Quartermaster Sergeant, three bars and a tie of three bars; for a Principal Musician, three bars and a bugle; for an Ordnance Sergeant, three bars and a star; for a Commissary Sergeant, three bars and a crescent (points front) of same color as chevron and above it; for a Hospital Steward, a half-chevron of emerald-green cloth $1\frac{3}{4}$ inch wide, piped with yellow cloth, running obliquely downward from the outer to the inner seam of the sleeve, and at an angle of about thirty degrees with a horizontal, and in the center a "caduceus" two inches long, the head toward the outer seam of the sleeve; for a First Sergeant, three bars and a lozenge; for a Battalion or Company Quartermaster Sergeant, three bars and a tie of one bar; for a Sergeant, three bars; for a Corporal, two bars; for a Pioneer, two crossed hatchets, of cloth, same color and materials as the facings of the uniform coat, sewed on each sleeve, above the elbow, in the place indicated for a chevron (those of a Corporal being just above and resting on the chevron), the head of the hatchet upward, its edge outward, of the following dimensions, viz.: handle, $4\frac{1}{2}$ inches long, $\frac{1}{4}$ to $\frac{1}{3}$ of an inch wide; hatchet 2 inches long, 1 inch wide at the edge. For Enlisted Men of the Signal Corps, crossed signal-flags, red and white, on dark blue cloth; size of flags, $\frac{3}{4}$ of an inch square; length of staff, 34 inches. This device is worn by the Non-commissioned Officers above the chevrons; by Privates of the First Class on both arms, and by Privates of the Second Class on the left arm only, in the same position as the chevron of Non-commissioned Officers.

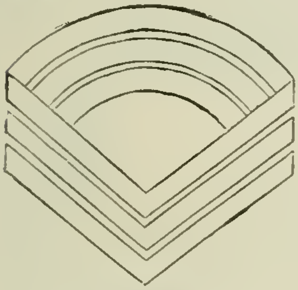
All Non-commissioned Officers, Musicians, and Privates who serve faithfully for one term of enlistment wear, as a mark of distinction, upon both sleeves of the uniform coat, below the elbow, a diagonal half-chevron, ½ inch wide, extending from seam to seam, the front end nearest the cuff and ½ inch above the point of the cuff, of the same color as the edging on the coat. In like manner an additional half-chevron, above and parallel to the first, is worn for every subsequent term of enlistment and faithful service. The distance between each chevron is ¼ of an inch.

The stripe indicative of War Service is white for all arms of the service or Corps. This stripe is known and designated as the "War Stripe," and is worn by enlisted men on the uniform coat as soon as the right to wear it has been earned. All soldiers who, during the War of the Rebellion, were in the Volunteer service are entitled to wear the War Stripe, provided they served in one or more campaigns in the field.

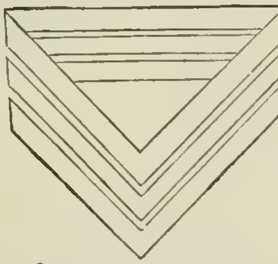
a separate portion. *On a chief* is when the object is represented on the chief divided off as above described. See *Heraldry*.

CHIEF OF DETACHMENT.—The senior non-commissioned officer of a gun-detachment. When in line, he is on the right of the front rank of his detachment. When, by facing about, the front becomes the rear rank, he does not change to the other flank, but steps forward into the rear (now become the front) rank. When in column of files, he is as if he had faced with his detachment from line.

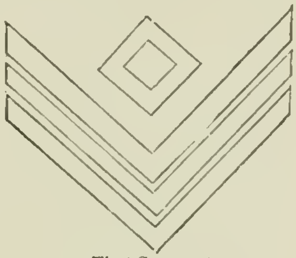
CHIEF OF ENGINEERS.—An officer of the army with the rank of Brigadier General, who has his headquarters at the seat of Government, and is charged, under the direction of the Secretary of War, with the command of the Engineer Department, including its Bureau, and with the regulation of the duties of the officers and troops of the Corps of Engi-



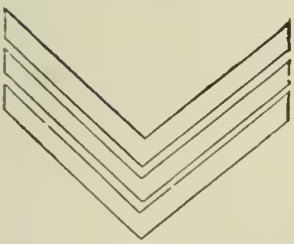
Sergeant Major.



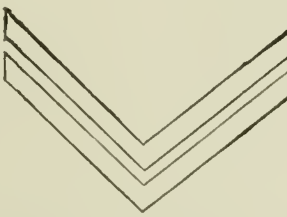
Quartermaster Sergeant.



First Sergeant.



Sergeant.



Corporal.

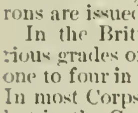
Ordnance Sergeant.

When, in addition to a War Stripe, an enlisted man is entitled to a Service Chevron, each edge of the latter is bound or faced by the former; and when, in addition to a War Stripe, an enlisted man is entitled to two or more Service Chevrons, they are separated by the War Stripe and the outer edge of each outside chevron is also bound or faced by the War Stripe. When worn in conjunction with the Service Chevron the War Stripe will be ¼ of an inch wide; when worn by itself its width will be the same as that of a Service Chevron, viz., ½ of an inch. War and Service Chevrons are issued without charge.

In the British service, the Corporals and the various grades of Sergeant have chevrons varying from one to four in number, either of white or of gold lace. In most Corps they are worn on the right arm only; but in the Guards, the Fusiliers, the Light Infantry, and the Grenadier and Light Infantry companies of the ordinary regiments, on both arms.

CHICANE.—To dispute every foot of ground by taking advantage of natural inequalities, etc.

CHIEF.—1. The head or leader of any band or community; a commander. 2. In Heraldry, an ordinary formed by a horizontal line, and occupying the upper part of the escutcheon. Like the other honorable ordinaries, the chief ought properly to take up a third part of the shield; but when the other charges are numerous, the chief is frequently diminished in size. Any object borne in the upper or chief part of the shield is said to be *in chief*, though the chief be not divided off from the rest of the field, as



Chief.

neers, as well as of all agents and others who may be employed under his direction within the limits of his Department. See *Corps of Engineers*.

CHIEF OF ORDNANCE.—An officer with the rank of Brigadier General who, under the Secretary of War, is, by law, charged with the administration and government of the Ordnance Department. By virtue of this authority he gives such orders and directions to its officers, soldiers, and employés as the necessities of the Ordnance service demand. He is also charged with the examination and settlement of the property accountability of all officers or other persons in the military establishment to whom Ordnance and Ordnance Stores are intrusted. The purchases and contracts for cannon, projectiles, powder, small-arms, and accouterments are made or specially ordered by the Chief of Ordnance, under the direction of the Secretary of War. See *Ordnance Corps*.

CHIEF OF THE STAFF.—An officer who ranks next to the General under whose orders he is serving, and is appointed to relieve the Commander-in-Chief of an army of an immense amount of detail work, and to harmonize the action of the several Departments. Such an officer is appointed in foreign armies. The question was raised, so far back as 1812, in England, whether a Chief of the Staff should be added to the Staff of the Commander-in-Chief. During the Crimean War, and subsequently in India during the Mutiny, an officer of this rank was appointed. In the United States, the Senior Staff Officer of a General is usually designated as the Chief of Staff.

CHIEF SIGNAL OFFICER.—An officer of the army, with the rank of Brigadier General, who is charged, under the direction of the Secretary of War, with the general Signal Service of the army; with the custody of all records and apparatus connected therewith; with the equipment and management of field-telegraphs used with active forces in the field; with constructing and operating lines of military telegraph; with maintaining signal stations at light-houses and at life-saving stations, and with the observations and reports required by law.

CHIEFTAIN.—A Captain, Leader, or Commander; a Chief; the head of a troop, army, or clan.

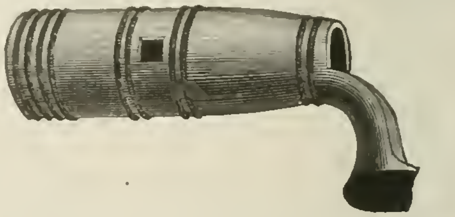
CHILIARCHIÆ.—The fourth of a Phalanx. The elementary tactical combinations of the Greeks were methodical, but very simple. An Army Corps was composed of a *Tetraphalangarchia*, or Grand Phalanx, an *Epitagma* of 8192 psiloi, and an Epitagma of cavalry of 4096 men. The Tetraphalangarchia = 4 Phalanxes = 16 *Chiliarchia* = 64 Syntagmata = 256 Tetrarchiæ = 1024 Lochoi or files = 4096 Enomitiæ of four men each.

CHILL.—A piece of iron introduced into a mold so as to rapidly cool the surface of molten metal which comes in contact therewith. Cast-iron, like steel, is hardened by rapid cooling, and softened by the prolongation of the cooling process. The extreme in the former direction gives *chilled iron* the hardness of hardened steel: the extreme in the direction of softness is obtained by prolonging the heat, abstracting the carbon from the cast-iron, reducing it to a nearly pure crystalline iron. See *Bronze Guns*.

CHILLED PROJECTILES.—Chilled-iron projectiles have been profitably employed to pierce armor-plates, on account of their intense hardness. The English projectiles recommended by Major Palliser may be described as an example of a chilled projectile. The form of these is cylindro-conoidal, the head being ogival, struck with a radius of 1½ diameters. The total length varies between 2 and 2½ calibers. The bottom is flat, and in the center of the bottom is a filling-hole for shells, closed with a composition screw-plug. All Palliser shells are lackered internally to give them a smooth, clean lining, which prevents the iron from either oxidizing at the expense of the powder, or firing it from friction by rapid rotation during flight. As the lacker does not always hold well to the metal, serge bags are introduced to contain the bursting-charge as an additional prevention against premature explosion. These bags are made bottle-shaped, and are introduced through the filling-hole. Palliser shot are cored. The hollow up the center enables them to cool more uniformly, and renders them less liable to split. It also slightly improves its proportions and its regularity of flight. The bottom is closed with a plug. These projectiles are made of carefully selected iron, which, if run in sand-molds, would solidify as mottled iron. The projectiles are cast point down, for the sake of density and soundness in the head. The mold is formed of a metal chill at the bottom extending up past the junction of head and body; the remainder of the mold is formed of sand, as also is the case for the formation of the interior. The chilling action therefore extends a little past the head of the projectile, which thus has a mottled body and a white head. The Grüson projectiles are cast with a dead-head on the base, which is afterwards cut off, the object being to obtain a solid bottom to stand well under the shock of the discharge. The chilling is effected by the metal molds, in virtue of their great conducting-power, their thickness greatly affecting the extent of their action. The head thus chilled white possesses generally the quality of white iron, intense hardness, crushing-strength, considerable brittleness, and increased density. The tip or point of a chilled projectile is occasionally broken off by the impact of a shell or shot rolled or struck obliquely against it; for the point which may penetrate directly through many inches of armor without injury may be fractured by a very slight transverse blow. See *Projectiles* and *Steel Projectiles*.

CHILL-HARDENING.—A mode of tempering steel cutting-instruments, by exposing the red-hot metal to a blast of cold air.

CHILLINGWORTH BAYONET.—The peculiarity of the essential feature of this invention, viz., the handle, consists in its affording a more convenient grasp for the hand in digging, or in using it as a side-arm, than does the ordinary bayonet-socket, without materially increasing its weight or losing the advantages of a secure fastening when it is fixed as a pike upon the gun. To secure this, besides the general shape of its profile, a shoulder is formed on the rearmost portion of the handle. To it is fitted a short sleeve, along the bore of which is cut a deep groove, intended to admit the bayonet-stud. When in fixing the bayonet on the musket the bayonet-stud strikes the shoulder, its longitudinal motion is arrested until the handle is turned



so that the square notch comes opposite to and receives the bayonet-stud; by then turning back the sleeve to its original position the bayonet is locked in place. By pushing back the pin through the bayonet-stud groove, the sleeve may be rotated until the stud which confines it comes opposite to the outlet of the internal circumferential groove in which it travels, when the sleeve may be slipped off. A catch-pin is kept in place by a transverse wire, and is pressed outward by a spiral spring. The blade and handle of the bayonet are forged in one piece. The curved neck of the handle is intended to be used as a muzzle-rest in firing, the point of the bayonet being then forced into the ground. See *Bayonet*.

CHIME.—The end of a tub or barrel. All powder-barrels are ordered to be rolled on the chime as being the safest mode of moving powder either in magazines or mill-houses.

CHINESE CAPSTAN.—A differential hoisting or hauling device, having a vertical axis, and therein only differing from the *differential windlass*.

CHINESE CROSS-BOW.—An ancient form of cross-bow, fitted with a case which turned on the stock by means of a lever moved by the wrist, and which furnished twenty arrows in succession, like our modern revolvers.

CHINESE FIRE.—A pyrotechnic composition consisting of gunpowder, 16 parts; niter, 8 parts; charcoal, 3 parts; sulphur, 3 parts; and cast-iron borings (small), 10 parts. See *Pyrotechny*.

CHINESE WHITE.—The white oxide of zinc has recently been introduced into the arts, under this name, as a pigment in place of the preparations of white-lead. It changes very little either by atmospheric action or by mixing with other pigments; but it has not the body of white-lead.

CHINESE WINDLASS.—A differential windlass in which the cord winds off one part of the barrel and on to the other, the amount of absolute lift being governed by the difference in the diameters of the respective portions. It is a good contrivance in the respect that great power may be attained without making the axle so small as to be too weak for its work. See *Chinese Capstan*.

CHINOOK.—The number of words constituting the *Jargon* proper does not exceed six hundred, and many of these are already obsolete or confined to certain limited localities. Not more than two hundred words of the *Chinook Language* proper are used in the *Jargon*, the balance coming from the Cree, Chehalis, Yakima, Klickitat, and various other Indian languages. In the *Chinook Jargon* the same word is frequently used as a noun, verb, etc., and generally has different meanings, according to the context; as, *lo-lo* (meaning whole, to earn, earnings, to carry and to conquer). Besides the words purely Indian, there are many derived from the Canadian French, and the following English words of easy pronunciation: *comb, haul, hook, house, lazy, man, musket, nose, sail, salt, ship, shoes, shot, sick, skin, smoke, soap, spoon, stick, stone, Sunday, tea,* and *wind.* The following are very common expressions: *Ab-ba,* well then; *Al-ah,* expressing surprise; *Au-ah,* expressing pain; *Kweesh,* an obstinate refusal. The *Chinook Jargon* is thoroughly understood by all Indians of the Northwest, and it is believed that a study of the following vocabulary, taken from FARROW'S MOUNTAIN SCOUTING, will enable any one to converse with any of the tribes. A great deal will depend upon the expression and gestures of the speaker, and experience only can teach him to intelligently say the most while using the fewest words.

Jargon Vocabulary. English—Chinook.

A

Above, sàh-a-le.
Absolve, mam-ook stoh.
Acorns, kàh-na-way.
Across, in-a-tl.
Afraid, kwash.
After, kim-tah.
Again (a so, more), weght.
Ague, colè-sick.
Ah! (admiration) wàh.
Ah (in pain), à-nah.
Alike, cock qua.
All, kon-away.
Almost, wake-siàh.
Alms (to give), mam-ook kla-how-i-am.
Alone, copet-ict.
Although, kegh-ti-chle.
Always, kwà-ne-sum.
American, Boston man.
Amusement, heè-hee.
And (then, besides, or) pee.
Angel, tà-màn-à-wis.
Angry, sollux.
Another, hul-o-ima.
Apple, le pome.
Apron, ki-see.
Arbutus, lahb.
Arm, le mah.
Arrive at, ko.
Arrow, kah-li-tan.
As, kock-wà.
As if, kàh-kw a, spose.
Ascend, clàt-à-wà sàh-a-le.
Ash-tree, is-ick-stick.
Ask (to), wà-wà.
At, kò-pa.
Aunt, kwalh.
Autumn, ten-as cole illà-he.
Awl, shoes keep-wot.
Axe, la hash.

B

Back, kimp-tà.
Bab, me-sà-chie.
Bad odor, humm.
Bad Spirit, mà-sà-chi tamàn-à-wis.
Bag, le sàk.
Ball, col-li-ton.
Bargain, ma-kook.
Bark, stick-skin.
Barrel, ta-mo-litsh.
Basket, ò-pe-kwan.
Be still, cul-tas mit-lite.
Beads, kà-mò-suck.
Bear (to), chet-woot.
Bear, its-hoot.
Beard, cha-pootch-us.
Beat (to), kok-shet.
Beaver, ce-naa.
Because, keh-wa.
Become (to), cha-ko.
Before, e-lip.
Behind, kim-ta.
Bell, tin-tin.
Belly, ya-kwah-tin.
Below, keè-kwil-lie.
Belt, là san-jel.
Berries, o-lil-lie.
Best, e-lip klosh.
Beyond, ten-às si-ah.
Big, hy-as.
Bird, kal-lak-a-la.
Biscuit, la bis-ke.
Bitter, klihl.
Black, klale.
Blackberries, klik-a-muks.
Blanket, pa-see-sie.
Blind, ha-lo see-à-host.
Blood, pil-pil.
Blow, puk-puk.
Blow out, mam-ook-poh.
Blue (light shade), spò-oh.
Blue (dark shade), klale.
Blunder (to), tsee-pie.
Bob-tailed, sis-ki-you.
Boil (to), lip-lip.
Bone, stone.
Boots, stick shoes.
Bore a hole (to), mam-ook thlà whop.
Borrow (to), a-yah-whul.
Both, kon-a-moxt.
Bottle, la-boo-ti.
Bow (of a boat), nose.
Bow (to shoot with), stick musket.
Bow, o-pitl-kegh.
Bowl, oos-kan.
Box, la ca-sett.
Boy, ten-as man.
Bracelet, klik-wal-lie.
Brass, pel chick-a-min.
Brave, skoò-kum tum-tum.
Bread, pia sa-pa-lil (san-de-lià).
Break, kok-shet.
Breast, to-toosh'.
Bridle, la bleed.
Bright, te-wagh.
Bring (to), màm-ook chà-co.
Broad, kluk-ulh'.
Broken, cha-cluck.
Brother, kàp-ho, if older than the speaker; ow, if younger.
Brother-in-law, ek-keh.
Brook, ten-às chuck.
Broom, bloom.
Bucket, ta-mò-litsh.
Buffalo, moos-moos.
Bullet, le bal, or ke-li-li-tan.
Bundle, kow.
Burn (to), mam-ook pia.
Biscuit, la-bisque.
But, pee.
Butter, to-toosh-la-klees'.
Button, chil-chil.
Buttons, tsil-tsil.
Buy (to), mah-kook.
By, co-pa.
By-and-by, win-a-pie.

C

Cabbage, cabbage.
Call (to), wà-wà.
Calf, ten-as moos-moos.
Calm (a), ha-lo wind.
Candle, la shan-del.
Canoe, ca-nim.
Cap, se-ah pult.
Capsize, kil-à-pie.
Carrot, la-ca-lat.
Carry (to), lo-lo.
Cart, tsik-a tsik.
Cascade, tum-wa-ter.
Cask, ta-mo-litch.
Cat, puss-puss.
Cataract, tum wa-ter.
Cattle, moos-moos.
Cedar, là med-cine stick.
Cellar, ket-wil-là.
Certainly, na-wit-kà.
Chain, chick-à-min lope.
Chair, la shase.
Change (to), huy-huy.
Cheat (to), là-lah.
Chicken, la pool.
Chief, ty-eè.
Child, ten-as man.
Chilly, ten-as cole.
Chimney, la-shum-ma-na.
Circle, que-u-que-u.
Clams, ò-na (emet-oks).
Clear, klah.
Clock, hy-as watch.
Cloth (dark), its-hoot.
Clouds, smoek.
Coat, ca-po.
Coffee, kau-py.
Cold, cole.
Color, 'tsum.
Come on, hy-ak.
Come (to), chà-co.
Come here, chà-co yockwa (ne-whàh).
Command (to), wà-wà.
Conceal, ipsoot.
Conjuring, ta-ma-na-wis.
Conquer (to), lo-lo.
Cook, mam-ook muck-a-muck.
Cool (to) mam-ook cole.
Copper, pil chick-à-min.
Cord, ten-as lo-pe.
Corn, ye-salth.
Corral, kul-lagh.
Cotton goods, sail.
Cough, hoh-hoh.
Count (to), mam-ook kwun-num.
Cow, clooch-man moos-moos.
Country, il-la-hè.
Coyote, tal-a-pus.
Crab-apple, pow-itsh.
Cranberry, so-le-mie.
Crazy, pelton.
Cream-colored, la clem.
Crooked, ky-wà.
Cross, là clo-a.
Crow, càw-càw.
Cry (to), cly.
Cup, oos-kan.
Curly, hunl-kih.
Cut (to), tl-ko-pe.

D

Dance, tanse.
Dark, polàk-lie.
Daughter, ni-ka ten-as clooch-man.
Day (this), o-kook sun.
Daybreak, ten-as sun.
Dead, mem-à-loos.
Deaf, ik-pooie kwil-lan.
Dear, hy-as mà-kook.
Deep, klip.
Deer, mow-itsh.
Demon, skoo-kum.
Desert (to sneak off), swal-là clat-à-wà càp.
Devil, deaub.
Different, kull.
Dig (to), mam-ook il-l.
Dirty, pot-tle il-la-he.
Dish, os-cun (plural la plà).
Dive (in water), clàt-a-wà keg-willy chuck.
Do (to), mam-ook.
Doctor, doc-tin.
Dogs, kam-ooks.
Dollar, dol-la.
Door, la pò-te.
Down stream, mi-mie.
Drink, mam-ook chuck.
Drive (to), kish-kish.
Drunk, pot-tle lum.
Dry, sun (dly).
Duck, kul-lak-a-la.
Duck (Mallard), hàht-huht.
Dust, pol-lal-lie.

E

Eagle, chak-chak.
Ear, kwo-lann.
Early, ten-as sun.
Earn, lo-lo.
Earth, il-la-he.
Eat (to), muck-a-muck.
Egg, la sap.
Elk, moo-luck.
Embrace, ba-ba.
Empty, ha-lo mit-lite.
Enclosure, kul-làgh.
End, o-boot.
Enemy, me-sa-chie til-la-cums.
Englishman (woman), King Gawge man (clootch-man).
Enlarge, hy-as mam-ook.
Enough, hy-u, or co-pet.
Entrails, ki-yah.
Evening, ten-as polak-lie.
Every, kon-a-wà.
Exchange, huy-huy.
Extinguish, mam-ook mem-a-loos (poh).
Eyes, see-a-host.

F

Face, see-a-host.
Fade (to), cha-co spo-ak.
Faded, spo-oh.
Falsehood, klim ia-a-whit.
Falsify (to), cla-man-a-whit.
Far, si-ah.
Far off, sy-àh.
Fast (quick), hy-ak.
Fast (tight), kwatl.
Fasten (to), kow.
Fat, glease.
Fat (to), hy-às gleece.
Father, pa-pa.
Fathom, it-lan (eth-low).
Fear, kwass.
Feet, là pe-à.
Fell (to), mam-ook-whim.
Fence, kul-lagh.
Fetch, mam-ook cha-ko.
Fever, waum sick.
Few, ten-as.
Field, klosh il la-he.
Fight (to), mam-ook sol-lux.
Fight (with fists), mam-ook puk-puk.
Figured, tzum.
File, la-leem.
Fill (to), mam-ook pahtl.
Find (to) klap.
Finished, co-pet.
Fingers, le doo.
Fire, pi-a.
First, e-lip.
Fish, pish (sa-mon).
Fish-hook, ik-kik.
Flag, Sun-day.
Flea, en-e-poo.
Flesh, il-wil-lie.
Flies, le moose.
Flint, kil-it sut.
Flour, sap-o-lil.
Flowers, klosh tip-so.
Fly (to), ka-wak.
Fog, smoke.
Food, muck-a-muck.
Foot, le-pee.
For what, pe-co-tu.
Forever, kwah-ne-sum.
Forenoon, èlip sit-cum sun.
Forget, copet cum-tux (mah-lie.)
Fork, la poo-shet.
Formerly, au-kot-tie.
Fox, tà-la-pos.
Frenchman, pa-si-ooks.
Friend, six.
Frog, swàh-kuk.
Fry (to), mam-ook la po-el.
Frying-pan, là po-el.
Full, pahtl.

G

Gallop (to), kwa-lal kwa-lal.
Gamble (to), ith-el-coom.
Gather (to), ko-ko-mulh.
Get (to), is-kum.
Get out, mash.
Get up, ket-op.
Ghost, skoo-kum.
Gift, cultus pot-lotch.

Girl, ten as clooch-man.
Give (to), pot-latch.
Glad, kwarm.
Glass, she-lockum.
Go, clat-a wà.
Go to bed, clat-a-wà moo-sum.
God, sa hà-lie ty-ee.
Gold, pil chick-a-min.
Good, klosh
Good-bye, kla-how-i-am.
Goods, ic-tas.
Goose, kàl-àk à-làh.
Grandfather, chope.
Grandmother, chitz.
Grass, tip-so
Grease, gleese.
Great, hy-as
Great many, hy u.
Green, pe-chugh.
Grey, le-gley.
Grizzly bear, se-àm.
Ground, il-la-he.
Gum-wood, là goom-stick.
Gun, suk-wal-lal.

H

Hail, cole-snass.
Hair, yak-so.
Half, sit-cum.
Hallo, nah.
Hammer, le-mah-to.
Hand, le-mah.
Hand (game of), it'lo-cum.
Handkerchief, kak-at-chum.
Handsome, hy-as klosh.
Hard, kull.
Hare, kwit-shad ie.
Harrow (to), mam-ook comb il-la-he.
Hat, se-ah-po.
Hazel nuts, tuk-wil-la.
He (she, it, his, etc.), yak-ka.
Head, la tet.
Heart, tum-tum.
Heaven, sà-hà-lie il-là-he.
Help (to), mam-ook e-lan.
Hell, ket wlt-là pià-hy-as.
Hen, la pool.
Here, yock-wa.
Hide, skin.
Hide (to), ip-soot.
High, sà-hà-lie.
Hit (to), kwulh.
Hoe, là-pe osh.
Hog, co-sho.
Hole, kla-wop.
Holiday, Sunday.
Horn, stone.
Horse, cu-l-tan.
How, kàh-tah.
How large? kon-si-ah.
How many? kon-se-à.
Hundred, tuk-a-mo-nuk.
Hungry, o-lo.
Hurry, hy-àk.
Husband, man.

I

I (me, my, or mine), ni-kà.
Ice, cole chuck.
If (suppose), spose.
In, ko-pà.
Indian, si-wash.
Indian corn, e-salth.
In shore, maht-wil-lie.
Iron, chick-a-min.
Island, ten-às il-la-he.
It (this, that), o-cook.

J

Jealous, sick tum-tum.
Joke (to), mam-ook làh-làh.
Joy, u-a-tle.
Jump (to), sò-pe-na.

K

Kamass root, là kà-mas.
Keep off (to), maht-lin-nie.
Kettle, ket-ling.
Key, la kley.
Kick (to), chuck-kin.
Kill (to), mam-ook mim-a-loos.
Kiss, be-be.
Knife, ò-pit-sah.
Knock (to), kò-kò.
Knotty, huul-kih.
Know (to), cum-tux.
Know (not to), wake cum-tux.

L

Lad, ten-as man.
Lame, klook te-hà wit.
Lamprey eel, skwák-wàl.
Land, il-la-hè.
Land otter, in-a mooks.
Language, là làng.
Large, hyas.
Last (hindermost), kimpta.
Lately, ten-às an-cot-tà.
Laughter, hee-hee.
Leap (to), sò-pe-na.
Leaf, tip so.
Lean (to), lagh.
Leave (to), mahsh.
Leave off (to), ko-pet.
Leg, te-ah-wit.
Leggings, mi-tas (sa-kol-eks).
Lend (to), a-yah-wuhl.
Length, youtl-kut.
Lick (to), kla-wun.
Lie (to), kla-man-a-wit.
Lift (to), mam-ook sa-ha-le.
Light (not heavy), wake-till.
Light (daylight), sun or twà (not dark), na wà.
Lightning, sa-ha-le pi-à.
Like, ka-kwa.
Like (to), tik-egh.
Listen (to), ne-whà.
Little, ten-as.
Live (to), mit-lite.
Liquor, lum.
Long while ago, là-lee.
Long, youtl-kut.
Long ago, an-cot-tie.
Look, nan-itch.
Looking glass, she lockum.
Loose, stoh.
Lose the way (to), tso-lo.
Lost, mash.
Love (to), tick-egh.
Lower, mam-ook-keg-wil-le.

M

Mad, sol-lux.
Magic, tà mà-nà-wàs.
Make (to), mam-ook.
Many, hy-u.
Mark, tsum.
Mark (to), mam-ook tsum.
Marry (to), ma-li-egh.
Mass (ceremony of), la mess.
Mast, ship stick.
Mat, klis-kwis.
Mattock, la peosh
Measure (to), ta nim.
Meat, itl-wil-lie.
Medicine, là med-sin.
Men, til-li-cums.
Mend (to), mam-ook tip-shin.
Metal, chick-à-min.
Middle (the), kat-sik.
Mid-day, sitcum sun.
Midnight, sit-cum po-làk-lie.
Milk, to-toosh.
Mind (the), tum-tum.
Mire, weght.
Miss (to), seè-pie.
Mixed, tzum.
Moccasins, skin-shoes.
Molasses, me-las.
Money, chick-a-min.
Month, moon.
Mosquito, mel-a-kwa.
Mother, ma mà
Mountain, la monti.
Mountain, hy-as il la-he.
Mouse, hool-hool.
Mouth, la boss.
Much, hy-u.
Mud, cle-min il-la-he.
Mule, la mel.
Music, tin-tin.
Mussels, to-luks.
Muskrats, cul-tus c-nah.
My (mine), ni ka.

N

Nails, le clou.
Name, yah-hul (nem).
Near, wake si-ah.
Neck, le cou.
Needle, ca-pu-ut.
Never, wake con-sè-àh.
Night, po-lak-lie.
No (not), wake.
Nobody, wake clax-to.
Noise, là tlah.
None, ha-lo.
Nonsense, cul-tus wa-wa.
Noon, sit-cum sun.
Not yet, wake al-ta.
Nothing, wake le-ta.
Notwithstanding, kegh-tchie.
Now, al-ta.
Nuts, til-wil-la.

O

Oak, kull stick.
Oar, la lahm.
Oats, la wen.
Obtain, is-kum.
Ocean, salt-chuck.
Off, klak.
Off shore, mahtl-in-nie.
Oil, gleece (la-kles.)
Old man, ole-man.
Old woman, lam-mi-ch.
On, co-pa.
One eyed, ict see-a-host.
Only, co-pet, ok-kook.
Open, hah-lakl.
Open (to), he-luck.
Opposite, in-a-ti.
Or, pe.
Order (to), mash tum-tum.
Other, hul-o-i-ma.
Otter, e-mam-ooks.
Our (we, us), ne-si-ka.
Out doors (outside), klagh-a-nie.
Over (above), sah-hà-lè.
Over (other side), en-a-ti.
Overcoat, ka po.
Ox, moos-moos.
Oysters, chet-lo.

P

Paddle, is-ick.
Paddle (to), mam-ook is-ick.
Paint, pent.
Paint (to), mam-ook pent.
Pants, se-ca-luck.
Path, o-e-hut.
Paper, pè-pah.
Peas, le pwan.
People, til-li cums.
Perhaps, klo-nas.
Petticoat, kal-a-kwah-tie.
Piebald, le kye.
Pin, kwek-wi-eus (keep-wot).
Pipe, la peep.
Pitch, la goom.
Plate, la se-et.
Plough (to), klugh il-la-he.
Pole, le pehsh.
Poor, ha-lo le-ta (kla-how-yam.)
Pork, co-sho.
Porpoise, qui-see-o.
Potato, wap-pa-to.
Pour (to), wagh
Powder, po-lal-lie.
Prairie wolf, tul-a-pus.
Present (a), cul-tus pot-latch.
Presently, al-kie (win-a-pie.)
Pretty, to-ke-ti.
Priest, le plet.
Proud, youtl (kwelth).
Provided that, spose.
Pull, haul.
Push, kwult.

Q

Quarter, ten-as sit-cum.
Quarter (of a dollar), kwahta.
Quick, hy-ak.
Quills, te-peh.

R

Rabbit, kwit-shad-ie.
Rain, snass.
Rat, holé holé.
Rattle, shugh.
Rattlesnake, shugh-ò-poots.
Razor fish, ò-na.
Reach, ko.
Red, pil.
Relate (to), yi-em.
Report (of a gun), poo.
Return, cha-co kil a-pie.
Ribbon, le lo-ba.
Rice, mit-whit.
Rifle, ca-li-peen.
Ring (a), kwèo-kwèo.
Ripe, pi-ah.
River, hy-as chuck.
Road, way-hut (o-chut).
Roan-colored, san-de-lie.
Roast, mam-ook la pellah.
Rock, stone.
Rooster, la cock.
Root, ka-mass.
Rope, lope.
Rotten, poo-lie.
Round, lo-lo.
Row (to), mam-ook le-lam.
Rudder, boat-o-poots.
Rum, lum.
Run, coo-ry.
Run away, cap-swal-la clat-a-wa.

S

Sack, le sak.
Saddle, la sell.
Saddle-housing, le-pish-e-mo.
Sailor, ship-man.
Salmon, sà-mon.
Sand, po-lal-lie.
Sandwich Islander, Oyee.
Sash, la saw-jel.
Saw, la see (la gwin).
Say (to), wa-wa.
Scarce, quass
Scissors, le see-zo.
Sea, salt chuck.
Seal, ol-hi-yu si-wash co-sho (ol-hy-in).
See (to), nan-itch.
Sell (to), mah-cook.
Send (to), clat-a-wà.
Sew (to), mam-ook tip-shin.
Shake, hul-hul.
Shake (to), to-to.
Shame, shem.
Sharp, pah kis-ilth.
Sharpen to), mam-ook tsish.
She, ya-ka.
Sheep, le mon-to.
Shell money (small), coop-coop.
Shell money (large) ai-qua.
Shingle, le bah-do.
Shining, to-wagh.
Shirt, shut.
Shoat (to), mam-ook poo.
Short, yutes-kut.
Shot-pouch, kl-li-tan le-sac.
Shout (to), hy-as wa-wa.
Shovel, la-pell.
Shut (to), ik-poo-ie.
Sift (to), to-to.
Silk, la-sway
Silver, t-kope chik-a-min.
Similar, kah-kwa.
Since, kim ta.
Sing (to), shan ti.
Sink, cli-a.
Sister (elder), lik-po.
Sister (younger), ats.
Sit (to), mit-lite.
Skunk, hum-o-poots (saub-bno).
Sky, kon-sah.
Slave, e-li-te (mist-chi-mas).
Sleep, moo-sum.
Slowly, kla-wa.
Small, ten-as.
Smell, hum.
Snake, o-luk.
Snare, la pe-nge.
Snow, cole-snass.
Soft, cla-min.
Sometimes, ict-ict.
Soon, wake le-ly.
Sorrell (color), le-blau.
Sorry, sick tum-tum.
Sour, kwates.
Spade, la pell.

Speak (to), wà-wà.
Spill (to), wagh.
Spirit (guardian), to man-no-us.
Spirits, lum.
Split, tsugh.
Split (to), mam-ook tsugh.
Spectacles, dal-la see-a-host.
Spit (to), mam-ook toh.
Spotted, le-kye.
Spurs, la see-blo.
Squirrel, kwis-kwis.
Stab (to), klem-a-hum.
Stag, man-mow-a-itch.
Stand, mit-whit.
Stars (buttons), tsil-tsil.
Stay (to), mit-lite.
Steal, cap-swalla.
Steam, smoke.
Steamer, ship (pia-ship).
Stirrup, sit lay.
Stockings, kush-is.
Stop, ko-pet.
Store, ma-cook house.
Story, eh-kah-nam.
Straight, si-pah (de-làte).
Strawberries, a-mo te.
Strike (to), cock-shet.
Strong, skoo-kum.
Sturgeon, stutch-un.
Subdue, quan.
Sugar, le sook.
Summer, waum il-la-he.
Sun, Otà-lagh.
Sunset, elip-sun.
Suppose, spose.
Swan, kah-loke.
Sweep (to), mam-ook bloom.
Sweet, tsee.
Swim, sit-shum.

T

Table, la tahb.
Tail, o-poots.
Take (to), iskum.
Take care, klosh nan-itch.
Take off, mam-ook klak.
Tale, yi-em.
Talk, wà-wà.
Tame, kwass.
Tattle (to), ya-yim.
Teach (to), mam-ook-cum tux.
Tear (to), klugh.
Teeth, le tah.
Tell (to), wà-wà.
Thank you, màh-sie.
That, o-cook.
That way (there, beyond), yah-wa.
They, klas-ka.
Thich, pit-lilh.
Thin, pe-what-tie.
Thing, ic-ta.
Thirsty, o-lo chuck.
This, o-cook.
This way, yàk-wà.
Thou (thy, thine), mi-kà.
Thread, kla-pite.
Throw (to), mash.
Throw away, mahsh.
Tide, chuck.
Tie (to), kow.
Tight, kwutl.
Tinware, ma-lah.
Tip (to), lagh.
Tired, till.
To (towards), ko-pa.
Tobacco, ki-noos.
To-day, o-cook sun.
To-morrow, to mà-tà.
Tongue, la lang.
Trade (to), hoè-hoè.
Trail, way-hut.
Trap, la piege.
Tree, stick.
Tree (fallen), whim stick.
Tremble, hul hul.
Trot (to), teh-teh.
Trouble, mam-ook till.
Trowsers, so-kol-eks.
True, de-làte.
Truth, de-làte wà-wà.
Tub, ta-mò-litsh.
Turn (to), howh.
Turn over (to), kil-à-pie.
Twice, moxt.
Twilight, twàh.
Twine, ten-as lope.

U

Uncle, tot.
Under, kee-kwil-lie.
Understand (to), cum-tux.
Unhappy, sick tum-tum.
United States, Boston il-la-he.
Untamed, le mo-lo.
Untie (to), mam-ook stoh.
Up (above, heavenward) sa-ha-lie.
Upset (to), kil-a-pi.
Us, ne-si-ka.
Useless, cul-tus.

V

Vancouver, kits-oat-qua.
Venison, mow-itch.
Very small, hy-as ten-as.
Vessel, ship.
Vest, la west.
Vomit (to), wagh.

W

Wagon, chik-chik.
Wander (to), ts-o-lo.
Warm, waum.
Wash (to), mam-ook wash.
Watch, tik-tik.
Watch (to), nàn itch.
Water, chuck.
Waterfall, tum-water.
We, ne si-ka.
Week (one), ict Sunday.
Weigh (to), mam-ook lil.
Wet, pahtl-chuck.
Whale, eh-ko-lie.
What, ic-ta.
What color? kà-tà tsum.
Wheat, sap-o-lil.
Wheel, chik-chik.
When, kan-sih.
Where, kah.
Whip, la whet.
White, t-kope.
Who, klax-ta.
Whole, lo-lo, kwa-nice.
Wicked, me-sa-chie.
Wide, kluk-ulh.
Wild, le mo-lo.
Will (the), tum-tum.
Willow, ee-na stick.
Win (to), to-lo.
Winter, cole il-la-he.
Wipe (to), klak-wun.
Wire, chik-a-min lope.
Wire (brass), klik-wal-la
Wish (to), tick-ey.
With, co-pa.
Without, ha-lo.
Wolf, le-loo.
Woman, clootch-man.
Woman (old), lam-mi-eh.
Wood, stick.
Work (to), mam-ook.
Worn out, ol-è-man.
Worthless, cul-tus.
Wound (to), klem-a-hum.
Write (to), mam-ook tsum.
Writing, tsum.

Y

Year (a), ict cole.
Yellow, kaw-ka-wak.
Yes, ah-ha.
Yes indeed, na-wit-ka.
Yesterday, tahl-kie sun.
Young, ten-as.
You, mi-ka.
Yours, me-sika.

NUMERALS.

One, ict.
Two, moxt.
Three, klone.
Four, lak-it.
Five, kuin-num.
Six, tagh-hum.
Seven, sin-à-moxt.
Eight, sto-te-kin.
Nine, kweest.
Ten, tah tel-lum.
Twenty, moxt tah-tel-lum.
Thirty, klone tah-tel-lum.
One hundred, ict ta-kà-mo-nuk.
One thousand, tah-tel-lum ta-ka-mo-nuk.

Greater numbers are expressed by a conjunction of the words expressing the numbers to be added, thus: Sin-a-moxt tah-tel-lum (seven times ten) express seventy.

THE LORD'S PRAYER IN JARGON.

Our Father who stayeth in the above, good in our hearts (be) thy name; good thou chief among all people; good thy will on earth as in the above; give every day our food; If we do ill, (be) not thou very angry, and if any one evil towards us, not we angry towards them; send away far from us all evil.

CHIN-STRAP.—1. The strap connecting the throat-strap and the nose-band of a halter. 2. A strap passing under the chin, employed to hold the helmet or dress-hat in place in windy weather.

CHIVALRY.—The system of knighthood, together with the privileges, duties, and manners of knights. The social arrangement to which this term is applied seems first to have assumed the character of a positive institution during the eleventh century; but so far from being an invention of that period, it had its roots in the manners of the Germanic races, amongst whom it ultimately arose, at the earliest period at which they are historically traceable. In the description which Tacitus has given us of the manners of the Germans we find the most unequivocal indications of the existence, not only of the general spirit, but, in a partially developed form, of many of the special arrangements of chivalry. But it was in connection with feudality that chivalry attained to its full proportions, and in many respects it must be regarded as the complement of that institution. Whilst feudality exhibits the political, in chivalry we see the moral and social side of the arrangements of mediæval life. It was in the feudal mansions of the barons that the system was developed; and to the lay portion of the youth of the higher classes the instruction which they there received in the usages of chivalry formed by far the most important part of education. In addition to the martial accomplishments, which corresponded to those of a modern cavalry-officer, they were instructed in the political relations which subsisted between the vassal and his lord, by which the whole body of society was then bound together; and in what might almost be called a system of ethics, strangely enough exhibiting unmistakable traces of the Stoic philosophy. The analogy between the severer virtues recommended to the special cultivation of their disciples by the followers of Zeno, and those inculcated on the novice in chivalry, and practiced by the knights of the Middle Ages, might be ascribed to other than historical causes, were it not that we are able to trace the connection between them with something approaching to certainty. If any one wishes to convince himself of the truth of our assertion, let him compare the last production of the intellectual life of antiquity with one of the earliest and most important of our own literature —the *Consolations of Philosophy* of Boethius with Chaucer's *Testament of Love*. The resemblance is so close that the latter work has, not without reason, been regarded as an imitation of the former; but the main features which distinguish them, and mark Chaucer's work as belonging to the modern world, are more instructive than even their similarity. What Chaucer has exhibited in the work to which we have referred may be regarded rather as the philosophical than the poetical side of the institution. But to poets of a lighter and more imaginative cast of mind chivalry has furnished, from the days of the troubadours down to the present Poet-laureate, no insignificant portion of their subject-matter. King Arthur and his Knights of the Round Table, the traditions regarding whom had been taken from a period altogether mythical and long anterior to the existence of chivalry as an institution, became to the poetry of the Middle Ages very much what the heroes of the Trojan War were to that of the whole ancient world. Much astonishment has often been expressed at the contrast between the lofty and ideal purity of the code of morals inculcated by chivalry, and the grossness of the lives of the men who were trained under its influences. The case is one which in a remarkable degree proves the practical importance of the inculcation of sound doctrine, for the practice gradually, though slowly, conformed itself to the principles; and it is probably in no insignificant degree to the elevated tone of the latter that we owe the moral superiority of the modern over the ancient world. See *Court of Chivalry*.

CHLORATE OF POTASSA.—Many oxydizing substances, such as the chlorate of potassa and nitrate of soda, may be used in the manufacture of gunpowder; but for this purpose they are inferior to the nitrate of potassa. The chlorate of potassa is a substance which parts with its oxygen easily, and makes a powder which has been found by experience to give at least double the range, with the mortar eprouvette, of that made with nitrate of potassa, but from its great quickness resembles the fulminates in its destructive effects on the gun. Besides, it is more costly than nitrate of potassa, renders the powder liable to explode by slight causes, and gives a residue which rapidly corrodes iron. Its use in the laboratory is chiefly confined to the preparation of colored fires and cannon-primers.

Chlorate mixtures are very sensitive to friction and percussion, and they explode with great sharpness. The potassium salt is the only one of the chlorates which is employed in these mixtures. Very many chlorate mixtures have been made, but few of them are of much value. Of many of them it may be said that they are so liable to accidental explosion that they are unfit for use. The following are examples of chlorate mixtures: potassium chlorate with rosin; potassium chlorate with galls (Horsely's powder); potassium chlorate with gambier (Oriental powder); potassium chlorate with sugar (used in chemical fuses); potassium chlorate with potassium ferrocyanide (White or German gunpowder); potassium chlorate with tannin (Erhardt's powder); potassium chlorate with sulphur (Pertuiset powder, used in explosive bullets). In the laboratory, however, potassium chlorate is the basis of many fuse-mixtures, some of which are used to a certain extent. See *Gunpowder*.

CHOCK.—A piece of wood by which the wheel of a carriage is prevented from moving forward or backward. In the United States Ordnance Department two kinds are employed, the simplest form being triangular in section, while another description of chock is wedge-shaped and provided with a handle. A common form of chock is attached to cast-iron garrison-carriages, on which the breech of the gun rests and is elevated.

CHOCKING HANDSPIKE.—A handspike employed when slewing a gun that rests on skids, and in other mechanical maneuvers.

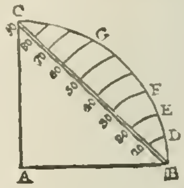
CHOKE.—1. A slightly narrowed part just in front of the chamber in certain guns, to insure that all projectiles are rammed to the same spot. 2. The tied end of a cartridge; also, the constriction of a rocket-case, etc.

CHOKER.—An instrument used for bringing the ends of a fascine to the girth, nearly where it is intended the fascine should be, when it is bound.

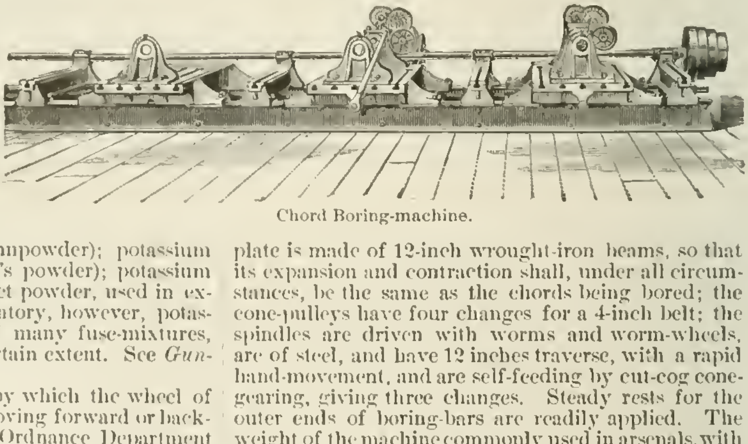
CHOKE-STRAP.—A strap passing from the lower portion of the collar to the belly-band, to keep the collar in place when descending a hill or backing.

CHOKEY.—A common expression for an East Indian guard-house and prison.

CHORD.—The chord of an arc of a curve is a right line joining its two extremities. A scale of chords is used in laying off angles. It is thus constructed: Let AB be the radius of the circle to which the scale is to be adapted. With the center A and radius AB describe a quadrant BEC. Divide the quadrantal arc BEC into nine equal parts BD, DE, etc. This may be done by taking a radius equal to AB, and from the centers B and C cutting the arc in G and F. As the radius is always equal to the chord of 60°, or $\frac{2}{3}$ of a quadrant, the arc CB is thus divided into three equal parts, BF, FG, GC, and each of these parts may then be trisected by trial, as no direct method is known. Draw the chord of the quadrant BC; from B as a center, and the chord of BD as a radius, describe an arc cutting BC at 10; with the chord of BE as a radius, describe an arc cutting BC in 20; with the chord of BF, describe an arc cutting BC in 30; and in a similar manner find the divisions 40, 50, 60, 70, 80. Then the arcs BD, BE, BF, being arcs of 10°, 20°, 30°, etc., respectively, the distances from B to 10, 20, 30, etc., are the chords of arcs of 10°, 20°, 30°, etc.; so that BC is a scale of chords for every 10°, from 0° to 90°. To lay down or measure angles with such a scale, the arc of 60° measurement must be described with the chord of 60°.



CHORD BORING-MACHINE.—A tool consisting of two horizontal boring-machines and an extra table to facilitate setting the work, so arranged that they can be adjusted and clamped on the bed-plate to suit the centers of the holes in the chords; it is of sufficient capacity to admit chords 3 feet by 2 feet; the bed-plate is made of 12-inch wrought-iron beams, so that its expansion and contraction shall, under all circumstances, be the same as the chords being bored; the cone-pulleys have four changes for a 4-inch belt; the spindles are driven with worms and worm-wheels, are of steel, and have 12 inches traverse, with a rapid hand-movement, and are self-feeding by cut-cog cone-gearing, giving three changes. Steady rests for the outer ends of boring-bars are readily applied. The weight of the machine commonly used in arsenals, with 55 feet of bed, is 32,200 pounds. See *Boring-machine*.



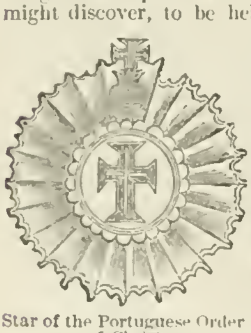
Chord Boring-machine.

CHOROGRAPH.—An instrument contrived by Professor Wallace, of Edinburgh, "to determine the position of a station, having given the three angles made by it to three other stations in the same plane, whose positions are known." The problem may be stated thus: To construct two similar triangles on two given straight lines.

CHOUANS.—Bands of insurgent royalists who, during the French Revolution, organized a reactionary movement in Brittany. They obtained their name from their leader, Jean Cottereau. This person, who had been a smuggler, went by the name of Chouan—a corruption, it is said, of *chat-huant* ("screech-owl")—because, while he and his accomplices were engaged in their nocturnal work, they were wont to be warned of their danger by some one on the watch imitating the cry of this bird. At the period of the revolt, however, he followed the humble occupation of a clog-maker. The first indications of an anti-revolutionary spirit in Brittany manifested themselves in the beginning of 1791, when several trees of liberty were destroyed at night, and other more serious outrages committed. These disturbances were fomented by seditious priests. In 1792 an insurrection was planned by the Marquis de la Rouarie, with the sanction and approval of the two brothers of Louis XVI. The agents of the Marquis entered into communications with Jean Cottereau—well known for the reckless audacity of his character—and other smugglers; but having the misfortune to be arrested, the carrying out of the insurrection devolved upon the latter. The *Chouanerie*, as the Insurrection was called, at first disgraced itself, both by the drunken license and the cruelty which marked it. After several successful exploits of the guerrilla sort, Jean Cottereau perished in an engagement which took place on the 28th of July, 1794, near the wood of Misdon, the theater of his first efforts. Before this, however, other and more illustrious leaders had appeared in Brittany to direct the movement, the chief of whom were Georges Cadoudal and Charette. Through their endeavors it was more widely extended, and for a time seemed likely to imperil the security of France, but was suppressed towards the close of 1799. Petty *spurts* of insurrection, however, broke out till about 1803, when the *Chouanerie* ceased for a while. In 1814–15 it again made its appearance on both sides of the Loire; and after the July Revolution, was once more excited by the Duchess of Berry on behalf of the Duke of Bordeaux, but crushed by the energetic measures taken by M. Thiers.

CHOUMARA SYSTEM OF FORTIFICATION.—Choumara, a French officer of engineers of distinguished abilities, is the author of several remarkable memoirs on the defects of the bastion system, and the means by which they may be removed and additional strength be thereby given to the defenses. His proposition for this purpose may be briefly stated as follows: 1. That part of a permanent work which can undergo no modification during the progress of a siege is the masonry, and it may therefore be regarded as the really permanent feature; all the parts of earth, as the parapets, etc., being susceptible of such modifications as circumstances may demand. In all cases of the application of the independence of the parapets, Choumara proposes to convert the space left between the foot of the parapet and the scarp-wall into a *chemin de ronde*, or corridor, which is covered in front by a slight parapet, and from enfilading fire by giving an increased height to the portion of the parapet adjacent to the salients, forming a *bonnet*. This corridor is occupied by sharp-shooters to annoy the besieger's trenches. Furthermore, Choumara regards the corridor as an additional security against surprise and escalade. 2. He proposes to place high traverses in the bastion-salients, to cover the faces from enfilade and the flanks from reverse views, and similar traverses at the shoulder-angles with the same object. These he also proposes to casemate, or else construct with blindages for artillery to obtain a fire in the directions of the capitals, and reverse views on the demi-lune glacis and the breach in the bastion-face. As these traverses, from their height, might give the besiegers in possession of them a plunging fire on the bastion-retrenchments, he proposes so to arrange them that they can be readily destroyed at any moment by mines, or, if of timber, be burned. 3. To mask the masonry of the enceinte and demi-lune from breaching-batteries, erected in their usual positions along the crests of the glacis, Choumara proposes to form what he terms an *interior glacis*, or covering mass of earth, in the ditches, the crests of which shall mask the masonry of the scarps from the positions in question; and the upper surface of which, forming a glacis, shall be swept by the fire of the works in its rear. In this manner he expects to force the besiegers to the difficult operation of making lodgments in this glacis to obtain suitable positions for their breaching-batteries. 4. By selecting for some of his outworks those points on the exterior which are most favorable to the action of the assailant's sharp-shooters, he proposes in this way to cripple this important means of attack. 5. By giving greater extent to the exterior side, and a more retired position to the curtain, which is also to be made as short as possible, Choumara obtains bastions of ample size, not only to admit of the modifications he proposes for the parapets, traverses, and *chemins de ronde*, but for strong interior retrenchments, so organized with bomb-proof shelters, and arranged defensively towards the interior, that each bastion will admit of a defense to the rear at its gorge, after the besiegers may have effected a breach at other points and penetrated within the enceinte. The essential modifications proposed by him may be summed as follows: detaching the scarp from the parapet; regulating the line of defense by the range of field-artillery, not musketry; introducing an interior glacis; and employing defensive barracks to serve as interior retrenchments. The memoirs in which Choumara brought his propositions before the public naturally attracted attention, as much, perhaps, from their polemical character and piquancy of style as their professional interest. They contain but few things the germs of which are not to be found in writers who preceded him. His modifications respecting the parapets, throwing them back from the scarps and breaking them into directions best suited for defense, are to be met with in Chasseloup's propositions. His proposals for lengthening the bastion-flanks and occupying the salient places-of-arms by redoubts with considerable command are to be found in the methods of De La Chiche. To Virgin he seems to be indebted for his organization of interior retrenchments, which are to convert each bastion into an independent work, equally provided for defense against approaches both from the interior and exterior of the enceinte. Like disputants, usually, of an ardent temperament, he overestimates the value of many of his propositions and loses sight of their countervailing defect. By laying down as a principle what may be exceptionally good in practice, he has rather weakened his own positions. This is the case, particularly, with his rule of independence of the parapets on the scarps, which, if adopted in all cases, might demand a greatly increased and hurtful command, and cut up to great disadvantage the interior spaces of the bastions. His introduction of the *chemins de ronde* on the faces of the bastion and the demi-lune adds really very little, if at all, to the exterior defense; whilst they contract the interior space of these works, break in upon the unity of the defense, and place the troops in them in a very exposed position to the means of annoyance possessed by the besieger. His expectations with respect to the effect of his fire in the direction of the capitals, in delaying the besieger's approach to the third parallel, were hardly warranted by the experience gained in artillery and small-arms, even at the time the last edition of his memoirs appeared. It is hardly to be questioned, now that these weapons have been so greatly improved, both in range and accuracy of fire, that, considering the increased development of the besieger's parallels, which gives him a choice of positions for his batteries on so extended a line, the concentrated fire he could bring to bear on the batteries in question would not only soon ruin their casemates, but would greatly damage the adjacent faces and also the flanks of the bastions, although covered from enfilading views, either by the direction of the parapets of the faces or the high traverses raised with the same object. These advantages in the position of the besieger, it is thought, would prevent any delay in pushing forward his approaches up to the third parallel. After this the approaches would probably be retarded beyond the usual time in the attack on Cormontaigne's front, owing chiefly to the redoubts in the bastion and demi-lune salient places-of-arms, and the arrangement of the face-cover in the enceinte-ditch. Supposing an enceinte organized according to his method, and containing interior retrenchments to oppose the besieger's approaches both from without and within the enceinte, Choumara estimates at least six separate epochs of breaching-batteries, as follows: 1st, against the redoubt of the demi-lune salient place-of-arms; 2d, against the demi-lune and the redoubt of the bastion salient place-of arms; 3d, against the bastions; 4th, against the bastion-retrenchment; 5th, against the retired retrenchment; 6th, and finally, against the bastions converted into citadels by the fronts with which their gorges are closed. According to the estimates of the time made by Choumara, it would require 112 days from the opening of the trenches to the final assault and reduction of last defenses. See *Fortification* and *System of Fortification*.

CHRIST.—The Portuguese Order of Christ has an interesting history. When the Templars were expelled from France, and their property confiscated by Philippe le Bel, with the sanction of Pope Clement V., they were received into Portugal, and their Order revived in 1317 under the title of "The Order of our Lord Jesus Christ." With some difficulty Pope John XXII. was induced to sanction the new order. The Knights of the Order of Christ joined the Portuguese in all their crusades against the infidel, and also in their African and Indian expeditions, receiving in compensation continual additions to their own possessions. The Grand Prior of the Order was invested by Pope Calixtus III. with power equal to that of a bishop; and as an encouragement to adventure, the Knights were promised all the countries which they might discover, to be held under the protection of Portugal. At length their wealth and power excited the jealousy of the kings of Portugal; their future acquisitions, and, subsequently, even their actual possessions, were declared to be Crown possessions, and the offices of Administrator and Grand-master were transferred to the Crown. A fine cloister belonging to the Order is still to be seen at Tomar, to which place the seat of the order was transferred from Castro-Marino in 1366. Noble descent, and three years' military service against the infidel, were required for admission. The members took the three monkish vows of chastity, poverty, and obedience, till the Pope released them from the first two, on condition of their applying the third part of their revenues to the support of Tomar cloister, the priests of which were bound by the three vows. This cloister is now a theological institution for the instruction of the priests of the Order. It is said that the Order still possesses 26 villages and farms, and 434 prebends. It is very numerous—consisting of six Knights of the Grand Cross, 450 Commanders, and an unlimited number of Knights. Catholics of noble descent alone are admitted, and foreigners are excluded from participation in the revenues, being exempted in return from its rules. The Papal Order of Christ is a branch of the Portuguese Order, created by Pope John XXII., and has only one class.



Star of the Portuguese Order of Christ.

CHRISTIAN CHARITY.—KNIGHTS OF THE ORDER OF CHRISTIAN CHARITY was the name of an Order instituted by King Henry III. of France for the support of maimed officers and soldiers who had done good service in the wars. He assigned revenues to the Order, drawn from all the hospitals in the kingdom. The Knights wore on the left breast an anchored cross embroidered on white taffety or satin, with a border of blue silk, and in the middle of the cross a lozenge of sky-blue charged with a *fleur-de-lis or*. The completion of the Institution was reserved for Henry IV., who placed it under the charge of the Marshals and Colonels of France; and by means of it, many of those who had served their country faithfully were enabled to spend the latter portion of their lives in peace and above want. The Order formed the germ of that noble hospital, the *Invalides*, which was founded by Louis XIV., and which served as a model for the English hospitals of Chelsea and Greenwich. When the Invalides was founded, the Order of Christian Charity was superseded.

CHROMATICS.—That part of the science of optics which explains the properties of the colors of light and of natural bodies. Before 1666, when Sir Isaac Newton began to investigate this subject, the notions which prevailed respecting the nature of colors were purely fanciful. Till Descartes' time, indeed, it seems not to have been conceived that color had anything to do with light. As examples of the notions prevalent at very early times, we may cite those propounded by Pythagoras and Zeno.

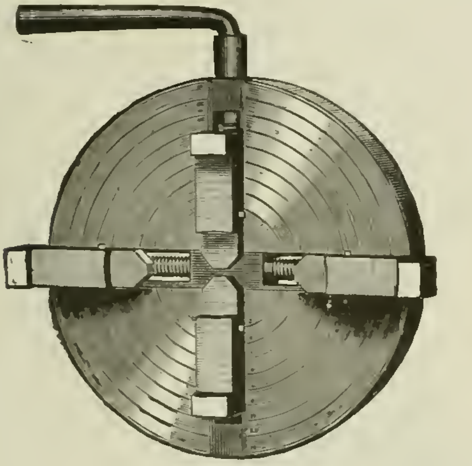
CHROMATYPE.—A photographic process, thus described by its discoverer, Mr. R. Hunt: One dram of sulphate of copper is dissolved in one ounce of distilled water, to which is added half an ounce of a saturated solution of bichromate of potash; this solution is applied to the surface of the paper, and when dry it is fit for use, and may be kept for any length of time without spoiling. When exposed to sunshine, the first change is to a dull brown, and if checked in this stage of the process we get a negative picture; but if the action of light is continued the browning gives way, and a positive yellow picture on a white ground is obtained. In either case, if the paper, when removed from sunshine, is washed over with a solution of nitrate of silver, a very beautiful positive picture results. In practice it will be found advantageous to allow the bleaching action to go on to some extent; the picture resulting from this will be clearer and more defined than that obtained when the action is checked at the brown stage. To fix these pictures it is necessary to remove the nitrate of silver, which is done by washing them in pure water. If the water contains any chloride, the picture suffers, and long soaking in such water obliterates it—or, if a few grains of common salt be added, the apparent destruction is rapid. The picture is, however, capable of restoration, all that is necessary being to expose it to sunshine for a quarter of an hour, when it revives; but instead of being of a red color, it assumes a lilac tint, the shades of color depending upon the quantity of salt used to decompose the chromate of silver which forms the shadow parts of the picture. Mr. Bingham suggested the substitution of sulphate of nickel for sulphate of copper, as yielding a higher degree of sensitiveness and greater definition. Neither process has been much used.

CHRONOGRAPH. — Different forms of time-measurers, or time-recorders, under this designation, have been invented within a recent period. Benson's chronograph is intended to measure intervals of time down to tenths of a second, for use at horse-races and other occasions where a seconds-watch is not exactly suited. It has an ordinary quick train-lever movement, carrying hands which move over a dial. One of these is a seconds-hand, very peculiarly made. The seconds-hand is double, consisting of two distinct hands, one superposed on the other. The outer end of the lowermost hand has a small cup with a minute hole at the bottom; while the corresponding end of the uppermost hand is bent over so as exactly to reach this puncture. The little cup is filled with ink having a consistency between that of writing-fluid and printers' ink. Suppose that a horse-race is about to take place. The observer keeps a steady lookout for the fall of the starter's flag, or whatever the signal may be: he gives a pull to a cord or string connected with the mechanism peculiar to the instrument; by this movement the outer and bent end of the upper seconds-hand dips down through the ink-cup in the lower hand, and through the puncture to the dial. A small black spot or mark is thus made upon the dial-plate; and this is repeated as each horse passes the winning-post. If the eye and hand of the operator are quick and accurate, there is a reliable record thus presented by the instrument of the duration of the race, sometimes as close as one tenth of a second. The instrument is now adopted at the principal races as a suitable one for the purpose; thus it is used for races such as the Derby, the Oaks, the Goodwood, the St. Leger, etc. It is also available for many other purposes. Strange's chronograph is designed for a more scientific purpose, and constructed with more careful details. The object is to measure extremely short intervals of time, for the determination of longitudes in great trigonometrical surveys. The observer, when a particular star traverses the field of his telescope, touches a small ivory key; and on the instant a dot or mark appears on a sheet of paper coiled round a barrel. The instrument being connected with an astronomical clock, there is a dot made for every beat of the pendulum; and as these dots are a considerable space apart (considerable, that is, for the refined instruments of the present day), it is possible to determine so wonderfully minute an interval as the one hundredth of a second. Other forms of chronographs have been adopted by astronomers. One was suggested by Professor C. A. Young in 1866 to assume the functions of a *recording* chronograph, by marking the instant of observation in hours, minutes, seconds, and hundredths of a second, in *printed* characters, and in a form suitable for preservation and reduction. Chronographs connected with electric and magnetic apparatus are used for determining the velocity of projectiles. Many forms have been devised by Noble, Bashforth, Navez, Le Boulengé, and other inventors. The most general arrangement consists in causing the bullet to pass through a series of screens; the rupture of each screen breaks for a moment the continuity of an electric current, sets in action an electro-magnetic apparatus, and makes a permanent mark or record. See *Chronoscope*.

CHRONOMETER.—The name given to a common form of time-measurer. The mechanism is essentially the same as that of a common watch; only the size is generally greater, and additional precautions are taken to secure regularity under changes of temperature and other deranging influences. See *Horology*.

CHRONOSCOPE.—An instrument contrived by Sir Charles Wheatstone to measure the duration of certain short-lived luminous phenomena, such as the electric spark, of which the eye itself can be no judge, owing to the persistence of impressions of light on the eye after the cause of sensation has ceased. The phenomenon is observed by reflection in a mirror, in such rapid motion that the image of the luminous object would appear to describe a circle, supposing the luminosity to endure long enough. Should the phenomenon be instantaneous, the image will appear as a mere point; should it last for an appreciable time, the image will form an arc, greater or less, of the circle. The electric spark is found by this test to have no duration. See *Bashforth Chronograph*, *Benton Thread-velocimeter*, *Electric Clepsydra*, *Le Boulengé Chronograph*, *Navez-Leurs Chronoscope*, *Noble Chronoscope*, and *Schultz Chronoscope*.

CHRYSOTYPE.—A photographic process invented by Sir John Herschel, and depending for its success on the reduction of a persalt of iron to the state of protosalt by the action of light, and the subsequent precipitation of metallic gold upon this protosalt of iron. The process is conducted as follows: Good paper is immersed in a solution of ammonio-citrate of iron of such a strength as to dry into a good yellow color, without any tinge of brown in it. It is then exposed to light under a negative until a faint impression is obtained. A neutral solution of chloride of gold is then brushed over the paper, when the picture immediately appears, and is rapidly developed to a purple tint. It should then be very freely washed in several changes of water, fixed with a weak solution of iodide of potassium, and again thoroughly washed and dried. The action of the iodide of potassium is to convert any unaltered chloride of gold into a soluble double iodide of gold and potassium, thus rendering the picture permanent.



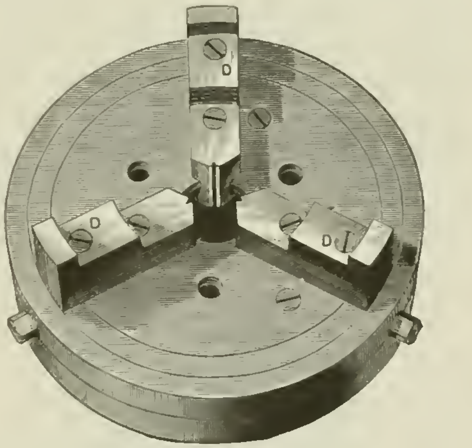


Fig. 1. Chucks. Fig. 2.

CHUCK.—An appendage to a lathe. Being screwed on to the nose of the mandrel, it is made to grasp the work to be turned. There are many varieties; the *eccentric*, *elliptic* or *oval*, and *geometric* chucks, with their combinations, are principally used in the arsenal.

The eccentric chuck is designed for changing the center of the work, and consists of two principal pieces; one attachable to the mandrel of the lathe, and the other adjustable, in a plane at right angles to the axis of motion, in a dovetail groove of the former piece. The sliding piece is moved by a set-screw.

The elliptic or oval chuck consists of three parts —the *chuck*, the *slider*, and the *eccentric* circle. The chuck is secured to and partakes of the circular motion of the mandrel. In front of the chuck is a dovetail groove for the reception of a slider, from the center of which projects a screw to which the work is attached. As the work turns round, it has a sliding motion across the center which generates an ellipse. The sliding motion is produced by an eccentric circle or ring of brass firmly fastened to the puppet of the lathe close to the collar in which the neck of the mandrel runs.

The geometric chuck has a radial slider to which the work is attached, and this is so governed as to give a combined circular motion and radial oscillation to the work relatively to the tool.

Fig. 1 represents the Pond independent four-jaw lathe-chuck. Each jaw is worked independently by its own screw, thus adapting it to hold any irregular-shaped piece, as well as round, square, or eccentric forms. The jaws are wrought-iron case-hardened; steel screws operating jaws are secured in the hub of the chuck to prevent irregular wear of same. This chuck has a solid hub so that it can be placed directly on the lathe spindle, thus bringing it nearer to the spindle-bearing and making less strain on the spindle; or the face-plates can be fitted to it, making the same chuck fit different lathes.

Fig. 2 represents the Skinner combination-chuck, which may be readily changed from *independent* to *universal*, and *vice versa*. To make the former change, it is only necessary to set all the jaws true on the line on face of the chuck, then slide the stud on the back of the chuck to the extreme end of slot and fasten it there by screwing down the nut. If the jaws do not come to center true, it is because they were not all set alike before throwing the rack into gear. To make the latter change, unscrew the nut and slide the stud to the extreme end of the slot and fasten it there by means of the nut.

Figs. 3 and 4 represent the Prouty planer-chucks. Fig. 3 shows the square base, and Fig. 4 shows a round swivel base. These chucks will hold regular or irregular shaped pieces, and can be quickly adjusted from their least to their greatest capacity. The round swivel-base chucks are accurately graduated, and the swivel is held in place by a single screw. See *Cushman Combination-chuck*, *Horton Lathe-chuck*, *Lathe*, *Sweetland Chuck*, and *Westcott Combination-chuck*.

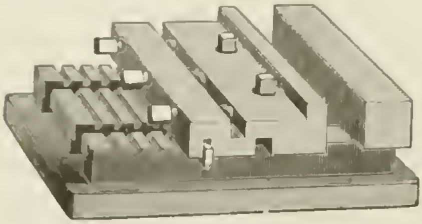

Fig. 3.

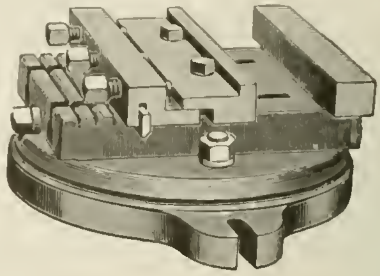

Fig. 4.

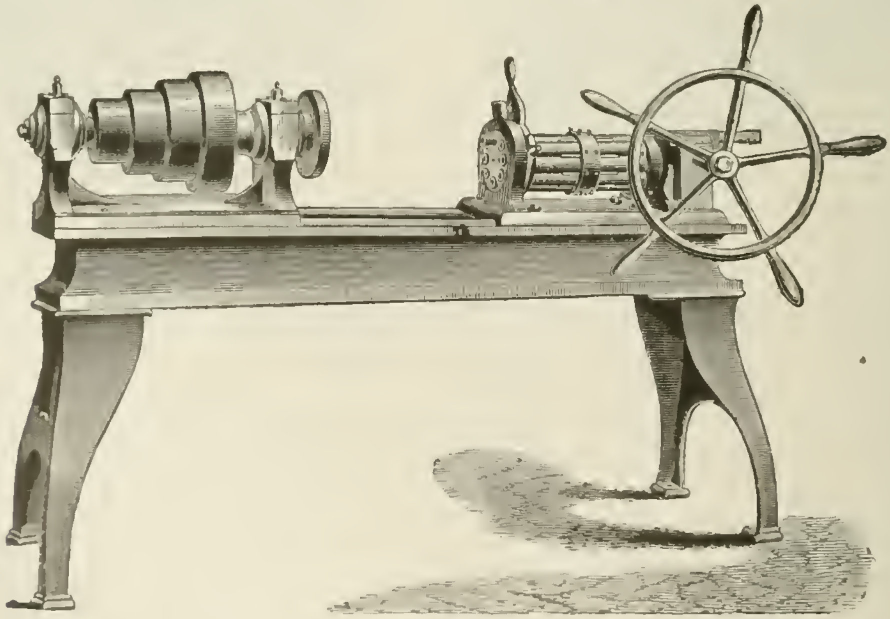
Planer-chucks.

CHUCKING-MACHINE.—A machine used in the armory for work on lock-parts and in chambering the barrels. The drawing shows the machine as made by the Pratt and Whitney Company, with horizontal revolving head. It is designed for a variety of work, such as drilling, facing, and tapping holes before removing the piece to be finished from the chuck or face-plate. The revolving head carries several spindles for the reception of tools. Each one is brought to the work successively by a single movement of a lever or handle, and is fed forward by a rack and pinion, operated by a convenient hand-wheel. The machine is rapid in its operation and very accurate in its results. The number of spindles in the head may be varied to suit the work to be done, and the length of the bed may be increased or diminished as desired. The machine is made in three sizes, 13, 18, and 24 inches swing. See *Drilling-machine*.



Chucking-machine.

CHUCKLER.—An Indian term, signifying a cobbler, or worker in leather. This class of men is employed in all the government establishments in India where leather-work is made up.

CIMBRI—KIMBRI.—A people who issued from the North of Germany in conjunction with the Teutons, and first came into hostile contact with the Romans in the Eastern Alps in 113 B.C. They were victorious in several great engagements, and were only prevented from devastating Italy by sustaining a terrible defeat from Marius, on the Raudii Campi, near Verona, or, according to others, near Vercelli, 101 B.C. Their infantry fought with their shields fastened together by long chains; their horsemen, of whom they had 15,000, were well armed with helmet, coat of mail, shield, and spear. Marius had so chosen his position that the sun and dust were in their faces, and yet they contested the victory most bravely with the Romans, who were 55,000 strong. When the battle was lost, the women, who remained in the camp formed of the wagons, killed themselves and their children. It is said that 140,000 Cimbri fell in the battle; the number of prisoners being given at 60,000. It is not till long afterwards, when the Romans themselves penetrated into Germany, that the name of the Cimbri again appears. Cæsar represents the Aduatici of Belgium as the descendants of the Cimbri and the Teutons. Tacitus speaks of a people bearing the name of Cimbri, few in number, but of great reputation, that sent ambassadors to Augustus. This people lived in the extreme North of Germany, on the borders of the ocean; according to Pliny and Ptolemy, at the extremity of the peninsula called from them the Cimbric Chersonese, now Jütland. The ethnology of the Cimbri is doubtful. Greek writers associated them groundlessly with the Cimmerians; Sallust calls them Gauls; Cæsar, Tacitus, and Plutarch looked upon them as Germans, and the opinion of their German origin has been adopted by most moderns. Yet H. Müller, in his *Marken des Vaterlands* (1837), has endeavored to show that they belonged to the Celtic race, and lived originally on the Northeast of the Belgæ, of kindred origin; and that their name is the same as that by which the Celts of Wales designate themselves to this day—*Cymri*.

CIMETER.—An Oriental cavalry-sword with a blade of great curvature. It is much used by the Persians and Turks, and is often written *Scimeter*.

CIMIER.—A heavy ornament which the ancient knights or chevaliers in France and in other countries were accustomed to wear upon their helmets; small figures were afterwards substituted in their stead.

CINCH—CINCHA.—A strong canvas girth used in packing. It is about 1 yard long by 11 inches wide. Two rectangular pieces of leather, 8 inches long by 5½ inches wide, are stitched on one end, one on either side; in one of these pieces of leather there is a slit through which a hard-wood hook is passed and firmly fastened with a leather thong. A ring, 3 inches in diameter, is securely stitched in the other end of the cincha. See *Hammer-cloth*, *Lash-rope*, and *Packing*.

CINCINNATI.—A Society or Order in the United States of North America established by the officers of the Revolutionary Army in 1783, "to perpetuate their friendship, and to raise a fund for relieving the widows and orphans of those who had fallen during the war." It was so named because it included patriots, headed by Washington, who in many instances had left rural affairs to serve their country. The badge of the society is a bald eagle suspended by a dark blue ribbon with white borders, symbolizing the union of France and America. On the breast of the eagle there is a figure of Cincinnatus receiving the Military Ensigns from the Senators, with the plow in the background; round the whole are the words, *Omnia reliquit servare rempublicam*. On the reverse, the same hero is represented crowned by fame with a wreath on which is inscribed *Virtutis præmium*, etc. As this distinction was made hereditary, it was attacked as opposed to republican equality. Franklin saw in it the germ of a future aristocracy, and at a meeting held in Philadelphia in 1784 several changes were made in the Constitution of the Society, and in several of the States it was quietly abolished. There are still, however, several State Societies, which hold a general meeting by delegates triennially.

CINQUAIN.—In ancient military history, an order of battle to draw up five battalions so that they might make three lines, that is, a van, main body, and reserve.

CINQUEFOIL.—A common bearing in Heraldry. It is usually depicted with the leaves issuing from a ball as a center-point. Cinquefoil, in architecture, is an ornamental foliation in five compartments, used in the tracery of windows, panelings, and the like. The cinquefoil is often represented in a circular form, the spaces between the points or cusps representing the five leaves. The cinquefoil of Heraldry and of architecture is not derived from any leaf of five leaflets, but, as its perfect regularity of form indicates, from the flower of the plant called cinquefoil, (*Potentilla*), or other similar flower of five petals or *leaves*. The cinquefoil thus closely resembles the rose, with which it would, indeed, be identified, but that a double and not a single rose is chosen for the purposes of Heraldry and decorative art.

CIPHER.—A preconcerted enigmatical system of communication. Much used in war when dispatches are liable to interception by the enemy,—both for written communication and for signaling. See *Cryptography*.

CIRCITORES.—A name generally applied, in the Roman armies, to the men who inspected the sentinels.

CIRCLE.—A plane figure bounded by a curved line, which returns into itself, called its *circumference*, and which is everywhere equally distant from a point within it called the *center* of the circle. The circumference is sometimes itself called the circle, but this is improper; *circle* is truly the name given to the space contained within the circumference. Any line drawn through the center and terminated by the circumference is a *diameter*. It is obvious that every diameter is bisected in the center. In co-ordinate geometry the circle ranks as a curve of the second order, and belongs to the class of the conic sections. It is got from the right cone by cutting the cone by a plane perpendicular to its axis. As an element in plane geometry, its properties are well known and investigated in all the text-books. Only a few of the leading properties will here be stated. 1. Of all plane figures, the circle has the greatest area within the same perimeter. 2. The circumference of a circle bears a certain constant ratio to its diameter. This constant ratio, which mathematicians usually denote by the Greek letter π, has been determined to be 3.14159 nearly, so that if the diameter of a circle is 1 foot, its circumference is 3.14159 feet. Archimedes, in his book *De Dimensione Circuli*, first gave a near value to the ratio between the circumference and the diameter, being that of 7 to 22. Various closer approximations in large numbers were afterwards made, as, for instance, the ratio of 1815 to 5702. Vieta, in 1579, showed that if the diameter of a circle be 1000, etc., then the circumference will be greater than 3141.5926535 and less than 3141.5926537. This approximation be made through ascertaining the perimeters of the inscribed and circumscribed polygons of 393,216 sides. By increasing the number of the sides of the polygons, their perimeters are brought more and more nearly into coincidence with the circumference of the circle. The approximation to the value of π has since been carried to 128 places of figures. It is now settled that π belongs to the class of quantities called *incommensurable*, i.e., it cannot be expressed by the ratio of any two whole numbers, however great. Though the value of π was at first approached by actually calculating the perimeter of a polygon of a great number of sides, this operose method was long ago superseded by modes of calculation of a more refined character, which, however, cannot here be explained. Suffice it to say, that various series were formed expressing its value; by taking more and more of the terms of which into account, a closer and closer approach to the value might be obtained. We subjoin one or two of the more curious.

$$\pi = 4\left(1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \frac{1}{9} - \frac{1}{11} + \text{etc.}\right).$$

$$\pi = 8\left(\frac{1}{1.3} + \frac{1}{3.5} - \frac{1}{3.5.7} + \frac{1}{5.7.9} - \frac{1}{7.9.11} + \frac{1}{9.11.13} - \text{etc.}\right)$$

3. The area of a circle is equal to π multiplied by the square of the radius ($= \pi r^2$); or to the square of the diameter multiplied by $\frac{\pi}{4}$; i.e., by .7854. Euclid has proved this. 4. The circular measure of angles is in frequent use in gunnery, and depends directly on the proposition that angles at the center of a circle are proportional to the arcs on which they stand. Let POA be an angle at the center O of a circle, the radius of which is r, and let the length of the arc $AP = a$. Then $\frac{\text{angle POA}}{2 \text{ right angles}} = \frac{a}{\pi r}$; and $\angle \text{POA} = \frac{2 \text{ right angles}}{\pi} \cdot \frac{a}{r}$. Now, supposing a and r to be given, although the angle POA will be determined, yet its numerical value will not be settled unless we make some convention as to what angle we shall call unity. We are free to make any convention we please, and therefore choose such a one as will render the preceding equation the most simple. It is made most simple if we take $\frac{2 \text{ right angles}}{\pi} = 1$. We shall then have (denoting the numerical value of the angle POA by θ) $\theta = \frac{a}{r}$. The result of our convention is that the numerical value of two right angles is π, instead of 180° as in the method of angular measurement first alluded to; and the unit of angle, instead of being the ninetieth part of a right angle, is $\frac{2 \text{ right angles}}{\pi}$, or 57° 17′ 44″ 48‴ nearly. Making $\theta = 1$ in the equation $\theta = \frac{a}{r}$, we have a (or AP) $= r$ (or AO), which shows that in the circular measure the unit of angle is that angle which is subtended by an arc of length equal to radius. It is frequently a matter of indifference which mode of measuring angles is adopted; the circular measure, however, is generally the most advantageous, as being the briefest. It is easy to pass from this mode of measurement to the sexagesimal. If θ be the circular measure of an angle, the angle contains $\frac{\theta}{\pi} \cdot 180°$; conversely, if an angle contain $n°$, its circular measure is $\frac{n°}{180°} \cdot \pi$.

CIRCUIT-CLOSER.—An arrangement by which submarine mines are fired electrically by the vessel herself closing the circuit. Circuit-closers are of two classes, one being that in which the charge and the circuit-closer are in the same case, and the other is where the circuit-closer is in a separate case, but connected with the charge of the mine by an electrical cable. In both ways the conducting cable is electrically charged from the battery on shore up to the circuit-closer; when this latter is closed by contact with a hostile vessel, the current passes through the fuse in the charge and the mine is exploded. A great number of different forms of both classes have been invented, all of which are more or less complicated and require special description and study to understand.

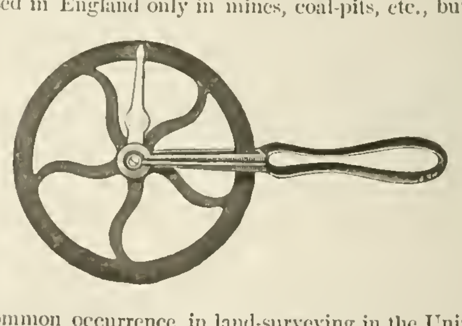
To render mines thus provided with circuit closers harmless to friendly vessels passing, it would be necessary only to detach the firing-battery—an operation usually performed by the operator simply removing a small plug. In this case the circuit-closer, if strongly made, may be struck time and again without injury. This power to resist heavy blows is essential to the efficiency of any form of circuit-closer, as, when in position in a channel through which there is much traffic, they are always liable to be struck with considerable force by blades of screws, floats of paddles, and other hard and sharp bodies. Another especial consideration is that the apparatus for closing the circuit shall not be set in action by agitation of the water, but only by impact with a floating body. The circuit-closer must furthermore have sufficient size to give the required amount of inertia. When the circuit-closer and charge are combined in the same case, this is assured; but when they are separate, it is effected by inclosing the mechanism in buoys made of wood or metal. The greater the size and weight of the circuit-closer, the greater will be the chances of the effective working of the apparatus. The destructive power of a mine decreases rapidly as the distance from it increases. The circuit-closer should not, therefore, be beyond the effective range of the mine. Forty to fifty feet should be the maximum distance for the heaviest charges. See *Mines*.

CIRCULAR CUTTER.—With the usual pyramidal form of the Rodman cutter it has been found difficult so to file the faces of the pyramid as to have two cutters identical in form and dimensions. The idea was therefore conceived of turning a beveled edge with a circular profile upon the perimeter of a steel disk, thus securing the perfect agreement of all cutters taken from that disk. The special advantage of the circular cutting or indenting edge is that it can be readily pressed into the indentation previously made in the copper disk while in the bore, upon its removal to the *dynamometer*, or testing-machine.

In the pyramidal cutter it is difficult to make the apex of the pyramid coincide with its former position in adjusting it to get the reading of the *estimator*. With the circular cutter no difficulty is experienced in adjusting its edge to the bottom of the indentation in the copper, when the operator wishes to make similar secondary cuts for determining the pressures. See *National Armory Circular Cutter*, *Rodman Cutter*, and *Rodman Testing-machine*.

CIRCULAR SAW.—This saw was introduced into England about 1790. General Bentham contrived the bench, slit, parallel guide, and sliding-bevel guide. He also invented circular saws made of segmental plates. In the modern and improved machine, the saw-arbor is carried in a swinging frame provided with an adjusting-screw for regulating its height, and a clamp-screw for holding it rigidly in any desired position. For simplicity of construction, ease of operation, and for rigidity in use this arrangement is superior to all others. To render the machines free from vibration, and to avoid the difficulties and disadvantages incidental to the use of short belts, excessive strain upon the bearings, difficulty of keeping belts at proper tension, etc., the counter-shafts are separate from the machines. In setting them the following rule should be observed: Set the saw midway between its highest and its lowest working positions, and then place the counter-shaft in a straight line with the arbor and the shaft on which the arbor-frame swings. See *Band-saw Machine*.

CIRCUMFERENTOR.—1. A surveying instrument used in England only in mines, coal-pits, etc., but of



common occurrence in land-surveying in the United States. Many of the old-fashioned surveyors yet use it, though it is disappearing as the theodolite becomes more and more commonly known.—2. An instrument employed to measure the tires of wheels. It consists of a wheel graduated on its periphery and axled in a holder. It has a circumference of known length, and is passed around the outside of the rim of a wheel to ascertain the length of the tire. The instrument having a perimeter, say, 2 feet in circumference, the zero is brought to a marked spot on the periphery of the wheel to be measured. The small wheel is then caused to travel around the larger, and indicates the length by making so many revolutions and such a fraction as the case may be. The instrument represented in the drawing and known as the Green River circumferentor is provided with an index-hand, which saves the trouble of marking the periphery.

CIRCUMVALLATION.—In fortification, a series of works surrounding a place when under siege,—not to serve offensively against the place, but to defend the siege-army from an attack from without. It usually consists of a chain of redoubts, either isolated or connected by a line of parapet. Such lines were much used in the sieges of the Ancient and Middle Ages; but in modern times they are not so necessary, because the use of artillery lessons the duration of a siege, and also because the besiegers have generally a corps of observation in the open field, ready to repel any force of the enemy about to succor the besieged. A remarkable example of circumvallation was that at Sebastopol, where, while a circuit cf batteries fired upon the town, an outer circuit of redoubts and lines kept off the Russians who were in the open field; but the necessity for this arose out of the smallness of the besieging force compared with that of the besieged. The narrow escape of the allies from utter overthrow at Inkermann showed the necessity for this external defense. See *Countervallation*.

CIS.—A Latin preposition, meaning "on this side," which is often prefixed to the names of rivers and mountains to form adjectives: Cisalpine, Cispadane, "on this side of the Alps," "of the Po." As most of these words are of Roman origin, Rome is considered the point of departure.

CITADEL.—A fort of four or five bastions, in or near a town. A citadel serves two purposes: it enables the garrison of a town to keep the inhabitants in subjection; and, in case of a siege, it forms a place of retreat for the defenders, and enables them to hold out after the rest of the town has been captured. A citadel must fully command the fortifications of the city, and have a large space round it clear of buildings. See *Castle* and *Fortification*.

CIVIC CROWN.—A crown considered among the Romans more honorable than any other reward. It was given for saving the life of a citizen in battle or assault. It was given to Cicero for his discovery of Catiline's Conspiracy, and to the Emperor Augustus. The Civic Crown was merely a wreath, at first of twigs of elm, then of beech, and lastly of oak. The one to whom it was given had the right to wear it always. When he appeared in public, if Senators were present, they rose to do him honor, and he was excused from all troublesome duties and services, with the same immunities for his father and his father's father.

CIVIERE.—A small hand-barrow which is carried by two men, and is much used by the artillery.

CIVIL AUTHORITY.—The relation between the military and civil authorities is set forth in the 59th Article of War. Respect for the civil authorities is the duty of all citizens, and especially of those in the military service. As the objects of the military service are of national interest, it is very desirable that kindly relations exist between soldiers and other citizens. A civil officer charged with the execution of process should receive proper facilities for its service on making known his character to the nearest Commanding Officer. See *Civil Service* and *Posse Comitatus*.

CIVIL DEPARTMENTS.—Branches of the British army under the War Office. They include the Control Department, Medical Department, Veterinary Department, Chaplain's Department, Education Department, and the Administration of Justice.

CIVIL EMPLOYES.—The Chief of each Military Bureau of the War Department, under the direction of the Secretary of War, regulates as far as practicable the employment of hired citizens required for the administrative service of his Department. He distributes the aggregate number which can be allowed, whether rated as clerks, teamsters, mechanics, or laborers, to the several Military Departments according to the number of troops therein, or according to the work to be done. Except for the Corps of Engineers, the grades of pay of clerks and other employés under the Staff Departments of the army whose salaries are not fixed by law are authorized as follows: There are six classes of clerkships, and each clerk or employé within the scope of this regulation is graded for pay in accordance therewith, viz.:

Class.	Pay per month.	Pay per annum.
First class	$83 33	$1,000
Second class	100 00	1,200
Third class	116 66	1,400
Fourth class	133 33	1,600
Fifth class	150 00	1,800
Sixth class	166 66	2,000

Any compensation greater than the above must receive the special approval and sanction of the Secretary of War; but nothing in this regulation is construed as prohibiting the payment of smaller salaries than the above for such lower grades of clerkships as the wants of the service may require. The selection of employés as clerks, etc., is left to the officer employing them, provided such selection has the approval of the Commander of the Division or Department in which the officer may be serving, and the approval of the Head of the Military Bureau, when serving at depots, arsenals, posts, and stations not under the immediate control of a Division or Department Commander. When practicable, persons hired in the military service are paid at the end of the calendar month, and when discharged. When a hired person is discharged and not paid, a certified statement of his personal services and of wages due is given. In computing the wages of laborers employed at a per-diem allowance, the actual number of days is to be ascertained and allowed. The day on which service begins and the day on which service ends should be counted in the computation of the wages earned. Laborers employed by the month and actually performing their first day's labor on the 31st day of any month are paid for that day. Citizens in the employ of any branch of the military service, except laborers, teamsters, and like classes of employés, when traveling under competent orders, or upon summons as witnesses before Military Courts, are entitled to transportation in kind; or, if no transportation be provided, they may charge the cost, actually paid by them, of travel fare by the usual conveyances, inclusive of transfer to and from depots, not exceeding fifty cents each, and of one berth in sleeping-cars, or on steamers where an extra charge is made therefor. Payment of parlor-car fare is prohibited. In addition to the above, the sum of four dollars per day west of the Mississippi River, and three dollars and a quarter east thereof, is allowed for each and every day unavoidably consumed in travel, or on duty under the order or summons; provided that where meals are included in the transportation, or fare, by steamers, no per diem shall be charged. Laborers, teamsters, and like classes of employés, traveling as above stated, are entitled to such actual and necessary expenses on account of transportation and subsistence as may be authorized by the Chief of the Bureau which makes payment of the account—except when the employé is in receipt of a ration from the United States, in which case, if it be impracticable to carry his rations with him, instead of expenses of subsistence, as above contemplated, he is paid commutation of rations at the usual rates. Actual expenses, as contemplated above, are payable as follows: To Paymasters' clerks and citizen witnesses before Military Courts, by the Pay Department; to citizens employed at arsenals and armories (cost of transportation included), from appropriations for the service of the Ordnance Department; to citizens employed on public works and fortifications (cost of transportation included), from the appropriation made specifically for the work; to Commissaries' clerks, Quartermasters' clerks and agents, and other citizens employed with the army, when traveling on public service, under orders of competent military authority, by the Quartermaster's Department.

CIVILIAN.—This term has three meanings, which are distinct, though intimately related. (1) In a popular sense it signifies a person whose pursuits are civil, i.e., neither military nor clerical. (2) As a law-term, it means either a person who is versed in the principles and rules in accordance with which civil rights may be freely, blamelessly, and successfully vindicated in society generally, or in the particular state in which he belongs. (3) One who has made a special study of these rules and principles as exhibited in the laws and government of Rome (the Roman civil law). The civil law of Rome exercised such influence upon the formation of the municipal systems of almost all the States of modern Europe that those who devoted themselves to its study were regarded as "civil" or municipal lawyers *par excellence*.

CIVIL SERVICE.—A general name for all the duties rendered to and paid for by the State, other than those relating to naval and military matters. Civil service in the United States was partially introduced in the Customs and some other offices in 1877 and the years following, but up to this time it has made no great progress. The general principles of the system are the same as in England, involving the separation of officials from all absorbing political partisanship, and, in general, the retention of capable and deserving Civil Officers through the successive changes of Administration. It involves also the promotion of worthy public servants as vacancies may occur. It lays the foundation for all this in conferring offices, not as reward for partisan services, but on strict competitive examination as to character, capacity, and education. By many it is pronounced both impracticable and undesirable; by others, a fine ideal not likely to be realized; and by others, an indispensable practical reform.

CIVIL WAR.—A war between two or more portions of a Country or State, each contending for the mastery of the whole, and each claiming to be the legitimate government. The term is also sometimes applied to war of rebellion, when the rebellious Provinces or portions of the State are contiguous to those containing the seat of government. See *Insurrection* and *Rebellion*.

CLAM.—In Heraldry, a term for an escalop or cockle shell, and supposed to indicate that the bearer has been a crusader, or has made long voyages by sea.

CLARIGATION.—In Roman antiquity, a ceremony which always preceded a formal declaration of war. The Chief of the Heralds went to the territory of the enemy, where, after some solemn prefatory indication, he, with a loud voice, intimated that he declared war against them for certain reasons specified, such as injury done to the Roman allies, or the like.

CLAY BREECH-LOADER.—An apparatus with which one side of the breech is enlarged to receive a screw-plug, a little more than twice the diameter of the bore. A hole in the plug forms, when the latter is unscrewed half a turn, a continuation of the bore, through which the charge is loaded. By screwing up the plug half a turn, the solid part of it covers the end of the bore and sets closely against it. The breech is thus opened by one movement, and the parts, though large, are simple; but the obvious defect is the great difficulty of applying a suitable gas-check.

CLAYES.—In sapping, hurdles to form blinds for working-parties. Reinforced with earth, they are substantially *gabions*, and as such are of a more permanent character. Frequently written *Clayonages*, and used to cover the timber-work of galleries.

CLAYMORE.—The Gaelic name for a kind of sword at one time much used, but not so well known at present. It had a double-edged blade, about 43 inches long by 2 inches broad; its handle was often 12 inches long, and its weight 6 or 7 pounds. This sword is now principally used by the officers and non-commissioned officers of Highland regiments.

CLEANING-MATERIALS.—Cleaning-materials for small-arms and accouterments are issued by the Ordnance Department to Company Commanders, at the rate of one box per company. On the under side of the cover of each box is pasted the following printed notice, viz.: "This box contains two quart cans of anti-corrosive and lubricating 'cosmoline' oil; one box holding 40 ounces scouring-material, marked 1, composed of 12 ounces paraffine, 18 ounces flour corundum, 6 ounces cosmoline oil, 4 ounces lamp-black, melted together; one box holding 16 ounces leather-polish, marked 2, composed of 13 ounces bayberry tallow, 3 ounces lamp-black, melted together; one box holding 40 ounces compressed whiting, marked 3; one chamois-skin; one wire scratch-brush. For removing rust and cleaning brass-work: Rub off a *very little* from box 1 on a cloth or on the end of the finger. For rust, use a soft stick. Finish with whiting for bright work, and oil for browned work. For polishing accouterments: 1. Rub off a little on the soft cloth from box; 2. Rub it well on the leather, and finish lightly with a soft cloth. Lubricating-oil: Apply the oil lightly with a rag.

"If the browning is rubbed off the barrel, dismount the barrel and remove the breech-block and parts of the extractor. Oil the bore of the barrel and stop up each end with a plug. Wash the outside of the barrel with hot soap-suds or lye of wood-ashes, to remove grease. Wash off with clean hot water. When dry, apply the browning-mixture, which is composed of 13 parts of water and 1 part of muriatic acid by measure, with a sponge or rag. Put the barrel aside to rust, in a damp and warm place, from three to four hours. Rub off the coat of rust so formed with the steel-wire scratch-brush; and repeat this three or four times. After each rusting pour on boiling water for several minutes to destroy the acid; use the scratch-brush as before, and finish with an oiled rag. In case the other parts get worn, a similar treatment should be employed. When convenient, the action of the browning-mixture can be promoted by laying the barrel in a closed box with a few cloths wet with hot water and spread so as not to touch the barrel; the box should be set in a warm place. The scratch-brush should be used lengthwise of the barrel. When the brush gets worn down, untwist the wire around it sufficiently to form a new head." The weight of the box filled, is 18 pounds. See *Care of Small-arms*.

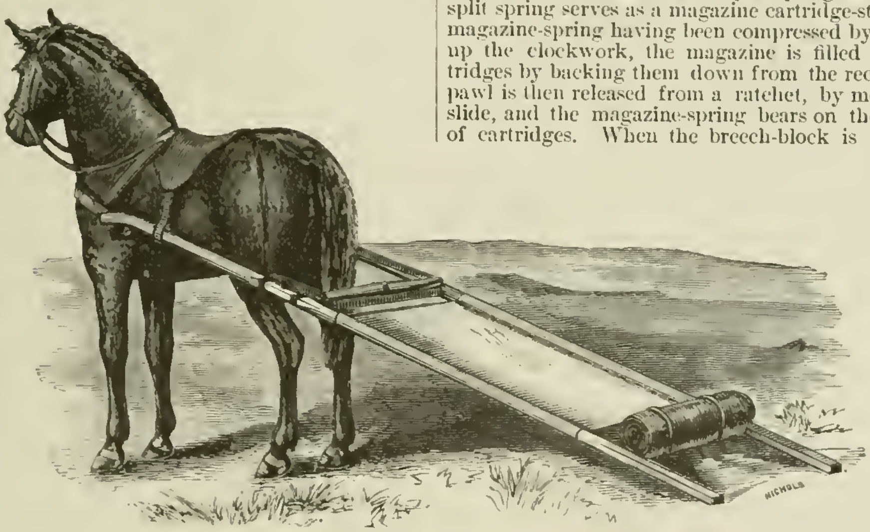
CLEARANCE.—In ordnance, the linear distance between the body of the projectile and the bore of the gun. The amount of the clearance before the projectile moves is the difference between the depth of the groove in the gun and the projection of the stud on the projectile; but when the projectile is in motion and centered in the bore, the clearance all round the projectile will be half the windage over the body.

CLEARANCE-ANGLE.—All guns fitted with a front sight on the top of the piece between the trunnions have what is called a *clearance-angle*. This may be defined as the angle of elevation obtained when the bottom of the notch of the rear sight and the top of the front sight and the notch on the muzzle are in line. If the rear sight is raised above this angle, the front sight falls below the line, joining the notch of the rear sight and the muzzle. The muzzle-notch must then be taken as the second point of sight.

CLEARING-SCREW.—In some fire-arms, a screw at right angles to the nipple, and affording a communication with the chamber.

CLEARY LITTER.—In 1875 Assistant Surgeon P. J. A. Cleary, U. S. Army, reported to the Surgeon General's Office his observations in the Indian Territory on the facility with which the Indians transported their sick and aged or infirm on litters dragged by ponies, and suggested that analogous conveyances might be utilized for the transport of wounded, in cavalry-scouts and in marches in difficult country where the use of wheeled vehicles was impracticable.

The drawing shows the modification of the Indian litter proposed. Each side-pole is jointed; by withdrawing a pin it comes apart, leaving the shafts in the harness, and the stretcher-frame disconnected. The length of the connected side-poles should be 17 feet, viz.: 5 feet occupied by the horse, 3 feet from rear of horse to first traverse or cross-piece of litter, 7 feet for bed of litter, 2 feet from bed of litter to the end. The advantages which the litter appears to possess are: 1. Simplicity of construction. 2. Facility of transportation, as it can be easily rolled up and carried either in a wagon or strapped to a horse. 3. It is drawn by *one* animal. 4. It requires but *one* man to work it. 5. The facility with which a patient can be brought into a hospital: by detaching it at the joint it is converted into a hand-litter on which the patient is readily conveyed to the ward of the hospital. 6. Its general adaptability for any kind of ground: in crossing cañons and deep gullies the litter proper could be easily detached, and a man at either end carry it as a hand-litter over any obstruction and again attach it; and finally, for any slight obstruction, the driver, without detaching it, could lift the rear end (the forward part being held in the harness) until the obstruction was passed. 7. Were it to be sent out with a cavalry command (with other supplies) and not required for actual use, it would occupy but a small space, and need not have even a horse sent with it—when, if required, the trooper's horse could be used to haul it. But one point in the harness needs special notice, viz., the straps across the horse's hips, which support the shafts; the object being to prevent the horse, in case he rears up, from jumping out of the shafts or kicking the patient. By these straps the horse *lifts* the litter every time he attempts to kick, and so cannot reach the patient. Straps attached to the side-poles, and passing under the arms and buttocks of the patient, counteract the tendency to slip due to the incline of the litter.



Cleary Litter.

CLEATS.—Small blocks of wood used commonly for securing movable articles which are likely, as at sea, to roll over or be displaced. In the artillery service they are used in different parts of gun-carriages for fixing tools, etc.

CLEMMONS MAGAZINE-GUN.—This gun is an adaptation of a magazine to the United States Springfield rifle. The alterations are as follows: The left side of the receiver is cut away nearly to the bottom of the well. The portion removed is replaced by a piece the interior of which is somewhat the shape of the half cartridge. This piece is open at the rear in order to receive cartridges from the magazine. A groove is cut in the left side of the butt-stock for the magazine-tube, and is covered by a brass plate. The magazine-spring and cartridge-follower are of the usual form. To the rear of the follower one end of a piece of tape is attached; the other end is connected with an ordinary clockwork by which the tape may be wound up, drawing back the follower and compressing the magazine-spring. On the inner surface of the piece attached to the receiver is a spring, pivoted at its front. This spring has a thumb-piece, which may be locked back by a spring-catch. The split spring serves as a magazine cartridge-stop. The magazine-spring having been compressed by winding up the clockwork, the magazine is filled with cartridges by backing them down from the receiver. A pawl is then released from a ratchet, by means of a slide, and the magazine-spring bears on the column of cartridges. When the breech-block is closed it strikes the thumb-piece, presses it back, and lets in a cartridge from the magazine. By pressing on this thumb-piece, the breech-block having been opened sufficiently to overcome the spring-catch, the cartridge is thrown into the receiver; it must then be pushed into the chamber in the usual manner.

As a magazine-gun, six motions are necessary to operate it, viz., cocked, opened, loaded (two motions), closed, fired. As a single-loader, the usual five motions are necessary to operate it. The gun carries five cartridges in the magazine, one opposite the receiver, and one in the chamber. See *Magazine-gun* and *Springfield Rifle*.

CLEPSYDRA.—An instrument for measuring time by the efflux of water through a small orifice. Two kinds have been in use—one wherein the fluid is simply allowed to escape through the orifice, the other in which the uniformity of the flow is secured by maintaining the fluid at a constant level in the instrument. The first would, like a sand-glass, give only an accurate measure of the time occupied in the escape of the whole fluid; of a shorter time it would be an inaccurate measure, as the pressure under which the escape takes place at the commencement is greater than at any instant thereafter, and constantly diminishes with the height of the fluid column. In the second, the flow must be nearly uniform; and if the water be received into a uniform graduated tube as it escapes, we have a tolerably good clock. The rate of the flow, however, is affected by temperature and barometric pressure. The clepsydra is supposed to have been used among the Chaldeans. The Romans employed it extensively. The invention of the pendulum has superseded it in modern ballistical investigations. The *electrical clock* is a clockwork machine, in which an electro-magnet, by means of an electric current regularly interrupted, is both the motor and the regulator. It is so constructed that at each oscillation of the pendulum the current is opened and closed, and thus an armature beats the seconds exactly. To illustrate the use of this contrivance, or the clepsydra, suppose that on the railroad from New York to San Francisco each station has an electric clock, and that from the New York station a conducting wire passes to all the clocks on the line as far as San Francisco. When the current passes in this wire, all the clocks will simultaneously indicate the same hour, the same minute, and the same second; for electricity travels with such prodigious velocity that it takes an inappreciable time to go from New York to San Francisco. See *Electric Clepsydra*.

CLICE.—An ancient Turkish saber, very long and curved. Now obsolete.

CLIDE.—A machine of war, used during the Middle Ages to throw rocks on besieging-parties.

CLIMAX GUN-CLEANER.—A gun-cleaning arrangement patented by the United States Cartridge Company, and said to be very effective in its work. It has a lower joint made of brass tubing, and forming a reservoir to contain the cleaning fluid. The *cleaner* is made of a solid piece of brass, and has a small hole drilled through it, which opens at one end into the reservoir, and terminates at a point between the rubbers. The *cleaner* is shouldered and has a brass washer on each side of each rubber, by which the rubbers can be expanded to produce any desired friction by turning the rod to the right after the *cleaner* is inserted in the barrel.

The operation is as follows: After putting the rod together, adjust the rubbers to fit the gun, then fill the reservoir with the liquid to be used, screw the *cleaner* in the reservoir, insert in the barrel, and the liquid will flow down into the chamber formed by the rubbers, and loosen the dirt. The rubbers will remove it. After cleaning, remove the *cleaner*, screw in a wiper, and wipe out the barrels. If it is wished to oil the gun, remove the rubbers, saturate the washers with oil, and put them on the cleaner in place of the rubbers.

CLINCHER-WORK.—A mode of uniting armor-plates in which the edges are lapped and secured by one row of rivets. It is distinguished from *carvel-build* in the respect that in the latter the edges of the plates are brought together and the joint covered by an interior *lap* or *welt*, to which the plates are secured by two rows of rivets, one to each plate.

CLINOMETER.—An instrument used in determining the slope of cuttings and embankments, the inclination of the trunnions, etc. It has a quadrant graduated to degrees and fixed at the end of a long bar which is laid adown the slope; an index turns upon the center of the quadrant, to which a spirit-level is attached. The level being set horizontally, the angle of the same will be indicated on the quadrant as the latter partakes of the motion of the rod.

The drawing shows the Abney level, an English modification of the "hand-level," combining with it an excellent clinometer. When the level is centered by setting the vernier-arm to zero on the divided arc, the bubble is seen through the eye end and the level ascertained precisely as with the Locke's level. And the main tube being square it can be applied to any surface, the inclination of which may be ascertained by bringing the level-bubble into its center, and reading off the angle to five minutes by the vernier and arc. The inner and shorter arc indicates the lines of different degrees of slope, the left-hand edge of the vernier being applied to the lines and the bubble brought into the center as usual. See *Hand-level*.

CLIP.—An instrument for lifting heavy shells. It is used in England with muzzle-loading guns from the 7-inch to the 12-inch.

CLIPEADUS.—The soldiers in ancient times who were armed with the Grecian buckler, which was large and round. By *clipeadus chlamyde* was understood combatants who, in place of the shield, wound their coats (*chlamyde*) around their left arms.

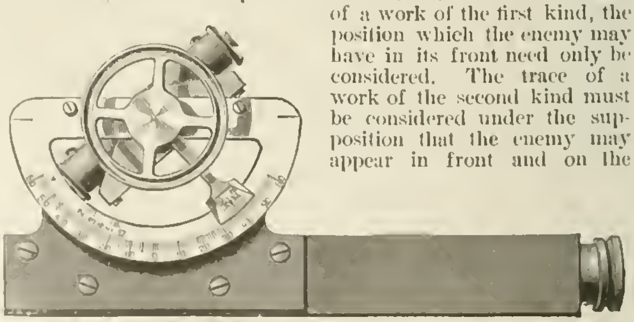
CLIPEUS.—A large shield worn by the ancient Greeks and Romans, which was originally of a circular form, made of wicker-work or wood covered with ox-hides several folds deep, and bound round the edge with metal.

CLITZ INTRENCHING-TOOL.—This proposed *intrenching-tool* consists of a sheet-steel blade, turned up on one edge and slightly curved cylindrically near the point. It is set in a light wooden handle split for its reception, and securely riveted together through the tang of the blade. This tool is intended for exclusive use as a mechanical implement, and frequently the straight edge is cut into saw-teeth. The soldier should never be separated from an intrenching-tool of some description. Many are the instances recorded where it was impossible to forward the *intrenching-tools* to the front until after the exigency for their use had passed, and the men were compelled to use tin plates, tin cans, fragments of canteens, knives, sticks, etc., in order to get temporary shelter from the enemy's most galling fire. See *Farrow Knife-trowel and Tent-peg* and *Trowel-bayonet*.

CLOSE.—A term in Heraldry. When the wings of a bird are down and close to the body it is described as *close*. The term is used only with reference to birds addicted to flight, such as the eagle, falcon, etc. Of dunghill cocks, and other domestic fowls, it is understood that their wings are in this position. Barnacles, and bits for horses, are said to be *close* when they are not to be understood as extended.

CLOSE COLUMN.—A column of troops in which the subdivisions are at less than full distance; that is, less than the length of one of the subdivisions.

CLOSED WORKS.—A field-work may have to fire on all sides of the position, over a limited portion of a circle, or in special directions only, according to the positions which may be occupied by the enemy's artillery. These different circumstances give rise to three kinds of field-works, viz.: 1. Field-works exposed to the artillery-fire of the enemy in one direction only, or in front; 2. Field-works exposed to artillery-fire of the enemy on the flanks as well as in front; 3. Field-works exposed to this fire upon all sides of the position. It is evident that in the trace of a work of the first kind, the position which the enemy may have in its front need only be considered. The trace of a work of the second kind must be considered under the supposition that the enemy may appear in front and on the flanks; that is, in a portion bounded by a part of a circle. The trace of a work of the third kind must be considered under the supposition that the enemy may appear on all sides of the work. Parapets are



Abney Level and Clinometer.

needed on all sides, in the works of the third kind, to shelter the men from the enemy's fire; and that they are only needed on the exposed sides, in works of the first and second kinds. The works of the first and second kinds may then be left open on the sides not exposed to artillery-fire, or they may be closed by some obstruction. The trace of a closed work may be of any form, either circular, square, quadrilateral, polygonal—regular or irregular—all salient angles, or some salient and some re-entering angles.

CLOSE ORDER.—In tactics, the space of about one-half pace between ranks. In the United States service, the distance between ranks, from back to breast, is *facing distance;* but on rough ground, and when marching in double time, it is increased to 32 inches; upon halting, the rear rank closes to facing distance. When the knapsack is worn, the distance between the ranks is increased by the depth of the knapsack. In alignments in double rank, the rear-rank men cast their eyes to the side of the guide with the front-rank men, and maintain the proper distance between the ranks.

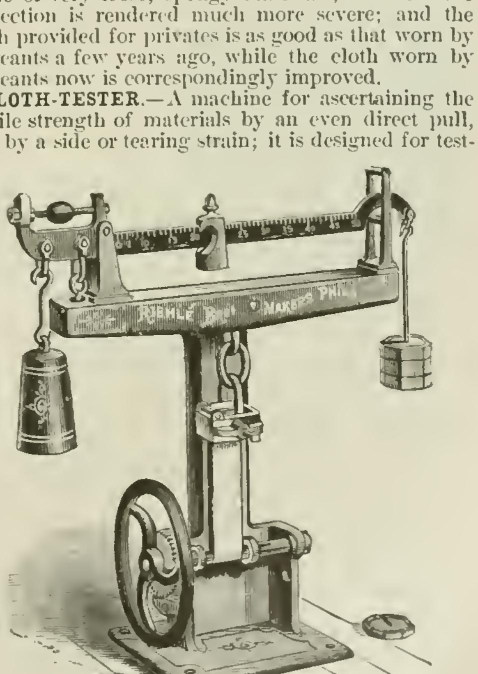
CLOTH.—A material formed by weaving or intertexture. In arsenals this material is much used, and is of various kinds—viz., book-muslin, buntin, canvas, doosootie (an Indian name), serge, vitry, waxed cloth, and silk. The cloths enumerated are made use of for the following purposes: Book-muslin, for the bottom of sieves, etc.; buntin, for colors; canvas, as shown under that head; doosootie, for capping carcasses, and it is also occasionally used for package and in making blowing-bags; serge, for service cartridge-bags; vitry, which is a fine kind of canvas, for making paulins and powder-cloths, occasionally for 13-inch blowing-bags, sponge-caps, and gun-aprons, also for saddle-wrappers; waxed cloth, for powder-barrels ($1\frac{1}{2}$ yard being required to pack a powder-barrel in), and for wrapping round elevating screws, fuses, etc.; silk, for exercising and saluting cartridges, though the use of this material is likely to be extended to service cartridges.

CLOTHING.—The President of the United States is authorized to prescribe the kind and quality of clothing to be issued annually to the troops of the United States. The manner of issuing and accounting for clothing is established by general regulations of the War Department. But whenever more than the authorized quantity is required, the value of the extra articles is deducted from the soldiers' pay; and, in like manner, the soldiers receive pay according to the annual estimated value for such authorized articles of uniform as shall not have been issued to them in each year. When a soldier is discharged, it is the duty of the Paymaster General to pay him for clothing not drawn. The Quartermaster's Department distributes to the army the clothing, camp and garrison equipage required for the use of the troops. Every Commander of a Company, Detachment, or Recruiting Station, or other officer receiving clothing, etc., renders quarterly returns of clothing according to prescribed forms to the Quartermaster General. All officers charged with the issue of clothing are required to make good any loss or damage, unles they can show to the satisfaction of the Secretary of War, by one or more depositions, that the deficiency was occasioned by unavoidable accident, or was lost in actual service, without any fault on their part; or, in case of damage, that it did not result from neglect. Purchasing clothing from a soldier is prohibited.

In England many changes and improvements have been recently made in the Clothing Department of the army. In the time of Henry VIII. the soldiers' dress was principally white, with green or russet for special corps. In Queen Elizabeth's reign a sum of 1*s*. 8*d*. was allowed weekly for each soldier's clothing. The uniform then consisted of a cassock of Kentish broadcloth, a canvas doublet, kersey stockings, trousers of kersey broadcloth, neat's-leather shoes, and Holland shirt. In 1678 an infantry soldier's dress was valued at £2 13*s*., and a dragoon's as high as £6 16*s*. At one time Lords-lieutenant attended to the clothing of the troops, each in his own County; but the duty was afterwards transferred to the State. Captains of companies clothed the men, stopped the money out of the pay, and made a profit on the transaction. The privilege afterwards passed to the Colonels of regiments. The sum provided by the State every year was for the "effective" strength of the regiment; and any vacancies put an additional sum into the pockets of the Colonel. From 1746 to 1855 soldiers' pay was debited with "off-reckonings," as a means of paying for the clothes supplied to the men. Under this system the Colonel received from the State so much money annually for clothing his regiment, and then contracted with wholesale tailors for a supply on the lowest terms. In 1854, just before a change was made in the system, the Colonel's profit, on the clothing for a private in the Line, was 15*s*. 3*d*. per man.

The disasters during the early months of the Crimean War having created a national demand for reforms in military matters, a change in the mode of army clothing was one of the results. By a Royal Warrant, dated June 21, 1855, the Colonels of regiments were awarded certain annual sums of money in lieu of off-reckonings. These sums varied from £1200 to £500, and were to be given in addition to the pay. From that date all the troops have been clothed by the Government, the off-reckonings being calculated nearly as before, but paid by the country to the Colonels. When the War Office was remodeled about the same time, a Clothing Department was added to it; and it was now found that the clothing for a full regiment of 1091 non-commissioned officers and rank and file, in the Line, cost about £2500 per annum. The clothing is now contracted for more openly than under the former system; and better materials are hence obtained without any increase in cost. The Government has a factory on its own account, but a large part of the supply is obtained by contract. Formerly soldiers' coats were too often made of very loose, spongy materials; but now the inspection is rendered much more severe; and the cloth provided for privates is as good as that worn by sergeants a few years ago, while the cloth worn by sergeants now is correspondingly improved.

CLOTH-TESTER.—A machine for ascertaining the tensile strength of materials by an even direct pull, also by a side or tearing strain; it is designed for test-



ing materials for tentage, blankets, clothing, etc. The drawing shows such a contrivance with the following dimensions: Extreme height, 2 feet 5 inches; extreme length, 2 feet 3 inches; extreme width, 12 inches; weight, 65 pounds. Adaptation: Tensile specimens 12 inches long by 3 inches wide or less, capacity 500 pounds. This machine is a recent invention, and is a great assistance to Quartermasters and others who purchase cotton and woolen materials and are responsible for their quality. The machine readily compares articles of clothing with that of any standard grade. See *Testing-machine.*

CLOUT.—An iron shield or plate placed on a piece of timber in a carriage—as on an axletree—to take the rubbing and keep the wood from being worn.

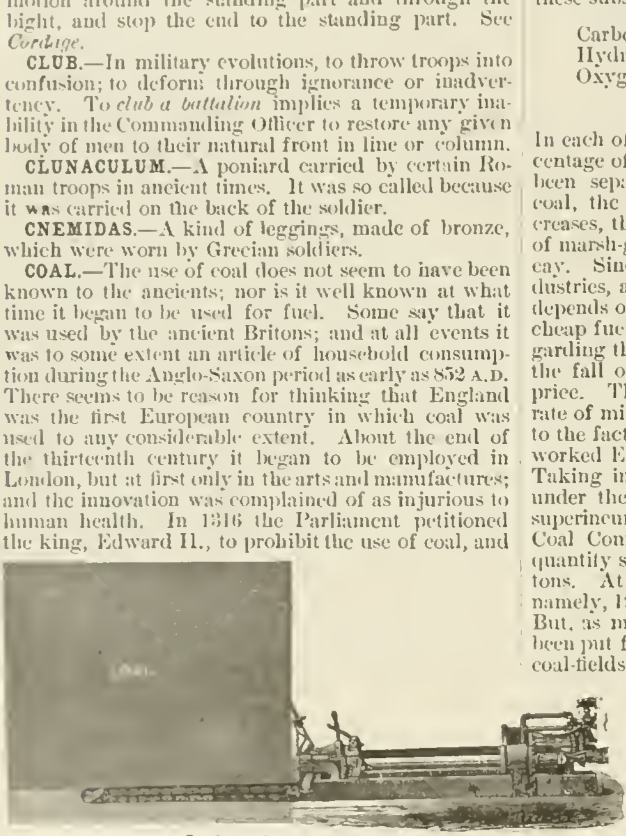
CLOVE-HITCH.—Two half-hitches. To make this hitch give the rope a turn around the object, pass the end of the rope round its standing part, and then through the bight. To make a *clove-hitch*, repeat the motion around the standing part and through the bight, and stop the end to the standing part. See *Cordage.*

CLUB.—In military evolutions, to throw troops into confusion; to deform through ignorance or inadvertency. To *club a battalion* implies a temporary inability in the Commanding Officer to restore any given body of men to their natural front in line or column.

CLUNACULUM.—A poniard carried by certain Roman troops in ancient times. It was so called because it was carried on the back of the soldier.

CNEMIDAS.—A kind of leggings, made of bronze, which were worn by Grecian soldiers.

COAL.—The use of coal does not seem to have been known to the ancients; nor is it well known at what time it began to be used for fuel. Some say that it was used by the ancient Britons; and at all events it was to some extent an article of household consumption during the Anglo-Saxon period as early as 852 A.D. There seems to be reason for thinking that England was the first European country in which coal was used to any considerable extent. About the end of the thirteenth century it began to be employed in London, but at first only in the arts and manufactures; and the innovation was complained of as injurious to human health. In 1316 the Parliament petitioned the king, Edward II., to prohibit the use of coal, and



Lechner Coal-cutting Machine.

a proclamation was accordingly issued against it; but owing to the high price of wood its use soon became general in London. It was for a long time known there as *sea-coal*, because imported by sea. Several theories as to the mode of the origin of coal have been put forth from time to time. The one now generally believed in is that the rank and luxuriant vegetation which prevailed during the carboniferous age grew and decayed upon land but slightly raised above the sea; that by slow subsidence this thick layer of vegetable matter sunk below the water, and became gradually covered with sand, mud, and other mineral sediment; that then, by some slight upheaval of the sea-bottom or other process, a land-surface was once more formed, and covered with a dense mass of plants, which in course of time decayed, sank, and became overlaid with silt and sand as before. At length thick masses of stratified matter would accumulate, producing great pressure, and this, acting along with chemical changes, would gradually mineralize the vegetable layers into coal. Some experiments made by Dr. Lindley, a few years ago, showed that of a large number of plants kept immersed in water for two years, the ferns, lycopodiums, and pines were those which had the greatest powers of resisting decay, and coal appears to be mainly composed of the substance of the ancient representatives of these three orders of plants. The interesting fact has also been lately proved, by Huxley, Morris, Carruthers, and others, that in many instances the bituminous matter in coal is almost wholly formed of the spore-cases and spores of plants allied to our club-mosses and ferns.

As will be seen from the following table, wood, peat, lignite or brown coal, and true coal indicate by their composition the changes which vegetable matter undergoes by decay and pressure; and a table in which a considerable number of examples of each substance could be given would show how gradually these substances pass into each other:

	Wood.	Peat.	Lignite.	Coal.
Carbon	50.0	60.0	65.7	82.6
Hydrogen	6.2	6.5	5.3	5.6
Oxygen	43.8	33.5	29.0	11.8
	100.0	100.0	100.0	100.0

In each of these bodies there is usually a small percentage of nitrogen, which in the above table has not been separated. In passing from wood or peat to coal, the proportion of oxygen and hydrogen decreases, these substances being given off in the form of marsh-gas and carbonic acid in the process of decay. Since the prosperity of our great national industries, as well as much of our domestic comfort, depends on the continuance of an abundant supply of cheap fuel, much anxiety has arisen of late years regarding the future supply and price of coal. Since the fall of 1872 a great rise has taken place in its price. This is partly owing to the unusually high rate of miners' wages which has prevailed, and partly to the fact that some of the richest and most easily worked English coal-seams are becoming exhausted. Taking into account the coal which probably exists under the permian, new red sandstone, and other superincumbent strata in the United Kingdom, the Coal Commissioners increase their estimate of the quantity still available for use to 146,480 millions of tons. At the present rate of annual production—namely, 123,500,000 tons—this would last 1186 years. But, as may be supposed, the estimates which have been put forth regarding the probable duration of our coal-fields are very various, some authorities asserting that, owing to increase in population and the increasing consumption of coal in factories, about 100 years will suffice to exhaust them. Between this and the other extreme of about 1000 years, formed on the assumption that the population of the country will but slightly increase, there are innumerable conjectures and estimates.

The annual production of coal throughout the world has been roughly estimated at 260,000,000 tons, including about 17,000,000 tons of lignite and coal from the formations newer than the coal-measures of Europe. Nearly one half of this total was raised in Great Britain. Excluding lignite the figures are as follows:

	Tons
Great Britain	125,000,000
United States	48,000,000
Germany	35,000,000
France	17,500,000
Belgium	17,000,000
Austria	4,700,000
New South Wales	1,300,000
Russia	1,000,000
Spain	750,000
India	700,000
Other Europe	125,000
British North America	750,000
Chili	200,000
Australia	50,000

In America the first coal discovered was by Father

Hennepin, near what is now Ottawa, Ill. The first mining of coal was in 1813, when five boat-loads of flinty coal were floated down the Lehigh River and sold in Philadelphia for $21 per ton. The fuel of the period was almost entirely of wood, Liverpool coal being a rare luxury. As late as 1821 only 22,122 tons of coal (Liverpool) were imported into the United States. The first regular shipments of coal from the Pennsylvania mines begin in 1820. The coal industry of Pennsylvania has reached enormous proportions, the annual product being valued at over $50,000,000. Besides more than 20,000,000 tons of anthracite coal there are mined in Pennsylvania near 10,000,000 tons of bituminous coal annually. Of bituminous coal the States of Ohio and Illinois produce the next most extensive yield, each about 3,000,000 tons annually. In 1870 there were 1566 collieries in the United States, employing 92,454 hands, and invested capital to the amount of $110,000,000. In 1820 the total coal product of Pennsylvania was less than 2000 tons. It is now more than 30,000,000 tons per annum.

One of the most successful applications of compressed-air engines has been in the working of coal-cutting machines. Of these machines, Firth's in England, Gladhill's in Scotland, and Brown's in America have been in practical operation for several years; but they can as yet only be economically worked under exceptionally favorable circumstances. A very satisfactory form of the coal-cutting machine has an engine with a reciprocating piston driving a massive steel pick, in any desired direction, and at a very material saving in hewing, or *kirving*. The motive power of the engine is highly compressed air, condensed by the steam-engine at the mouth of the pit, and this elastic air is conveyed by slender pipes down the shaft and along the mine to the breast where the coal is being worked. The compressed air is pumped by the steam-engine into a receiver at the pit-head during its otherwise idle hours, or by its surplus power when drawing up the coal, or pumping out the water from the mine, and is condensed to a tension of forty or fifty pounds to the square inch. It is conducted in metallic pipes 4½ inches in diameter, down to the bottom of the shaft, and thence in pipes of a smaller diameter to the workings, tubes of 1 or 1½ inch caliber bringing it to the cylinder of the machine. This compressed air, when set free at each alternating stroke of the piston, imparts to the adjacent portions of the mine a pure dry, cool atmosphere, from a well-known law of all air and gases, that when compressed they develop heat, and when expanded under a relaxation of pressure they are relatively cool.

The drawing represents the Lechner coal-cutting machine, much used in America. The under-cutting by this machine is done by a revolving horizonal cutter-bar of from three to four feet in length, driven into the coal by two small engines attached to a stationary frame. The cutter-bar is revolved by two endless steel chains, and when the desired depth of cut is reached, is withdrawn almost instantly by the smaller reversed screw. The cuttings are removed by means of scraper-chains, as seen in the drawing. The machine is placed in front of the coal at one side of the room, on the floor of the mine; the cutter-bar is driven into the coal five feet, and by the reversed screw mentioned above is withdrawn, when the machine is moved over the length of the cutter-bar used, and another cut is made, withdrawn again, and set over as before, and so on continually, until the entire room is under-cut, when the machine is placed on a car for the purpose, and run into another room. The time required to make the cut, 3 to 4 feet wide, 4 inches high, and 5 feet deep, is from 6 to 8 minutes; withdrawing and setting over, 2 minutes. Time consumed by each cut, 10 minutes. See *Anthracite* and *Coke*.

COAST-BATTERIES.—Batteries erected along a coast to protect the entrances of harbors and ports. They are armed with artillery of the largest caliber to oppose the landing of an enemy. The nature of ordnance for coast-defenses in England was in 1860 recommended to be as follows: the 10-inch gun of 86 cwt.; the 68-pdr. of 95 cwt.; the 8-inch gun of 65 cwt.; the 32-pdr. of 56 cwt.; the 13-inch sea-service mortar. Since the introduction of rifled artillery and armor-plated ships, the old smooth-bore guns, which formerly were used for coast-defense, have been superseded by the heavier rifled ordnance of the present day. See *Ordnance*.

COAST-GUARD LIGHT.—A light used for signals, and which burns about five minutes. It has superseded the coast-guard port-fire, and its composition consists of saltpeter, 7 pounds; sulphur, 1 pound 12 ounces; red orpiment, 8 ounces. The top of the composition is primed with mealed powder, and the flash blows off the cap. It is ignited by placing a G.S. primer in the hole in the head of the apparatus, and a sharp blow with a pin projecting from it sets the light on fire. The primer is made on a similar plan to the friction-tube; the pin is roughed and coated with friction-tube composition.

COATED PROJECTILES.—The surfaces of projectiles to which the lead covering is attached is smooth, and the cannelures formerly in use to secure strength in the attachment of the lead are now omitted. The lead coating is held on by tinning, and at first cast on quite thick, but afterwards turned off in a lathe, leaving the usual projecting bands. The iron surface of the projectile is cast smooth, and then dipped in a solution of sal-ammoniac; after this it is immersed in a bath of melted zinc, and at the same time revolved on its long axis by means of an iron rod inserted in the fuse-hole. During this revolution, which is done by one workman, another presses a mass of sal-ammoniac, fastened to the end of an iron rod, on the surface of the projectile. After a sufficient amount of zinc is made in this way to adhere to the surface, the projectile is placed in an iron mold and the lead coating cast on it. The lead coat occasionally becomes detached in spots, where the lead has risen up into blisters from the formation of gas underneath it, occasioned by voltaic action between the different metals. Such blisters are generally very small, and may be pricked and then hammered down, without affecting the fitness of the projectile for service. If left to develop themselves, they have been known to attain a large size.

The surface of the coating usually has raised bands or welts to take the rifling of the piece. In the German service the front band, *a*, as shown in Fig. 1, is

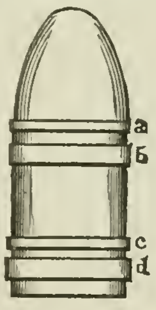


Fig. 1.

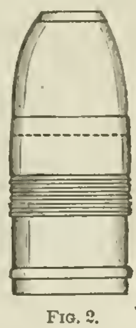

Fig. 2.

smaller in diameter than the others. Next larger is the band *b*, then comes the band *c*, and largest in diameter of all is the rear band, *d*. The lead coating is preserved from injury by two grommets, which are nearly severed to facilitate removal, and the projectiles are stored in racks fitted in the shell room. Sometimes the body of the projectile is not strictly cylindrical, but rather smaller at the base, the lead coating bringing the finished body into a cylinder. This form is considered good for penetration, but any lead coating must considerably retard the projectile in endeavoring to force its way through armor.

This lead covering causes a great waste of power, as it is the iron part alone, of the shell, that can do work against the iron plates, and consequently a considerable force is expended in projecting a part of the projectile which is useless for the work which has to be performed. A bearing of lead upon iron is, mechanically speaking, one of the worst conceivable, and particularly under high pressures and velocities. The coefficient of friction for a bearing of lead upon cast-iron, wrought iron, or steel is greater than for that of almost any other two metals; and it increases very decidedly in some contacts with an increase of temperature.

The projectiles of the 3-inch steel boat-gun are fitted with a copper rotation-belt over the center of gravity, as shown in Fig. 2. The belt has a length of bearing of 2 inches and a taper towards the front; it is grooved around the rear part. About .3 of an inch from the base is fitted a steadying-ring, .25 of an inch broad, and semicircular in section. On the exterior of the cylinder of the projectile, and about over its center of gravity, a broad groove or recess is cut .02 of an inch in depth, and as long as the rotation-belt (which it is to receive). At .4 of an inch from the base of the projectile another groove is cut, of similar depth and ¼ inch wide; this is to receive the guide-ring. A cold-chisel is then used to nick the bottoms of these grooves all around at intervals of about ½ an inch; the direction of the chisel-marks being lengthwise of the projectile, and their depth about two or three hundredths of an inch.

Cylindrical rings of copper are cast in sand-molds, and of length suitable for making rotation-belts and guide-rings. The interior diameter of these rings is very slightly greater than that of the cylindrical part of the projectile. The thickness of the metal is .15 of an inch. The rings are then slipped over the projectiles, and squeezed (or permanently compressed) by a screw press into the grooves prepared for them. This operation not only fills the grooves completely and makes the rings hug the body of the projectile, but also forces the copper slightly into the marks left by the cold-chisel at the bottom of the grooves; thus powerfully assisting to prevent any possibility of the belt slipping circumferentially upon the projectile. The projectiles, with their rough belts and rings on them, are then centered in the lathe, and the bearings are carefully turned down to the diameters and profiles given on the drawings. See *Compression-projectiles*, *Lead-coating Process*, and *Projectiles*.

COAT OF ARMS.—In the military trappings of the Middle Ages, the coat of arms held the place of the *paludamentum* of the ancient Roman Captains. It was a coat worn by Princes and Great Barons over their armor, and descended to the knee. It was made of cloth of gold or silver, of fur or of velvet, and bore armorial insignia. The "coat of arms," as understood by Heraldry in the present day, is nothing more than a relic of the ancient armorial insignia, divested of the coat on which it used to be embroidered.

COAT OF MAIL.—In the armor of the Middle Ages, a suit made of metal scales or rings, linked one within another. See *Armor*.

COCKADE.—According to Wedgwood, this word signified originally a cocked hat, or a hat with the broad flap looped up on one side, and was then applied to the knot of ribbon with which the loop was ornamented. Another view is that it is derived from *coquart*, a beau, or one fond of gay trappings. The word is now, however, restricted to signify an appendage to the head-dress worn as a military or naval distinction. Badges of distinction were early had recourse to in party and civil warfare. A sprig of broom (*planta genista*) was the badge of the House of Plantagenet. In England, during the wars between the Houses of York and Lancaster, the adherents of the former party were distinguished by a white and the latter by a red rose worn in the cap. The party organized at the Court of Charles IX. of France to perpetrate the massacre of St. Bartholomew recognized one another by a paper cross. The faction of the *Fronde*, opposed to Cardinal Mazarin, wore stalks of corn for the same purpose; and certain military bands were called *lances vertes*, from decorating their lances with green twigs. The use of cockades, as marks of distinction in campaigns and battles, became very general about the beginning of the eighteenth century. Eugene and Marlborough gave the Germans, English, and Dutch, composing their army, a tuft of corn or grass as their signal or cockade. The use of the cockade began to be more fixed in the War of Succession. White being the color of France, and red of Spain, the two colors were united in the cockade of the combined army. At last, in 1767, an authoritative regulation determined that every French soldier should wear a cockade of white stuff; and in 1782 cockades were prohibited to all but soldiers. From this time till the Revolution the cockade was an exclusively military badge; and, both in France and England, "to mount the cockade" was synonymous with becoming a soldier. But in the enthusiasm of 1789, the citizens of France generally assumed the tricolored ribbon as the badge of nationality and patriotism, which was soon also given to the army. The three colors were blue, white, and red: white had long been the color of France and its kings; the blue is understood to have come from the banner of St. Martin, and the red from the orillamme. Long before the Revolution, the three colors were used in combination: they were given by Henry IV. to the Dutch, when they desired him to confer on them the national colors of his Country, and have ever since been borne by the Dutch Republic and Kingdom of the Netherlands. At the Restoration, the white cockade of the Monarchy again took its place, but had to give way once more to the tricolor, which continues to be the cockade of the French army. Black, with some distinction, enters into the cockades of the German nations. The Austrian is black and yellow; and the Prussian was black and white, abandoned for the black, yellow, and white of the German Empire. After the German War of Liberation in 1813, a national cockade of black, red, and gold came into general use, and was afterwards assumed by the military and by officials. The wearing of these German cockades was prohibited in 1832 by a Resolution of the German Diet; but in 1848 they were again introduced, not only by patriots as a badge of German union, but into the armies. The national colors of Belgium are black, yellow, and red. Cockades of these colors were worn by almost the whole population of Brussels on occasion of the Constitutional Festival, July 21, 1860. Cockades of green, white, and red are worn in Italy. The Continental cockade is generally in the shape of a flat disk, sometimes of metal, sometimes of silk or other stuff, with the colors disposed concentrically.

COCK-FEATHER.—In archery, the feather which stood up in the arrow, when it was correctly placed upon the string, perpendicularly upon the cock or notch.

CODE.—1. A body of laws established by the Legislative Authority of the State, and designed to regulate completely, so far as a statute may, the subjects to which it relates. The earliest and most complete Code of the American States is that of Louisiana, finished in 1824, the work of Edward Livingston, a member of the celebrated family of that name in New York, and was based on the Code Napoleonenne. It has 3522 Articles in one series, but comprises three books—(1) of Persons; (2) of Things, and the Modification of Property; (3) of the Different Modes of Acquiring Property. A Code was completed in Massachusetts in 1835, and it was revised twenty years later. New York's first Code formed the Revised Statutes of 1830. There have been various more or less complete revisions, and there is the whole or a part of a further revision now before the Legislature. All except the latest new States have compilations of the codified editions of their laws. David Dudley Field of New York has been active and eminent in the work of codification.—2. A list of signal-symbols.

COEHORN MORTAR.—The Coehorn mortar, which takes its name from its inventor, General Coehorn, is a very small bronze mortar, designed to throw a 24-pounder shell to distances not exceeding 1200 yards. Its weight is 164 lbs., its maximum charge ½ lb. of powder, and it is mounted on a wooden block furnished with handles, so that two men can easily carry it from one part of a work to another. In the late war this piece was much used in the field against troops covered by rifle-pits. At Fort Wagner, General Gillmore says that it followed close on the heels of the sappers and did good service against the enemy who were not sheltered against vertical fire. If fired with friction-primers, this mortar should be provided with a shield of sheet-iron so placed as to prevent the fragments of the primers from flying among the gunners.

To serve the piece, four men are necessary: one chief of detachment, one gunner, and two cannoneers. The implements and equipments are carried in a basket, which is put near and in rear of the mortar. They are as follows: primer-pouch, containing priming-wire, primers, and lanyard; gunner's pouch, containing gunner's level and a pair of small pincers; one quadrant, one sponge, one plummet, and one mallet. A small wedge is used as a quoin. The mortar should have a permanent line of metal marked on it; otherwise this must be marked as for the 10-inch siege-mortar. The shells should be strapped with tin, and be provided with cord handle. They, together with the powder and fuses, are kept in the service-magazine. The service of the piece is analogous to that for the 10-inch siege-mortar.

When Coehorn mortars accompany troops in campaign, they may be carried on ordinary field-caissons; each caisson carrying one mortar, together with sixty rounds of ammunition. The mortar is carried on the caisson-body, the front chest being removed for this purpose. The piece is securely lashed with ropes through the handles. The remaining ammunition-chests are arranged to carry thirty shells each. The powder is in cans, and a set of measures (from one to six ounces) should be provided. The shells should be charged and the fuse-plugs driven, ready for the insertion of the fuses. A caisson with chest similarly arranged should accompany each piece. The mortars may also be carried in ordinary army transportation-wagons. Each wagon will carry one Coehorn and its equipments (weighing 311 pounds), and sixteen boxes, each containing eight shells and weighing 168 pounds, or 2688 pounds, making a total of 2999 pounds: a fair load, on good roads, for four horses or six mules. See *Mortar*.

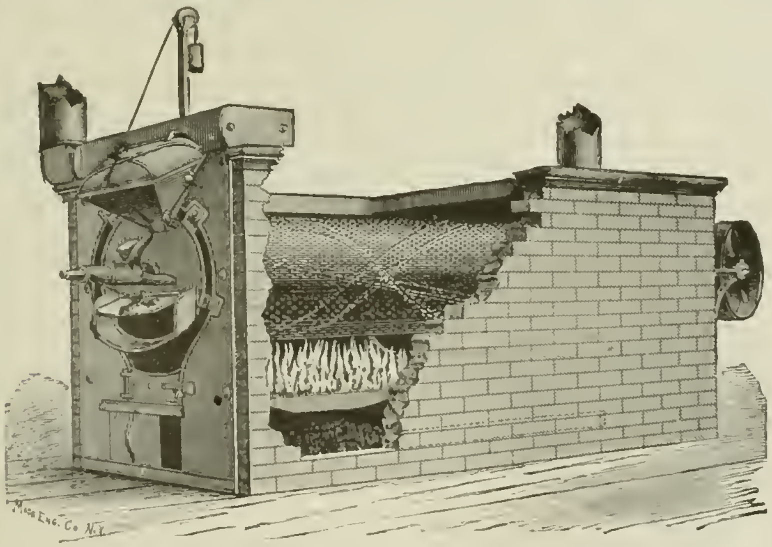
COEHORN SYSTEM OF FORTIFICATION.—Coehorn's method of attack was the very opposite of that of his contemporary and rival; whilst Vauban advanced surely and slowly, sparing life and intrenching every step, Coehorn sacrificed everything to time, and trusted to an overwhelming fire of artillery and audacious assaults. At Bonn, in 1703, besides a large park of heavy ordnance, he employed 500 small mortars to throw grenades. Coehorn has been placed at the head of the modern Dutch school.

COFFEE.—This most important article of the soldier's ration owes its exhilarating and refreshing properties to the presence of three substances: 1. *Caffeine*, which occurs in the roasted bean to the extent of ¾ to 1 per cent; 2. A *volatile oil*, which is not present in the raw bean, but is developed during the process of roasting to the extent of only one part in about 50,000 of the roasted coffee; 3. Astringent acids, resembling tannic acid, but called caffeo-tannic and caffeic acids. The average composition of unroasted coffee is as follows:

Caffeine	0.8
Legumin (vegetable caseine)	13.0
Gum and sugar	15.5
Caffeo-tannic and caffeic acids	5.0
Fat and volatile oil	13.0
Woody fiber	34.0
Ash	6.7
Water	12.0
	100.0

When the beans are roasted till they assume a reddish-brown color, they lose 15 per cent by weight and gain 30 per cent in bulk; when further roasted till they become chestnut-brown, they have lost 20 per cent by weight and increased 50 per cent in bulk; whilst if the roasting is continued till the beans become dark brown, they lose 25 per cent in weight and acquire 50 per cent in bulk. The beans should never be darker than a light brown color, which is quite sufficient to bring out the excellent aroma and other qualities of the coffee; and when the roasting is carried further, more or less charring is the result, and a disagreeable burned smell is produced, which tends to overcome the natural pleasant aroma.

Frequently on the march and in camp there are no-



Abele Coffee-roasting Machine.

facilities for properly roasting coffee, and experience has shown that it is well for troops in the field to be supplied with coffee previously roasted at the depots. The drawing shows the Abele roasting-machine, employed at most military posts and supply-depots. This machine has every advantage of the old-style sliding cylinder, together with numerous important improvements. Charged and discharged, both at the same end in front, it saves 50 per cent of space; with time and labor to the tender, and maintains perfect ventilation throughout, to oxidize the coffee by inhaling currents of air; with outlets for the exhalation of gas and steam from within. When desired it may have forced circulation, as by a fan (and water admitted from the hydrant or from a tank above); while the coffee is easily examined at every stage in oxidation, without interfering with the work or stopping the action of the machine. The important points accomplished in the machine are:

1. To keep the material in uniform motion, to and fro, by means of ingeniously constructed shovels and stirrers that will expose every particle to exactly the same degree of heat.

2. To draw in through openings in front a current of oxidizing air to surround the coffee during that chemical change; making up in part, by the oxygen absorbed, for any subsequent loss and neutralizing the gases, to be blown off by the same currents of air towards the rear of the furnace into the smoke-stack above.

3. To provide for the immediate escape of steam from within, by means of an exhaling ventilator, located over the cylinder in front.

The usual methods of preparing coffee are, first, by *filtration;* second, by *infusion;* third, by *boiling.* Filtration gives often, but not always, a good cup of coffee. When the pouring the boiling water over the ground coffee is done slowly, the drops in passing come in contact with too much air, whose oxygen works a change in the aromatic particles, and often destroys them entirely. The extraction, moreover, is incomplete. Infusion is accomplished by making the water boil, and then putting in the ground coffee; the vessel being immediately taken off the fire and allowed to stand quietly for about ten minutes. The coffee is ready for use when the powder swimming on the surface falls to the bottom on slightly stirring it. This method gives a very aromatic coffee, but one containing little extract. Boiling, as is the custom in the East, yields excellent coffee. The powder is put on the fire in cold water, which is allowed merely to boil up a few seconds. The fine particles of coffee are drunk with the beverage. If boiled long, the aromatic parts are volatilized, and the coffee is then rich in extract but poor in aroma.

Coffee does not retard the action of the bowels, as strong infusions of tea generally do, partly because there is less of the astringent principle, and also owing to the presence of the aromatic oil which tends to move the bowels. The important offices which coffee fulfills are, to allay the sensation of hunger; to produce an exhilarating and refreshing effect; and, most important of all, to diminish the amount of wear and tear, or waste of the animal frame, which proceeds more or less at every moment. The grounds of coffee are very nutritious, from containing so much legumin; and some of the Eastern nations take advantage of this and use the grounds as well as the infusion. In many other respects, coffee possesses similar properties to tea.

An endless variety of apparatus have been contrived (and some of them of great complexity) for preparing coffee for the table. The chief object aimed at is to obtain the liquor free from all sediment. One of the simplest of these contrivances is the percolating coffee-pot. The easiest way of making coffee, requiring no special apparatus, and as satisfactory in the result, perhaps, as any, is to put two ounces of coffee into a small saucepan or coffee-pot; pour over it a pint of boiling water, and allow it to stand, closely covered up, by the side of the fire (but *not* to boil) for five minutes. The liquor may then be simply poured off the grounds, or it may be strained through a cloth, and then returned to the saucepan or coffee-pot (previously rinsed out), and warmed again. Soyer recommends that before the boiling water is poured in the saucepan should be set dry on the fire, and the powder stirred till it is quite hot, but not in the least burned. In France, a pint of boiling milk is added to a pint of coffee. The chief effect of adding chicory to coffee is to deepen the color.

For special cases, such as journeys and marches, where it is impossible to be burdened with the necessary machines for roasting and grinding, coffee may be carried in a powdered form, and its aromatic properties preserved by the following process: One pound of the roasted berries is reduced to powder and immediately wetted with a syrup of sugar, obtained by pouring on three ounces of sugar two ounces of water, and allowing it to stand a few minutes. When the powder is thoroughly wetted with the syrup, two ounces of finely-powdered sugar are to be added, mixed well with it, and the whole is then to be spread out in the air to dry. The sugar locks up the volatile parts of the coffee, so that when it is dry they cannot escape. If coffee is now to be made, cold water is to be poured over a certain quantity of the powder and made to boil. Ground coffee prepared in this way, and which lay exposed to the air for one month, yielded, on being boiled, as good a beverage as one made of freshly-roasted berries.

COFFER-DAM.—A water-tight structure used in engineering for excluding the water from the foundations of bridges, quay-walls, etc., so as to allow of their being built dry. Coffer-dams are generally formed of timber piles driven close together (called sheeting) in two or more rows, according to the depth of water and the nature of the bottom; the space between the rows, which may vary from four to ten feet, being spooned out down to the solid and impervious bottom, and filled up with clay puddle. Sometimes they are made of only one row of piles of the full height, calked above low water, with a low or dwarf row outside to confine the puddle up to that level, or, where there is no wave or current, with a mere bank of clay thrown against the outside; and occasionally the upper work is formed of horizontal planking, fixed on open main piles, and calked in the joints. When the bottom is rock, so as to prevent piles being driven, and is not much below low water, coffer-dams are occasionally formed of two stone walls, with a space between filled with clay.

The coffer-dams spoken of are all what are called high-water dams, and exclude the water at all states of the tide. They require to be provided with sluices, to allow of the water, when first to be excluded, getting out during the ebb, and to shut against it during the flood. The remainder of the water, and all leakages, must be got rid of by pumps, generally worked by a steam-engine. For moderately shallow foundations, and more especially where there is a great rise and fall of tide, tidal dams are often used. These are sometimes made of sheeting-piles, but are often boxes formed of planking or of iron, weighted and sunk into the ground by digging inside in the same way that wells are sunk. These dams can only be used for a couple of hours or thereabouts at low water, and of course require to be pumped out every tide. All coffer-dams require to be strongly shored within, to prevent their being forced inwards by the pressure of the external water; and the rows of piles require to be strongly bolted together, to overcome the pressure of the clay puddle, which otherwise would burst them.

COFFER-MAGAZINE.—A magazine of coffer-work formed by making the frames of six-inch scantling; each frame is composed of two uprights, termed *stanchions*, and a cap and ground-sill, well nailed together; it is six feet wide, and six feet high in the clear. These frames are placed upright, and parallel to each other, about two and a half feet apart; they are covered on the top and sides by 1½-inch plank, which is termed a *sheeting*. The magazine otherwise is constructed in the usual manner. See *Magazine*.

COHESION.—The name given to that species of attraction by which the particles of matter are held together so as to form bodies, and its measure is the resistance which bodies offer to any mechanical force tending to separate their parts. In gaseous bodies cohesion is altogether wanting; their atoms even repel one another. In liquids, notwithstanding the ease with which the particles slide on one another, the operation of cohesion is distinctly seen in the formation of drops. Cohesion is strongest in solids; and degrees of cohesion, in this case, are much the same thing as degrees of solidity. It is the force of cohesion that constitutes the strength of materials. After the particles of a body have been completely separated, it is found that through cohesion they will reunite, if pressed sufficiently close together. Two clean, smooth, freshly cut pieces of lead placed together will cohere so as to require a very considerable force to separate them; and it has not unfrequently happened in plate-glass manufactories that polished plates of glass have cohered so completely that they have been cut and worked as a single piece.

If the particles of matter had no property in relation to one another, except their mutual impenetrability, the universe, it has been said, would be like a mass of sand, without variety of state or form. As it exists, however, it demonstrates the cross-action of several universal properties of matter. Among those which most affect its state and form are heat and cohesion. It may be said that bodies assume the solid, liquid, or aëriform states, just according to the proportion that the cohesion of their particles bears to those forces which, like heat, tend to separate them. Upon modifications of the cohesive force, and its relations to other molecular forces, would seem to depend such properties as elasticity, brittleness, ductility, etc.

COHORT.—In the ancient Roman armies, a cohort was a portion of a legion, consisting usually of 600 men. Generally there were ten cohorts to a legion. Marius introduced the cohort instead of the maniple as the unit of force; forming it of three maniples, and abolishing the ancient modes of classification. The cohort preserved both the number and designation of the officers attached to the maniples. It was commanded by the First Centurion, until, under the emperors, it received a Superior Officer, termed the Prefect of the Cohort. The use was also introduced of making of the first cohort a *corps d'élite*, to which was intrusted the eagle, under the orders of its primiple. The order of battle by cohorts depended upon circumstances; usually five were placed in the first and five in the second line. The number of ranks of the cohort was also variable; depending on the front necessary to be presented to the enemy.

COIF.—Among the armor of the Middle Ages, the coif was a sort of defensive hood, surmounted by a helmet, sometimes continuous with the hauberk, and sometimes separate. See *Armor*.

COILED TUBES.—The pig from which is made the bar-iron employed at the West Point foundry in the fabrication of tubes for gun-conversion is derived chiefly from the Lake Champlain magnetic ores, and from some of the hematite ores of Pennsylvania, the suitable proportions of kind and grade to yield a satisfactory metal being the result of much careful experiment. The various operations of puddling, rolling, etc., differ in no particular respect from the ordinary methods employed, except in the greater care exercised to secure a high standard for the quality of the product. A brief notice here will therefore suffice. The charge of pig-iron is first heated to redness by the waste heat from the reverberatory furnace, and is then thrown into the hearth along with a quantity of cinder. The charge consists of 448 pounds, the yield of blooms amounting to about 95 per cent of the metal charged; the amount of coal consumed is 2375 pounds per ton of puddle-bars, and the time occupied from the charging of the furnace to the withdrawal of the puddle-balls is about 1¾ hours. The process in the furnace is what is termed the "boiling process," and the regulation of the draught during this period is an operation requiring great care and good judgment, as upon it the quality of the bar-iron will in great measure depend. It is important that the iron designed for gun-tubes shall not be too "dry," i.e., deficient in cinder, as such an iron crumbles under a high heat, and, at best, welds but imperfectly. On the other hand, the presence of any considerable quantity of cinder indicates an insufficient "working," besides furnishing for the bore of the gun a material that is not sufficiently homogeneous and compact to resist well the eroding action of the powder-gases. The puddle-ball, under the action of the hammer, is formed into a bloom about 18 inches long, by 4 or 5 inches square, and weighing about 100 pounds. The blooms, before cooling, are passed between the rollers—both "roughing" and "finishing"—and result in what are termed "muck-bars," long flat bars from 4 to 2 inches wide, and ⅝ inch thick. The "muck-bars" are cut up and piled. The piles are then placed in the furnace and raised to a white heat, when they are subjected to a succession of rollings, by which they are converted into bars about 23 feet long and ½ inch thick. Each time, before being passed between the rollers, the piles are turned one fourth round, so that the compression of the metal takes place in directions that are alternately parallel and perpendicular to the layers. The operations of cutting, piling, and rolling are then repeated, and the resulting bar or plate cut into lengths of 53 inches, and piles made about 9½ inches high by 7 wide, for the final rolling. The top and bottom plates of these last piles are about ⅝ inch thick, while the intermediate plates are ½ inch thick. At this stage the piles are passed between the rollers, at first with the layers horizontal, but are afterward so manipulated that the corners of the piles shall take the groove in the rollers. The precaution is taken in heating the piles to separate slightly the successive layers, in order that the heat may more readily penetrate the mass, and both in piling and rolling the iron it is important that the direction of the fiber should be preserved always the same. In the finished bar the elementary plates stand parallel with the depth, the position most favorable to their final consolidation in the subsequent process of coil-welding. The length of the bar is about 23 feet, and the cross-section hexagonal in form, to compensate for the changes in form incident to the process of coiling.

By making the bar simply trapezoidal in cross-section, it was found that in coiling the sides become concave, thereby forming a pocket which, in the subsequent process of uniting the folds of the coil, served as a receptacle for cinder, and proved an obstacle to perfect welding. In order to avoid a feature so objectionable the shoulders were added, whence a supply of metal can be drawn to fill up the cavity of the sides. The ends of the finished bar are cut off to where the material is thoroughly welded and perfectly sound, the greater length being taken from the end nearer the furnace-door, as being the colder end. The bar is now ready for shipment to the foundry.

	Sample marked English.	Sample marked American.
Sulphur	0.047	0.037
Phosphorus	....	Trace.
Manganese	0.374	1.228
Silicon	0.018	0.089
Slag and oxide of iron	1.308	2.144
Carbon	0 094	0 034
Iron	98.159	96.468
	100 000	100.000

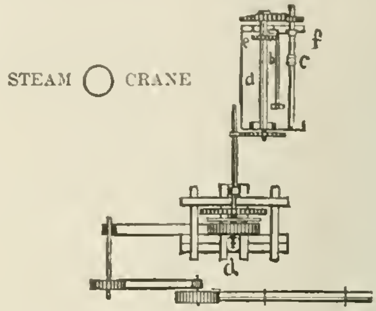
The table herewith exhibits a resemblance between the two varieties of iron which is remarkable, since the American manufacturers possessed no accurate knowledge of the mode of fabrication of the English iron, but were guided almost entirely in their efforts by such imperfect data as could be gleaned from reports of Parliamentary Committees on the failure of a large number of coiled wrought-iron tubes in England; reports of which the chief value lay in their pointing out the nature of existing defects in material and manufacture, rather than the course of practice by which those defects might be removed or avoided.

The bar-iron, as received at the foundry, is in lengths of 16½, and 18 feet for the A tube, and of 26 feet for the B tube, the cross-section of the latter being a square of 2¾ inches on a side. The weights are about as follows:

	Pounds.
Long bar for A tube	749
Short bar for A tube	678
Bar for B tube	608

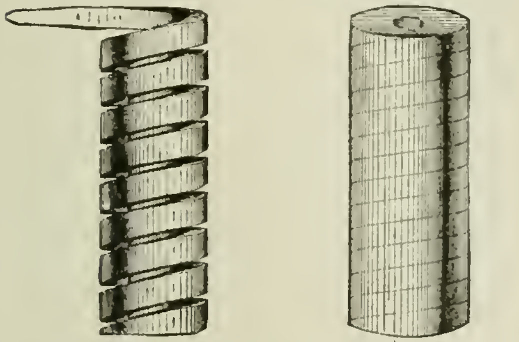
The A tube is composed of four sections or short tubes welded together, each section, as well as the B tube, consisting of two bars, which are united end to end before coiling. The long bars for the A tube are employed in the breech-section, in order to give that section such length that the joint between it and the next section shall be well in advance of the B tube.

To prepare the bars for welding they are sorted in pairs, and the ends to be united shaped for scarfing. At the same time the other ends are tapered by heating and hammering, and an eye and shoulder formed for purposes in coiling. The V scarf, by affording a firm grasp to the ends, and by exposing a large surface for welding, is thought to insure a strong joint; yet so great is the strain thrown upon the bar in the operation of coiling that separation does sometimes take place at that point. The welding is readily performed by means of a "hollow fire" and an adjacent steam-hammer. The joint is subjected to three heats. At the first heat the bars are butt-welded by means of sledges; at the second and third heats the joint is lap-welded by the steam-hammer, the hexagonal cross-section being afterward restored by interposing a wedge-shaped tool between the bar and the hammer. While in the fire, one end of the bar abuts against a heavy timber, and the other end is repeatedly struck upon with a sledge to close and upset the joint. The coiling process is a familiar one, the method pursued at West Point differing in no important respect from the English method. The grates and ash-pits, seven in number, are ranged along one side, and the draught enters under the grates. The blower is worked by the engine that revolves the coiling apparatus. The number of fires employed at any one time depends upon the length of the bars to be heated. About ninety bushels of anthracite coal a day are consumed in each grate. At the rear of the oven is a roller-way upon which the bars are moved into the oven. The slope of the oven and trestle-work facilitates the insertion of the bars; but, as a feature of the construction, it resulted rather from the inclination of the ground on which the oven is built than from design. The bars are pushed into the oven as far as it is possible to push them, and then a long iron hook is passed in from the front and hooked into the eye in the end of the bar. A chain leading from the windlass of a steam-crane is connected with the hook, and the bar is drawn forward by the revolution of the windlass. It requires about three hours to heat the oven, and after that about one hour to heat the iron to a bright redness, the temperature required. The oven has a capacity for eight bars; but, to secure greater facility in handling, more than four are seldom heated at once. The coiling apparatus is shown in the drawing: *a* is a mandrel, slightly conical in form, on which the bar is wound; *b* is a roller-guide over which the bar passes, and by means of which the exterior diameter of the coil is regulated; *c* is a sliding guide which regulates the spiral of the coil. At *d* is the steam-piston which communicates the motion. On the mandrel is an iron disk, *e*, through which is inserted a pin or key, *f*, and the end of the bar is attached to the mandrel by passing between it and the key, and hooking over the latter by means of



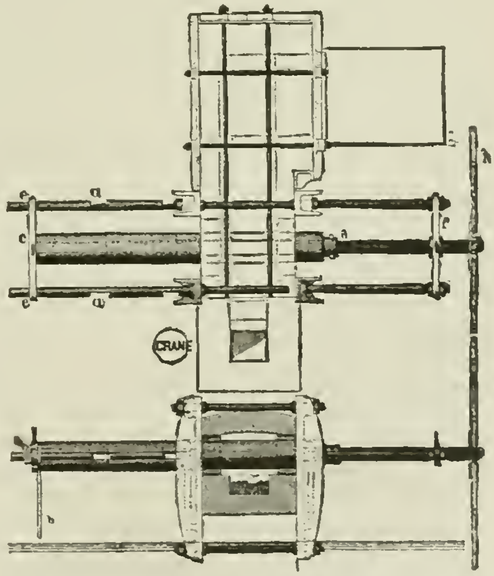
the shoulder. In this position the narrow side of the bar is down or against the mandrel. The apparatus having been put into gear, the mandrel revolves, winding the bar around it. To remove the coil the apparatus is thrown out of gear, the cap-squares of the mandrel are removed, and, by means of the steam-crane standing immediately in rear, the mandrel is unshipped and swung round. The coil is then started by driving in wedges between the end of the coil and the disk, *e*, after which it is readily removed. After coiling, the cross-section of the bar is slightly concave on the exterior and convex on the interior of the coil, while the distances between the folds are less on the interior than on the exterior. It requires one hour to coil four bars.

When removed from the mandrel, the ends of the bar project out from the coil, and the folds are very open, varying from ⅜ to 1¼ inch on the exterior. The ends are therefore heated and hammered round to conform to the curvature of the coil. The next step is one of closing the folds and welding them. For these operations there are provided two cast-iron tubes, banded with wrought-iron hoops, termed "welding-pots." These pots are cylindrical without, but slightly conical within, and are of two sizes, the diameter of the smaller being 14¼ inches, and of the larger 14⅝ inches, at bottom. In connection with the pots is used a short iron cylinder about 9 inches in height and 14 inches in diameter, termed the "cheese," which receives directly the impact of the hammer. The coil is at first heated to redness in an ordinary reverberatory heating-furnace, and then transferred, by means of a porter-bar suspended from a crane, to the smaller welding-pot, where it is simply pressed under the hammer. The effect of this operation is to close the folds along the surface of the bore. The porter-bar is provided with a heavy sliding counterpoise to facilitate handling it. In order to avoid weak or imperfect welding of the folds, it is desirable that the process should commence at the interior surface of the coil and progress gradually outward, thus leaving to the last an open joint at the exterior for the escape of the cinder squeezed out in the operation. This end, it is thought, is secured by the particular form of cross-section given to the bar, and by the precaution taken of first closing the folds along the interior surface before proceeding to the welding. The coil is now replaced in the furnace and subjected to a welding-heat, which occupies from 2½ to 3 hours. It is then removed to the smaller welding-pot, and the "cheese" dropped upon it, and hammered till the latter sinks to a certain mark chalked upon it. The pot is then turned over, and the coil withdrawn by means of blocks and tackle. The coil is then heated for the third time, and the same operation as above repeated, except that the larger pot is employed. The length of the coil after closing folds is about 4¼ feet, and the exterior diameter 13 or 13½ inches. After being withdrawn from the large pot, the length is about 3 feet; the exterior diameter about that of the pot, and the interior diameter from 5 to 7 inches. The width of fold in the coils for the A tube is now about 2.75 inches, while in those for B tubes it is about 2 inches. The hammer employed in welding the coils is an 8-ton steam-hammer. The drawing shows the coil at the following stages of its



fabrication, viz.: after being removed from the mandrel of the coiling apparatus, and after welding of the folds. In England, the process of coil-welding differs as follows from the above: The coil having been subjected to a welding-heat, "it is placed vertically under the steam-hammer, and receives a few smart blows to weld the folds. It is then thrown on its side, and being gradually turned is hammered (or patted) all round to straighten it. It is then raised vertically again, and a punch or mandrel—rather over half the length and a little larger than the interior diameter of the coil—is hammered down its own length. The coil is next placed on its side and hammered round that half of its length, thus being made very compact, and large enough to let the mandrel fall out. After this the coil is again raised vertical, and the mandrel is forced in the opposite end, and the process repeated. The reason a long mandrel is not forced through the whole length of the coil is that it would tend to separate the folds. The coil is replaced (upright) in the furnace for the second heating, and much the same process is followed to render the ring more consolidated as well as more shapely." By the American process, there seems to be no tendency whatever to separate the folds during any part of the operation. The coil is withdrawn from the welding-pot by connecting the tackle with an iron rod, which passes down the interior of the coil, and is held by a key at the bottom, so that the strain is transmitted to that point.

After welding the folds, the coil is extremely rough and uneven on the interior; it is therefore removed to the shops, where it is rough-bored to within .75 inch of the true diameter of the tube, which furnishes a straight and uniform bore for the formation of the tube. The exterior is comparatively smooth and cylindrical. To unite two or more coils to form a tube, the ends are faced and reciprocally recessed; that is, a projection is formed at one end of a coil, while a recess is bored in the corresponding end of another coil. The height of the projection is a little greater than the depth of the recess, in order that a close joint may be obtained on the interior. The recess is then expanded by heat and shrunk over the projection, so that the two coils are sufficiently stuck together to admit of being put into the furnace for welding. An iron rod, with a key at one end and a nut on the other, is passed through the sections, and the nut screwed up to prevent separation in shrinking. The furnace for welding the sections is so constructed that an intense heat shall act only upon the joint. The butt-welding is performed by means of a powerful screw-press. The furnace and welding apparatus are shown in the following drawing. The tube is placed in the furnace by means of a crane and a porter-bar; the bars *a a* are then raised on the supporting-props *b*, the cross-head *c* and the screw *d* adjusted to the ends of the tube, and the wedges *e* inserted. The furnace is then entirely closed around the tube, and the draught turned on. It requires about three hours to raise the temperature of the metal on the interior of the tube to a welding-heat, a point which is ascertained by means of a hole pierced through the cross-head *c* and covered with a plate of mica, which permits of the interior of the tube being seen. A welding-heat being obtained, the screw, which works in the cross-head *f* as a nut, is tightened by means of the handle *h*, till the tube is compressed lengthwise ½ inch. The tube is then turned half around, the heat renewed for about ten minutes, and another turn given to the screw, by which a further compression of ½ inch is obtained. The props are then knocked out, the bars fall down, and the tube, which is considerably bulged at the joint by the compression it has undergone, is removed to the steam-hammer and "patted" into shape, as well as lap-welded. Sand is thrown on the joint during this operation, to protect the iron and prevent the formation of scale. The face of the hammer, as well as the top of the anvil, is semi-cylindrical, to conform to the exterior of the tube. Two sections being thus welded together, another is added in a similar manner, and then another section which completes the tube. The English method of welding the sections is as follows: After shrinking two sections together, as above, the tube is put crossways through a furnace so constructed that the heat acts only on the joint. When the joint arrives at a welding-heat, a stout iron bar is passed through the tube; this bar is keyed up at one end, and



by means of a screw-nut worked by a long lever at the other end, the two coils are welded or pressed together. The joint is afterwards tapped under the hammer. The furnace and apparatus as described for welding sections were devised by Mr. Colin Tolmie, Superintendent of the Forge-shops at the West Point foundry, and the experience so far had with them has been very satisfactory. The furnace has a capacity for about 1500 pounds coal (anthracite coal being employed) and is so arranged as to consume its own gases. The amount of coal consumed in welding thirteen sections is about 6900 pounds. It requires ten hours to heat up the furnace when cold, and about four hours when working daily. The fire is always replenished during an interval when the tube is withdrawn, so as not to interfere with the heating. While in the furnace, should the joint become unequally heated, sand is thrown in upon the hotter part to equalize the temperature.

The tube is now transferred from the forge to the shops, and placed in the lathe, where it is rough-turned and rough and fine bored. The breech-cup is then screwed in, the breech end of the tube turned down over a length of 32 inches for the reception of the B tube, and the spiral gas-channel cut upon it. The breech-cup is a solid forging stamped into shape under the steam-hammer, turned inside and out, and screwed on the exterior with a thread of five to the inch. The B tube consists of two bars united, coiled, etc., in the same manner as a section of the A tube. It is rough-turned to 13.75 inches, the exterior diameter of the main portion of the A tube, and finished bored to 10 inches. It is shrunk on the A tube with .003 inch shrinkage in the diameter. The shrinking operation is a simple one. The B tube stands vertically, breech down, over a wood-fire, while a large open cylinder of sheet-iron surrounds it. When sufficiently heated the A tube is lowered by a crane into place, the weight of the A tube forcing the B tube well "home" to the shoulder upon the former. Water is then thrown upon the exterior near the shoulder, to cool the B tube in that vicinity first, and thus prevent an open joint, which is apt to occur from the longitudinal contraction of the B tube in cooling.

The tube at this stage is subjected to a water-test of 140 pounds to the square inch, and is turned to fit the casing, allowing a "play" of .007 inch in the diameter between it and the casing for a distance of 32 inches from the bottom, and of .015 inch for the remainder of its length To determine this play, it is necessary to accurately measure the diameters of the bore of the casing and of the exterior of the tube; the former are measured with the star-gauge, the latter either by means of horseshoe-gauges or a diameter-calipers specially designed for the purpose, and measuring to .001 inch. The tube is rifled either before or after its insertion into the casing, as may happen to be most convenient. The weight of bar-iron employed is about 6770 pounds. The weight of the finished tube is about 3100 pounds. The operations of inserting the tube into the casing and securing it, of venting, final proof, etc., are fully described in the fabrication of converted guns. The collar for securing the tube at the muzzle is made of tube-iron, fagoted and hammered out to a proper size. It is then bent to a circle over a mandrel, and the ends welded together. See *Converted Guns*, *Fabrication of Tubes*, and *Water-test*.

COIN.—In gunnery, a kind of wedge to lay under the breech of a gun in order to raise or depress the metal. Written also *Quoin*.

COIR.—The fiber of the cocoanut. Very excellent rope for naval purposes is made from it, and is valued on account of its lightness, elasticity, and strength. Coir-cable is prepared in Ceylon, on the Malabar Coast, in the Maldive and Laccadive Islands, and in most places along the eastern and western coasts of the Bay of Bengal, where cocoanut-trees grow. Sponges for guns have been made from the fiber, but they are not equal to sponges made of wool for this purpose, and are, moreover, liable to take fire.

COKE.—A fuel much used for melting iron in the foundry cupola, and obtained by the heating of coal in ovens, or other arrangements where little air is admitted. Caking coal is most suitable for the manufacture of coke. The process is conducted either (1) in heaps or ridges, or (2) in ovens. The coking in heaps is called the Meiler method, and consists in placing the coal in round stacks, or in long ridges, occasionally to the length of 200 feet. During the building of the coal, wooden stakes are driven in, which are afterwards taken out, and lighted coal introduced at numerous places at the same time. As the coal becomes heated, much smoke and vapor are evolved, which mainly consist of tar, water, and coal-gas. Whenever the smoke ceases to be evolved, the process of coking is regarded as concluded, and the mound or ridge of red-hot cinder, or coke, is covered over with fine coal-dust, which, excluding the air, extinguishes the combustion. At places where the operation of coking is conducted regularly on the large scale, it is customary to erect brick chimneys or columns, about the height of the proposed mound, and to build the coal round these, placing the larger masses in the center, the smaller pieces outside, and ultimately covering the whole with fine coal or dross.

A more economical plan of preparing coke is to introduce the coal into fire-brick ovens. The coal is introduced by the top, and being lighted, a little air is admitted by openings in front. Whenever the coal ceases to evolve smoky vapor, every opening is closed, and the oven is allowed to cool down for 12 to 24 hours. A door in front is then opened, and the coke being raked out whilst still hot, water is thrown upon it, to stop the combustion. Small coal may be used if it belongs to the caking kind; and a little water sprinkled over it causes the caking operation to proceed more completely. The proportion of coke obtained from coal in Great Britain ranges from 54 to 73 per cent, so that in round numbers the better class of coal for this purpose loses a fourth of its weight. At the same time the coal increases in volume to the extent of about one fourth. Coke is a hard, brittle, porous solid, with a color varying from iron-gray to blackish gray, and more or less of a metallic luster, and does not soil the fingers. It absorbs moisture from the air, sometimes to the extent of 30 per cent, and contains an amount of ash ranging from ½ up to 15 per cent. It gives off no smoke in burning, is of great value as a fuel, evolving a very large amount of heat.

The advantages of coke of the best quality (Connellsville coke) may be enumerated as follows: 1st. Coke will melt iron much more quickly than coal. 2d. Coke melts iron so much softer than any other fuel as to save very considerably on that alone, by making solid and perfect castings. 3d. One pound of coke will melt two to four pounds more iron than a pound of coal. 4th. Coke makes minimum quantity of slag. Furnace does not have to be "picked out" when coke is used. 5th. Coke requires much less blast. 6th. Coke contains the smallest percentage of sulphur and other impurities, and the highest percentage of fixed carbon. 7th. By melting the iron very soft and hot, it admits the use of much more scrap than with any other fuel. 8th. On account of saving in time, reduction of strain on blowers and power for blast, there is a consequent great saving in labor and other general expenses. 9th. A good, clean "drop" at end of heat, and furnace is left in good shape. See *Anthracite* and *Coal*.

COLD-BLAST.—Air forced into a smelting-furnace at a natural temperature, in contradistinction to a heated blast, which is more economical, but produces an inferior quality of iron.

COLD-SHORT.—A void or seam in a casting occasioned by the too-rapid congelation of the metal, which failed to fill the mold perfectly.

COLD-SHORT IRON.—Iron containing phosphorus, which may be forged and welded while hot, but is brittle when cold.

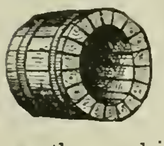
COLDSTREAM GUARDS.—A regiment in the Foot-guards or Household Brigade; it is the oldest corps in the British army except the First Foot. General Monk, in 1660, raised a corps at Coldstream, which was at first called "Monk's Regiment;" but when Parliament consented to give a brigade of guards to Charles II., this corps, under the name of Coldstream Guards, was included in it.

COLIC.—A complaint with which horses are not unfrequently attacked, caused by indigestion, constipation, spasm, strangury. The remedy for this complaint is thus explained: The attack will generally yield to the first or second dose of the usual colic-mixture, with injections of warm soap-and-water, and with a little spirits of turpentine in it; friction being used to the surface of the belly. If there is constipation, give a dose of the prescribed mixture, with a teaspoonful of ginger in it; if the pain continues and becomes more constant, bleed, taking from six to ten quarts of blood, continue the injections, and give a dram of opium every hour, blister the belly, clipping the hair off first. The cure for colic is powdered opium, 1 dram; ginger, powdered, 2 drams; allspice, powdered, 3 drams; caraway-seeds, powdered, 4 drams—made into a bolus.

COLICHEMARDE.—A variety of sword in great favor for dueling in the reign of Louis XIV. Its peculiarity is, that from the hilt the blade for some length is tolerably broad, then suddenly by a rectangular step, on each side, it becomes narrow, and terminates in a very sharp point. This conformation of the blade has the advantage of placing the center of gravity in the hilt, and consequently the weapon is remarkable for its lightness and convenience in the hand. This is sometimes called *Königsmark sword*, and the word *Colichemarde* is only a corruption of the word Königsmark.

COLISMARDE.—A long slender sword used in ancient times; a combat-sword. See *Colichemarde*.

COLLAR.—A device placed upon the chase of a gun to make its diameter equal to that of the body of the piece. This enables the gun to be rolled with facility. It is made of pieces of scantling jointed together after the manner of the staves of a cask, and hooped with stout bands of iron. It is shoved over the muzzle on to the chase, and is secured with wedges of wood.



COLLAR-MAKERS.—Artificers appointed for the repair of draught-harness. In the English artillery, on first appointment, they have the rank and clothing of Bombardiers, and reckon service, as such, without increase of pay. After five years' service, if Bombardiers, they have the rank and clothing of Corporals, and reckon service for pension, as such, without increase of pay. The four senior Collar-makers of each brigade are allowed the rank and clothing of a Sergeant, but without increase of pay.

COLLEGE OF ARMS.—A collegiate body, founded by Richard III. in 1483, consisting of the heraldic officers of England, who were assigned a habitation in the parish of All-hallows-the-Less, in London. Various charters confirmed the privileges of the College of Arms, and it was reincorporated by Philip and Mary, who bestowed on it Derby House, on whose site in Doctors' Commons the present College was built by Sir Christopher Wren. The presidency of the College is vested in the Earl Marshal, an office now hereditary in the family of Howard Duke of Norfolk; he nominates the three kings of arms, six heralds, and four pursuivants, who are the members of the collegiate chapter. Persons having a hereditary claim to arms, which has been disused for one or more generations, are empowered by the Heralds' College to resume them, on proof and registration of pedigree. A person who has no hereditary claim, and wishes a grant of arms, must memorialize the Earl Marshal, and show that he is in a condition to "sustain the rank of gentry." An important department of the College is the recording of pedigrees. Any pedigree showing the existing state or descent of a family may, if accompanied with sufficient evidence, be entered on the books of the College. The members of the College have salaries, but derive their principal income from fees charged for assistance in tracing pedigrees and titles, and for the granting and registration of arms. In Scotland the corresponding functions belong to the Lyon Court. See *Heraldry*.

COLLET.—In gunnery, that part of a cannon which is between the astragal and the muzzle.

COLLETIN.—The ancient name for that part of the armor which protected the neck and upper part of the breast. See *Armor*.

COLLIMATOR.—An instrument for laying guns and mortars, and especially adapted for laying them for night-firing. But the same appliance as is used by night could be made available by day, with the embrasures closed, thus protecting the gunners from the fire of the enemy.

COLLODIONIZED-PAPER PROCESS.—Paper being substituted for glass in this process, as a basis upon which to support the film, a great increase in portability is arrived at, as the sensitive sheets may be carried in a portfolio, and employed in the same manner as dry collodion plates. There are difficulties, however, in the way of its successful practice, which have prevented it from becoming as popular as it deserves to be. The following is a brief summary of the manipulations. Mr. Corbin, the inventor of the process, ascertained that a peculiar collodion was requisite, the formula of which is as follows: ether, 650 parts; alcohol, 350 parts; pyroxyline, 15 parts; iodine, 1¼ parts. The collodion so prepared is poured on the glass in the usual way, and sensitized in a bath containing only 1 per cent of nitrate silver and ½ per cent of nitric acid. The plate having remained in this bath about 2 minutes, is withdrawn, and freely washed with water; it is then immersed in a solution of 1 per cent of iodide of potassium, to insure the complete decomposition of the whole of the free nitrate of silver not removed by the washing. A piece of negative paper is now coated with a solution of gelatine, containing 6 parts gelatine to 100 parts water; the dimensions of the paper should be rather less than the glass, and the gelatinized side is brought into contact with the collodion film in a dish of water, any intervening water being expelled by passing a glass rod lightly over it. The edges of the collodion film which project beyond the paper are folded back on it, and the film and paper removed together. The now collodionized paper is laid, film uppermost, on a glass plate, coated with a preservative solution, composed of equal parts of albumen and honey, diluted sufficiently to enable it to flow freely over the paper. The film is lastly sensitized in a solution of nitrate of silver, 5 parts; glacial acetic acid, 5 parts; water, 100 parts; it is then freely washed as before in water, and hung up to dry. As it is apt to wrinkle in drying, it should be attached by all four corners to two lines, running one under the other. See *Photography*.

COLONEL.—The highest officer of a regiment; any grade above this converts him into a General Officer belonging to the army collectively, rather than to any one regiment. Before the reign of Elizabeth the chief officer of an English regiment was Captain, but in 1588 the title of Colonel had become familiar. In the British army at the present day, except in the Artillery and Engineers, the office of Regimental Colonel is a sinecure, the real active Commander of the Battalion being the Lieutenant Colonel. The Colonel receives higher pay and dignity. The Colonels are Generals who have had what is called a regiment "given to them" as a reward for long service, and virtually as a retirement. The pay, except in the Guards (where it is higher), is £1000 a year. The army estimates provide for about 150 regimental (otherwise called "honorary") Colonels of Cavalry and Infantry, and for about a sixth of that number Colonels Commandant in connection with the Artillery and Engineers. There is a frequent outcry against these appointments when viewed as sinecures, but looked upon as retirements for deserving old officers there is little that is objectionable in them. The rank of Colonel was above those which were purchasable. Apart from regimental rank there is the army or brevet rank of Colonel, through which all officers must pass on the way to General Officer. It is attained by specified service in certain positions as Lieutenant Colonel. In the Austrian, Prussian, and Russian armies, where the regiments are very large, the Coloneleies are mostly honorary posts, held by Emperors, Kings, Princes, and other distinguished persons. There is no material difference in the position of Colonel in the American as compared with the British army. The rank is between Lieutenant Colonel and Brigadier General, and the extent of command is usually a single regiment.

COLONEL COMMANDANT.—The Chief of a Brigade of Artillery, Engineers, or Marines, in the English service. This position is analogous to that of a Colonel of a Regiment, who receives what is termed the "Colonel's Allowance." In the early days of this rank in the Artillery, the connection of the Colonels Commandant with their battalions remained of the closest description. No officer was allowed to be promoted, under the rank of Field Officer, without a recommendation from the Colonel Commandant of the battalion in which he might be serving. Nor was any exchange allowed without the consent of both the Colonels Commandant concerned. Even nowadays, before an Adjutant is appointed to a Brigade of Artillery, the Colonel Commandant has to be consulted, and nominates the officer subject to the approval of the Commander-in-Chief.

COLONEL GENERAL.—An honorary title, or military rank, which is bestowed in foreign services. Thus, the Prince of the Peace in Spain was Colonel General of the Swiss Guards.

COLONIAL ALLOWANCE.—An allowance granted to British regiments in certain Colonies to meet the extra expenses of foreign service. The amount varies with the Colony; in some it is half as much more as the ordinary pay; in others it is more. The names of the Colonies at which a colonial allowance is granted are the Mauritius, Ceylon, Straits, China, West Indies, Africa, Cape of Good Hope. No such allowance is granted to regiments in Canada. Australia and New Zealand have no British troops.

The only advantage enjoyed by troops in the Mediterranean is the issue of "extra rations." Regiments in India receive Indian pay.

COLONIAL CORPS.—Certain regiments forming part of the regular army of the British Empire, and paid for out of the Imperial Revenues. They were never very fixed in number, varying with the circumstances of the Colonies in which they were located. The following were the names of the Corps, the numbers provided for in the army estimates for 1860-61, when these regiments were at their largest recent establishment, and the composition of each Corps, whether British or native:

Three West India regiments (afterwards raised to five)	3,420	Negro.
Newfoundland Veterans...	229	British.
Ceylon Rifles............	1,585	Native.
" Invalids..........	163	Native.
Cape Mounted Rifles......	1,084	Boers and natives.
Malta Fencibles..........	638	Native.
Canadian Rifles..........	1,106	British.
St. Helena Regiment......	433	"
Gold Coast Artillery......	351	Native.
Falkland Islands Company.	37	British.
African Artillerymen......	64	Native.
Hong Kong Gun Lascars..	88	"

These Corps, comprising about 95 companies, had somewhat over 1000 officers, commissioned and non-commissioned, and about the same number of horses. All the Corps were officered by British, except the Malta Fencibles. The Cape Mounted Rifles was a Mounted Infantry Corps.

As the Colonies obtained self-government, and the military theory of employing troops only in large bodies gained ground, it was considered as against Imperial Polity to maintain, out of the Imperial Revenue, Corps which were tied to one Colony, and not available for the general defense of the Empire. Accordingly the Colonial Corps have been gradually disbanded, and there survive only two West India regiments and the Malta Fencibles.

COLOR-BEARER.—The bearer of the colors. The Color-sergeants are the Regimental Color-bearers. See *Color-sergeant*.

COLORED FIRES.—The materials for colored fires should be as pure as can be obtained; those which crystallize should be procured in the crystalline state. They should be generally first dried, ground fine, weighed out and mixed. The composition is then moistened and pressed into shape. Some of the materials, such as the flowers of sulphur and lamp-black, ought to be first well washed in warm water. Antimony, glass, copper filings ought, as well as other materials, to be passed through sieve No. 1. All the materials should be perfectly dry. Those which contain water of crystallization, as the barium nitrate, strontium nitrate, and copper sulphate, should have it driven off. For this purpose, place the salt in a broad, shallow vessel in a water-bath, or on a moderate fire, and stir it till it be perfectly dry, taking it off the fire some minutes before. As the copper sulphate is easily decomposed in this operation, and as the sulphuric acid set free might occasion a spontaneous explosion when the copper sulphate was brought in contact with the chlorates, two parts of liquid ammonia are poured by degrees on the copper sulphate powdered and yet hot. (The ammonia neutralizes the acid, and, instead of injuring the color, it heightens it. The same process should be adopted with other decomposable salts.) A thick liquid of an indigo-blue color is obtained; place it on the fire, and warm it gently until it becomes a thick paste; then, leaving only a few coals under it, stir it with a spatula and crush it into a powder.

The materials are ground in a mortar with a pestle, or on a sieve with copper balls .4 inch in diameter, of equal weight with the composition to be ground. All the utensils should be kept perfectly clean. To pulverize antimony melt it and pour it into a cast-iron mortar previously warmed; when the metal is on the point of congealing stir it briskly with the pestle; it is thus reduced to fine grains, which are then pulverized with a pestle. Zinc and other similar metals are treated in the same way. To obtain shellac in the state of a fine powder, it is first broken into pieces and melted with its weight of niter. The mass is then ground as usual, and the powder thus obtained is washed in pure water till all the niter is removed. The resins and other substances insoluble in water and, difficult to pulverize in their pure state are treated in the same manner. All materials when pulverized should be passed through hair-sieve No. 1. They ought, if possible, to be sifted when warm, and placed away immediately in well-stoppered bottles to preserve them from moisture. The chlorates should be pulverized in a marble mortar with a hard-wood pestle. The mortar, pestle, and sieve should be used only for a single chlorate, and the whole operation be performed in a place apart to avoid accidents. The chlorate can be ground and manipulated by itself without danger; but when it is mixed with sulphur, charcoal, etc., it explodes very readily.

Each material should be weighed accurately by itself, according to the proportions laid down by authority. The materials, after being weighed out, are poured on a sheet of pasteboard, and mixed as well as possible with the hand; they are then passed three times through sieve No. 2, keeping the sieve stationary, and stirring the materials with the hand. If a chlorate enters into the composition, begin by mixing all the materials on a pasteboard, except the sulphur, charcoal, lamp-black, sugar, tallow, and shellac. When they are well mixed, add the combustible materials separately, mix them thoroughly, and then add the chlorate. Pass the composition three times through sieve No. 2, using a feather for the purpose. All these manipulations with compositions into which a chlorate enters should be performed in a place aside, and with a small quantity at a time. Compositions thus prepared should be preserved in well-stoppered bottles, carefully labeled. Those containing chlorates should be placed away from the rest, and apart from each other.

Compositions are dampened by pouring the pure or gummed liquid on them, a little at a time, and mixing it well with the hand or a wooden knife. Compositions should not be dampened until just before they are to be molded. All compositions may be firmly compressed, provided care be taken to avoid friction and blows with those containing chlorates. However great the care taken in the choice of materials, their proportions and manipulations, it is difficult always to get uniform results. It is necessary, therefore, to try the mixtures and modify the proportions as may be required. In every composition there are certain substances which are used to furnish oxygen for the consumption of the rest; the nitrates and chlorates are such. There are other substances, as sulphur, charcoal, and vegetable matters, which are burned; and others which are only used to give color to the flame, as antimony, lead, copper, strontia, etc. The same substances may furnish oxygen and color the flame at the same time. Certain materials are used only to heighten the color, as the mercuric chloride and the ammonium chloride; the action of the latter is weaker than that of the former.

When a composition burns too slowly, there is an excess of coloring matter, or of that which is to be burned, or some other substance (as water, for example), very rarely of that which furnishes oxygen. When the composition burns too fast, it is necessary to add coloring matter, or such substances as sugar, rosin, or tallow, which operate by separating the substances, supplying the oxygen from those which are burned, and at the same time keeping up the combustion. Generally, the quicker the combustion the more will the flame approach to whiteness, whatever may be the coloring principle; and the slower the combustion the more certainty there will be of obtaining the desired color. See *Compositions* and *Fire-works.*

COLOR-GUARD.—In each Infantry Battalion of the United States Army there is a Color-guard, composed of a Color-sergeant and seven Corporals, which is posted as the left four of the right center company. The front rank is composed of the Color-sergeant and three senior Corporals, one posted on his right and two on his left; the rear rank is composed of the four remaining Corporals. The Corporals are placed in the order of rank from right to left. The Color-sergeant and Color-corporals are selected from those most distinguished for bravery, and for precision under arms and in marching. The Color-sergeant carries the national color. The regimental color (when present) is carried by a Sergeant, who takes the place of the Corporal on the left of the Color-sergeant.

The colors, delivered by the Colonel into the hands of the Color-bearer, are escorted by the Color-guard to the Color-company, on its parade-ground; and in like manner are escorted back to the Colonel's quarters. The Color-guard, by command of the Color-sergeant, *presents arms* on receiving and on parting with the colors; in the latter case the Color-guard returns to the carry by command of the senior Color-corporal.

The Color-guard executes the *order arms, carry arms,* the *loadings* and *firings*. In rendering honors it executes the *present, reverse,* and *rest on arms*. On drill, in addition to the above, it executes *support* and *right shoulder arms*. It executes the other movements in the manual only when specially directed. The bayonets of the Color-guard are habitually carried in the scabbard.

COLOR-PARTY.—The two Officers, in the English service, who carry the colors of a regiment; as a rule, the two junior Lieutenants. Four Sergeants are also told off to assist, of whom one stands between the two Officers and three form a rear rank.

COLORS.—1. In Heraldry, the colors used are generally red, blue, black, green, and purple; which are called gules, azure, sable, vert or sinople, and purpure. Tenne or tawny, and sanguine or blood-color, sometimes occur, but they are not common. Yellow and white, again, are not colors in the heraldic sense, but metals; they are called or and argent, and are always represented by gold and silver. It is a fundamental and invariable rule in blazon not to put color upon color, or metal upon metal; thus, if the field be of a metal, the bearing must be of a color, and *vice versa*. The only exception is said to be the arms of Jerusalem, which were given to Godfrey of Bouillon, which are *argent, a cross potence or, between four crosslets of the same*. Apparent exceptions to this rule in common blazon are (1) abatements or marks of cadency or difference, labels, crescents, batons, and the like; and (2) extremities or adjuncts to animals, or other objects, such as tongues, claws, horns, etc.; but neither of these are regarded as independent bearings. Colors and metals, when engraved, are generally indicated by dots and lines: *or*, gold, by dots; *argent*, silver, is left plain; *gules*, red, is indicated by perpendicular lines from top to bottom; *azure*, blue, by horizontal lines from side to side; *sable*, black, by horizontal and perpendicular lines crossing each other; *vert*, by diagonal lines from right to left; *purpure*, by diagonal lines from left to right; *tenne*, by diagonal lines from left to right, crossed by horizontal lines; and *sanguine*, by lines crossing diagonally from left to right, and from right to left. See *Heraldry*.

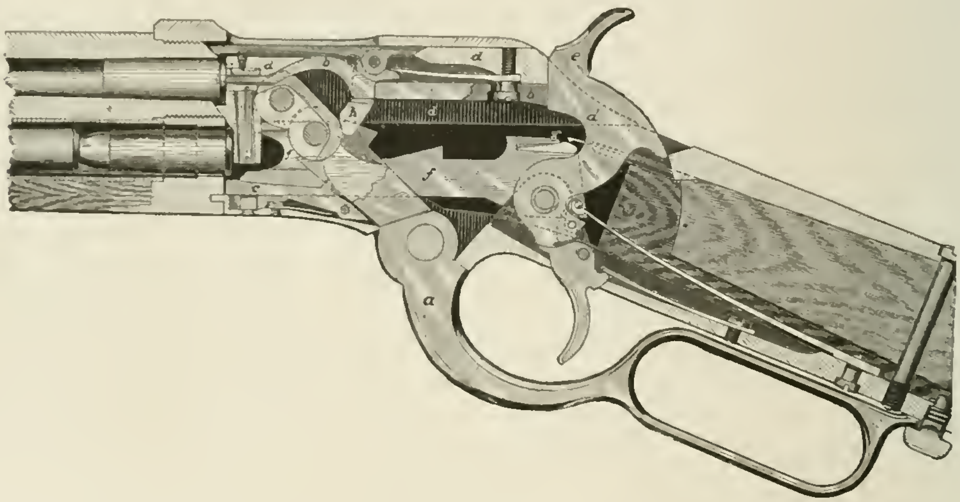
2. Certain kinds of flags carried with the army. Standards, banners, pennons, guidons, ensigns, and colors are military flags, each originally having a distinct meaning, now to some extent departed from. The ensigns were the original of those which are now called colors, and which especially belong to infantry regiments, in England. The colors are square flags, larger than the standards carried by the cavalry. In former times there was one for each company; but now there are generally two for a battalion, constituting "a pair of colors;" one of which is called the Royal or First, and the other the Regimental or Second. Both are about 6½ feet by 6, made of silk, with cords and tassels of crimson and gold, and fixed to a staff about 10 feet long. The Royal Color or Flag is nearly alike for all the regiments; with a blue ground, an imperial crown, the number of the regiment, and the union cross of St. George, St. Andrew, and St. Patrick. The Regimental Color depends for its tint on the facings of the uniform of the regiment; in its center is inscribed the number or designation of the regiment, with its crest and motto, if any; and around are the names of the victories and campaigns in which the corps has served. A subaltern officer carries the colors, and certain non-commissioned officers are set apart as a guard. The colors symbolize the good name and fame of the regiment, and are on that account protected in action with sedulous care; a victor always counts among his achievements the number of colors captured from the enemy. When a regiment obtains new colors, they are usually solemnly presented by some lady of distinction. The presentation is made with much military pomp, and the Chaplain of the Regiment reads a prayer prepared for the occasion. A member of the Heralds' College is "Inspector of Regimental Colors," the post being at present held by Garter-King-at-Arms. Besides the above, there are small camp-colors of the same tint as the facings of the regiment, to designate the part of the camp the corps occupies. Rifle regiments do not carry colors.

In the United States, each regiment of infantry and artillery has two colors, one national and one regimental. See *Artillery Colors, Camp Colors, Engineer Colors, Escort of the Color, Flags, Infantry Colors,* and *Standard*.

COLOR SALUTE.—The Color-bearer carries the heel of the color-lance supported at the right hip; the right hand grasps the staff at the height of the shoulder, to hold it steady. The Color-bearer salutes with the colors as follows: 1. Slip the right hand along the staff to the height of the eye; lower the staff by straightening the arm to its full extent, the heel of the lance remaining at the hip. 2. Bring back the lance to the habitual position.

COLOR-SERGEANT.—The Sergeant detailed to carry the Regimental Colors. He is usually selected for military deportment and soldierly bearing, and when carrying the colors is escorted by a guard of seven Corporals. In the British army the Color-sergeant is a non-commissioned officer of higher rank and better pay than the ordinary Sergeants. There is one to each company of infantry; and the office is specially given to meritorious soldiers. The Color-sergeant wears an honorary badge over the chevrons, and receives 2*s*. 5*d*. per day. He fulfills the ordinary regimental and company duties of Sergeant; but in addition to these, he attends the colors in the field, or in the front of a camp, or near headquarters in a garrison. A Color-sergeant may be degraded to the rank of Sergeant for misbehavior, but only by the decision of a Court-Martial.

COLT MAGAZINE-RIFLE.—A new rifle recently developed and perfected by the Colt Arms Company. The drawing shows the arm and its parts in the position that they will have immediately after the piece is fired. The action of the movable parts is as follows: The guard-lever, *a*, is set free and thrown forward by the right hand. The first part of this movement draws the firing-pin, *b*, from the head of the cartridge, and releases the magazine-gate, *c*, causing it to hold back and stop the cartridge which follows that which has already entered the carrier. As the movement of the guard progresses, the bolt, *d*, is drawn to the rear, ejecting the empty shell, cocking the hammer, *e*, and raising the carrier, *f*, so that when the movement forward is finished, the cartridge in the carrier is in line with the chamber of the rifle, and just in its rear. Reversing the movement of the guard-lever pushes the bolt forward, drives the cartridge into the chamber, and throws the carrier down into position, so that it receives another cartridge just as the reverse motion is completed. The bolt is brought clear forward, and the extractor hooked over the cartridge-head before the magazine-gate, *c*, is released, thus preventing the blocking of the breech-action. This feature is peculiar to this rifle. The firing-pin is held back positively until the cartridge has entered the chamber and the bolt is locked, preventing the possibility of premature explosion. The carrier has at its rear two notches, *g*, with a spring arranged to hold it in one of two positions. If the lever be brought forward, and the carrier be raised without a cartridge, the spring will drop into the forward notch of the carrier and hold it in position; then if a cartridge be dropped on the carrier from the top, a slight pressure on it will drop the carrier to the rear notch, leaving the cartridge in the proper position for entering the chamber by the action of the guard-lever. This arrangement enables the rifle to be used as a single breech-loader when the magazine is empty. The firing-pin lever, *h*, throws the firing-pin back by the first motion of the guard-lever, and holds it back until the completion of the loading. The ejector, *i*, throws out the empty shell as soon as it has been extracted from the chamber. The ejector works by the action of the V-spring contained in the lug of the bolt. There is a cleaning-rod in the stock of the rifle, which can be taken out by opening the cover in the butt-plate. See *Magazine-gun.*



Colt Magazine-rifle.

COLT REVOLVER.—This widely known revolver differs from others in the following points, viz.: The hand, or finger, or pawl which revolves the cylinder has two points, one above the other. The upper engages the ratchet of the cylinder when the revolution begins. But before the necessary sixth of a revolution could be made, as the pawl moves in a plane, and the ratchet-tooth in the arc of a circle whose plane is quite perpendicular to the pawl's plane of motion, the pawl would lose its hold on the tooth, and the revolution of the cylinder would stop. To prevent this the second point is added, and just as the first point will disengage from the ratchet, the second or lower point engages another tooth of the ratchet and completes the revolution. By this arrangement the pawl actuates a larger ratchet than it could otherwise, and therefore exerts more force upon the cylinder, by acting upon a longer lever-arm. This permits a smaller-sized cylinder for the same diameter of ratchet. The cylinder has a bushing which projects in front of it, and gives three surfaces upon which the cylinder revolves, thus diminishing the chance of sticking from dirt or rust, and also giving a very small axis upon which to revolve, decreasing the moment of friction. When the ejector is used it springs back to its place and is ready for use again, avoiding the necessity of putting it back.

To take the arm apart, half-cock the pistol, loosen the catch-screw which holds the center-pin, draw out the center-pin, open the gate, and the cylinder can then be withdrawn. To remove the ejector, turn out the ejector tube-screw, then push the front end away from the barrel and pull it towards the muzzle. The barrel can then be unscrewed. The stock can be removed by turning out the two screws just behind the hammer, and that at the bottom of the strap. All the parts of the lock are then displayed, and can be readily separated. The cylinder bushing should be pushed out for cleaning. To remove the gate, turn out a screw in the lower side of the frame (hidden by the trigger-guard), then the gate-spring and catch can gate, cock and fire it (taking it in the right hand), or bring the hammer to the safety-notch as may be desired. *To Eject the Cartridge-shells.*—1st motion: Holding the pistol in the left hand, half-cock with the right

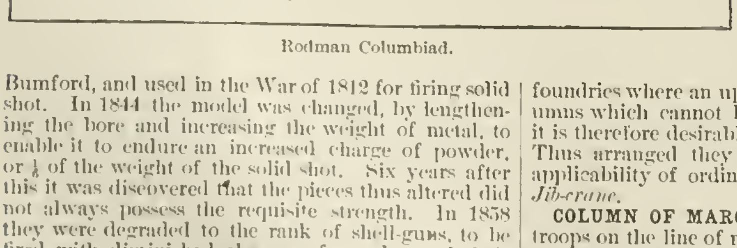
be withdrawn, and the gate can be pushed out. The best sperm-oil should be used for oiling the parts. *To Load the Pistol.*—1st motion: Holding the pistol in the left hand, muzzle downwards, half-cock it with the right hand and open the gate. 2d motion: Insert the cartridges in succession with the right hand, close the hand and open the gate. 2d motion: Eject the shells in succession with the ejector pushed by the right hand, moving the cylinder with the thumb and forefinger of the left hand. When the shells have been ejected, the pistol is ready for the 2d motion of loading. There are three notches in the hammer of this pistol.

The first is the safety-notch, the second is the half-cock-notch, and the third is the cock-notch. The pistol cannot be fired when the hammer rests in the safety-notch or half-cock-notch, and can be fired by pulling the trigger when the hammer rests in the cock-notch. The pistol should be carried habitually with the hammer resting in the safety-notch.

The drawings are vertical projections of this arm (one-half size). Fig. 2 shows the arrangement of the working parts, and is referred to in the nomenclature. The two back-strap screws just behind the hammer, the stock, the long-guard screw, gate, gate-catch screw, gate-spring, and gate-catch are not shown in Fig. 2. The gate is shown in Fig. 1. The operation of the parts is very simple. As the hammer is cocked, the hand, which is pivoted to its lower portion, rises and engages the ratchet on the base of the cylinder, and causes it to revolve. The lower point or finger of the hand engages with one of the teeth of the ratchet just as the revolution of the cylinder has carried away the preceding tooth from the upper finger of the hand. This completes and insures the revolution by increasing the effective leverage of the hand. The bolt M engages the stop-notches in the surface of the cylinder, to prevent the momentum of the cylinder from carrying it past the firing-point. It is caused to disengage from them by the action of the hammer-cam K, which, rising during the cocking of the hammer, presses up the rear end of the bolt and liberates its front end from the notch. When the revolution is about complete the beveled lower surface of the hammer-cam comes opposite the point of contact on the bolt. At this moment the tail of the bolt (being slit so as to have a lateral spring, and the head being pressed upward by the flat spring U) slides down over the inclined surface of the cam, and the head engages with the stop-notch in the cylinder. The spring U is slit and bent so as to act upon both the bolt and the trigger. The bushing around the base-pin is useful by affording another surface for the revolution of the cylinder, and thereby diminishes the chances of sticking from dirt or rust. Both the cylinder and bushing may revolve on the base-pin, which in turn may revolve in its own bearings.

COLUMBIADS.—A species of sea-coast cannon which combine certain qualities of the gun, howitzer, and mortar; in other words, they are long, chambered pieces, capable of projecting solid shot and shells, with heavy charges of powder, at high angles of elevation, and are, therefore, equally suited to the defense of narrow channels and distant roadsteads. The columbiad was invented by the late Colonel Bumford, and used in the War of 1812 for firing solid shot. In 1844 the model was changed, by lengthening the bore and increasing the weight of metal, to enable it to endure an increased charge of powder, or ⅙ of the weight of the solid shot. Six years after this it was discovered that the pieces thus altered did not always possess the requisite strength. In 1858 they were degraded to the rank of shell-guns, to be fired with diminished charges of powder, and their places supplied with pieces of improved model. The changes made in forming the new model consisted in giving greater thickness of metal in the prolongation of the axis of the bore, which was done by diminishing the length of the bore itself; in substituting a hemispherical bottom to the bore, and removing the cylindrical chamber; in removing the swell of the muzzle and base-ring; and in rounding off the corner of the breech. From the fact that all the trial-pieces have successfully endured very severe tests, it is to be inferred that the defects of the previous model arose from the presence of a cylindrical chamber, and a deficiency of metal in the prolongation of the bore. In 1860 the model proposed by Captain Rodman was adopted for all sea-coast cannon. This model is shown in the drawing; it does not differ, however, in its essential particulars from the model of 1858. See *Sea-coast Artillery*.



Rodman Columbiad.

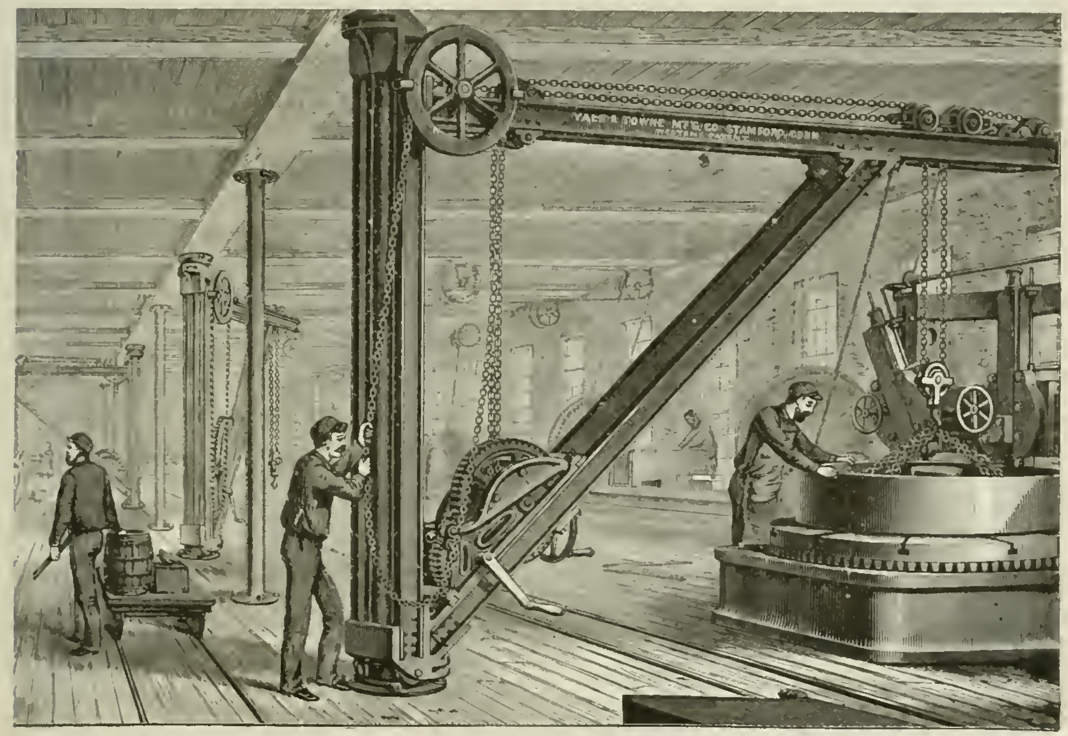
COLUMN.—In military evolutions, a mass of soldiers several ranks in depth, presenting a formation different from that which arises from spreading them out *in line*. There may be columns of brigades, of regiments, of battalions, or of companies; presenting a front of limited width, but a depth depending on the number of elements in the column. If a battalion consists of ten companies, then a "battalion in column" has all the companies posted one behind another. According to the density of the column it is called *open* or *close*. In a battalion, when the distance between any one company and the one immediately before it is such as to admit of their wheeling into line, the formation is called *open column;* when the distance between the front rank of one company and the rear rank of the one before it is only a few yards, it is *close column;* when intermediate between these two, it is *half-distance column*. The relative advantages of column and *line*, in drawing up troops for action, are among the matters closely studied by the commanders of armies: the French, as a general rule, have rather favored the formation in column; the English, that in line. Sometimes the name *column* is given to that which, in effect, is a small army.

COLUMN-CRANE.—Essentially a jib-crane arranged to revolve around a fixed center-column within the mast, the column being utilized for supporting the floor above. This type of crane is built of any desired capacity from 1 ton to 10 tons, although for capacities above 5 tons it is best if possible to arrange the cranes independently of the supporting columns. As seen in the engraving on the opposite page, the mast consists of two wrought-iron channel-beams securely fitted to heavy castings at top and bottom, each of which latter contains horizontal rollers, traveling upon turned paths on the center column, the lower or foot casting being provided also with vertical rollers, traveling upon a circular path around the foot of the column. The vertical rollers carry the weight of the crane and load, while the horizontal thrust at top and bottom is received upon the horizontal rollers. Thus arranged, the rotation of the crane is as smooth and easy as that of a crane turning upon pintles in the usual way. All of the other details of this crane are similar to those of the jib-crane.

This type of crane is designed especially for use in foundries where an upper floor is supported upon columns which cannot be removed, and around which it is therefore desirable that the cranes should rotate. Thus arranged they have all the convenience and applicability of ordinary jib-cranes. See *Cranes* and *Jib-crane*.

COLUMN OF MARCH.—A formation assumed by troops on the line of march, which is governed partly by tactical considerations, partly by arrangements for supply, etc. This formation consists first of an advanced-guard, which is purely *tactical*. At the head of the column, or with the advanced-guard, come the sappers to clear the roads, to repair bridges, and generally to facilitate the march of the column. Next comes the first brigade of infantry, with intrenching tools, for throwing up covering works, if needed. Its ambulance-wagons are kept in the rear, or should be so, and are not allowed to be under fire. All transport of sick from the field of battle should be carried out by stretchers. The position of artillery with such a force should be regulated by tactical considerations. If not required it should be in rear of the infantry, but if wanted should be in rear of the first battalion, or first brigade, sometimes between brigades. Artillery, if between infantry, must conform *exactly* to the pace of infantry, which is very fatiguing and trying to the horses; if in rear, they can make longer halts and vary pace. Mounted corps, when practicable, should march at later hours than dismounted men; if the column comes unexpectedly on the enemy, it is easier to trot artillery past infantry than to hurry up infantry past artillery. The same principles which are applied to artillery may be also to cavalry, and such of it as is not with the advanced-guard is generally in rear of all the force. It is desirable, if not imperative, that artillery and cavalry should not have to conform to infantry pace. See *Marches*.

COLUMN-SHAPER.—A machine much used in armories for die-work, and in a large proportion of cases a substitute for the more expensive shaping-machine. It is employed in various sizes for different work. The 6-inch machine has a stroke 6 inches, adjustable to any less distance; traverse of table 8 inches. Cutter-slide has a quick return, and the cross-feed is automatic and adjustable. The vertical adjustment of the table is 3 inches, and the extreme distance between the top of the table and the under side of the cutter slide is 6 inches. A hand-wheel attached to the cone-shaft permits the machine to be run by hand in an emergency. Weight, including vise and countershaft, 600 pounds. Speed of countershaft, having 8 by 2¼ inches tight and loose pulleys, 180 revolutions per minute.



Column-crane.

The 10-inch machine stands on a hollow column, the base of which measures 36 by 27 inches. The stroke may be graduated to any point within its extreme limit. The cutter slide has a quick return, and the cross-feed is automatic and adjustable. Extreme length of stroke, 10 inches; traverse of table, 16 inches; distance between table-top and bottom of slide, 11½ inches. Weight, including countershaft and vise, 1750 pounds. Speed of countershaft, having 12 by 3 inches tight and loose pulleys, 120 revolutions per minute.

The 24-inch machine designed for very heavy work, by the Pond Machine Tool Company, United States, has a stroke of 24 inches, automatic cross-feed of 21 inches. The table can be lowered to admit of a piece being planed 16 inches high. This table is provided with an angle-plate on one side, with a V-shaped slot to admit of a round piece being planed upon its end. Has a quick return on the back stroke, and a cone-pulley with two changes for cast-iron or steel. Weight, 2000 pounds. Speed of countershaft, 150 revolutions a minute. See *Shaping-machine*.

COMBAT.—An engagement of no great importance or magnitude, or one in which the parties engaged are not armies. See *Single Combat*.

COMBINED MARCHES.—When the movements of divisions and corps are made independent of each other, but having the same object in common, they are known as *combined marches*. They are arranged with the intention of having the several columns arrive at a given position, but coming from different directions. It would be a great risk to select the point of concentration within an area controlled by the enemy, and a plan made with this intention would be faulty. Each column, until it came within supporting distance of the others, would be a detached force and exposed to the dangers of being overwhelmed before support could reach it. Military writers, as a rule, condemn the independent action of detachmets, either to effect a diversion or make a combined march. See *Concentration-marches* and *Marches*.

COMBINED METALS.—The term "built-up" is applied to those cannon in which the principal parts are formed separately and then united together in a peculiar manner. The object of this mode of manufacture is to correct the defects of one material by introducing another of opposite qualities. As for instance: trials have been made to increase the hardness, and therefore endurance, of bronze cannon, by casting them around a core of steel, which formed the surface of the bore. Built-up cannon are not necessarily composed of more than one kind of metal; some of the most noted are made of steel, or wrought-iron alone. In this case, the defects which we have seen to accompany the working of large masses of wrought-iron, viz., crystalline structure, false welds, cracks, etc., are obviated, by first forming them in small masses, as rings, tubes, etc., of good quality, and then uniting them separately. The mode of uniting a built gun may be by welding the parts, by shrinking or forcing one over the other, or by screwing them together. It has been shown by Barlow's law that all parts of the sides of a cannon are not strained equally and are therefore not brought to the breaking point at the same time. Any arrangement of the parts by which the explosive strain is distributed equally over the entire thickness of the piece necessarily brings a greater amount of resistance into play to prevent rupture.

There are two general plans for accomplishing this, viz.: First, by producing a strain of compression on the metal nearest the surface of the bore. This is termed an "initial strain," and is brought about by shrinking heated bands or tubes around the part to be compressed, or by slipping a tube into the bore, which has been slightly enlarged by heat. In either case it is apparent that the extent of the strain depends on the relative size of the fitting surfaces and the amount of heat used to produce expansion. Owing to the difficulty of regulating the heat, it is preferred by some to force the parts together by hydraulic pressure after they have been carefully bored and turned to the proper size. The second plan is based on "varying elasticity," and is accomplished by placing that metal which stretches most within its elastic limit around the surface of the bore, so that by its enlargement the explosive strain is transmitted to the outer parts. By the selection of suitable materials and their proper management, both of these plans may be combined in the same gun, and thereby give it increased strength. See *Cannon-metals.*

COMBLAIN RIFLE.—A breech-loading arm resembling the Sharp rifle. The mountings, receiver, and breech-block of this arm are made of phosphorus-bronze; the barrel is made of steel. The militia of Belgium are armed with the Comblain rifle, while the regular troops have the Albini-Brändlin gun, which has a breech-block operating like that of the Springfield rifle. See *Albini-Brändlin Gun* and *Small-arms.*

COMBUSTION.—The term applied to the process of burning, which usually consists in the oxygen of the air uniting with the constituents of the combustible substance. Thus, the combustion of coal is due to the oxygen of the air passing into a state of chemical union with the carbon and the hydrogen of the coal, forming carbonic acid (CO_2) and water-vapor (HO). Such chemical combinations are always accompanied by the production of more or less heat, as in the case of decaying wood and other vegetable matter; but it is only when the action is so rapid as to evolve intense heat accompanied by light that the process is called burning or combustion. Though the gaseous oxygen has as much to do with the process as the more solid material, coal, wood, paper, or cloth, yet the latter is alone styled the *combustible* or *burning body*, whilst the oxygen is invariably named the *supporter* of combustion. A few substances burn at ordinary temperatures, such as phosphorus, which glows when exposed to the air; but the generality of substances, such as wood, coal, etc., require to be raised in temperature or be set fire to before they possess the power of combining with the oxygen of the air. The amount of heat given out by the various combustibles when burned is capable of being measured, and is definite. The same weight of the same combustible invariably evolves the same amount of heat during its complete combustion; but different combustible substances give off different amounts of heat. The mode in which the heat evolved may be measured is either; (1) to observe the quantity of ice which a given weight of the combustible will melt when burning; (2) to notice the weight of water which the combustible will convert into steam; or (3) to estimate the number of pounds of water which the burning body will raise from 32° to 212° F. The last plan is the more easily managed and accurate. The amount of heat evolved appears, however, to be proportional to the quantity of oxygen required to burn the various combustibles. Thus, when a similar volume of oxygen gas, or even ordinary air, is allowed to flow against the various combustible substances, the following results are obtained:

One pound of Oxygen combined with	Raises from 32 to 212 degrees F.
Hydrogen	29½ lbs. of water.
Charcoal	29 "
Ether	28 "
Alcohol	28½ "

While the absolute amount of heat evolved during the combustion of any burning body is the same, yet the sensible heat may vary according to the rapidity of the process. Thus, when phosphorus is exposed to the air at ordinary temperatures, it very slowly combines with oxygen, and gives out little heat at any one moment, but it is diffused over a great length of time; whilst if the phosphorus is set fire to in the air, it burns vividly, and gives out much heat and light for a short time; and still further, if the burning phosphorus be placed in pure oxygen, it enters into most vivid combustion, and evolves a most intense heat and brilliant light for a still shorter time. In the latter instances, the heat evolved at any one moment is greater, because more rapid, than that given off at the same time during the slower process of combustion; but when allowed to proceed to a termination, there is as much heat produced during the whole time occupied in its development. The same remark applies to the coal placed in a furnace. So long as the door of a furnace is open, and there is little draught of air through the fuel, a moderate amount of heat is evolved, which may last for several hours; but when the door is shut, and much air is drawn through the coal, the latter is more quickly burned, and more heat is evolved during a shorter period of time than before, but in the long-run there is the same amount of heat evolved.

Temperature and atmospheric pressure considerably influence the products obtained from burning gunpowder. When exposed in the open air to a temperature gradually increasing to 572 degrees Fahrenheit, the sulphur sublimes, taking with it a portion of the carbon. This was shown by Saluces, who passed the volatilized products through a screen of very fine cloth, and found carbon deposited on it. Powder may be, therefore, completely decomposed by a gradual heat, without explosion; but when suddenly brought in contact with an ignited body, the temperature of which is at least 572 degrees Fahrenheit, the sulphur has not time to sublime before explosion takes place. The proportions for war-powder for the United States service are seventy-six parts of niter, ten of sulphur, and fourteen of carbon. By the atomic theory the proportions should be 74.64 niter, 11.85 sulphur, 13.51 carbon. If we adopt these last proportions, the formula for gunpowder becomes

$$(NO_5 + KO) + S + 3C.$$

If we suppose the ingredients to be pure, and to arrange themselves under the influence of heat according to their strongest affinities, there will result one equivalent of nitrogen, three of carbonic acid, and one of sulphide of potassium, for

$$(NO_5 + KO) + S + 3C = N + 3CO_2 + SK.$$

The products are, therefore, either solid or gaseous. Usually, powder contains a slight quantity of moisture; the ingredients are not absolutely pure, nor are they proportioned strictly according to their combining equivalents; it might be expected, therefore, that the actual would differ from the theoretical results. The actual gaseous products obtained by combustion are principally *nitrogen* and *carbonic acid*, sometimes *carbonic oxide*, a little *sulphuretted hydrogen*, *carburetted hydrogen*, and *nitrous oxide*. The solid products are *sulphide of potassium*, *sulphate of potassa*, *carbonate of potassa* (mingled with a little *carbon*), and traces of *sulphur*. When the sulphide of potassium comes in contact with the air, it is converted into sulphate of potassa, and gives rise to the white smoke which follows the explosion of gunpowder. A portion of the sulphide is sometimes condensed on the surface of the projectile, which accounts for the red appearance of shells sometimes observed in mortar-firing. The solid products are probably volatilized at the moment of explosion by the high temperature which accompanies the combustion; but, coming in contact with bodies of much lower temperature, they are immediately condensed. In chambered arms,

Density of products of combustion	No. of volumes of expansion.	Total Work that the Gunpowder is capable of Realizing.	
		Per kilogramme burned, in kilogrammeters.	Per pound burned, in foot-tons.
.95	1.0526	3210.8	4.70

small drops of sulphur may be observed condensed on the sides of the bore, which show that the sulphur has been volatilized; and we know that good powder burns on paper and leaves no trace. This fact, however, was most completely shown by the experiments of Count Rumford. This celebrated observer used a small eprouvette of great strength, which he partially filled with powder, and hermetically closed with a heavy weight. The powder was fired by heating a portion of the eprouvette to redness. Whenever the force was sufficient to raise the weight, the entire products escaped; when it was not, a solid substance was found condensed on the surface of the bore furthest from the source of heat.

The late researches of Captain Noble and Mr. Abel on fired gunpowder have resulted in certain important conclusions. From them it appears that the permanent products of fired gunpowder are only 43 per cent of gas and 57 per cent of matter, which ultimately assumes a solid form. The temperature of the explosion is about 4000 degrees Fahrenheit, and though much of the heat is spent in performing the work of moving the shot or conducted away by the metal, so that the expanded gases would contract and lose a great deal of their power, the matter which will ultimately be solid but is at the moment of explosion fluid, by reason of the great heat, gives up much of its heat when coming to the solid form, and thus keeps up the temperature of the gases, causing them to retain their high expansion. These gases, if allowed to cool down to a freezing temperature, would occupy about 280 times the bulk of the powder they sprang from. The tension of the products of combustion, when the powder entirely fills the space in which it is fired, is about 6400 atmospheres, or about 42 tons per square inch. Therefore, if no air-space be left and the shot be delayed until the powder is entirely consumed, there will be a pressure everywhere within the powder-chamber of 42 tons in each square inch of the interior. From the results of their experiments they formed the foregoing table, which shows the greatest amount of work in projecting a shot that can be obtained per pound of powder from a charge in any gun. When the charge is fired, it begins to push the shot forward. If the gun is very short, so that the shot can escape from the pressure at once, the velocity given to it will be small. Thus, within practical limits, the longer a projectile is kept under the influence of the fired charge, the greater will be the velocity. This subject will be further considered under other headings. See *Explosion*, *Gunpowder*, and *Velocity of Combustion*.

COMES.—An officer among the Romans, with territorial jurisdiction in the provinces, and especially on the frontiers.

COMIGNE.—A shell of extreme magnitude, which takes its name from the person who originally invented it.

COMMAND.—1. A body of troops, or any military force or post, under the command of an officer.

2. The height of the interior crest above the site is the *command* of the work. The term is also used to express the height of the interior crest of one work above that of another, or above any particular point within range.

3. An officer may be said to command at a separate post when he is out of the reach of the orders of the Commander-in-Chief, or of a Superior Officer, in command of the neighborhood. He must then issue the necessary orders to the troops under his command, it being impossible to receive them from a Superior Officer. If, upon marches, guards, or in quarters, different corps of the army happen to join or do duty together, the officer highest in rank of the Line of the army, Marine Corps, or Militia, by commission, there on duty or in quarters, commands the whole, and gives orders for what is needful to the service, unless otherwise specially directed by the President, according to the nature of the case. In all matters relating to the rank, duties, and rights of officers, the same rules and regulations apply to officers of the regular army and to volunteers commissioned in or mustered into said service, under the laws of the United States, for a limited period. Officers of the militia of the several States, when called into the service of the United States, shall on all detachments, Courts-Martial, and other duty wherein they may be employed in conjunction with the regular or volunteer forces of the United States, take rank next after all officers of the like grade in said regular or volunteer forces, notwithstanding the commissions of such militia officers may be older than the commissions of the said officers of the regular or volunteer forces of the United States. The Acts of Congress giving rank to officers of the Medical and Pay Departments of the army provide that they shall not, in virtue of such rank, be entitled to command in the Line or other Staff Departments of the army; and so, if any other legal restrictions on rank exist, they must be found in some

positive statute. This necessity is made plain by the consideration that *military rank means a range of military subordination.* Higher rank, therefore, created by law cannot be made subordinate to lower rank, except by positive law; or, in other words, a junior cannot command a senior, unless the law shall otherwise decree. The 122d Article of War is ambiguous, from the use of the words "Line of the Army;" our legislation having applied those words to contradistinguish Regular Troops from Militia, and also, in many cases, the same words are correlative and contradistinctive of Staff of the Army. "But," says President Fillmore, after a careful examination on his part, to determine the question, "I find but one Act of Congress in which the words 'Line of the Army' have been employed to designate the Regular Army in contradistinction to the Militia, and none in which they have manifestly been used as contradistinctive of brevet." Whatever ambiguity, therefore, may exist under the 122d Article, in respect to the right of command on the part of officers of Staff Corps and Departments, the article does not decree any restriction on brevet rank; and hence the great principle that rank on duty confers military command has its full force in respect to commissions by brevet, and all other commissions not restricted by law. The President, as Commander-in-Chief under the 122d Article of War, may relieve any officer from duty with a particular command, or he may assign some officer of superior rank to duty with a command; but the laws have not authorized him to place a junior in command of a senior, and that power which creates rank, viz., Congress, is alone authorized to place restrictions on its meaning. See *Rank*.

COMMANDANT.—In military matters, a temporary Commander, in place of the real Chief; such as a Captain Commandant, Lieutenant Commandant, etc. In foreign armies the designation is more frequently applied than in the British, especially to the Commanders of Garrisons.

COMMANDANT OF CADETS.—The Commandant of Cadets, appointed by the President, has the immediate command of the battalion of Cadets at the U. S. Military Academy. He is also the Instructor in the Tactics of the three arms of the service, and in the rules of Military Police, Discipline, and Administration. For instruction in infantry tactics and military police and discipline the Cadets are organized into a battalion of four companies, under the Commandant of Cadets, and assigned to quarters accordingly; each company being under the command of an officer of the army, designated as Assistant Instructor of Tactics. The officers and non-commissioned officers are appointed by the Superintendent, from a list submitted by the Commandant of Cadets. This selection is made from those Cadets who have been most studious, soldier-like in the performance of their duties, and most exemplary in their general deportment. In general, the Officers are taken from the first class, the Sergeants from the first and second classes, and the Corporals from the second and third classes. The Commandant of Cadets is charged with the command of the battalion, and with the instruction of Cadets in all the rules of military police, discipline, and administration. He is assisted in these duties by the four Assistant Instructors of Tactics, who are quartered in the Cadet Barracks during the academic year. During the encampment the Commandant and these four Assistants are quartered in camp.

COMMANDER-IN-CHIEF.—The President, by the Constitution, is "Commander-in-Chief of the army and navy of the United States, and of the militia of the several States, when called into the actual service of the United States." Under the same authority he nominates, and by and with the advice and consent of the Senate appoints, and commissions all commissioned officers of the regular army. In the British army the Commander-in-Chief is the highest Staff appointment. It is held by the General commanding all the forces in India, and would probably be given to the leader of any *large* army in the field, whether abroad or at home. Formerly the army at home was administered by an officer of this rank; but since the death of the Duke of Wellington, in 1852, the military administration has vested in an officer holding no higher commission than that of "General on the Staff;" who is called the General (or Field-Marshal, according to the holder's army rank) Commanding-in-Chief. Since 1855 this officer has been strictly subordinate to the Secretary of State for War. The office of the Commander-in-Chief, technically known as the "Horse-guards," is a Department of the War Office, and comprises the sub-departments of the Military Secretary, the Adjutant General, and the Quartermaster General, with a staff of clerks. Under the "War-Office Act" of 1870, and by Orders in Council of that year, the officer Commanding-in-Chief is one of the three great officers who administer the military affairs of the country under the Secretary of State for War; his department being that of military command, discipline, and promotion. In practice he makes all promotions and military appointments, though in theory these are all made on the responsibility of the Secretary of State. Appointments to very important positions on the Staff would not be made without the supervision of the Minister and probable concurrence of the Cabinet. The officer Commanding-in-Chief is responsible for all recruiting operations, and for the appropriation of troops to particular localities; but he exercises rather a general inspectional control than any immediate command over the men. The actual command vests in the General Officers commanding the districts into which the Kingdom is parceled.

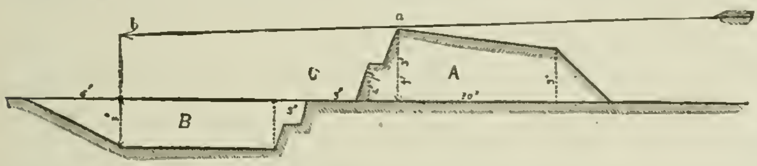
COMMANDER-IN-CHIEF'S DEPARTMENT.—A department of the British army which consists of the Adjutant General and Quartermaster General, nominally amalgamated, but working apart. The following branches, at the Horse-guards, are called divisions, and are thus told off: Military Secretary; Intelligence; Auxiliary Forces; Military Education. Adjutant General and Quartermaster General are ordinary combatants, to whom are intrusted respectively the departments of—Adjutant-General: Recruiting, Discharges, Discipline, Inspections. Quartermaster General: Returns, Movement of Troops, Intelligence. To the Military Secretary's Department are intrusted First Appointments, Promotion, Rewards, Staff Appointments, and Exchanges. The above is the distribution of the Staff at the Horse-guards, and these divisions are adhered to in the smaller fractions as closely as possible.

COMMANDERY.—The title of the meeting or meeting-place of Freemasons who have reached the degree of Knights Templar. Its origin was with the Knights of Malta of the Middle Ages, and was first applied to sums saved from the revenues of the Order for the support of war against the Moslems. It soon came to mean persons and places rather than things, and the "Grand Commander" became the next office to the Grand Master. Among the religious establishments suppressed in England by Henry VIII. were more than fifty Commanderies of Knights Templars.

COMMAND OF FIRE.—An expression for the difference of command of two works situated on the same horizontal ground.

COMMAND OF OBSERVATION.—When the command of the parapet is only sufficient to permit the defenders of a work to look over the parapet of another work it is named *command of observation.*

COMMAND OF PARAPET.—In horizontal sites the parade may be taken either on the natural surface or below it. In inclosed works it should always be on the natural surface to keep the parade dry. In lines, particularly if of great extent and thrown up merely to receive battle or for a short occupancy, the parade may consist of a shallow trench behind the parapet which is formed of the earth taken from the trench. The general form of the parapet is the same in both cases. Its dimensions will vary with the kind of soil used in its construction; with the time and means that can be employed; with the time that the work is to remain occupied; and, finally, with the time and means that the enemy can dispose of in the attack, and the degree of resistance that the work should offer. The command of the interior crest should be so regulated as to intercept the enemy's missiles and to shelter the assailed. Men of the greatest ordinary stature, in bringing their muskets to an aim, do not fire at a higher level than about five feet; therefore any mass of this height in front of them will just intercept their fire; but this mass would not shelter a man standing behind it; to effect this, in the case of the tallest men usually found in the ranks, the interior crest should be at least six feet six inches above the terre-plein. The command must then be regulated by these two facts, and this principle may be laid down: *The command of a field-work over the ground occupied by the assailant should be at least five feet; and six feet six inches over that occupied by the assailed.* In following this rule for the command, we deprive the assailant of a *plunging* fire upon the parade; but as a breast-height of five feet is too high for men of ordinary stature to fire over it and give their pieces any sensible depression, it would be necessary to throw up a banquette for this purpose behind the parapet, which would add to the time and labor of constructing the work. On this account it is best to give the parapet only the height to admit effective firing over it, which is about four and a quarter feet. In the drawing, which represents a profile of this height, the plunge of a man standing



A, Parapet; B, Trench; C, Banquette-tread.

at sixty feet in advance of the parapet would be only three inches below the level of the point *a*, at the point *b*, or his bullet would strike seven feet above the point at the rear of the parade, which is the most exposed position for a man to be standing. See *Field-fortification*.

COMMANDS.—There are two kinds of commands in the military service: the *preparatory command*, such as *forward*, which indicates the movement that is to be executed, and the command of *execution*, such as *march* or *halt*, or, in the Manual of Arms, the part of the command which causes the execution. The tone of command is animated, distinct, and of a loudness proportioned to the number of men under instruction. Each preparatory command is pronounced in an ascending tone of voice, but always in such a manner that the command of execution may be more energetic and elevated. On foot the command of execution is pronounced in a tone firm and brief. In mounted movements the preparatory commands are more or less prolonged to insure their being heard; the command of execution is always prolonged. The trumpet is used for giving commands whenever it can be done to advantage.

COMMILITONES.—A word having the same significance with the Romans as the English term *comrade-soldiers*.

COMMISSARIAT.—A name given to the organized system whereby armies are provided with food and daily necessaries other than those connected with actual warfare. Among the ancients the Romans devoted the most attention to the Commissariat; the *Quæstors* were the Commissaries. In feudal times the soldiers were mainly dependent for food on their lords; but they lived very much by plunder. During the wars of the Crusades the Commissariat was so utterly neglected that thousands died of starvation. In England the first germ of the modern Commissariat appeared in the office of *Proviant-master*, in the time of Queen Elizabeth. Under Charles I., Commissaries were stationed in the different Counties. Under Marlborough's command the troops were supplied by contract; he received a percentage, and peculation was very common. After many changes during the eighteenth century a Commissary General was appointed in 1793, to superintend all contracts for food and forage. The dire experience of the Crimean War showed how greatly reform was required in this important Department. In 1858 and 1859, accordingly, it was newly organized; and remained until 1870 a War-Office Department, under a Commissary General-in-Chief. In 1870 the Commissariat was merged with other supply departments in the great "Control Department," which, under the Surveyor General of the Ordnance, performed all the civil administrative duties of the army. In December, 1875, the Control Department fell from its high estate, and the "Commissariat and Transport Department" arose from its ashes. Its duties are the provision of food, fuel, lodging, and transport: a function on which it is needless to say the very existence of the army depends. The Department is administered by the Director of Supplies at the War Office, who is an officer on the Staff of the Surveyor General. In the United States service this Department is under charge of the Commissary General of Subsistence, who has the rank of Brigadier General. See *Subsistence Department*.

COMMISSARIAT DEPARTMENT.—A warrant has been lately issued by which the Control Department of the English army has been abolished; and all its branches except the *Pay Sub-department* have been reclassified and divided into (*a*) the Commissariat and Transport Department, (*b*) the Ordnance Store Department, placed under the direction of the Surveyor General of Ordnance. Its organization is laid down as follows: 1. All officers of the Commissariat and Transport Department and of the Ordnance Store Department shall hold commissions. 2. Officers of these Departments shall be the officers of and shall command the Army Service Corps. 3. The ranks of the officers of the respective Departments shall be as follows: Commissary General, Deputy Commissary General, Assistant Commissary General, Commissary, Deputy Commissary, Assistant Commissary, Sub-assistant Commissary. 4. The relative rank of these officers shall be as follows: Commissary General—with an army in the field, special; otherwise as Major General; Deputy Commissary General, as Colonel; Assistant Commissary General, as Lieutenant Colonel; Commissary, as Major; Deputy Commissary, as Captain; Assistant Commissary, as Lieutenant; Sub-assistant Commissary, as Sub-lieutenant; and such relative rank shall regulate their quarters and military allowances, including pensions for wounds, and pensions and allowances to their wives and families, except in the case of a Sub-assistant Commissary, who for these purposes shall rank as Lieutenant. 5. Appointments to the Commissariat and Transport Department and to the Ordnance Store Department shall be conferred upon such officers, non-commissioned officers, and civilians as may be recommended by the Secretary of State. 6. Candidates shall be subject to such educational examination as the Secretary of State may from time to time determine. 7. Sub-assistant Commissaries shall be liable to be removed from the service for moral or physical unfitness, or if they fail to make satisfactory progress in qualifying themselves for permanent service in the Department. 8. Sub-assistant Commissaries, after two years' satisfactory service as such, may receive commissions as Assistant Commissaries. Those officers who may have been appointed from the army shall resign their commissions as combatant officers upon receiving commissions as Assistant Commissaries. 9. Service as Sub-assistant Commissary shall count towards retirement from the higher ranks of the respective Departments. 10. The periods of service towards retirement specified in Article 17 shall be applicable to officers of the Commissariat and Transport Department or of the Ordnance Store Department, and in the case of officers promoted from the ranks shall include service in all grades, but not less than one half of such periods shall consist of service as a commissioned officer. 11. Officers of the rank of Deputy or Assistant Commissary shall be selected for the appointments of Adjutant and Quartermaster in the Army Service Corps. 12. Combatant officers while under probation may at any time be ordered to return to their regiments. 13. An officer shall be eligible for promotion to the under-mentioned ranks if he shall have served on full pay for the following periods, dating from his first entrance into the service: To the rank of Commissary General, thirteen years, of which at least three shall have been as Deputy Commissary General; to the rank of Deputy Commissary General, ten years, of which at least three (including probationary service) shall have been as Assistant Commissary General. 14. If, during active service, a temporary augmentation of the Commissariat and Transport Department or of the Ordnance Store Department shall become necessary, the General Officer Commanding may grant to Officers of those Departments permission to hold temporarily the higher rank in which they may in such an emergency be called upon to act, or may temporarily appoint Combatant Officers, reporting his proceedings for the approval of the Secretary of State. 15. A Combatant Officer so appointed shall receive the pay and allowances of the departmental rank in which he shall be employed, in lieu of all other emoluments. 16. Officers shall be allowed to count their previous departmental or combatant service as service in the Commissariat and Transport Department or in the Ordnance Store Department. 17. Officers who shall have completed a total full-pay service of thirty years, including previous departmental or combatant service, shall, on giving six months' notice, have an unqualified right to retire on retired pay. It shall, however, be competent to the Secretary of State to place officers on the retired list after a meritorious service of twenty years, including departmental or combatant service, if by reason of mental or bodily infirmity of a permanent nature (to be certified by a Medical Board), contracted in the service, they shall be unfit for further duty; or in case of reduction of establishment, or retirement under the provisions of Articles 18 and 19. 18. The retirement of officers who have attained the rank of Assistant Commissary General, or who are above that rank, shall be compulsory at the age of sixty years. 19. The retirement of officers below the rank of Assistant Commissary General shall be compulsory at the age of fifty-five years.

COMMISSARY.—A name applied to an officer who has charge of the subsistence of troops, musters, etc. The term is applied in general to any one to whom the power and authority of another is committed. In this sense it is nearly equivalent to Commissioner. In ecclesiastical law a Commissary is an officer appointed by a bishop to exercise jurisdiction in parts of the diocese which are so distant from the episcopal city that the people cannot be conveniently summoned to attend the principal Court. When the papal authority, and all jurisdiction which flowed from it, was abolished in Scotland, by the Acts of 1560 and 1567, a supreme Commissary Court was established in Edinburgh, by a grant of Queen Mary, dated February 8, 1563. This Court had jurisdiction in actions of divorce, declarators of marriage, nullity of marriage, and all actions which originally belonged to the bishop's Ecclesiastical Courts. Its powers were gradually conjoined with those of the Court of Session, and it was finally abolished in 1836, the small remains of its once important jurisdiction being united in the Sheriff of Edinburgh. The inferior Commissariats, which had usually been commensurate with the dioceses, were dealt with by a previous statute, each County being erected into a separate Commissariat, of which the Sheriff was Commissary. The jurisdiction of these Courts so conjoined with that of Sheriffs was, in 1876, finally transferred to the Sheriffs absolutely, and the separation between the two sets of officers ended, except in the case of the Commissary Clerk of Edinburgh.

The term was used in the old French service to express a variety of military occupations, as it is in the Control Department of the British service at the present day.

COMMISSARY GENERAL OF PRISONERS.—An officer announced in time of war to superintend the treatment of prisoners, and charged with the enforcing of such regulations as may be necessary for their welfare. He has authority to call for such reports from officers in command of guards over prisoners as may be necessary for the proper discharge of his own duties, and he should be prepared to furnish all information in relation to prisoners called for by the Adjutant General. A full record of all prisoners is kept in the office of the Commissary General of Prisoners, in suitable books, giving the name, rank, regiment, and company of each military prisoner, the residence of each civil prisoner, with the charges against him, and the time and place of capture or arrest. Any special information of importance is added from time to time in the column of remarks. When disposed of by exchange or otherwise, the fact and authority for it, with the time, should be noted on the record. The Commissary General of Prisoners is empowered to visit places at which prisoners may be held, and to recommend to the General whose guards are responsible for them whatever modification in their treatment may seem to him proper or necessary, and report the same to the War Department. See *Prisoners of War*.

COMMISSARY OF MUSTER.—An officer charged with mustering in and mustering out of troops. During the Civil War in the United States this duty was extensively performed by Staff-officers, who were known officially as Commissaries of Musters.

COMMISSARY OF ORDNANCE.—The departmental title given to an officer of English artillery who has charge of an arsenal in India. Each officer, on being appointed to the Ordnance Department, remains on probation until he has passed an examination in the various subjects appertaining to the charge of an arsenal, such as accounts, the nomenclature and use of stores, the working of metals, etc., when, if found qualified, he is posted to the Department. The duties attached to the office of a Commissary of Ordnance will be found in the Ordnance Codes of each Presidency.

COMMISSARY SERGEANTS.—Non-commissioned Staff-officers appointed by the Secretary of War from Sergeants who have faithfully served five years in the Line, three of which shall have been in the grade of non-commissioned officers. Sergeants receiving these appointments are dropped from the rolls of the regiment or company in which they have been serving. Captains report to their Colonels such Sergeants as, by their conduct and service, merit appointments as Commissary Sergeants, setting forth the description and length of service of the Sergeant; the portion of his service he was a non-commissioned officer; his general character as to fidelity and sobriety; his qualifications as a clerk, and his fitness for the duties of the position for which he is recommended. From the nature of the duties assigned to these Sergeants it is evident that their judicious selection is of no small importance to the interests of the service. While the law contemplates in the appointment of Commissary Sergeant the better preservation of public property at the several posts, there is also a further consideration—that of offering a reward to faithful and well-tried Sergeants, and thus giving encouragement to deserving soldiers to hope for substantial promotion. Colonels and Captains cannot be too particular in investigating the characters of the candidates, and in giving their testimony as to their merits. The duty of the Commissary Sergeant is to assist the Commissary in the discharge of all the duties of his office, viz., such as receiving, storing, preserving, transferring, issuing, selling, and accounting for the subsistence supplies at the post, according to the regulations of the Subsistence Department; but the presence of a Commissary Sergeant at a post in no manner relieves the Commissary from the responsibility for, and proper care of, subsistence supplies. At posts where there is no commissioned officer the Commissary Sergeant is responsible for subsistence supplies, and is governed by the Regulations of the Subsistence Department in issuing and accounting for the same.

COMMISSION.—A writing, in the form of a warrant or letter-patent, authorizing one or more persons to perform duties or exercise powers belonging to another, or to others. Instruments of delegation, bearing this title, are issued to Officers in the Army and Navy, Judges, Justices of the Peace, and others. In the British service, commissions, commencing with the Sub-lieutenants of the army, are given to candidates after passing the prescribed examination before the Civil-Service Examiners, when they are sent to Sandhurst College for further instruction, chiefly of a military nature. They are not posted to regiments until they have passed the final examination, except those who are gazetted to regiments in India, which they proceed at once to join. After serving one year with their regiments, they are attached to garrison classes in India, and undergo a course of military instruction required to qualify them for promotion to the rank of Lieutenant. Militia Lieutenants are eligible for commissions in the regular army after serving for two trainings in a militia regiment; on passing the usual examination they are further subjected to such regulations as to age or otherwise as may be issued from time to time by the Secretary of State for War.

COMMISSIONAIRES.—A body of old or disabled soldiers who, on being pensioned, are formed into a Corps, and stationed in London and Edinburgh. They are employed, for the most part, as porters and in positions of trust, such as door-keepers over jewellers' shops. They run also as messengers. They must be men of unexceptionable character to whom these posts and duties are intrusted.

COMMISSIONERS OF ARRAY.—The predecessors of the modern Lords-lieutenant, whose duties consisted, amongst others, of seeing enforced in feudal times the observance of regulations which had for their object the maintenance of able-bodied men in the realm for the protection of the land.

COMMON MINE.—The term *common mine* is applied to a crater when its radius is equal to the line of least resistance. When the crater radius is greater than the line of least resistance, the terms *overcharged mine* and *globe of compression* are used. When the crater radius is less than the line of least resistance, the mine is termed *undercharged*. A small mine with a line of least resistance not greater than nine feet, formed by sinking a shaft from the surface of the ground and placing the charge at the bottom of it, is termed a *fougasse*. The term *camouflet* is applied to small mines used to suffocate the enemy's miners without producing an external explosion.

COMMON TIME.—In marching, the length of the direct step in common time in the United States service is 28 inches, and the cadence is at the rate of 90 steps per minute. The length of step and cadence varies in different services. See *Cadence* and *Step*.

COMMUNICATIONS.—1. In speaking of the communications of an army, common roads, railroads, navigable rivers, canals, and telegraph lines are usually meant, as it is by means of these that the different parts of an army, in its military operations upon land, are connected with each other. The establishment of these communications, and their maintenance, give the General in command of an army great solicitude. So important are they in military operations that they largely influence the General in his selection of the theater of operations, if the choice is left to him. The establishment and maintenance of these communications form a part of the duties ordinarily assigned to the Engineers, and the construction of bridges plays a most important part of this particular duty.

2. The communications form a very important element in the defense of permanent works. The size and disposition of the communications should vary with the character of the work in which they are placed. In small works, which from the size of their garrisons are calculated to make only a strictly passive defense, communications of just sufficient dimensions for the passage of the troops from point to point will serve every purpose, and can be more easily barricaded and otherwise defended. But for large works having full garrisons the communications should be such that sorties of all arms and in large bodies can be quickly made. With communications of this character a besieging force would be constrained to adopt extraordinary measures of safety, keeping large guards in the trenches to secure them from such sorties, to which they would be continually exposed.

All communications, to serve properly their ends, should fulfill the following conditions: 1. They should never, from their position, compromise the safety of the enceinte. Frequent instances could be cited of works which have been surprised by an enemy obtaining possession of the gates. Therefore too many precautions cannot be taken to secure the principal outlet from the body of the place from similar attempts. 2. They should admit of a convenient circulation of the besieged. To subserve this purpose, the dimensions, slopes, etc., of the posterns, ramps, and other similar works should be convenient for the service to which they are applied; and they should be placed in such positions as lead directly to the point to be reached. 3. The position chosen for any communication should be such that when an enemy gets possession of it he may obtain no advantage by it. To be useless to an enemy, the communication, when in his possession, should not offer a shelter for his works, nor enable him to carry them on with more ease. This end will be obtained by placing the communications in a position to be swept by the fire of the works in their rear, and so arranging them as to preserve the counterscarp wall unbroken. 4. The communications should be covered from every point where an enemy might establish himself, during the whole period that they can be of service to the besieged; and they should be swept by the fire of the enceinte. Without these precautions, an enemy might cut off all communication from the enceinte with the outworks; and in case of retreat, the troops could not derive any assistance from the enceinte, if he attempted to press upon them. 5. They should be so placed as not to compromise the retreat of the troops. This is effected by placing the communications in the re-enterings, which are the most secure points, as an enemy to reach them will have to brave a powerful column of flank fire. Barriers, gates, and movable bridges of timber should be placed at suitable points, to cut off one communication from another, and thus arrest the progress of a pursuing enemy. 6. Finally, each work should be independent of every communication except that one destined for its particular use. This is an important object, as it prevents an enemy, should he succeed in gaining possession of a communication leading through it, from seizing upon the work itself. See *Bridges*, *Covered Communication*, *Gateway*, *Postern*, *Ramp*, and *Stairs*.

COMMUTATION OF QUARTERS.—Officers on duty without troops at places where there are no public quarters are entitled to commutation, which is paid by the Pay Department at the rate authorized by law. Commutation of quarters is paid only at the station for which it is claimed, and by the senior disbursing Paymaster thereat, or, if there be no Paymaster at the station, by the Chief Paymaster of the Department, or such of his subordinates as he may designate upon the officer's application. The following officers are entitled to the allowance of quarters, and to purchase fuel at the legal rates, viz.: Officers who, for the convenience of the Government, are directed to await orders for a limited period at a designated station where there are no public quarters until the proper time arrives for giving them specific orders. The following are the present rates of commutation in the United States army: Lieutenant General, $100 per month; for all other grades the rate is $12 per month per room.

COMMUTATION OF RATIONS.—Commutation of rations at thirty cents may be paid to soldiers stationed where the Government does not otherwise provide for their subsistence, on satisfactory evidence that they have not received rations or an equivalent therefor during the period for which commutation is claimed. Commutation may also be paid a soldier traveling under orders on detached command, when it is impracticable to carry his rations, at the rate of one dollar a day, or less, as the Secretary of War may direct. The amount is paid by the Commissary when due, or in advance upon the order of the Commanding Officer, for the necessary number of days' travel. The voucher should show the nature and extent of the duty, and the certificate of a Commissioned Officer or the affidavit of the soldier must be added that it was impracticable for him to carry his rations. It should also be accompanied by the order directing the journey to be made, or a duly authenticated copy thereof. When it is proper that the original order should be retained by the soldier, the amount paid him for commutation should be noted thereon, with time and place of payment, duly signed by the Commissary. Commutation of rations, at the rate of twenty-five cents, is allowed to soldiers on furlough by competent authority. Payment is not made until the expiration of the furlough, or after discharge, if furloughed till then. The furlough must state the date up to which the soldier has been subsisted, and must be presented with the claim for commutation with the certificate of a Commissioned Officer that the soldier had returned to duty at its expiration. The officer who pays the commutation indorses the fact upon the furlough, and certifies upon his account of the payment that he has so done.

COMPAGNIES DE DISCIPLINE.—Companies created by Napoleon I. in 1802; the basis of their original organization was laid by a royal order in 1818. This order fixes the number of companies at ten—six of fusileers and four of pioneers, the former to be composed of soldiers of the army who were guilty of indiscipline, and the latter to be formed of men of the former who were deemed incorrigible. The number of companies is now reduced to seven, and these are stationed in Algeria. There are also four companies similarly organized which are stationed in the French Colonies.

COMPAGNIES D'ORDONNANCE.—The name of a corps of cavalry which was organized in France by Charles VII. in 1439; it numbered sixteen companies, and the entire strength was 9600 men. This was the first regular cavalry organized in France.

COMPANY.—In military organization, a company is an aliquot part of a regiment or battalion. In the British service, the companies in an infantry regiment are generally ten or twelve, or, if there are two battalions, each has this number of companies. The arrangement is made to facilitate command and evolutions. The Captains and Lieutenants are all *Company Officers*. The Captain is the chief of the company, and the Lieutenants are his subalterns or assistants. The company is further separated into two *subdivisions*, of two sections each. In round numbers, and without reference to special instances, a full company may be considered to comprise about 100 men, a subdivision 50, and a section 25. Under the Captain's superintendence the Lieutenant commands the first and second sections, the Sub-lieutenant the third and fourth, with a Sergeant to each section. Each company has its own arm and accouterment chests, and keeps its own books. A cavalry regiment is subdivided into *troops* instead of companies; the Engineers and Marines, into companies; but the artillery corresponding term is *battery*. In the German army, a company comprises about 250 men, under a Captain, who is a mounted officer, and three Subalterns.

In the United States army, all branches of the service are divided into companies. Infantry companies in time of war are expected to number about 100 men. A battalion of infantry has 10 companies, and each company has a Captain and two Lieutenants. In the cavalry a company is sometimes called a troop, and in the artillery a battery

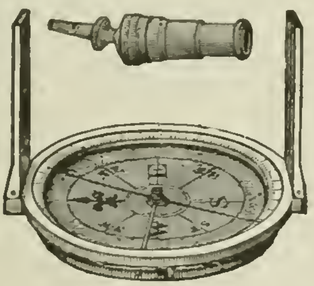
The company, dismounted, is formed in double rank, the men being arranged according to height, with the Corporals in the front rank, and on the right and left of platoons. In the right wing of the battalion, the tallest Corporal and tallest man form the right file, the shortest Corporal and shortest man the left file. In the left wing, the tallest Corporal and tallest man form the left file, the shortest Corporal and shortest man the right file. The company is divided as nearly as possible into two equal parts, called *platoons;* the division falling between two fours. For the purpose of making the platoons equal, the number of fours may be increased by leaving vacant the places of numbers two and three in some of the fours of the rear rank. When the company is small, the division into platoons may be omitted, in which case the Corporals are posted according to height on the right and left of the front rank. The company, when small, may also be formed in single rank. The right platoon, when in line, is designated the *first platoon;* the left, the *second platoon*. In column, the leading platoon is the *first*, the rear the *second*. The designations change whenever, by facing to the rear, the left becomes the right of the line, or the rear becomes the head of the column.

Posts of Officers, Sergeants, and Trumpeters or Field-music.—The *Captain* is two yards in front of the center of the company. As instructor, he goes wherever his presence is necessary. The *First Lieutenant* is two yards in rear of the center of the first platoon; the *Second Lieutenant* is two yards in rear of the center of the second platoon. Each Lieutenant is the chief of the platoon behind which he is posted. The *First Sergeant* is on the right of the front rank; the *other Sergeants* are in the line of file-closers, the *second* opposite the left file of the company, the *third* opposite the second file from the right, the *fourth* on the left of the First Lieutenant, the *fifth* on the right of the Second Lieutenant; the file-closers are as equally distributed along the line as possible. The battalion being in line, the Second Sergeant of either the left or right company places himself in the front rank, whenever his flank of the company is the flank of the battalion. The *Trumpeters*, when not united as the Trumpeters of the battalion, are in the line of file-closers, between the First Lieutenant and the Third Sergeant, and conform to all the movements of the file-closers. On the march, when the Trumpeters are required to play, they march at the head of the column. When there is a Third Lieutenant, he is posted between the First Lieutenant and the Fourth Sergeant. *File-closers* are officers or non-commissioned officers posted two yards in rear of the line; it is their duty to rectify mistakes and to insure steadiness and promptness in the ranks.

COMPANY FUND.—The savings arising from an economical use of the rations of a company (excepting the saving of flour) constitutes the *company fund*, which is kept in the hands of the Captain or other Commander of the company, and disbursed by him *exclusively for the benefit of the enlisted men of the company*, as follows: 1. For improvement of the soldiers' table-fare, and for their comfort in quarters. 2. For garden-seeds and utensils. 3. For such exercise and amusement as may be, in the judgment of the Company Commander, for the benefit or comfort of the majority of the enlisted men of the company. An account of the company fund is kept by the officer in whose hands it is deposited, which is subject to the inspection of the Commanding Officer of the post or regiment, and returns of it are rendered quarterly (or oftener if required) to the Commander of the regiment. After examination at regimental headquarters of these returns, an abstract, showing in detail the receipts and expenditures, is forwarded to the Adjutant General of the army through the Department Commander. See *Post Fund* and *Regimental Fund*.

COMPASS.—The directive power of the magnet seems to have been unknown in Europe till late in the twelfth century. It appears, however, on very good authority, that it was known in China, and throughout the East generally, at a very remote period. The Chinese annals indeed assign its discovery to the year 2634 B.C., when, they say, an instrument for indicating the south was constructed by the Emperor Hou-ang-ti. At first they would appear to have used it exclusively for guidance while traveling by land. The earliest date at which we hear of their using it at sea is somewhere about 300 A.D. According to one account, a knowledge of the compass was brought to Europe by Marco Polo, on his return from his travels in Cathay. It was long contended that the compass as a nautical instrument was first invented by Flavio Gioja, a native of Amalfi, about the year 1362; and that that part of the kingdom of Naples where he was born has a compass for its arms. For this there is no authority whatever, as the compass was well known as a nautical instrument before his time. It is probable, however, that Gioja may have made some improvement in the instrument or in the mode of suspending it.

The compass is variously mounted. The drawing shows the plain pocket-compass, having a 3-inch needle and sights folding down close to the glass. A variety of the compass known as the "dip" consists



Plain Compass.

essentially of a magnetic needle so suspended as to move readily in a vertical direction, the angle of inclination or "dip" being measured upon the divided rim of a small compass-box. When in use, the ring or bail is held in the hand—the compass box by its own weight takes a vertical position—and must also be in the plane of the magnetic meridian. In this position the needle, when unaffected by the attraction of iron, assumes a horizontal line, as shown by the zeros of the circle. When brought over any mass of iron it dips, and thus detects the presence of iron ores with certainty. If the compass is held horizontally it serves as an ordinary pocket-compass, and indicates the magnetic meridian, in the plane of which it should be held when used to ascertain the dip of the place where the observation is made. The Norwegian compass is a modification of the one used in northern Europe. It has a needle of either 3 or 4 inches resting upon a single vertical pivot so as to move freely in a horizontal direction, and thus place itself with certainty in the magnetic meridian; while at the same time, being attached to the needle-cap by two delicate pivots, one on each side, it is free to dip, like that of the ordinary compass.

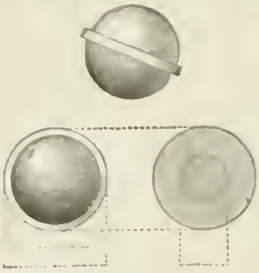
The following method of finding the points of the compass by means of a watch is novel and quite useful when traveling without the compass, or when the compass used has its needle deflected by local causes. *Halve the number of hours since the last midnight and point the corresponding dial-number toward the sun—the line from VI to XII will be then due north.* As an example, suppose the time to be 4 P.M. = 16 hours since the last midnight. Hold the watch in front of the body with the VIII pointed toward the sun: the line from VI to XII will then run due north. See *Solar Compass*.

COMPASSIONATE ALLOWANCE.—An allowance made to the children of deceased British military and naval officers left in necessitous circumstances. The annuities vary from £8 to £20 a year, according to the rank of the deceased officer, and are tenable up to the age of 18 in the case of boys, and to that of 21 as regards females, or until marriage if that happen earlier. This measure is more general than a compassionate allowance which arose out of the sympathy of the British nation with the army during the Crimean War. Royal warrants were issued in 1854 and 1856 defining and explaining allowances made to the widows and children, or other specified relations, of military officers who, after the date of the declaration of war with Russia, had been killed in action, or had died of wounds received in that war. The claims on this fund die out as years advance, of course.

COMPENSATING-GUNPOWDER.—A new mechanico-chemical explosive for heavy artillery purposes, proposed by Lieutenants A. E. Miltimore and C. A. L. Totten, United States Army. The latest American powder, hexagonal, and the English, cubical, the latter used in the 81-ton gun, are steps in retrograde. They are not accelerators: this principle has been sacrificed to the attainment of density and uniformity. These forms of powder beautifully illustrate the relation between a large surface of combustion and a diminished strain upon the gun, and thus fulfill their mission; still they are but temporary expedients. It is different, however, in the case of the perforated cake. Powder thus treated conserves its force well and strains the gun toward the minimum, and for this reason it has very naturally been adopted by one of the greatest military powers in Europe, for use in the strongest gun. In the mean time, with the detonating class of explosives we have been mainly engaged in reducing the intensity of their action, nor have any of them yet come within the limits of artillery requirements. Explosion in the case of gun-cotton is not combustion; it is more of a disintegration, a loss of equilibrium, taking place as it were instantly throughout the entire mass.

Both of these explosives possess valuable resources for the artillerist, yet neither of them fulfills in itself all the requirements of a projectile agent. While powder has considerable, gun-cotton has almost unlimited power; the explosion of the former can be governed, that of the latter has hitherto been unruly. But the very means we take to curb the first force of powder reduces to a minimum its already relatively small power-capacity. If we could obtain an explosive whose action would be similar to that of hexagonal powder until the projectile had taken up a rapid velocity, and which should then burn up with all the energy of gun-cotton, we would have a most valuable accelerator.

The endeavor to use these two substances in combination led to the invention of compensating-powder. The idea is to "build up" grains, cakes, or masses out of two or more explosives, or out of the same explosive in varying conditions, in such a manner that these explosives shall be ignited *successively* by the actual combustion of the several layers down to them. For instance, suppose we have a large grain of such powder. Its form, for discussion, is immaterial; let it be a sphere of gunpowder an inch in diameter, and imagine it to possess an interior and concentric core of gun-cotton half an inch in diameter. Such a grain would be constructed with a scientific regard to the peculiar characteristics of each substance, and would evidently burn upon the accelerative principle. Let us examine the theoretical combustion and effect of a charge of such powder fired in a gun. The relative amounts of the two explosives would satisfy the demands of the compensating principle, and at the same time the reasonable precaution of reducing the more explosive substance to its minimum effective quantity. Immediately after inflammation the gunpowder would commence to be rapidly consumed in towards the cotton. The exterior layer burning first would prepare the way for the more violent explosion of the interior one, and being itself in large grains, would offer a minimum surface to combustion during its first and most decisive instants. The powder part of the grain would thus be suited to large charges and guns.



It takes but a few one-hundredths of a second for all the powder to be consumed. In the mean time the projectile will have acquired its motion as in the case of the ordinary charge of powder alone, for thus far there has been no difference in the explosion, and will have reached a point in the bore beyond which, with powder alone, no material gain is to be realized from the gun's length. The small amount of powder which would now remain unconsumed, were the grain homogeneous, would barely evolve gas rapidly enough and in sufficient quantities to fill up, or *compensate* for, the increasing space behind the projectile, and would, of course, be useless for acceleration. For all practical purposes a powder-grain might as well be *hollow* from this point inwards. But just here the valuable part to be played by the interior core of the compensating grain is to be noticed. Exploding at this moment with great rapidity and force, it checks any tendency of the gas to lose its tension, compensates for the increasing space in rear of the projectile, and indeed actually gives it a final and valuable accelerating impetus. The great force thus developed by the gun-cotton in this last stage will not be exerted against the walls of the gun, as would be the case in the explosion of a charge of gun-cotton alone, but will evidently be directed towards the line of least resistance thus artificially prepared for it. The cotton, in fact, will find a condition of affairs in the bore of the gun that is especially favorable for its action. It is no longer confined to a space just sufficient to contain it before combustion, but finds a continually increasing one into which to expand, a cushion of gas against which to impinge, and an already rapidly moving projectile to accelerate.

In the employment of mammoth powder, even in its most approved form, we have to contend against a very serious element—*wastage*. These large grains are found to be only partially consumed; still burning they are thrown out of the gun along with the projectile. That is, when the combustion has reached a certain point the projectile leaves the gun, and all the powder remaining unconsumed is wasted. This waste reaches the enormous amount of 60 per cent. The introduction of an interior core of higher explosive properties can be made to do away with this expensive loss. Forty pounds of powder do all the work in a service-charge of one hundred pounds. Reckoning gun-cotton as only four times the strength of gunpowder, fifteen pounds of it would be equivalent to the sixty pounds of powder that are wasted. If, then, we imagine this amount of cotton introduced as a core into the forty *working* pounds of powder (the size and number of the grains remaining the same), we shall have a charge stronger, by the equivalent of sixty efficient pounds, than the present service-charge of the 15-inch Rodman gun. It must be remembered, moreover, that such a charge will expend its first forty pounds in impressing the projectile with its present normal velocity (1500 or 1600 feet), and that the remaining 15 pounds (*once and a half the value of the first forty*) of force-generator will work under the most favorable circumstances as a pure accelerator. We shall thus eliminate the great waste of the one, curb the straining action of both, and obtain a true *artillery powder*,—lighter and four and one half times more effective, charge for charge, than our best gunpowder.

It will, perhaps, repay us to examine this proposed combination, and its constituent parts, under their chemical symbols. The theoretical burning of gunpowder is expressed by the following equation:

$$2NO_3K + 3C + S = 3CO_2 + 2N + SK_2 \ldots\ldots\ldots (A)$$

The explosion of the gun-cotton is given by the formula

$$2C_6H_7(NO_2)_3O_5 = 3CO_2 + 9CO + 6N + 7OH_2 \ldots (B)$$

In the explosion of compensating-powder, the element *succession* is most noticeable. This is favorable to the stability of the several gases of its constituents when *brought together* under such peculiar conditions. The similar nature of the products of combustion of gunpowder and gun-cotton seems to preclude any tendency (which very *dissimilar* gases might have) to result differently in combination than they do when separated. Hence we may simply combine these two reactions by addition, and obtain a legitimate expression for the explosion of compensating-powder, namely:

$$[2NO_3K + 3C + S] + [2C_6H_7(NO_2)_3O_5] = (3CO_2 + 3CO_2) + 9CO + (2N + 6N) + 7OH_2 + SK_2 = 6CO_2 + 9CO + 8N + 7OH_2 + SK_2 \ldots\ldots\ldots (C)$$

It is barely possible that the water in this reaction may be turned to account for the oxidation of the sulphide. But in this case *hydrogen*, a still more elastic gas, would be freed, and take the place of the steam. Such a variation would result in greater chemical action and therefore in the production of a higher temperature, all of which would finally be appreciated in ballistics as an accelerator. Comparing these reactions critically, we may obtain a very clear idea of the gas-capacity and character of the powder that will result from the combination proposed. It must be recalled, in this comparison, that while the powder-gases result from a progressive *combination* of its elements, those of the detonator come from its almost instantaneous *disintegration*. It is also to be noticed that the volume of the latter gases is many times greater than that of the former, and, from the large amount of water it contains, that it has all the elasticity of steam.

It is claimed that gunpowder itself acts as an accelerator, from the fact that the great heat of its confined explosion must expedite the change into gas of its interior layers,—just as a coal-fire burns better and better until it reaches its maximum. This is obviously the case, though it is not an appreciable argument when offered against a combination that *is* a noticeable accelerator. This very feature, however, will work in favor of the compensating construction, for the accelerated burning of the powder-jacket will only be of importance during a very brief period, until the grain has become relatively small,—beyond this point it is valueless; but the interior core explod ing at this same moment will take up and carry to its climax this action, so well begun. See *Gunpowder*.

COMPLEMENT OF THE CURTAIN.—That part in the interior side of a fortification which makes the demi-gorge.

COMPLEMENT OF THE LINE OF DEFENSE.—The remainder of the line of defense after the angle of the flank is taken away.

COMPLIMENT.—The usual military marks of respect shown by a body of troops to official personages, to an officer, or to another body of troops.

COMPONE.—A term in Heraldry synonymous with Gobony. When a bordeur, pale, bend, or other ordinary, is made up of two rows of small squares, consisting of alternate metals and colors, it is called *componé*. See *Heraldry*.

COMPOSITIONS.—The term *composition* is applied to all mechanical mixtures which by combustion produce the effects sought to be attained in pyrotechny. If these compositions be examined, it will be found that many of them are derived from gunpowder, by an admixture of sulphur and niter, in proportions to suit the required end. Compositions are prepared in a dry or liquid form; in either case it is necessary that the ingredients should be pure and thoroughly mixed.

For dry compositions the ingredients are pulverized separately, on a mealing-table, with a wooden muller; they are then weighed and mixed with the hands, and afterwards passed three times through a wire sieve of a certain fineness. When a highly oxidizing substance, as the chlorate of potassa, is present, great care must be observed in mixing to avoid friction or blows which might lead to an explosion. When coarse charcoal or metals in grains are used, they should be added after the other ingredients have been mixed and sifted.

When it becomes necessary to use fire to melt the ingredients, the greatest precaution is necessary to prevent accident, especially when gunpowder enters. The dry parts of the composition may be generally mixed together first, and put by degrees into the kettle, when the other ingredients are fluid, stirring well all the time. When the dry ingredients are very inflammable, the kettle must not only be taken from the fire, but the bottom must be dipped in water to prevent the possibility of accidents.

The following table shows the rate of burning of the more important compositions:

Dimensions.	Wheel-fires.			Standing-fires.		
	Common	White.	Chinese.	Sun.	Star.	Roman candles.
Length of case .... inches	8.75	8.75	8.75	11	8	19
Interior diameter .... do.	0.75	0.75	0.75	0.75	0.75	0.75
Weight of composition .... ounces	3.5	3.5	4	5	4	5
Time of burning, per inch .... seconds	17	17	21	22	20	45

Dimensions.	Lances.					Port-fires.						Changeable wheels.
	Red	White.	Blue.	Yellow.	Green.	Red.	White.	Blue.	Yellow.	Green.	Lilac.	
Length of case .... inches	4	4	5	4	4	3	3	3	3	3	3	3
Interior diameter .... do.	0.32	0.32	0.32	0.32	0.32	1	1	1	1	1	1	0.75
Weight of composition ...... grains	141	140	150	150	160	547	560	546	545	560	550	250
Time of burning .... seconds	90	90	90	90	90	60	65	45	65	65	45	60

See *Cases* and *Fire-works*.

COMPOSTELLA.—St. James, the elder, was adopted as the patron saint of Spain, after the victory of Clavijo, and his relics were preserved at Compostella, the capital of the province of Galicia. The marvels supposed to be performed by these relics drew vast numbers of pilgrims, for whose support hospitals were established by the pious canons of St. Eloy. The vicinity of the Moors having subsequently rendered the highroads unsafe, 13 noblemen united for the protection of the pilgrims, and, in conjunction with the canons, resolved to found an Order of the same kind as that of the Hospitallers or Templars. The Pope granted his assent in a bull, dated 5th July, 1175, accompanied with the statutes of the Order. Whatever conquests were made from the infidel were declared the property of the Order, and a council of 13 knights was vested with authority to elect and depose a Grand Master. The knights made vows of poverty, obedience, and celibacy, and professed their belief in the Immaculate Conception. To protect Christians and convert infidels they vowed to be the only object in their wars with the Saracens. In most of the great battles between Christian and Moor the red cross of the Order was conspicuous. The conquests of the Order itself, combined with the grateful munificence of the nation, speedily increased its wealth and power beyond those of any of the other orders of knighthood. In addition to the three large commanderies of Leon, Castile, and Montalvan, it possessed nearly 200 minor commanderies, comprising, it is said, more than 200 priories, with many fiefs, cloisters, hospitals, castles, boroughs, two towns, and 178 villages, exclusive of its possessions in Portugal. This enormous wealth and power of the Order excited the jealousy of the Crown, in which, in 1522, the Grand-mastership was permanently vested by the Pope. Having thus become merely honorary and dependent on the Crown, the order rapidly decreased in importance.

Cross of the Order Compostella.

COMPRESSED BRONZE.—The density and hardness of bronze have been increased by tempering, by compression when in a fluid state, and, with still greater success, by the process of Mr. Dean, first tried in the United States in 1868, and a method exactly similar introduced by General Uchatius in Austria in 1873. The latter experimented with bronze cannon compressed whilst fluid, with others cast about a copper core, and finally with the plan proposed by Mr. Dean, which consisted in casting the piece solid in an iron mold or "chill," and, after boring it to near the required size, compressing and hardening the layers of metal by forcing into the bore a series of mandrels or plugs of hard steel. Guns so made compare most favorably with those of banded steel; they have internally the same strength, homogeneity, and hardness, and the elasticity increases from the exterior toward the interior. They show no spots of tin, and the alloy, not being brittle, is much less subject to erosion than ordinary bronze. General Uchatius considered erosion to be the result of a purely mechanical action, and that brittle metal, or in bronze guns the hardest parts, was most liable to be so affected. Mr. Dean increased the density of his bronze from 8.321 to 8.875, and the tenacity from 27,238 lbs. to 41,471 lbs. per square inch, whilst General Uchathus obtained a tenacity of over 72,000 lbs. This mode of construction has been adopted by the Austrian Government, and is now being tried in the United States. See *Bronze*.

COMPRESSION-PROJECTILES.—The systems under this class differ in the nature and arrangement of the metal to be compressed. Solid shot, shells, and shrapnel can be used in each. A projectile of this system is composed of a cast-iron or steel body, and of a lead coating cast over and between rings projecting from the body of the projectile. Bands of lead, extending beyond the general surface, are compressed by the lands as the projectile is forced through the bore of the piece. A construction more generally used is to have the body smooth, and to attach the coating chemically; to accomplish this, the body is thoroughly cleaned, and immersed in a solution of sal-ammoniac; next it is covered with powdered sal-ammoniac, and dipped first into melted zinc and afterwards into melted tin; it is then placed in a metal mold and the lead cast upon it. The hole in the base is closed by a screw-plug, which has a ring for handling the projectile and for extracting it from the piece when necessary.

In the French system these projectiles have two *bands*, B and B , of copper, attached by being forced into annular undercuts as shown in the drawing. To favor the compression, triangular grooves are cut around the surface of the bands. The forward band is placed near the center of gravity of the projectile; its diameter is only about .02 inch greater than the caliber of the piece, and therefore does not assist in giving rotation, but only in centering the projectile; the accuracy of fire is thereby increased, but the velocity at the muzzle of the piece is slightly reduced. See *Coated Projectiles*, *French Projectiles*, and *Projectiles*.

COMPRESSIVE SYSTEM OF RIFLING.—This system embraces all projectiles which are loaded in a chamber and then forced by the action of the powder through the bore of the gun, the diameter of which across the lands is less than the superior diameter of the projectile. Projectiles of this class are necessarily confined to breech-loading guns, and, as the name of their class implies, take the grooves by compression. The general character of the rifling in breech-loaders consists in a great number of shallow grooves usually narrowing toward the muzzle to make up for the slip and abrasion of the leaden jacket of the projectile. The Armstrong system of rifling for breech-loaders, formerly used in the English service, does not differ in principle from this. The rifling consists of a great number of shallow, narrow grooves (the 7-inch has 76), the object being to give the soft-metal covering a very large bearing on the driving-side of the grooves, and thus prevent stripping, and make up for want of depth. See *System of Rifling*.

COMPULSION.—A constraint upon an officer's will whereby he is compelled to do that which his judgment disapproves, and which, it is to be presumed, his will (if left to itself) would reject. As punishments are, therefore, only inflicted for the abuse of that free will which God has given to man, it is highly just and equitable that an officer should be excused for those acts which are done through unavoidable force and compulsion.

COMPULSORY SERVICE.—The power a government has of compelling the people of a country to take up arms in defense of the nation. This nature of enlistment is unknown in the British army, except in the militia, and then only in case of a deficiency of recruits; but in Continental armies the system is universal.

COMRADE.—A fellow-soldier in the same regiment or company, and who acts as the friend of another soldier. The term *comrade* is also extended so as to include all the members of a particular corps, branch of the service, or the army generally.

CONCAVE ORDER OF BATTLE.—If an attack is made simultaneously on both wings, and the center is refused, the attacking army will assume a line of battle which will be concave towards the enemy's line. If the attacking army possesses a decided superiority in numbers, this order obtained by a simultaneous attack on both wings and refusing the center might be employed. It is evident that even in this case mutual assistance could not be given by the troops making the attacks, and it would possess all the defects of a division of forces upon the field of battle. This order of battle was used by Hannibal when he won his great victory over the Romans at Cannæ. Circumstances will generally decide when this order of battle should be used; all other things being equal, it should not be used in preference to the oblique order. See *Convex Order of Battle*.

CONCENTRATION.—Collection into a narrow space round a center. In strategy, the collecting on a certain point of the different bodies forming an army, to meet the enemy with the greatest number of men possible. For a General to divide his forces, unless for special purposes, is to court defeat in detail. An instance of this is afforded by the War of 1870–71, when the French, divided into six separate *Corps d'Armée*, incapable of supporting each other, were defeated piecemeal by the Germans, who had concentrated all their forces into three powerful armies.

CONCENTRATION-MARCHES.—Marches made by several bodies of troops starting from points separated from each other for the purpose of bringing these troops together at some stated place. Forced marches are much used in concentrating troops, especially before a battle. Many examples are given in military history. As strategical operations, marches may be divided into two principal classes: those of *concentration* beyond the sphere of action of the enemy, and those of *maneuver* executed within this sphere. In the former the forces are only brought to that point where the latter commences. In the campaign of 1805 it is noted that the two corps in Hanover and Holland, under Bernadotte and Marmont, were directed upon Wurtzburg, whilst those on the English Channel were directed on the Rhine between Mannheim and Strasburg. Having reached these points without any apprehension of an enemy's presence, the grand maneuver for throwing them on the enemy's right flank and rear commenced; those columns on the right, being nearer the enemy, moving more slowly, and having their flank nearest the enemy carefully guarded by a corps assigned to this service; those on the left moving more rapidly and pivoting on the right; whilst the whole was so combined that in a few hours a large force could be concentrated on any fraction, if unexpectedly attacked whilst carrying out this grand movement.

In the second splendid campaign of Napoleon in Germany against the Austrians, that of 1809, the same admirable series of provisions is to be seen. Seeing the evidently hostile attitude of Austria, the first step of Napoleon was to mass his forces at those points from which they could be rapidly thrown upon the Austrian dominions. For this purpose he chose Wurtzburg, Augsburg, and Strasburg as the points for concentration. On and towards the first point he directed the major part of his forces from Saxony and from the north of Germany; on the second, the forces in the neighborhood of Hanau; on the third, those from the interior of France. Whilst in Italy he directed Prince Eugene with 50,000 men to approach the Frioul. These, with other minor movements, drew around Austria another of those Napoleonic meshworks which had already proved so disastrous to her. The Austrian army of 200,000 men were to concentrate in the neighborhood of Ratisbonne, on the Danube; part on one side and a part on the other side of this stream, but so as to render mutual assistance. Not knowing where he with certainty should find the main body of the Austrians, Napoleon decided upon trusting nothing to mere hazard, but to be governed in his movements by recognized military principles. To this end he withdrew Davoust from Ratisbonne, on the Danube, and threw forward Massena so as to concentrate his entire force at Ahensburg, a small place on the river Abens, and about midway between Ingoldstadt and Ratisbonne. Here he decided to break through the Austrian center, thus separating the two Archdukes, Charles and Louis. In these plans he was aided by the tardiness of movement of the Austrians upon which he counted, and also by the state of the weather, by which the roads were much injured. The result of these skillfully combined marches was that the Archduke Charles was forced upon Ratisbonne, and obliged to retreat across the Danube into Bohemia; the other main fraction of the Austrian army retiring successively behind the Inn and the Traunn, leaving the road to Vienna open to Napoleon.

In this conjuncture of operations, Napoleon, after considering the military aspect of affairs, decided to march direct upon Vienna. In taking this step he had not only to follow up the Archduke Louis, but to provide against the junction of the Archduke Charles with him, by recrossing the Danube. The principal points where this passage might have been effected are Straubing, Passau, Lintz, and Krems. These it was of the first importance to secure by anticipating the Austrian movements on them. To carry out these measures, Massena received orders to descend along the Danube, to be followed by Davoust, and by General Dupas; and each in succession to occupy the places just mentioned, thus securing the army from an attack either in flank or in rear by the Austrians on the left bank of the Danube. At the same time Bessières was ordered to push forward beyond Landshut, on the Iser, and keep closely on the heels of the enemy's retreating column; whilst Lannes, under the immediate command of Napoleon, moved between the columns of Massena and Bessières, so as to throw this force upon either of these two, as circumstances might demand. Further to secure his right on their flank, the Bavarians, his allies, were directed to occupy Munich, and, pushing from there through Salzburg into the Tyrol, observe the Archduke John, and give timely warning of his movements. These profound combinations met with all the success they merited. Anticipated by the rapid movements and daring of the French at every point, the Archduke Charles was unable to join the forces on the right bank of the Danube, which last, despairing of being able to cover Vienna, effected a crossing to the left bank at Krems. See *Marches*.

CONCENTRIC.—Having a common center. This term in warfare is applied to a covering army operating from a common center against widely separated bodies of the enemy advancing towards that center; hence it becomes a concentric army. The invasion by the enemy may take place either on one or two lines. To operate methodically, and to the best advantage, the covering army, if assailed on two lines, should place on each of these a retarding force at first, considering these as wings, while the mass in reserve is held ready to give a preponderance to either wing, or to both in succession. In all Napoleon's operations against a divided enemy this principle is apparent. See *Concentration-marches*.

CONCRETE.—A mixture of hydraulic or other mortar with gravel or shingle, which, on hardening, forms an artificial conglomerate. The best concrete is made by well mixing hydraulic mortar (see CEMENT) with sand and sufficient water for complete hydration, and then adding the shingle or screened ballast, and mixing them well together. An inferior concrete may be made by laying the shingle into the foundation or other place where the concrete is required, and then pouring mortar upon it, to fill the interstices between the pebbles. The principal use of concrete is to form a basis of artificial stone for buildings that rest upon loose or damp subsoils. Such a basis, if well made, forms a solid foundation-slab upon which the weight of the whole structure is equally distributed. It also resists the capillary ascent of moisture from the soil, which would otherwise take place through brick-work or porous stone.

CONCUSSION-FUSE.—A fuse put in action by the discharge, but the effect of that action is restrained until it strikes the object. Such a fuse, in order to be serviceable, must not only produce explosion on striking, but it must not produce it on the shock of the explosion of the charge, nor of that produced by the ricochets of the projectile in or out of the gun. These fuses have usually consisted of some combination of the highly explosive fulminates, but the extreme danger of using them has been a great obstacle to their adoption. See *Fuse*, *Percussion-fuse*, and *Splingard Fuse*.

CONDEMNED ANIMALS.—Animals in the public service condemned as unfit for work. In the United States army, all horses and mules inspected and condemned as unfit for military service are advertised for sale, and disposed of within ten days from date of advertisement, and if not sold within the ten days are shot on the eleventh day. The advertisement is made in accordance with advertising regulations in force, but at posts remote from places where newspapers are published the advertisement is made by posted notice. When horses and mules condemned are sold, or, in default of sale, shot, report is made at once to the Quartermaster General, through the regular military channel, of the execution of the order. Great care is exercised in the branding of condemned horses and mules with the letters I. C. (Inspected—Condemned).

CONDEMNED PROPERTY.—In the military service, property unfit for further service and worthless. Property unfit for the purpose for which it was designed may often be applied to other uses. Inspecting officers, in recommending the disposition to be made of condemned property, especially of the Quartermaster's Department, should bear in mind that there is hardly any species of material, however worn, which cannot be put to some use. Old linen, cotton, wool, iron, etc., can all be worked up in some new form, and wood can be used as fuel. No condemned articles that have any salable value should be recommended "to be dropped," unless there be special reasons therefor, which reasons should be stated in the report. The Inspector should mark the letters I. C. (Inspected—Condemned) upon all property condemned and ordered to be dropped from the returns, with a brand, stencil, cold-chisel, steel cutter, or punch, depending on the material to be marked. Should it happen, when final action is had, that the Inspector's recommendation is disapproved, the marks should be canceled, and a certificate of the fact given to the officer accountable. See *Inspection of Condemned Property*.

CONDOTTIERI.—The name given in the fourteenth century to the leaders of certain bands of military adventurers who, for booty, offered their services to any party in any contest, and often practiced warfare on their own account purely for the sake of plunder. These mercenaries were called into action by the endless feuds of the Italian States during the Middle Ages. Among the most celebrated of their leaders were Guarnieri, Lando, Francis of Carmagnola (about 1412), and Francis Sforza (about 1450). The last-mentioned made himself Duke of Milan. The *Compagnies Grandes* in France, during the fourteenth century, resembled the bands led by the Italian Condottieri. They originated in the long bloody wars between France and England. The mischief done by them became so intolerable that in several parts of the country the peasantry armed themselves and, under the name of *Pacifères*, formed associations against the plunderers. Nevertheless, these French Condottieri were so powerful that, in 1361, they routed the king's forces which had been sent against them, at Brignais, near Lyon, and slew the Constable of France, Jacques de Bourbon; but the Constable du Guesclin persuaded them to seek their fortune in the Spanish service.

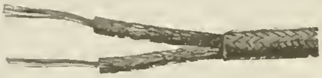
CONDUCTORS.—1. In the Royal Artillery, Conductors are those artillerymen who have charge of the ammunition-wagons in the field; they are, to some extent, under the control of the Commissariat Officers, who have to provide means of transport; but since the recent changes in the Commissariat Department they have been more exclusively under the control of their own proper artillery officers.

2. Conductor, in electricity, is a term applied to a body capable of transmitting an electric current. If a rod of metal be made to touch the prime conductor of an electrical machine immediately after the plate has ceased to rotate, every trace of electricity immediately disappears. But if the rod were of shellac, little or no diminution would be perceptible in the electrical excitement of the conductor. The metal in this case leads away the electricity into the body of the experimenter, and thence into the ground, where it becomes lost, and it receives in consequence the name of a conductor. The shellac, for the opposite reason, is called a non-conductor. Different substances are found to possess the power of conducting electricity in very different degrees. The following series classifies the more common substances according to their conducting powers, beginning with the best and ending with the worst conductors: Conductors—The metals, graphite, sea-water, spring-water, rain-water. Semi-conductors—Alcohol and ether, dry wood, marble, paper, straw, ice at 32° F. Non-conductors—Dry metallic oxides, fatty oils, ice at 13° F., phosphorus, lime, chalk, caoutchouc, camphor, porcelain, leather, dry paper, feathers, hair, wool, silk, gems, glass, agate, wax, sulphur, resin, amber, and shellac.

The arrangement into conductors, semi-conductors, and non-conductors is made with reference to frictional electricity, or electricity of a high tension. The substances which are semi-conductors for frictional electricity are found to be almost, if not altogether, non-conducting for the electricity of the galvanic battery, which is too feeble to force a passage through them. The metals, which appear to be all nearly alike conducting for frictional electricity, offer widely differing resistances to the transmission of the galvanic current. By experiments made with galvanic electricity, it is found that the more ordinary

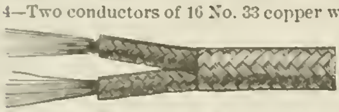
No. 1—One conductor of 16 No. 33 copper wires.

No. 2—One conductor of 16 No. 31 copper wires.



No. 3—Two conductors of 5 No. 30 copper wires.

No. 4—Two conductors of 16 No. 33 copper wires.

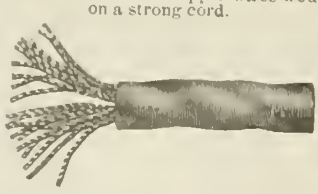


No. 5—Two conductors of 30 No. 33 copper wires.

No. 6.—One conductor of 8 No. 36 copper wires.

No. 7—One conductor of copper wires wound spirally on a strong cord.

No. 8—One conductor of small copper wires wound spirally on a strong cord.



No. 9—Two conductors, heavy switch-cord, Western Union style, each conductor composed of 10 flat copper wires wound spirally on cord, each conductor heavily wrapped with silk.

No. 10—One conductor of 50 No. 32 copper wires, with green and gold colored silk braid cover. For Rheostats and other purposes where large and flexible conductors are required.

No. 11—One conductor, tinsel cord, with lateral cotton and double wrap of cotton cover. Much used for Kidder and other battery electrodes.

No. 12—Two conductors of 14 No. 33 copper wires in strands insulated with silk, and laid up in form of three-strand cord.

No. 13—One conductor, tinsel cord, covered with worsted braid.

No. 14—Two conductors, tinsel cord. Both conductors covered with worsted braid, the whole covered with fine worsted braid.

No. 15—One conductor, tinsel cord, covered with silk braid

No. 16—One conductor, tinsel cord. One wrap of worsted and two cotton braids outside. For telephone-switches.

No. 17—Two conductors of 25 No. 36 copper wires, each conductor insulated with a wrap of cotton, a layer of gutta-percha, and an outside braid of silk. This is an entirely water-proof cord, much used in electric lighting.

No. 18—Gold tinsel cord, not covered, small size.

No. 19—Gold tinsel cord, not covered, large size.

metals stand thus as regards their powers of conduction, beginning as before with the best conductor: Silver, gold, copper, brass, zinc, iron, platinum, tin, nickel, lead, German silver, mercury. An increase of temperature has in the metals the effect of lessening the conducting power, whilst in almost all other substances it has an opposite effect. Glass becomes conducting at a red heat, and so do wax, sulphur, amber, and shellac, when fused.

When a conductor is placed on non-conducting supports, so as to prevent the electricity communicated to it from passing into the ground, it is said to be insulated. The usual insulating material employed in the construction of electrical apparatus is glass, which, though not so perfect a non-conductor as the others lower in the scale, far exceeds them in hardness and durability. In a damp atmosphere glass becomes coated with a thin layer of moisture, which very considerably diminishes its insulating power. Hence arises the necessity in certain states of weather of heating so as to dry all electrical apparatus previous to use. This imperfection is very much lessened by covering the glass with shellac varnish. The very fact that a conductor may be insulated indicates that the air is a non-conductor. Dry air possesses this property in a high degree, while moist air renders insulation for any length of time impossible.

The drawing shows a variety of conducting cords, manufactured by Messrs. L. G. Tillotson & Company, New York, and used for various military purposes, principally in ballistic experiments and sub-marine mining. See *Mines*.

CONDUCT PREJUDICIAL TO MILITARY DISCIPLINE.—All crimes not capital, and all disorders and neglects, which officers and soldiers may be guilty of, to the prejudice of good order and military discipline, though not mentioned in the Articles of War, are taken cognizance of by a General, or a Regimental, Garrison, or Field-officers' Court-Martial, according to the nature and degree of the offense, and punished at the discretion of such Court. See *Articles of War*.

CONDUCT UNBECOMING AN OFFICER AND A GENTLEMAN.—This offense is punished with dismission by sentence of a General Court-Martial. What constitutes the offense is not defined, but it is left to the moral sense of the Court-Martial to determine.

CONE.—The vent-plug which is screwed into the barrel of a fire-arm. The outer end is the *nipple* for receiving the percussion-cap. The functions of the cone are to support the percussion-cap when exploded by the hammer, and to conduct the flame to the vent of the piece. To increase the effect of the hammer, the upper surface of the *cone* is diminished by chamfering the corners. See *Barrel*.

CONE OF DISPERSION.—The cones of dispersion of projectiles comprise all the causes of error in firing, whether resulting from the arm itself, from the projectile and the resistance of the air, or from the want of practice or skill in the marksman. The causes of irregularity in firing, although greater in the horizontal than in the vertical direction, are considerable in the latter. They raise or depress the projectiles, and change the ranges to an appreciable extent. The general form of the *cone of dispersion* will present a curved surface, which is concave outwards; for experiment goes to prove that when a variable cause acts an infinite number of times, the variations of this cause tend to neutralize each other, and we may then assimilate its effects to those of a constant accelerating force, acting in the same manner as gravity. The separation of the projectiles is not in proportion to the ranges, but increases more rapidly. The *cone of dispersion* becomes longer, with equal deviations, as the velocity of the projectiles increases; or in other words, the fire is more accurate as the velocity is increased. Ancient artillerists were aware of this principle, and in consequence employed for small-arms charges much larger than those now in general use.

CONE OF SPREAD.—The imaginary cone containing the diverging bullets or fragments upon the explosion of a shell. With shrapnel shells this *cone* is very long; while with segment shells it is very short and wide, and these shells are consequently most effective when burst close up to the object. See *Cone of Dispersion*.

CONE-SEAT.—A projecting piece of iron welded to the barrel, near the breech, for the purpose of sustaining the cone. See *Barrel*.

CONFEDERATE PROJECTILES.—The rifle-projectiles used by the Confederates in the late war belonged, with a few exceptions, to the expanding class. Fig. 1 represents a shell with a copper ring (*b*) fitting into a rabbet formed around its base in casting. This projectile would seem to resemble the Parrott projectile in its construction. The lower edge of the band, however, projects below the bottom of the base, which in Parrott's it does not. Recesses are formed in the sides of the rabbet to prevent the ring from turning.

The projectile represented in Fig. 2 has a thick circular plate of copper attached to its base by means of a screw-bolt at its center. To prevent it from turning around this bolt there are three pins, or dowels, fastened into the base of the projectile, and projecting into corresponding holes in the circular plate. This plate is slightly cupped, and the angle between it and the bottom of the projectile is filled with a greased cord for lubricating the bore of the gun.

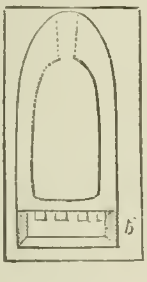


Fig. 1.

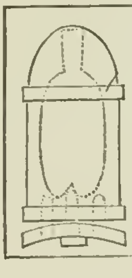

Fig. 2.

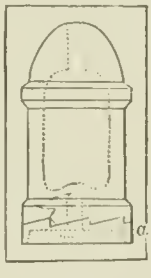

Fig. 3.

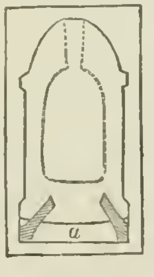

Fig. 4.

Fig. 3 represents a projectile of the Blakely class, with its expanding cup of copper (*a*). Instead of the soft-metal studs which are placed on the forward part of the Blakely projectile, this projectile has a raised band carefully turned to fit the bore.

Fig. 4 represents a Reed projectile, in which the expanding cup is made of copper, as shown at *a*. This cup is placed in the mold, and the body of the projectile is cast upon it. See *Expanding Projectiles* and *Projectiles*.

CONFEDERATION.—An alliance of Nations, States, or Princes; sometimes used for a single Nation, as that of the Mexican Republic, the official title of which is "The Mexican Confederation." The German Confederation was formed immediately after the Vienna Congress of 1815. In July, 1778, the United Colonies (afterwards the United States of America) agreed to the "Articles of Confederation and Perpetual Union between the States of New Hampshire, Massachusetts Bay, Rhode Island and Providence Plantations, Connecticut, New York, New Jersey, Pennsylvania, Delaware, Maryland, Virginia, North Carolina, South Carolina, and Georgia." In these Articles are set forth the principles of government which were a few years later embodied in the Constitution of the United States, with such additions as were necessary "in order to form a more perfect union." In South America is the Argentine Confederation, and Switzerland is sometimes called the Swiss Confederation. The Confederation of the Rhine was formed in 1806 by a number of German States, under the protection of Napoleon.

CONFIDENCE.—This term, in a military sense, has reference to the facility with which some officers gain the confidence of their men. This most essential quality in a Commander is of the highest importance, and cannot be overrated: without it, a disaster may at any moment occur in the day of battle; but with it, and the knowledge of military science combined, success in the operations of an army may be assured. History affords examples of battles having been lost by the most celebrated Generals because they did not possess this confidence. At the battle of Thymbra, when Cyrus's horse fell under him, Xenophon takes notice of what importance it is to a Commander to be loved by his soldiers. The danger of the king's person became the danger of the army; and his troops on that occasion gave incredible proofs of their courage and bravery.

CONFIDENTIAL REPORTS.—Reports on Regiments, as to their efficiency, conduct, etc., forwarded yearly, in England, by General Officers Commanding to the Adjutant General for the information of the Commander-in Chief. Reports on the qualifications of officers for promotion are sent to the Military Secretary at the Horse-guards for submission.

CONFINEMENT.—Non-commissioned officers and soldiers charged with crimes are usually confined until tried by Court-Martial or released by proper authority. No officer or soldier who is put in arrest should continue in confinement more than eight days, or until such time as a Court-Martial can be assembled.

CONFISCATION.—The appropriation to the public use of private property. A right which is conferred under certain circumstances by the laws of war. See *Contraband of War*.

CONGREVE GUN.—A 24-pounder gun of conical form, proposed in 1813 by Sir W. Congreve. It had a much greater thickness of metal at the breech than those of the old construction; the extra thickness was supposed to give a reacting power to the gun, which, however, is an erroneous idea, not supported by facts. The gun is now obsolete,

CONGREVE ROCKET.—A rocket guided by a long wooden stick attached to its base, and a terrible weapon of war, with ranges which no ordnance of its time could attain. Discarding the small sizes, Congreve made 12-pound, 18-pound, and 32-pound rockets, which he charged with canister-shot, bullets, and other missiles. The stick for a 32-pound rocket was 18 feet in length, and the maximum range 3500 yards. The range could be increased by discharging the rocket from a cannon, with a time-fuse to ignite it at the cannon's utmost range, when the rocket commences its own course. As missiles, these rockets were found to annoy most seriously the defenders in any fortified work, and, in a bombardment, they speedily set houses and buildings on fire. In the field, also, the plunging, ricochetting motion of the rocket greatly disturbed both cavalry and infantry. The Congreve rockets were first tried on actual service, and with fatal effect, at the attack on Copenhagen in 1807. See *Rocket*.

CONROY RIFLE.—A breech-loading small-arm having a fixed chamber closed by a movable breech-block, which rotates about a horizontal axis at 90 to the axis of the barrel, and lying above the axis of the barrel and in rear—being moved from below. This arm is provided with a falling breech-block, moved by a sliding trigger-guard, the withdrawal of which retracts the firing-pin, brings the hammer to the half-cock, and drops the block, which strikes in its descent and operates the usual bent-lever extractor. By pushing the trigger-guard forward again, the block is raised, when by bringing the hammer to the full-cock the piece is closed and ready to be fired. The blow of the hammer is not delivered directly upon the firing-pin, but on an intermediate lever pivoted below its point of impact on the firing pin, and striking it so as to impel it forward in the line of the axis of the bore. This gun has been modified by substituting for the sliding guard the more powerful motor found in the usual swinging guard-lever, the angle formed by which with the stock when the piece is opened being about 30°.

CONSCRIPTION.—The system whereby the French, since the year 1795, and some other foreign armies are recruited. It differs essentially from the English system in being compulsory, and, taken for all in all, as a disturbance of the system of employment in all grades of society, is probably the most expensive means of recruitment yet devised. Every Frenchman may be called to enter the army at the age of 20; but those who choose to enlist, as early as 18. He cannot again be called upon to serve. The term is for 5 years in the Regular Army, 4 in the Army Reserve, 5 years in the Territorial Army (Militia), and 6 in the Territorial Reserve. This brings the conscript to 40 years of age, when his liability to service ceases. The law of 1872 reorganizing the French army forbids the providing of substitutes by conscripts. An account is kept of the number of youths in France who reach the age of 20 in each year (about 280,000). All those are exempt from conscription who are under 5 feet 2 inches in height; or have any natural infirmities unfitting them for active service; or are the eldest of a family of orphans; or are the only sons of widows, or of disabled fathers, or of fathers above 70 years of age; or are intended for the Church; or are pupils at certain Colleges. Moreover, if two brothers are drawn as conscripts, and the younger is efficient, the elder is declared exempt; and if of two only brothers one is already in the army, or has retired through wounds or infirmity, the other is exempt. Culprits and felons are not allowed to enlist. The law of 1872 making military service obligatory on all Frenchmen (save in the above cases) has assimilated the French army system to that enforced in Prussia since 1813.

CONSTABLE.—Whether this officer was called originally *Comes Stabuli*—the Count of the Stable, or Master of the Horse (as alleged by Ducange)—or the *Koning Stapel*—Staff and Stay of the King (as Coke, Selden, and others, with less reason, have maintained)—the Constable, both in France and England, was a military personage of the very highest rank. The Constable of France rose gradually in importance from the comparatively modest position of an Officer of the Household, till at last he became, *ex officio*, the Commander-in-Chief of the army in the absence of the Monarch, the highest Judge in military offenses and in all questions of chivalry and honor, and the supreme regulator and arbitrator in all matters connected with tilts, tournaments, and all martial displays. The office of Constable is traced back by Anselme to Alberic, who held it in 1060; but the first Constable of France who appeared at the head of an army was Matthew, the Second Seigneur de Montmorency. The office was suppressed by Louis XIII. in 1626. Among the offices of the Ancient Monarchy which were restored by Napoleon for mere purposes of state, that of Constable was one. His brother, Prince Louis Napoleon, afterwards King of Holland, was created Grand Constable, the Vice-Constable being Marshal Berthier. The office was again abolished on the restoration of the Bourbons, and has not since been re-established. But besides the Constable of France, almost all the great vassals of the Crown had Constables who filled analogous offices at their minor Courts. There were Constables of Burgundy, of Champagne, and of Normandy; the latter of whom may be regarded as the progenitor of the Constable of England.

Shortly after the Conquest, a Lord High Constable of England appears, having powers and privileges closely corresponding to those of the Constable of France. His position as Judge of the Court of Chivalry, in conjunction with the Earl-Mareschal, and the limitation of his power, which followed, are explained under COURT OF CHIVALRY. The office was abolished by Henry VIII. on the attainder of Edward Stafford, Duke of Buckingham; and a Lord High Constable is now appointed only on the occurrence of great State Ceremonies, e.g., a Coronation. The High Constable of Scotland was an officer very similar to the Constable of France and England. After the Rebellion the offices of the Inferior Constables dependent on the High Constable, such as the Constable of the Castle, were abolished, but that of the High Constable himself was expressly exempted, and still exists in the noble family of Errol. The privileges attaching to this office are now entirely honorary; but in virtue of it, the Earl of Errol is said to be the first subject in Scotland after the Blood-Royal; and on the occasion of the visit of King George IV. to Edinburgh, the then Earl was allowed to take precedence of the possessors of all other hereditary honors. The present Earl of Errol is the twenty-second High Constable of Scotland.

CONSTABLE OF THE TOWER.—In England, a General Officer who has the chief superintendence of the Tower, and is Lord-lieutenant of the Tower Hamlets. He holds his appointment by letters-patent from the Sovereign, and is not removable at pleasure.

CONSTITUTION.—The following provisions of the Constitution relate to the land and naval forces: *Preamble*—We, the people of the United States, in order to * * provide for the common defense * * do ordain and establish this Constitution for the United States of America. Art. I. Sec. 1. All legislative powers herein granted shall be vested in a Congress of the United States, which shall consist of a Senate and House of Representatives. Art. I. Sec. 8. The Congress shall have power—*Clause* 1. * * To pay the debts and provide for the common defense and general welfare of the United States. * * *Clause* 9. * * To define and punish offenses against the law of nations. * * *Clause* 10. To declare war, grant letters of marque and reprisal, and make rules concerning captures on land and water. *Clause* 11. To raise and support armies; but no appropriation of money to that use shall be for a longer term than two years. *Clause* 12. To provide and maintain a navy. *Clause* 13. To make rules for the government and regulation of the land and naval forces. *Clause* 14. To provide for calling forth the militia to execute the laws of the Union, suppress insurrections, and repel invasions. *Clause* 15. To provide for organizing, arming, and disciplining the militia, and for governing such part of them as may be employed in the service of the United States, reserving to the States, respectively, the appointment of the officers, and the authority of training the militia according to the discipline prescribed by Congress. *Clause* 16. To exercise exclusive legislation * * over all places purchased, by consent of the legislature of the State in which the same shall be, for the erection of forts, magazines, arsenals, dock yards, and other needful buildings. *Clause* 17. To make all laws which shall be necessary and proper for carrying into execution the foregoing powers, and all other powers vested by this Constitution in the Government of the United States, or in any department or officer thereof. Sec. 9. *Clause* 2. * * The privilege of the writ of habeas corpus shall not be suspended, unless when, in cases of rebellion or invasion, the public safety may require it. * * Sec. 10. *Clause* 2. * * No State shall, without the consent of Congress * * keep troops or ships of war in time of peace * * or engage in war, unless actually invaded, or in such imminent danger as will not admit of delay. Art. II. Sec. 1. *Clause* 1. The executive power shall be vested in a President of the United States of America. * * Sec. 2. *Clause* 1. The President shall be Commander-in-Chief of the army and navy of the United States, and of the militia of the several States, when called into the actual service of the United States. * * Sec. 3. *Clause* 1. * * He shall take care that the laws be faithfully executed; and shall commission all officers of the United States. Art. III. Sec. 3. *Clause* 1. Treason against the United States shall consist only in levying war against them, or in adhering to their enemies, giving them aid and comfort. No person shall be convicted of treason, unless on the testimony of two witnesses to the same overt act, or on confession in open Court. *Clause* 2. The Congress shall have power to declare the punishment of treason; but no attainder of treason shall work corruption of blood, or forfeiture, except during the life of the person attainted. Art. IV. Sec. 4. *Clause* 1. The United States shall guarantee to every State in this Union a republican form of government; and shall protect each of them against invasion, and on the application of the legislature, or of the executive (when the legislature cannot be convened), against domestic violence.—*Amendments to the Constitution:* Art. I.—Congress shall make no law respecting an establishment of religion, or prohibiting the free exercise thereof; or abridging the freedom of speech or of the press; or the right of the people peaceably to assemble, and to petition the Government for redress of grievances. Art. II.—A well-regulated militia being necessary to the security of a free State, the right of the people to keep and bear arms shall not be infringed. Art. III.—No soldier shall, in time of peace, be quartered in any house without the consent of the owner, nor in time of war but in a manner to be prescribed by law. Art. V.—No person shall be held to answer for a capital or otherwise infamous crime, unless on a presentment or indictment by a grand jury, except in cases arising in the land or naval forces, or in the militia, when in actual service, in time of war or public danger; nor shall any person be subject for the same offense to be twice put in jeopardy of life or limb; nor shall be compelled, in any criminal case, to be a witness against himself, nor to be deprived of life, liberty, or property, without due process of law; nor shall private property be taken for public use without just compensation.

The power of making rules for the government and regulation of armies, as well as the power of raising armies, having in express terms been conferred on *Congress*, it is manifest that the President as Commander-in-Chief is limited by the Constitution to the simple command of such armies as Congress may raise, under such rules for their government and regulation as Congress may appoint. "The authorities [says Alexander Hamilton] essential to the care of the common defense are these: To raise armies; to build and equip fleets; to prescribe rules for the government of both; to direct their operations; to provide for their support. These powers ought to exist without limitation; because it is impossible to foresee or to define the extent and variety of national exigencies, and the correspondent extent and variety of the *means* which may be necessary to satisfy them." Defective as the present (old) Confederation has been proved to be, this principle appears to have been fully recognized by the framers of it; although they have not made proper or adequate provision for its exercise. Congress has an unlimited discretion to make requisitions of men and money; to govern the army and navy; to direct their operations. The government of the military is that branch of the code which embraces the military *Hierarchy*, or the gradual distribution of inferior authority. From this principle proceeds the localization of troops, their discipline, remuneration for important services, the repression of all infractions of the laws, and everything, in fine, which the legislature may judge necessary either by rules of appointment or promotion, penalties or rewards, to maintain an efficient and well-disciplined army. But, as if to avoid all misconstruction on this point, the Constitution not only declares that Congress shall make rules for the *government*, but also for the *regulation* of the army; and *regulation* signifies precise determination of functions, method, forms, and restrictions not to be departed from. It is evident, therefore, that the design of the framers of the Constitution was not to invest the President with powers over the army in any degree parallel with powers possessed by the King of Great Britain over the British army, whose prerogative embraces the *command* and *government* of all forces raised and maintained by him with the consent of Parliament; but their purpose, on the contrary, was to guard in all possible ways against executive usurpation by leaving with *Congress* the control of the Federal forces which it possessed under the Articles of the Confederation, and at the same time to strengthen the powers of Congress by giving that body an unrestricted right to *raise* armies, provided appropriations for their support should not extend beyond two years. The command of the army and navy and militia called into service, subject to such rules for their government and regulation as Congress may make, was given by the Constitution to the President; but the power of making rules of government and regulation is in reality that of Supreme Command, and hence the President, to use the language of the *Federalist*, in his relation to the army and navy, is nothing more than the "*First General and Admiral of the Confederacy;*" or the first officer of the military hierarchy with functions assigned by Congress. A curious example of this contemporaneous construction of the Constitution is found in a letter from Sedgwick to Hamilton. Congress, in raising a provisional army in 1798, created the office of Commander of the Army with the title of *Lieutenant General*. A year subsequently a provision was made by law for changing this title to that of *General*. This last provision gave great offense to Mr. Adams, then President, who considered it as an evidence of the desire of Congress to make "*A General over the President.*" So strangely was he possessed with this idea that he never commissioned Washington as General, but the latter died in his office of *Lieutenant General;* the President evidently thinking that the title of General conveyed a significancy which belonged to the President alone, although the Commander of the Army might in his opinion very properly take the title of *Lieutenant General*, and thus have his subordination to the Commander-in-Chief of the army and navy and militia clearly indicated. It is plain, therefore, no less from the appointment by the Constitution of the President as Commander-in-Chief, than from all contemporaneous construction, that his functions in respect to the army are those of First General of the United States, and in no degree derived from his powers as First Civil Magistrate of the Union. The advocates of Executive Discretion over the army must therefore seek for the President's authority in his military capacity, restrained as that is by the powers granted to Congress, which embrace the raising, support, government, and regulation of armies; for there can be no limitation of that authority which is to provide for the defense and protection of the community, in any matter essential to its efficacy; that is, in any matter essential to the *formation, direction,* or *support* of the National Forces. After the foregoing investigation of the unrestricted power of Congress in respect to the army, *save only in the appointment of the head of all the national forces, naval and military*, it will be plain that the 2d Section of the Constitution, in giving to the President the nomination and appointment, by and with the advice and consent of the Senate, of *all other officers* of the United States *whose appointments are not herein otherwise provided for, excludes* officers of the army and navy. The power of raising armies and making rules for their government and regulation necessarily involves the power of making rules of appointment, promotion, reward, and punishment, and is therefore a provision in the Constitution otherwise providing for the appointment of officers of the land and naval forces. So true is this that the principle has been acted on from the foundation of the Government. Laws have been passed giving to general and other officers the appointment of certain inferior officers. In other cases the President has been confined by Congress, in his selection for certain offices in the army, to particular classes. Again, rules have been made by Congress for the promotion of officers, another form of appointment; and in 1846 an army of volunteers was raised by Congress, the officers of which the Acts of Congress directed should be appointed according to the laws of the States in which the troops were raised, excepting the General Officers for those troops, who were to be appointed by the President and Senate—a clear recognition that the troops thus raised by Congress were United States troops and not militia. It is certainly true that the military legislation of the country has for long years vested a large discretion in the President in respect to appointments and other matters concerning the army; but it may well be asked whether fixed rules of appointments and promotion which would prevent the exercise of favoritism by the Executive might not, with the greatest advantage to the army and the country, be adopted by Congress? Military prejudices are not only inseparable from, but they are essential to, the military profession. The government which desires to have a satisfied and useful army must consult them. They cannot be molded at its pleasure; it is vain to aim at it. These are maxims which should lead Congress to the adoption of rules of appointment and promotion in the army which would prevent all outrages to the just pride of officers of the army. The organization of every new regiment, where the appointment of the officers has been left to Executive Discretion, shows that, if the desire has been felt in that quarter to cherish or cultivate pride of profession among the officers of the army, the feeling has been repressed by other considerations. All pride of rank has been so far crushed by this system of Executive Discretion that it is apparent, if Congress cannot provide a better rule for the government and regulation of the army, a generous rivalry in distinguished services must be superseded by political activity. Rules of appointment and promotion limiting the discretion of the President, and at the same time giving effect to opinions in the army, might easily be devised; or borrowed from existing rules in the French army, which, without ignoring the important principle of seniority, would at the same time afford scope and verge for rewards for distinguished services. No army can be kept in war in the highest vigor and efficiency without rewards for distinguished activity, and the appointment of Todleben at the siege of Sebastopol shows how far almost superhuman efforts may be prompted by investing a Commander in the field with the power of selecting his immediate assistants. Colonels of regiments with us now exercise this authority in selecting Regimental Adjutants and Quartermasters. Why should not the same trust be reposed in Commanding Generals of Departments, Brigades, Divisions, and Armies? And why should not all necessary restrictions (such as those in operation in the French armies) be put upon the President in making promotions for distinguished services, and also in original appointments, in order to secure justice to the army, and thereby promote the best interests of the country? See *Articles of War*.

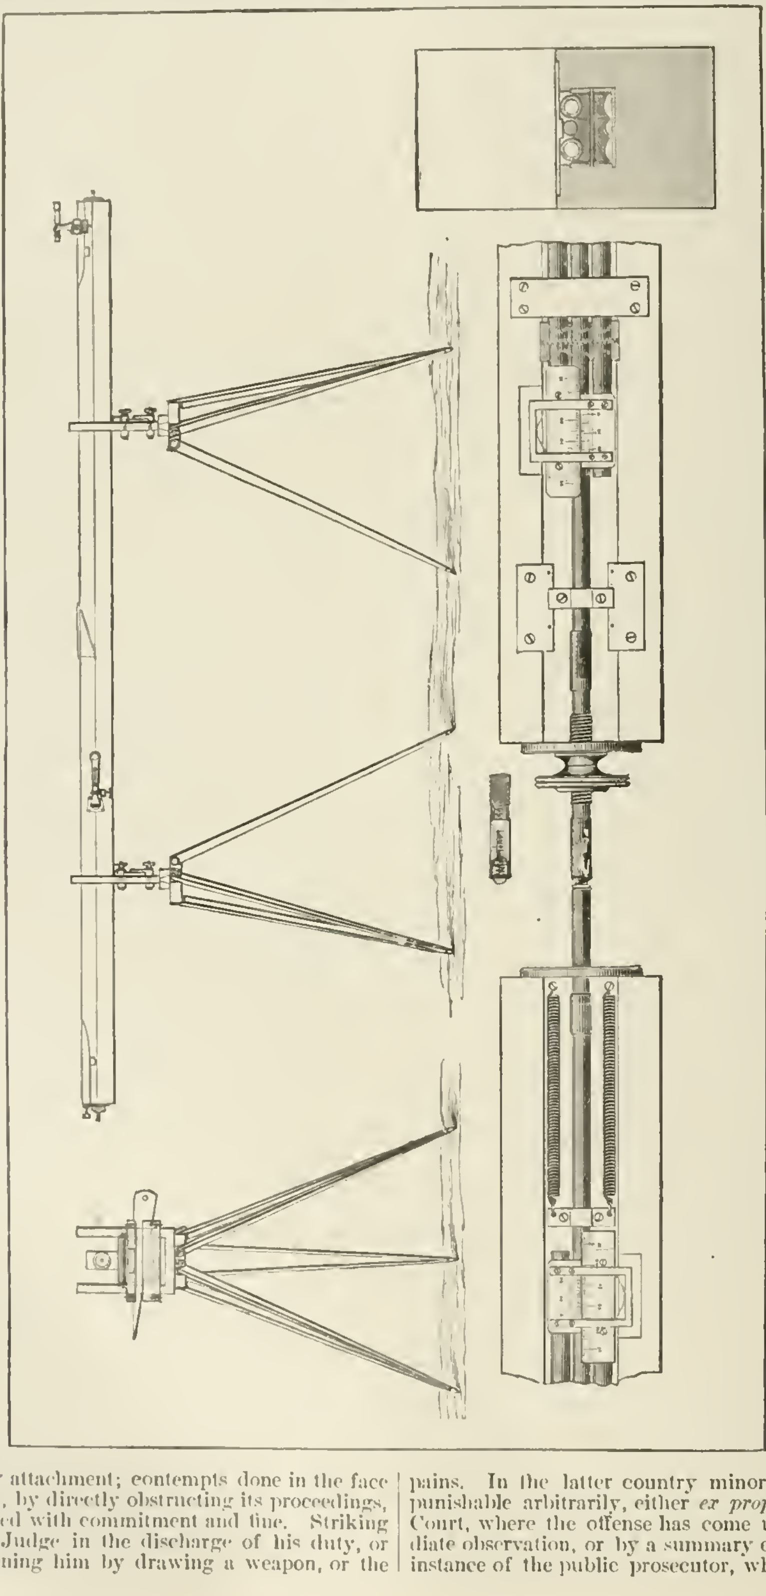
CONSULATE.—This supreme magistracy of the French Republic was established after the Revolution of the 18th Brumaire, and lasted to the Coronation of Napoleon. On the sudden overthrow of the Directory with the Constitution of the year III., the members of the Council of the Ancients and the Five Hundred, or rather those of them who approved of, or submitted to, that act of violence on the part of Bonaparte's grenadiers, appointed three Consuls—Sièyes, Bonaparte, and Roger Ducos. This approach to a monarchical government was confirmed, December 13, 1799, by the Constitution of the year VIII., by which Bonaparte was made First Consul, with Cambacérès and Lebrun as second and third; each was elected for ten years, and was re-eligible. The powers of the First Consul were made almost absolute. He promulgated the laws, appointed or dismissed Ministers, Ambassadors, Members of the Council of State, Military and Naval Officers, and all Civil and Criminal Judges, except Justices of Peace and members of the Court of Cassation. His income was fixed at 500,000 francs, and that of his inferior colleagues at 150,000 francs each. Bonaparte took up his residence at the Tuileries, and held a splendid Court. By Resolutions of the Senate, in May, 1802, Bonaparte was re-elected for ten additional years, and in August of the same year was made First Consul for life. In the appeal made to the nation, out of 3,577,259 votes, 3,568,885 were in favor of Bonaparte. The adulation of the Senate and people now knew no limit. Nothing but the imperial name and insignia were wanting to complete the picture of absolutism, and these were supplied May 18, 1804, when Napoleon was made Emperor.

CONTACT-LEVEL.—A valuable adaptation of the spirit-level for the production of exact divisions of scales, and generally for the determination of very minute differences of length. The device consists of a very delicate level pivoted at its middle and across its length, with a small tilt-weight at one end, which tips always in one direction. From the center of the level downward, a short rigid arm extends with a plain polished surface perpendicular to the chord of the level, and against which the contact is made. The carrier of this arrangement is either fixed, or mounted on a slide governed by a micrometer-screw. If now the end of a rod terminating in a hardened steel point be moved along horizontally till it bears against the contact-arm, the level will gradually assume the horizontal position, and the movement of the bubble as indicated by the scale upon the glass will depend upon the relation between the radius to which the level-tube is ground and the length of the contact-lever. If the latter is $\frac{1}{2}$ an inch long, and the radius of the glass tube is 400 feet (levels for astronomical purposes are ground to a sweep of 800 and 1000 feet radius), we have the relation between the lever and radius as 1 is to 9600; and as $\frac{1}{50}$ of an inch can readily be read from the level-scale, $\frac{1}{480000}$ of an inch will be the difference in length which each division on such a scale indicates. When it is remembered that such a determination of length can be repeated indefinitely, and that the readings are made without the aid of a magnifying-glass or artificial illumination, the perfection and beauty of the method will be appreciated.

CONTACT-SLIDE BASE APPARATUS.—This perfected apparatus, designed by Professor J. E. Hilgard, Superintendent of the United States Coast Survey, and represented on page 396, consists of two measuring-bars 4 meters long, exactly alike, and supported on trestles. The measurement is made by bringing these bars successively in contact, which is effected by means of a screw motion and defined by the coincidence of lines on the rod and contact-slide. Each bar consists of two pieces of wood about 8 by 14 cm. square and a little less than 4 meters long, firmly screwed together. Between the pieces of wood is a brass frame carrying three rollers, on the central one of which rests a steel rod about 8 mm. in diameter. On each side there is a zinc tube 9 mm. in diameter. The rod and tubes are supported throughout their length on similar systems of rollers. The zinc tubes form with the steel rod a metallic differential thermometer, and are so arranged that one tube is secured to one end of the rod, being free to expand in the other direction, the other tube being in a like manner fastened to the other end of the rod. The zinc tubes, therefore, with any change of temperature, expand or contract in opposing directions, and the amount by which the expansion of the zinc exceeds that of the steel is measured by a fine scale attached to the rod, while the zinc tube carries a corresponding vernier. The cut shows this arrangement, which is identical on both ends of the bars; a perforation in the wood of the bar allows this scale to be read. In addition to these metallic thermometers a mercurial thermometer is attached to the bar about midway of its length. The rods and tubes thus forming a united whole are lengthwise movable on the rollers by means of a milled nut working in threads cut on the steel rod, which passes through a circular opening in the brass plate screwed to the wooden bar, and against which the nut presses. Two strong spiral springs pull the rods back, and the nut is always pressed against the plate. One end of the rod is defined by a plain agate securely fastened to it; the other end carries the contact-slide, having an agate with a horizontal knife-edge. This slide is a short tube, fitting over the end of the rod, and pushed outward by a spiral spring. A slot in the tube shows an index-plate, with a ruled line fastened to the rod. To align the bars properly a small telescope is placed on each bar, and can be adjusted to bring the line of collimation over the axis of the rod. The trestle, shown in the upper left-hand corner of the illustration, consists of a strong tripod-stand, carrying a frame with two upright guides for two cross-slides, which are separated by a movable wedge. These cross-slides can be clamped in any position. By moving the wedge, the bar resting between the uprights is either elevated or depressed. To obtain smooth movements, friction-rollers are provided. To move the bars sideways, a coarse screw takes hold of a projection on the lower side of the bar, by turning which the bar can be moved laterally. There are three pairs of trestles, alike in construction with the exception that the upper slide of the trestle intended for the forward end of the bar carries a roller on which the bar rests, while the other has a fixed semi-cylindrical surface for the support of the bar. In making the measurement, the bars being four meters in length, the stands are set up at distances of two meters, each bar being supported at one fourth its length from the ends, as indicated by the painted black bands. Each bar has a sector with level alidade attached to one side, by which its inclination can be read off to single minutes.

CONTEMPT.—Any officer or soldier who shall use contemptuous or disrespectful words against the President of the United States, the Vice-President, against the Congress of the United States, or against the Chief Magistrate or Legislature of any of the United States in which he may be quartered, shall be punished as a Court-Martial shall direct. Any officer or soldier who shall behave himself with contempt or disrespect towards his Commanding Officer shall be punished by the judgment of a Court-Martial. No person whatsoever shall use any menacing words, signs, or gestures in presence of a Court Martial, or shall cause any riot or disorder, or disturb their proceedings, on the penalty of being punished at the discretion of the said Court-Martial. *Contempts* thus rendered summarily punishable by Courts-Martial are of public and self-evident kind, not depending on any interpretation of law admitting explanation or requiring further investigation. Courts-Martial sometimes act on this power. At other times individuals so offending are placed in arrest, and charges are preferred for trial. A Regimental Court-Martial may punish summarily, but are not competent to award punishment to Commissioned Officers. A Regimental Court-Martial in such cases would impose arrest. Citizens, not soldiers, would be removed from Court.

CONTEMPT OF COURT.—There is probably no country in which Courts of Law are not furnished with the means of vindicating their authority and preserving their dignity by calling in the aid of the executive, in certain circumstances, without the formalities usually attending a trial and sentence. Of this, the simplest instance is where a Judge orders the police to enforce silence, or to clear the Court. Contempts by resisting the process of a Court are in England punished by attachment; contempts done in the face of the Court, by directly obstructing its proceedings, may be visited with commitment and fine. Striking a Supreme Judge in the discharge of his duty, or even threatening him by drawing a weapon, or the like, has been an offense at common law in England of the highest kind since the times of the Anglo-Saxons; and in Scotland it is a statutory offense, punishable either capitally or by very severe arbitrary pains. In the latter country minor contempts are punishable arbitrarily, either *ex proprio motu* of the Court, where the offense has come under its immediate observation, or by a summary complaint at the instance of the public prosecutor, where, though not



Hilgard Contact-slide Base Apparatus.

committed in the immediate presence of the Court, it has relation to a matter which is, or has been recently, in dependence before it. See *Contempt*.

CONTEST.—An earnest struggle for superiority, defense, or the like; strife in arms. In a strictly military sense, to struggle to defend; as, the troops contested every inch of ground.

CONTINENTAL.—A term intended as the opposite of Provincial, assumed by the revolted American Colonies early in the War of the Revolution, an effort being made to induce Canada to join the Thirteen Colonies. Had the Canadians agreed, the whole of the Continent under English rule would have been in revolt. The first general representative body of the Thirteen Colonies was called the *Continental Congress*. See *Congress*.

CONTINGENT.—1. The quota of troops furnished to the common army by each member of an Alliance or Confederation of States. The word was especially applied to the proportions contributed by the several German States to the Army of the Confederation, which has given place to the Empire.—2. In the British service, the sum paid monthly to each Captain of a troop, company, or battery to defray the expense of stationery, the care of arms, and other minor demands.

CONTINUED LINES.—There are two classes of lines—*continued lines* and *lines with intervals*. Continued lines present no openings through which the enemy can penetrate except the ordinary outlets. Lines with intervals consist of detached works, which are inclosed partly, or entirely, throughout their perimeters, arranged in defensive relations with each other, and presenting wide intervals between them defended only by their fire. The same general principles apply to lines as to other field-works; but from their great extent they usually receive a slight relief, and the simplest angular figures are adopted for their plan. In laying them out, the Engineer should avail himself of all the natural features presented by the position, so as to diminish the labor of erecting artificial ones. See *Lines*.

CONTLINE.—The space between the strands on the outside of a rope. In *worming*, this space is filled up with spun yarn or small rope, which brings the rope thus treated to a nearly cylindrical shape, either to strengthen it or to render the surface smooth and fair for *serving* or *parceling*. See *Cordage*.

CONTOISE.—A flowing scarf worn with the earliest crests attached to the helm. It gave way to the *mantling*.

CONTOURING.—A term applied to the outline of any figure, and consequently to that of any section of a solid body; but when used professionally in connection with the forms of ground or of works of defense, the outline of a horizontal section of the ground or works is alone to be understood by it.

CONTRABAND OF WAR.—A name applied to certain commodities, or the rules relating to them, during hostilities between States which acknowledge what are called the Laws of Nations. One such law is that neutral Nations must not carry on, for the advantage of either of the belligerent powers, any branches of commerce from which they are excluded in time of peace. Another is that the name of Contraband of War shall be given to such articles as pertain to military or naval warfare—guns, ammunition, and stores of all kinds. Unless there are special treaties, defining exactly what articles are contraband of war, the interpretation of this law often leads to much embarrassment. Another law insisted on by England during the last great war was that each belligerent shall have a right to visit and examine neutral ships, to see whether they carry any articles which are contraband of war, and which seem likely to be intended for the enemy. A neutral State may carry on ordinary trade with either belligerent, except when prevented by blockade; but the ships, according to the above rules, must not contain articles contraband of war; nor must a conterminous land-frontier be crossed by such commodities. If a merchant evades these rules, he does so at his own risk; his merchandise may be seized, and his own Government will not protect him. By the law and practice of Nations it is for the Admiralty Court of the capturing power to decide what is or what is not contraband of war. Upon such questions it is the province of this Tribunal to adjudicate; and from its final judgment there is no appeal. At various times discussions have arisen whether corn, hay, or coal can ever be included in the list of articles contraband of war; they are manifestly articles of peaceful commerce, but they are also essential to the maintenance of an army, and sometimes a supply would give one belligerent a great advantage over the other. Especially is this the case in reference to coal, in the present age of war-steamers.—Contraband in commerce depends, however, upon the special laws of each country.

CONTRACTION.—1. The state of being drawn into a narrow compass, or of becoming smaller. In horses' feet it is brought on from bad shoeing, hot stables, or confinement. The foot becomes oblong instead of round. The remedy to be applied should be thin sole and quarters, and the feet kept moist; also tips or spring shoes, tar or hoof ointment.

2. All solid bodies contract their size in the operation of cooling. It follows, therefore, that if the different parts of a body cool unequally they will contract unequally, and the body will change form, provided it be not restrained by the presence of a superior force; if it be so restrained, the contractile force will diminish the adhesion of parts by an amount which depends on the rate of cooling of the different parts, and the contractibility of the metal. This is an important consideration in estimating the strength and endurance of cannon, particularly those made of cast-iron, as will be seen by examining the form of the casting and the method of cooling it. The general form of the casting is that of a solid frustum of a cone; it is therefore cooled from the exterior, which causes the thin outer layer to contract first, and force the hotter and more yielding metal within toward the opening of the mold. Following this, the adjacent layer cools and tends to contract; but the exterior layer, to which it coheres, has become partially rigid, and does not fully yield to the contraction of the inner layer. The result is, the cohesion of the particles of the inner layer is diminished by a force of extension, and that of the outer layer increased by a force of compression. As the cooling continues, this operation is repeated until the whole mass is brought to a uniform temperature; and the straining force is increased to an extent which depends on the size and form of the mass, the rapidity with which it is cooled, and the contractibility of the particular metal used. All cannon, therefore, that are cooled from the exterior are affected by two straining forces—the outer portion of the metal being compressed, and the interior extended, in proportion to their distances from the *neutral axis*, or *line* composed of particles which are neither extended nor compressed by the cooling process.

The effect of this unequal contraction may be so great as to crack the interior metal of cast-iron cannon, even before it has been subjected to the force of gunpowder; and chilled rollers, which are cooled very rapidly by casting them in iron molds, have been known to split open longitudinally, from no other cause than the enormous strains to which they are thus subjected. The strain produced by the action of a central force, as gunpowder acting in a cannon, is not distributed equally over the thickness of metal. Barlow shows *that it diminishes as the square of the distance from the center increases.* It follows from this that the sides of a cannon are not rent asunder as by a simple tensile force, but they are torn apart like a piece of cloth, commencing at the surface of the bore. This is confirmed by experience; for the inner portion of the fractured surface of a ruptured gun is found to be stained with the smoke of the powder, while the outer portion is untouched by it. It will thus be seen that the effect of ordinary cooling is to diminish the strength and hardness of the metal of cannon at or near a point where the greatest strength and hardness are required, i.e., at the surface of the bore.

The strains produced by unequal cooling increase with the diameter of the casting and the irregularity of its form. This explains the great difficulty which is encountered in making large cast-iron cannon proportionally as strong as small ones; and also how it is that projections like bands, moldings, etc., injure the strength of cannon. It also explains why cannon made of "*high*" cast-iron, or cast-iron made more tenacious by partial decarbonization, are not so strong as cannon made of weaker iron; for it is well known that such iron contracts more than the latter in cooling, and therefore produces a greater strain of extension on the surface of the bore. The foregoing considerations led Captain Rodman to propose a plan for cooling cannon from the interior, hoping thereby to reverse the strains produced by external cooling, and make them contribute to the endurance rather than to the injury of the piece. The method employed is to carry off the internal heat by passing a stream of water through a hollow core, inserted in the center of the mold-cavity before casting, and to surround the flask with a mass of burning coals to prevent too rapid radiation from the exterior. Extensive trials have been made to test the merits of this plan; and the results show that cast-iron cannon made by it are not only stronger but are less liable to enlargement of the bore from continued firing. Indications were shown, however, in these and in other trials, that the strains produced by unequal cooling are modified by time, which probably allows the particles to accommodate themselves, to a certain extent, to their constrained position, as in the case of a bent spring or hoop. See *Cooling*.

CONTRACTS.—All purchases and contracts for supplies or services for the military and naval service are made by or under the direction of the chief officers of the Departments of War and of the Navy, respectively. And all agents or contractors for supplies or services as aforesaid render their accounts for settlement to the accountant of the proper department for which such supplies or services are required, subject, nevertheless, to the inspection and revision of the officers of the Treasury. Contracts for subsistence supplies for the army, made by the Commissary General, on public notice, provide for a complete delivery of such articles, on inspection, at such places as shall be stipulated. The Quartermaster's Department of the Army, in obtaining supplies for the military service, states in all advertisements for bids for contracts that a preference shall be given to articles of domestic production and manufacture, conditions of price and quality being equal, and that such preference shall be given to articles of American production and manufacture produced on the Pacific coast, to the extent of the consumption required by the public service there. In advertising for army supplies the Quartermaster's Department requires all articles which are to be used in the States and Territories of the Pacific coast to be delivered and inspected at points designated in those States and Territories; and the advertisements for such supplies are published in newspapers of the cities of San Francisco, in California, and Portland, in Oregon. Contracts are not made at posts unless specially ordered, and are not so ordered unless the stores required can be procured at such posts as economically as if sent from other markets or from depots; and all such contracts are made out in the name of and signed by the chief officer of that branch of the Staff of the command to which they pertain. Whenever practicable, contracts for supplying military posts with fuel, forage, straw, etc., provide for delivery, monthly, of the quantities required each month, in order to avoid unnecessary accumulation of property at posts, and to distribute expenditure therefor throughout the year, and to prevent risk of great loss by fire or other cause.

Except in the rare cases where the United States may elect to exercise its reserved right to reject proposals, contracts are awarded to the lowest responsible *bona-fide* bidder, who, when required, produces a proper article, and whose proposal therefor is not unreasonable in amount. The following is the Form of a General Contract:

Articles of agreement entered into this —— day of ——, eighteen hundred and ——, between ——— ———, United States Army, of the first part, and ——— ———, of the county of ——, State of——, of the second part: This agreement witnesseth, That the said ——— ———, for and in behalf of the United States of America, and the said ——— ———, for ——— ———, —— heirs, executors, and administrators, have mutually agreed, and by these presents do mutually covenant and agree, to and with each other, as follows, viz.: [Here give the name of the contractor, and state what he agrees to do by introducing in succession those articles of the agreement which define his duties; such, for instance, as fix the place and date of delivery of the supplies or performance of the services; as give the quantity, quality, and description of the supplies to be furnished, character of their packages, etc., or nature of the service to be rendered; all in such detail as may be requisite. Also here insert those articles which relate to terms of payment; the action to be taken by the United States in case of failure or deficiency on the part of the contractor; and any other conditions which should be embodied in a contract stipulating for the delivery of supplies or for the performance of a service.] No member of or delegate to Congress, nor any person belonging to, or employed in, the military service of the United States, is or shall be admitted to any share or part of this contract, or to any benefit which may arise herefrom. [*Here add, to any contract made with an incorporated company for its general benefit, the following words, viz.: "But this stipulation, so far as it relates to members of or delegates to Congress, is not to be construed to extend to this contract."*] This contract shall be subject to approval of [*name the proper officer*]. In witness whereof, the undersigned have hereunto placed their hands and seals the date first herein before written.

Approved: ———, 18.

——— ———,
—— *Commanding* ——.
——— ———.
——— ———.

I do solemnly swear that the foregoing is an exact copy of a contract made by me personally with ——— ———; that I made the same fairly without any benefit or advantage to myself, or allowing any such benefit or advantage corruptly to the said ——— ———, or any other person; and that the papers accompanying include all those relating to the said contract, as required by the statute in such case made and provided.

——— ———,
—— ——.

Subscribed and sworn to before me this —— day of ——, eighteen hundred and ——.

——— ———,
—— ——.

No contract is entered into on the part of the United States unless the contractor, upon the execution of the contract or as soon thereafter as practicable, furnishes a bond according to the form prescribed. Execution of bonds may be waived when the contract involves no greater sum than five hundred dollars in value. The amount of the penalty of the contractor's bond is not less than one tenth of, nor more than the full sum of, the total consideration of the contract; the amount to be fixed, in each case, by the officer representing the United States. The Form of the Contractor's Bond is as follows:

Know all men by these presents, That we [*name of obligor*], of [*residence of obligor, giving town, county, State, etc.*], as principal, and [*name of surety*], of [*residence of surety*], and [*name of surety*], of [*residence of surety*], as sureties, are held and bound unto the United States of America in the penal sum of —— dollars, to the payment of which sum, well and truly to be made, we do bind ourselves, our heirs, executors, and administrators, jointly and severally, firmly by these presents.

Given under our hands and seals this —— day of ——, 18—.

The condition of this obligation is such that, Whereas the above-bounden [*name of obligor*], has, on the —— day of ——, 18—, entered into a contract with [*name and description of officer*], for [*here set forth in brief the subject of the contract*]:

Now, therefore, if the above-bounden [*name of obligor*], ——

heirs, executors, and administrators, shall and will, in all respects, duly and fully observe and perform all and singular the covenants, conditions, and agreements in and by the said contract agreed and covenanted by ——— ——— to be observed and performed, and according to the true intent and meaning of the said contract, and as well during any period of extension of said contract that may be granted on the part of the United States as during the original term of the same, then the above obligation shall be void and of no effect; otherwise to remain in full force and virtue.

Witnesses:

(Executed in duplicate.)

The sureties are to make and subscribe affidavits of justification on the back of the bond; the sum in which they jointly justify to be double the amount of the penalty; the affidavit to be taken before any official or person authorized or permitted by the laws of the United States, State, Territory, or District, to administer oaths.

The justification is, if practicable, followed by the certificate of a Judge of a United States Court or United States District Attorney, or, in their absence, by some other civil official of the United States, who certifies that the sureties are known to him, and that, to the best of his knowledge and belief, each is pecuniarily worth, over and above all his debts and liabilities, the sum stated in his affidavit of justification. But, if necessary or more convenient, separate certificates may be furnished as to each surety. See *Proposals*.

CONTRACT-SURGEONS.—In the United States army, these are physicians employed from civil life, at a specified compensation, to perform the duties required of Commissioned Medical Officers, when for any reason the number of the latter is insufficient. While they have no rank, they still have the allowances of an Assistant Surgeon, and are entitled to the same protection in their positions, also to the same respectful subordinate conduct and to the same military courtesy from enlisted men, as if they were Commissioned Officers. They are placed in the position of Commissioned Officers, so far as relates to their duties as Surgeons, by the Government. Surgeons from civil life who tender their services for the benefit of the sick and wounded in the field, under the invitation of the Secretary of War, are each allowed transportation to and from the place where their services may be needed, and, while so employed, the use of a public horse, a tent, and the privilege of purchasing subsistence stores from the Subsistence Department. See *Acting Assistant Surgeons*.

CONTRAMURE.—In fortification, a wall erected before another partition-wall to strengthen it, so that it may receive no damage from the adjacent buildings.

CONTRAVALLATION.—A name sometimes given to a belt of field-works thrown up around and facing the place invested, to render the besiegers secure against surprise. See *Countervallation*.

CONTREFORTS.—Brick-work which is added to the revetment of a rampart on the side of the terre-plein, and which is equal to its height. Contreforts are used to support the body of earth with which the rampart is formed. They are likewise used in the revetments of counterscarps, in gorges, and demi-gorges, and frequently form a part of the construction of the powder-magazines, which are bomb-proof. See *Counterfort*.

CONTRIBUTION.—In a military sense, an imposition or tax levied on the people of a conquered town or country.

CONTROL DEPARTMENT.—One of the Civil Departments of the British army, having for its object an efficient and economical control over the Departments it supervises. It may be said without exaggeration to be one of the most important Departments, for on it depends the custody and supply of all stores, whether of food or ammunition, the provision of transport, etc. It takes the place of what was formerly the Commissariat Department, in addition to other duties, such as were formerly in the hands of the Quartermaster General. Without the thorough efficiency of this Department no army can exist in the field; failure would probably entail defeat and all the disasters attending such a calamity. We have an instance in the Franco-Prussian War of the disasters likely to occur to an army whose Commissariat is unequal to the demands upon it. Take the case of the French army at Sedan, which, it is said, from want of proper Commissariat arrangements, was one of the causes that prevented it from effecting the relief of Metz, and was consequently overwhelmed by the Prussian army. The Control, as at present organized, is comparatively a new Department. The history of its formation is to be found in the various Blue Books on the subject, dating back to 1859; but it was in the year 1870 that the Department was consolidated, and divided into three administrative ranks, namely: Controller's, ranking with a Major General; Deputy Controller's, ranking with a Colonel; Assistant Controller's, ranking with a Lieutenant Colonel; and two Executive Sub-Departments—(1) *Supply and Transport*, which include the issue and account of stores and provisions, superintend and direct all transport, officer and command the Army Service Corps; and (2) *Pay*. For the management of the Supply and Transport, three Commissaries are attached who command the Army Service Corps, and who rank as follows: Commissary, with Major; Deputy Commissary, with Captain; Assistant Commissary, with Lieutenant. For the duties of the Pay Department there are three grades of officers, viz., Paymaster, Deputy Paymaster, and Assistant Paymaster, ranking in the same position as stated for Commissaries. First appointments in the executive branches of the Control Department are conferred on Civilians selected by competitive examination, or on Subalterns of the army and well-deserving Non-commissioned Officers. The limit of age is 17 to 20 for Civilians, 22 for Subalterns of the army and militia. In the regulations of 1870 for the Control, it will be found that the first ten paragraphs relate to general duties of the Department, and 11 to 18 lay down the duties of Control Officers towards the General Officer Commanding. These instructions show that the Control Officer is independent of the General in Command, in being able to communicate direct with the Secretary of War—which means that the Control Department is under the War Office, instead of the Commander-in-Chief, which appears to be a mistake. On this point most military men are in accord, and there is in *Blackwood's Magazine* for October, 1874, a very good article on the subject of the Control Department, showing its unsuitableness, as at present constituted, either for war or peace. The article is written by a General Officer of great experience, General Lysons; it is full of good sense and military knowledge, and may be taken as the view entertained by most military men who have passed their lives in the field. A return to the old organization of the Commissariat Department seems to be demanded, and will doubtless be reverted to before long: it was sound and good; it stood the test of years of practical experience; it grew under the hard hand of necessity; it carried the army through all the difficulties of the Peninsular War, and led the troops to victories the most brilliant in the annals of history. Many officers think it unadvisable to mix up, in one Department, supply, store, passage transport, and half a dozen other things, each of which should be a Department of itself. To crowd Department upon Department under one head, and to expect efficiency, is simply courting failure. On the formation of the Control, the following separate branches of the army were amalgamated with it, viz.: Commissariat; Barracks; Military Stores; Purveyor's; Army Transport—then known as the Military Train, to which a large number of civil and military employés were also attached, dispersed in a variety of Sub-Departments, having no connection with each other. The Control Department is presided over by a Surveyor General of Ordnance at the War Office, who has under him a Director of Transport and Supplies, and a Director of Military Stores. The administrative branch consists as is shown above.

CONTROLLER.—An officer whose duty it is to keep financial accounts, or to see that they are properly kept and audited. In the United States Treasury Department there are the First and Second Controllers to examine accounts and sign drafts; and also a Controller of the Currency, who furnishes circulating notes to banks. In some of the States, as New York, a Controller is elected by the people who has general charge of the financial affairs of the State. There is also a Controller in the city of New York, elected by popular vote. In the British service, the Controller is the highest grade in the Control Department. He ranks with a Major General.

CONVALESCENT.—A soldier discharged from hospital, but who is not strong enough to do his duty.

CONVALESCENT-HOSPITAL DEPOTS.—Encampments of huts or tents for the reception of men discharged from the general hospital, and who require no longer medical attendance, but at the same time are not fit to join the ranks, from a want of strength. Such depots relieve the general hospital, and are better places for the convalescent than a crowded sick-room, as they are removed from a bad atmosphere, and have consequently a favorable chance of gaining strength. As regards hospitals, the Medical Departments is responsible for the use of all stores, and for timely requisitions, but the Control Department is responsible for such stores being supplied.

CONVENTION.—An agreement entered into by troops which are opposed to one another, either for the suspension of hostilities or the exchange of prisoners. See *Truce.*

CONVERSION.—1. A term used in ordnance nomenclature when condemned stores are converted or turned into use for other purposes. The term is made use of when smooth-bore guns are converted into rifled guns.—2. A change of front, as of a body of troops attacked in the flank.

CONVERTED GUNS.—A term applied to cast-iron guns lined with wrought-iron or steel tubes. The coils for the tubes are made entirely of wrought-iron bars, specially prepared by being put three times through roughing-rolls; puddled iron is hard and brittle and is not by itself suitable for guns. A sufficient number of bars are piled or faggoted together to form a bar of the size it is intended to roll. The pile, composed partly of puddled iron and partly of scrap, the former being placed always on the outside, on account of the more even surfaces, is raised to white heat and rolled into a long bar about 24 feet long, and varying in section from 2¼ to 7 inches, according to the purpose for which it is intended. It is then cut into lengths, again faggoted, raised to a welding heat and passed between the rollers; one rolling may be sufficient. The section of the bar is slightly trapezoidal, in order that when the hot bar is wound round the mandrel, narrow side inward, the spreading of the inside and the narrowing of the outside may be neutralized, and no space left between the folds of the coils. To weld the bars together, the ends must be scarfed down and placed from opposite sides in a furnace, from which, when they arrive at a white heat, they are withdrawn and welded under an adjacent steam-hammer, sand having been thrown on the hot bars (as is indeed customary in the case of all forgings) in order to clean the surface and prevent scale forming, by converting the superficial oxide into a liquid silicate which will flow off of its own accord or be squeezed out by the hammer. Another bar is welded on in a similar manner, and so on until a sufficient length is obtained for the required coil.

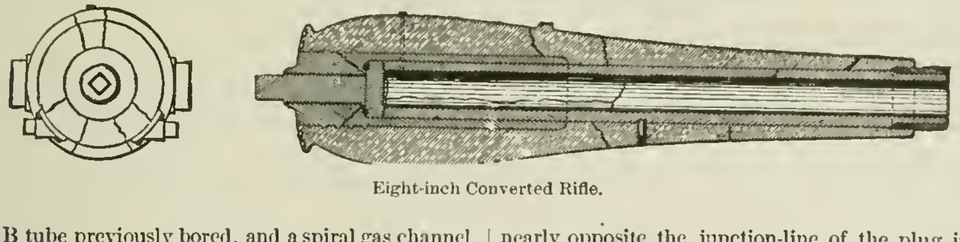
The bar to be coiled, having the ends flattened down, is placed on trestle-rollers in front of a long reverberatory furnace with a chimney at the far end and grates along its sides. A chain being hooked into an eye or hole in the end, the bar is drawn by machinery into the furnace. When the bar arrives at a bright-red heat, the end near the door is drawn out by means of the same eye, and is attached to a pin, this end being cooled with water to prevent it tearing away with the weight of the bar; this pin is connected with a slightly tapering iron roller or mandrel fixed across and in front of the door of the furnace; the mandrel tapers in order to facilitate the removal of the finished coil. The apparatus is then put into gear, and the mandrel revolves, winding the bar around it. During the process scales form between the folds, but their effect is almost nullified by subsequent heating and forging, sand being used to assist in liquifying the oxide as stated above. When the coil is formed, the fixed extremity is hammered off the pin and water is poured on that end to cool it, in order that the folds there may not be opened out in taking off the coil. If the coil is large, a short iron bar is placed with one end resting on the ground and the other end against the extremity which has been removed from the pin. The mandrel is then turned in the same direction as that in which it revolved when the coil was being formed, and the coil, being prevented from revolving by the iron prop, is loosened and slips down toward the narrow end of the mandrel. The mandrel is then lifted up by a crane and the coil drops off.

For the welding, which, especially in tubes for lining guns, must be done with great care, the coil is placed upright in a reverberatory furnace, for were it placed on its side it should be turned over in order to be equally heated all through, and moreover drippings from the fire-brick which line the furnace would probably drop from the roof in between the folds. The tube being intended for an inner one, two furnaces have to be used; one is at a low temperature, (termed a blue light), and when the coil arrives at a red heat it is brought out and transferred to the other, where it is brought to a welding heat. This is found to be more economical than by placing the cold coil at once into a very hot furnace, and also prevents any injury to the iron which would result from so doing. In all cases of welding it is necessary not only to strike while the iron is hot, but that the surfaces to be joined should be perfectly clean; the white hot coil is therefore transferred from the furnace to the steam-hammer as quickly as possible, not neglecting to throw sand upon it. The coil is first placed vertically under the hammer, and receives a few smart blows to weld the folds; it is then thrown on its side, and being gradually turned, is hammered (or patted) all round to straighten it. It is then raised vertically again and a punch or mandrel rather over half the length and a little larger than the interior diameter of the coil is hammered down its own length; the coil is next placed on its side and hammered round, that half of its length thus being made very compact and large enough to let the mandrel fall out; after this the coil is again raised vertically, and the mandrel is forced in the opposite end, and the process repeated. The mandrels are of coiled iron and very hard. The reason why a long mandrel is not forced through the whole length of the coil is that it would tend to separate the folds.

The coil is replaced in the furnace for a second heating, and much the same process is followed to render the ring more consolidated as well as more shapely; a fine mandrel is also used to make the interior more perfect; and in order to prevent the tube from being bell-mouthed, a flexible steel bar is used under the hammer to flatten the ends. Before the coil is removed from the hammer, water is thrown over it, which, forming into steam, blows off the black scales and shreds where the work is good, but a black spot is left by the water if there is a bad part. In order to form lining-tubes, several of these coils have to be united. To weld them together, the coils have to be faced (turned smooth at the ends) and reciprocally recessed; that is, a projection (spigot) is formed at one end of a coil, while a recess (faucet) is bored in the corresponding end of another coil. The height of the shoulder is a little greater than the depth of the recess, in order that a close joint may be obtained on the interior. The recess is then expanded by heat and shrunk over the projection, so that the two coils are attached securely enough together to admit of their being put into the furnace for welding. For the inner barrel, which is intended to be the entire length of the bore, the tube is put crossways through a furnance so constructed that intense heat acts on the joint while the remote ends project outside. When the joint arrives at a welding heat, a stout iron bar is passed right through the tube; this bar is keyed at one end, and by means of a screw-nut, worked by a long lever at the other end, the two coils are pressed and thus welded together. This pressure slightly bulges the metal at the junction, so it must be straightened under a steam-hammer. Another coil is then added on in a similar manner, and so on until the tube is of the required length.

The tube, if for an 8-inch rifle, after having its necessary length, is then rough and fine bored to about 7.92 inches diameter, and the recess in the breech cut and tapped for the wrought-iron cup. The cup for closing the breech-end of the barrel is forged and stamped into shape under the steam-hammer. It is turned inside and outside, and furnished on the outside with a thread of four or five to the inch. It is then screwed tightly home. The tube in this state is proved with water-pressure of 120 pounds to the square inch, to ascertain that the cup fits tightly and that there is no leakage. The breech-end of the A tube is then turned over a length of 40 inches for amount of extension, in fact, as that due to its elastic limit or pressure of 12 tons to the square inch of section). Therefore it is not necessary to have more than 500° F., which will allow a good working margin. With respect to the mode of cooling during the process of shrinking, care must be taken to prevent a long coil or tube cooling simultaneously at both ends, for this would cause the middle portion to be drawn out to an undue state of longitudinal tension. Therefore, in some cases, water is projected on one end of a coil so as to cool it first. In order to prevent the expansion of the inner tube, thus obstructing or retarding the operation of cooling, water is circulated through the interior by means of the usual supply-pipe and siphon. In the manufacture of these tubes, samples of each week's work are tested for tensile strength and elasticity, and usually with most favorable results; the stretching-weight being about 12 tons, and the breaking-weight 23 tons, per square inch.

Before inserting the coiled wrought-iron barrels, the cast-iron gun should be bored out to the required size and the bore afterwards carefully adjusted by lapping with leaden block and sand and water. The taper, if any, from the breech toward the muzzle, should be uniform, and in no place should the eccentricity exceed .002 inch. The muzzle-end should be screwed with an allowance of .015 between the diameters of the ring and the gun; the screwed part should be longer than required for the ring, so as to insure the rear end of barrel being in contact with the cast-iron at the end of the bore. A "gas-indicator hole" is drilled through the breech-end, so that it will come



Eight-inch Converted Rifle.

the B tube previously bored, and a spiral gas channel, .05 inch deep and .1 inch wide, is cut round its exterior, communicating with the star grooves cut in the end of the barrel and the gas-escape through the cast-iron breech.

The B tube consists of two coils united, and being rough-turned to a diameter of about 13.75 inches, and finished-bored to 10.75 inches, it is shrunk on with .003 inch shrinkage in the diameter. The B tube in order to be shrunk on the A tube has to be bored to that degree of smoothness which is necessary for close contact and mutual support, and is gauged to $\frac{1}{1000}$ of an inch every few inches of its length as well as at every shoulder it may have. To these measurements the shrinkage is added, and a plan made out according to which the exterior of the inner coil or A tube must be fine-turned in order that it may exceed in diameter the bore of the outside coil by the required amount of shrinkage at the respective points. This plan, together with a series of corresponding "horseshoe" gauges (very accurately adjusted), is then furnished to the turner, who turns down the inside coil to the proper size. The operation of shrinkage is very simple. The outer coil is expanded by heat until it is sufficiently large (if a large mass, by means of a wood-fire, for which the tube itself forms the flue; if a small mass, in a reverberatory furnace at a low temperature). It is then raised up by a traveling crane overhead, and dropped over the part on to which it is to be shrunk, which is placed vertically in a pit ready to receive it, and where the tube and jacket cool off. The heat required in shrinking is not very great. Wrought-iron, on being heated from 62° F. (the ordinary temperature, say) to 212°, expands linearly about $\frac{1}{1000}$ part of its length (the same nearly opposite the junction-line of the plug in the barrel. All sharp edges in the interior of the gun should be taken off, and the bore carefully cleaned and oiled. The barrel is turned to the measurements taken from the gun when finally prepared to receive the barrel. These measurements should be taken at least every 6 inches from the muzzle to within 12 inches from the breech, when they should be taken at every inch. From the muzzle to a point 24 inches from the breech, the difference between the bore and the size of the barrel should not exceed .015 of an inch, and from thence to the bottom of the bore .007 of an inch.

The barrel can be turned by means of an expanding mandrel placed in the muzzle, the center being left in the plug at the bottom of the barrel. The reduced part for the muzzle-ring should be .01 of an inch less in diameter than the bore of the ring; the breech of the ring should be square to the face against which it is screwed. The radius at the breech-end of barrel should not be in contact with the casing, but should have .05 of an inch clearance; thus if the gun has been bored out with a 1.7 radius tool, the barrel should be turned to 1.75 inch radius. When fitting the barrel into the gun, all bearing-surfaces should be well oiled. It is most convenient to place the gun on trestles about 3 feet 6 inches high. The barrel is lifted by a crane and entered as far as the slings will permit. The slings are then placed round the end of the expanding mandrel, and at the outer end of the mandrel are bolted two strong cross-bars by which the barrel is worked round while it is being drawn in by the crane. The indicator-hole allows the air to escape. The plug-center should not be taken off until it comes in contact with the bottom of the bore, when it may be turned off and the breech-end well marked with thin red-lead paint. The barrel should then be again tried in and well worked against the casing, great care being taken that the end of the barrel abuts truly against the bottom of the bore. A small screw is inserted at about the middle of the length of the barrel, to prevent the possibility of the barrel turning round in the gun during firing. When the tube is properly adjusted, the collar is securely screwed into the muzzle. The muzzle of the gun is then faced, and the bore lapped and rifled. The old vent is closed with a wrought-iron screw-plug, a new vent (copper-bushed) being placed nearer the muzzle.

The drawing represents an 8-inch converted rifle, tested with the following results: Six preliminary rounds were fired, using charges ranging from 20 to 30 pounds. Four hundred and fifty rounds were fired with battering-charges of 35 pounds of hexagonal powder and an average weight of projectile (Butler) of 171 pounds. All examinations up to the one hundred and seventieth fire failed to discover any evidence of injury to the system; but impressions taken of the bore at this round showed a fine line extending from the commencement of the land immediately in front of the vent to the copper bushing. This proved to be an initial rupture, as at 175 rounds a crack had developed from the vent to the muzzle in and through the tube. The firings were continued from this point up to the four hundred and fifty-sixth (the breaking round), making a total of 286 rounds which the system endured after the rupture of the tube. The gun was fired after the complete rupture of the inner tube—at the one hundred and seventy fifth round—to test how long the jacket and the cast-iron casing would stand battering-charges. Evidence of rupture of the jacket was noted at the last few rounds, and the gun, when burst, evidently was being held together by a weakened cast-iron casing, probably cracked on its interior surface. The steel in both jacket and tube, although of good quality, was evidently too high and inextensible to secure the very best results.

An analysis of the record shows as follows: A mean initial velocity of 1379 feet, using 35 pounds powder and projectile of about 185 pounds; the mean maximum pressure being 30,453 pounds per square inch, and, for a shot of 170 pounds, a velocity of 1425 feet, and a corresponding mean maximum pressure of 29,622 pounds. Forty-six shots of about the weight of the former, and 283 shots of about the weight of the latter, were fired. The mean weight of all projectiles—using 35-pound charges—is 171 pounds; the mean velocities and pressures obtained are respectively 1419 feet and 29,668 pounds. No anomalies are apparent in these respects, and the record shows a general accordance with the results attained in other trials. The star-gauging at the one hundred and seventieth round indicated a maximum enlargement of .010 inch; at the one hundred and seventy-fifth round, of .0115 inch, the result of the crack; from this point to the four hundred and fifty-second round the maximum enlargement was .0235 inch. The gutta-percha impressions taken at various times during the progress of the trial indicated no special erosion from the gases; but, as the firings progressed, spawls were gradually developed along the line of the crack in the tube. See *Breech-insertion, Coiled Tubes, Fabrication of Tubes, Ordnance, Palliser Gun,* and *Parsons Gun.*

CONVERTER.—In metallurgy, a receptacle holding iron which is to be converted into steel; a spherical vessel lined with fire-clay, the bottom having numerous holes through which a powerful blast is driven during the process. From this vessel the liquid steel is poured into molds. See *Blistered Steel.*

CONVERTING.—1. Decarbonizing, or changing cast-iron into steel. 2. A name applied to changing muzzle-loading arms to breech-loaders, and which in some form has taken place with the small-arms of most national armaments. From among the various competing plans for converting the Enfield rifle of the English service into a breech-loader, that of Snider was adopted. The cost of conversion is about 15s. English for each rifle. The method is as follows: About two inches of the barrel are cut away at the breech, and a solid breech-stopper working sideways on a hinge is placed in the opening thus made. Through this stopper passes a piston, one end of which, when the breech is closed, receives the blow from the hammer, while the other communicates it to the center of the cartridge, thus firing the latter. The empty cartridge-case is retracted after each discharge by means of sliding back the stopper on its pintle, when the tilting of the piece tips out the shell and another can be inserted. The Springfield rifle is also converted into a breech-loader. See *Converted Guns.*

CONVEX ORDER OF BATTLE.—If an attack is made in the center of the enemy's line, refusing both wings, the general direction of the line of battle of the attacking army will be convex towards the enemy's line. This order of battle has been frequently used, and possesses the advantage of producing great results when the attack is successful. It possesses the disadvantage of selecting as a point of attack the strongest part of the enemy's line, and in case of repulse the failure is apt to be followed by great disaster if the enemy makes a vigorous counter-attack. See *Concave Order of Battle.*

CONVOY.—To conduct a convoy in safety through an enemy's territory, where it is exposed to attacks either of regular or of partisan troops, is one of the most hazardous operations of war; owing to the ease with which a very inferior force may take the escort at disadvantage in defiles, or other positions favorable to an ambuscade or surprise, and to the difficulty of securing a long column, like that presented by a convoy, from a sudden attack.

The escort should be of sufficient strength to beat off any presumed force that the enemy can bring against it. A weak escort will only hold out a temptation to the enemy to attack the convoy. When the convoy is of very great importance, it may be necessary, besides giving it a strong escort, to throw out detachments between its line of march and the enemy; and when there are posts occupied by our troops along this line, they should keep up a vigilant system of patrols, pushing them as far out as practicable, so that the escort may receive aid and timely notice of any hostile movement. The escort, when it is deemed necessary, should be composed of all arms; but always of both infantry and cavalry, as, from the necessity of gaining timely information of the enemy's approach, patrols of cavalry must be pushed out to some distance, both in front and on the flanks.

As the convoy must be perfectly hemmed in and guarded on all points by its escort, the latter is usually divided into five principal portions with this object; an advanced-guard, which is preceded by a small detachment to scour and search the ground in front of the line of march; a rear-guard; flankers; and the main body. For the purpose of presenting a sufficient force upon those points of the convoy that will probably be assailed, the main body is subdivided into four unequal portions; one half of it will constitute a reserve; one fourth will form a guard for the center of the convoy; and the remaining fourth will be divided into two equal portions, one of which will march directly at the head of the convoy, and the other close in its rear. This subdivision of the main body is made on the supposition that the enemy will attack the convoy either at the center, or in the front or rear. If the attack is made upon either of the two last points, the divisions for their protection can be readily reinforced by the advanced- or the rear-guard. As the reserve must be in readiness to reinforce any point menaced, and to offer a vigorous resistance, its strength should be greater than either of the other divisions.

The order of march of the escort will be regulated mainly by the natural features of the ground passed over. The advanced-guard will precede the convoy about a thousand paces. The detachment by which it is preceded, and which should consist of cavalry, will push forward as far as it can with safety, taking care to scour thoroughly all the ground passed over. The flankers, which will also usually be composed of cavalry, will be divided into platoons, and be thrown out as far as circumstances will permit. Each platoon will throw out a small detachment, on its outer flank, which last will furnish vedettes to move along the outward flank of the detachment. The reserve will usually occupy some point near the center of the convoy. The rear-guard will leave about 1000 paces between it and the tail of the column. The divisions immediately at the head and tail of the train will keep close to the convoy. The center division will usually be divided into two portions, one being on each flank of the convoy; a space of eight or ten paces being left in the center of the train, for these portions to pass to either flank, as circumstances may require.

The convoy is placed under the orders of an officer, subordinate to the Commandant of the escort, who is charged with everything appertaining to its police, etc. A detachment of Pioneers, or Sappers, should precede the convoy, to repair the roads and bridges, etc. A few wagons, with all the necessary implements for the Sappers, should accompany the convoy; and it is also recommended to carry with it a few *chevaux-de-frise*, the lances of which are of iron, and connected with the bodies by hinges, to pack conveniently, in order to form a temporary obstacle against the enemy's cavalry, when the convoy parks for the night, or when threatened with an attack. When a part of the convoy consists of bat-horses or mules, they should be placed at the head of the column of wagons, as they are found to travel better in this position than when in the rear.

All the usual precautions to guard a column on the march against a surprise should be redoubled in cases of convoys. The patrols on the flanks and in front should push as far out as practicable, so that the convoy may have timely warning of an enemy's approach, in order to park, according to circumstances, before an attack can be made. With drivers accustomed to their business, half an hour at least will be required for this operation. The advanced-guard should be particularly careful to occupy by detachments any lateral roads which might offer the enemy a favorable point of attack on the convoy. These detachments will keep their posts until the convoy has passed; and they will join the rear-guard as it comes up. The officer in command of the head division, marching with the convoy, will see that his detachment moves on regularly, as the pace of the convoy will be regulated by it; and from time to time he will bring it to a halt, to allow the carriages to close up: this precaution must be carefully attended to when near an enemy.

If menaced with an attack, the divisions at the head and rear of the convoy will keep their positions and repel the enemy by their fire should he attack; the center division will move to the flank menaced, and take position to cover the two center sections of the convoy; the reserve will move towards the point threatened; the advanced- and rear-guards and flankers will close upon the convoy to be in readiness to act as circumstances may require. Before entering a defile, a detachment from the reserve should be sent forward to secure its flanks and outlet, and then send out patrols in all directions to examine the ground in front and see that all is safe. As the convoy comes up to a point designated in rear of the defile, it is parked in lines of sections. The center division of the escort will join the advanced-guard to cover the front; the rear-guard will take position to cover the rear, the flankers on the flanks, and the reserve in a central position to advance upon the point which may be attacked. When the patrols report all safe, the advanced-guard and center division pass the defile, and proceed far enough beyond it to cover the ground where the convoy will park as it reaches the other side; the reserve and flankers will cover the flanks of the convoy as it moves to its new position, and will then take post as before; the rear-guard, joined by any detachments left to secure particular points on the flanks of the defile, will follow so soon as the convoy and the rest of the troops are in position. When all the troops have passed, strong detachments are sent forward, in all directions, at least one hour before the convoy is again put in motion.

When the escort takes position at night within the park for defense, the reserve will be posted in the center, and the divisions that march with the convoy in rear of their respective sections. The advanced- and rear-guards and the flankers will take post without, and establish their outposts and sentinels in the usual way for safety. The cannon, placed at the angles of the park, will be supported by detachments of infantry and cavalry in their rear. The different divisions will throw forward skirmishers to meet the enemy if he attacks; whilst others will occupy the wagons from which they can fire. Should the enemy not be beaten off by the fire of these troops, the reserve will sally out and attack with the bayonet.

An attack upon a convoy is a comparatively easy and safe operation, and may be made with a force quite inferior to the escort, as the latter is obliged, for the security of the convoy, to keep on the defensive. It will usually be best to attempt a surprise, choosing points which are favorable to ambuscades. The manner of conducting the attack will depend upon its object, whether it be to capture the entire convoy, to cut off a part of it, or simply to delay its march. In the first case, the escort must be beaten and dispersed, whilst a detachment is sent to secure the convoy. In the second, an attack may be made on one point with the view of drawing the main body of the escort to the defense of that point, whilst a detachment attempts to cut off the part of the convoy from which the escort has been withdrawn. In the last case the convoy will be frequently menaced with an attack, to force it to halt and park for defense; the roads will be obstructed, bridges broken down, etc.

If the attack is successful, the main body of the troops should be kept together in position, to cover the captured convoy, whilst the detachment sent to secure or destroy it is performing its duty. The cavalry will endeavor to disperse the escort, and bring in all the horses that may have been cut loose from the convoy. The precaution should be taken of having spare horses in harness, in readiness to take the places of those which the escort may have cut loose, or maimed, to prevent the wagons from being carried off. For the attack of a convoy parked for defense some pieces of artillery will be necessary, and howitzers will be found particularly useful. Without the aid of this arm it will be very difficult to force a defensive park with infantry, unless the escort is very feeble, or the position chosen for the park presents covers within the effective range of musketry, from which, after keeping up a well-directed fire, a rush may be made on the park. See *Train*.

CONVOY OF PRISONERS.—The rules laid down for convoys in general apply equally to this particular class; but this is an operation presenting many difficulties, owing to the fact that they are always ready and on the alert to aid any efforts made to recapture them. Under such circumstances, when the convoy is attacked, the prisoners should be made to lie down, and warned not to arise under penalty of being shot. See *Convoy*.

COOKING.—Army cookery has become an important feature in all military systems. The sufferings in the Crimea in the winter of 1854–55 drew public attention to the subject; it was then found that cooking was little understood by the British troops, and that the soldiers seldom had meat otherwise than boiled. M. Soyer was sent out by the Government, principally to advise in reference to hospital cooking, but also to improve the system of camp-cooking, so far as military routine would allow. He devised new forms of stoves, and constructed recipes for using to the best advantage all the available provisions for a camp. The officers at Sebastopol made a highly favorable report of Soyer's *field-kitchen*, a kind of camp-stove, with a caldron holding 12½ gallons: two such stoves would easily cook for a company of 100 men; both could be carried by one mule, with sufficient dry wood for three days' fuel. Though mainly intended for boiling, the apparatus afforded facilities for many varieties of cooking. When M. Soyer returned to England he made a few improvements; and finally the apparatus presented itself as a sort of upright can, suitable for boiling, steaming, baking, roasting, stewing, and making tea or coffee: with fourteen pounds of fuel one of these would cook for fifty men; and if twenty such were placed near together, four cooks could serve for 1000 men.

A Committee which inquired into the subject of barrack economy some years ago, recommended that every large barrack should have a bakery with two ovens, where the men could learn to make and bake their own bread ; and also that the barrack-kitchens should be so furnished as to enable the men to bake their meat if so inclined, instead of being confined, as heretofore, almost wholly to boiled dinners. A School of Cookery has been formed at Aldershott, where men are trained to act as Sergeant-cooks, of whom there is now one to each regiment. His duty is to superintend and direct the operations of the soldiers detailed from the several companies to act as cooks.

At various times in 1859 and 1860 certain highly ingenious forms of apparatus were tried, to test the possibility of cooking for troops while *the kitchen itself is on the march*. One of these inventions consists of a compact set of stoves and caldrons, fitted into a wagon, and has been found on trial to answer the purpose perfectly. For a detailed account of field-cookery and campaign recipes, see FARROW'S MOUNTAIN SCOUTING, Chapter XII. (New York, 1883).

COOLING.—The operation following *casting* in the fabrication of cast guns. The water for cooling the gun is taken from a hydrant where the supply is constant and uniform, the connection being made by rubber hose. It is conducted into the core by means of a metallic tube which passes through a water-tight joint in the center of the cap and extends to within a few inches of the bottom of the barrel. The water consequently passes into the core at the bottom and ascends until it reaches the escape-pipe and is discharged. The flow of the water commences as soon as the furnaces are tapped, and is regulated to produce, half an hour after the casting, a certain change of temperature, about 25°, between entering and leaving the core. When this is effected the rate of flow remains constant until the core is removed. As soon as possible after the casting the fire in the pit is kindled and kept up until the withdrawal of the core-barrel; it is allowed to die out gradually. Meanwhile the mouth of the pit is kept closely covered. When the change of temperature of the outflowing water has become constant or nearly so, the core-barrel is withdrawn. To effect this, it is sometimes necessary to largely increase the flow of water for a short time, in order to contract the barrel enough to loosen it from the casting. As soon as this is effected the flow is stopped. The rope with which the barrel is wrapped takes fire from the heat of the casting and is consumed, leaving the barrel detached from the composition surrounding, and allowing its withdrawal without difficulty. As soon as the core-barrel is withdrawn the water is turned into the bore, being conveyed by the conducting pipe to the bottom, and escaping by means of a tube cast into the gun-head, entering the bore a few inches from the upper end of the casting. The rate of flow of the water through the bore is so regulated as to produce a change of bout 100° between entering and leaving at half an hour after the removal of the barrel. It is then allowed to remain constant until the gun becomes cool. The time occupied in cooling by this process varies from four to six days, according to the size of the gun; for a 20-inch gun a longer time may be required. In case the condition of the metal in the furnace before casting should indicate that a slower rate of cooling is desirable, the process of cooling by air is resorted to after the withdrawal of the core-barrel. The current of air is furnished by a rotary blower driven by steam or water power, and is conducted into the gun by a sheet-iron pipe which extends to within a short distance of the bottom of the bore. Cooling by this process usually requires two or three days more than by the water process. See *Cooling of Castings* and *Rodman Gun*.

COOLING OF CASTINGS.—The enormous time required by a large casting for cooling is not generally known. A solid casting sufficiently large for a 15-inch gun weighs about 35 tons; it is red-hot three days after having been cast, and only becomes cold enough to handle after a fortnight. The cooling of a casting must be uniform, so far as uniformity is possible. This is impossible strictly in any casting; the approach to it is most difficult in heavy solid castings, and hence the great advantage of the practice of hollow-casting upon a suitably made core, admitting of internal cooling by artificial means.

The contraction of cast-iron in becoming solid introduces strains into the mass by consolidation of one portion of the casting before another. When a large gun is cast solid and the metal cools in the ordinary way, the external portions solidify long before the interior has ceased to be liquid, and the process of solidification is propagated, as it were, in parallel layers from the outside to the center of the mass. When the first layer or thickness of solid crust has formed in the exterior, it forms a complete arch all round, so that the contraction between fluidity and solidification of each subsequent layer is accommodated by portions of matter withdrawn radially from the interior toward the still cooling exterior; that is to say, from a smaller toward a larger circumference.

The final effect of this, propagated to the center of the mass, is twofold. First. To produce a violent state of internal tension in the particles of the metal in radial lines from the axis of the gun inward as a cylinder, tending to tear away the external portions of the mass from the internal nucleus. Second. To produce about the center or along the axis a line of weakness, and one in which the texture of the metal is soft, porous, and of extremely low specific gravity. The effect of this unequal contraction may be so great as to crack the interior metal of cast-iron cannon, even before it has been subjected to the force of gunpowder ; and large masses of iron which have been cooled very rapidly by casting them in iron molds have been known to split open longitudinally, from no other cause than the enormous strains to which they are thus subjected.

The great improvement in the fabrication of cast-iron guns is Captain Rodman's process of cooling them as far as possible from the interior, and for this purpose casting them hollow. The design is to remedy the various defects of the old process; principally to obviate the tendency of solid castings to burst by their own initial strains, by reversing the process of cooling and shrinking described above. Since there would then be no force opposed to the contraction of the inner layers of metal, except the trifling cohesion of the liquid or pasty mass that they shrink away from, they would not be left in tension, and therefore they could not exert any power to pull the exterior layers into compression.

The method employed is to carry off the internal heat by passing a stream of water through a hollow core, inserted in the center of the mold-cavity before casting, and to surround the flask with a mass of burning coals to prevent too rapid radiation from the exterior. Extensive trials have been made to test the merits of this plan, and the results show that cast-iron cannon made by it are not only stronger, but are less liable to enlargement of the bore from continual firing, the surface of the bore being the hardest and densest part of the casting, and best calculated to resist pressure and abrasion. See *Cast-iron Guns*, *Ordnance*, and *Rodman Gun*.

CO-ORDINATES.—What is termed the method of co-ordinates is an invention of Descartes, whereby algebra and the calculus may be employed in geometrical investigations. The method is sometimes called algebraical geometry—sometimes, and more properly, analytical geometry; and it is commonly treated under the head of "geometry of two dimensions" or of "geometry of three dimensions," according as it is applied to investigate the properties of figures all in one plane, or of curved surfaces. The method is capable of a popular explanation. Co-ordinates are lines so measured off from a fixed point, called the origin of co-ordinates, and along fixed lines passing through it, called the axis of co-ordinates, as to determine by their quantities the position of any other point relative to the origin. The first step is to find how to determine the position of a point in a plane. Take any fixed point in it for the origin of co-ordinates, and through it draw two fixed lines—the co-ordinate axes—at right angles to one another. Then, if the perpendicular distance of the point from each of these axes be given, its position will be determined. Referring to Fig. 1, if P be the point, and O be taken for the origin of co-ordinates, OX, OY for

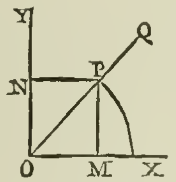


FIG. 1.

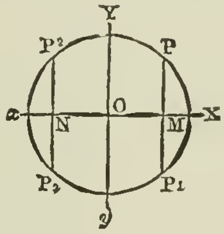

FIG. 2.

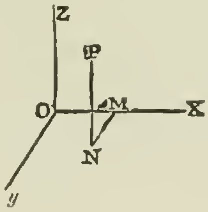

FIG. 3.

the axes, then if we know NP or OM, the perpendicular distance of P from OY, and measure off from O, OM on the axis OX, and through M raise a line perpendicular to OX, P must lie in this line, for it contains all the points in the plane which are at the perpendicular distance OM from the axis OY. Similarly, if ON or PM, the perpendicular distance of P from the axis OX, be known, and we measure that distance off from O along OY, and through N draw a perpendicular to OY, the point must be in that perpendicular. It is therefore at the intersection of the perpendiculars through M and N respectively. When, as in the figure, the fixed lines are at right angles to one another, the co-ordinates OM, ON are called the rectangular co-ordinates of the point. Let us now see what use can be made of this mode of determining the position of the point, for the discovery of the properties of lines and surfaces. As the values of the co-ordinates change for the different points in the plane, they are denoted by the variables x and y. Now, if we suppose the point P to begin to move according to a determinate law, and the co-ordinates to change their magnitudes so as always to be its co-ordinates, knowing the law of P's motion, we are able to express in algebraical phraseology the law of the corresponding changes in its co-ordinates. For instance, if P moves so as to be always at the same distance from O, OP is constant, and the square on OP is equal to the sum of the squares on OM and PM. Putting this into algebraical language, we have the equation $x^2 + y^2 = R^2$, or $y = \pm \sqrt{R^2 - x^2}$, where $R = OP$. This is called the equation of the circle referred to its center as origin, and to rectangular co-ordinates; and it expresses the law according to which the changes of the co-ordinates must take place: and from this equation, combined with that of a straight line, etc., every property of the circle may be determined. If P move so that the sum of the distances from two fixed points shall be always the same, and we express the relation between x and y in that case, we should have the equation of an ellipse. This suffices to show in a general way the nature of the method. Equations between x and y are called the equations of the lines, whether straight or curved, traced out by the point P; and by means of them, though they but express relations between *quantities*, the *qualities* of the lines to which they refer may, by artifices explained in every treatise on the subject, be detected. Nay, by assuming equations between x and y, and examining the lines which points represented by them would trace, many singular curves have been discovered. There are a variety of conditions to be attended to in the interpretation of such equations, depending on the assumptions set out with, in choosing the origin and axis. The axis of x or OX being taken to the right of the origin, and the axis of y or OY being perpendicular to it and above it, x and y are counted positive when they are measured along their axes to the right of and above the origin respectively, and negative when they are measured to the left and downwards respectively. Suppose $x = OM = ON$, and $y = MP = MP_1 = NP_3 = NP_2$: the co-ordinates of the points P, P_1, P_2, P_3 would be $(+x, +y)$, $(+x, -y)$, $(-x, +y)$, $(-x, -y)$ respectively. These points being equidistant from O, we may suppose a circle to pass through them. Recurring now to the equation of the circle, $y = \pm \sqrt{R^2 - x^2}$, the meaning will be seen of the two values $+$ and $-$ of y given by the quadratic. Often the axes of co-ordinates selected for convenience are oblique, i.e., inclined at some other angle than a right angle. An equation between co-ordinates referred to one set of axes may always be transformed to co-ordinates referred to another, by the process known as the transformation of co-ordinates. A similar transformation of equations by the same process may be made where it is desired to refer the line to a new origin.

What has been said above refers to the co-ordinates of a point in a plane, or to what is called geometry of two dimensions. But the rationale is the same with that of connecting in equations the co-ordinates of points in space—the subjects of geometry of three dimensions. The position of a point in space requires three co-ordinates to determine it, and these are usually denoted by the symbols x, y, z. An origin being taken, and three axes, OX, OY, OZ, mutually at right angles to one another, the point is referred to the three planes through these axes. z, or PN, is its height above the plane through YOX; y, or NM, is its distance perpendicularly from the plane XOZ; and x, or OM, is its perpendicular distance from the plane ZOY. It is clear that these three determine the position of the point. In three dimensions, as in two, the problem may be stated to be: Given the law of the motion of P, to express the law regulating the variations of its co-ordinates as it moves. The algebraic expression of the latter law is, the equation of the surface traced by the point in moving over all the space it can traverse consistently with the law of its motion. The method of co-ordinates, besides its use in geometry, is of great value for resolving forces in gunnery, and also for finding the resultant of a great many of them. See *Trajectory*.

COPING.—The merlons or rising parts of battlements are sometimes called cops, but the term *coping* is usually applied to the covering course of a wall, which is made either sloping or round, so as to throw off water. Where the coping is of hewn stone, it is frequently ornamented with a circular molding running along the top, and sometimes the angle at the top is simply taken off to prevent it being chipped.

COPPER.—One of the most anciently-known metals, whose name is derived from the Island of Cyprus, where it was first obtained by the Greeks. In the earlier times copper does not appear to have been employed by itself, but always in admixture with other metals, principally tin, forming what is now called bronze. There is every reason to believe that, next to the large quantities of tin which they obtained, one of the great inducements which the Phenicians had in making searches for metals in Great Britain was the copper which they procured in their workings in Cornwall.

Copper is sometimes met with in nature in a state of purity, but generally it is associated with oxygen, water, and carbonic acid, forming the native carbonate of copper or *malachite* ($CuO,HO + CuO,CO_2$), or with iron and sulphur, forming the native sulphurets of copper and iron or copper *pyrites* (Cu_2S,Fe_2S_3). In smaller quantity copper occurs as the oxide (CuO) and sulphate ($CuOSO_3$), and in all cases the ore is obtained from fissures or veins in other rocks. The principal yield of copper-ore in Great Britain is from the mines in Cornwall, but large supplies are also obtained from Australia, and from Cuba and Chili in South America. In North America, in the neighborhood of Lake Superior, copper-ore occurs abundantly, and a vein of metallic copper is there found which in some places is about two feet in thickness.

In the extraction of copper from its ores the metallurgic processes followed are very tedious and complicated, which mainly arises from the difficulty of separating the iron and sulphur from the copper. The general principle which regulates the working-up of the ore is to burn away the sulphur (S) as sulphurous acid (SO_2), and to carry off the iron by means of fluxes in the form of scoriæ or slag. Metallurgists enumerate ten distinct steps in the production of commercially pure copper.

Copper has the equivalent 31.7—new system, 63.4. It is the only red metal, has the specific gravity 8.78 when cast, and 8.96 when rolled or hammered; fuses at 1996° F., and at a white heat passes off in vapor, and burns with a green flame. It is very malleable, and can thus be beaten out into thin leaves; is very ductile, so as to admit of being drawn out into thin wires; and its tenacity is only inferior to that of iron. It is a powerful conductor of electricity, and hence is employed in the construction of lightning-conductors and in telegraph-wires for underground or submarine communication. Copper is also employed largely in the sheathing of wooden vessels and in the arsenal.

Copper forms many compounds. There are two oxides, the black oxide (CuO) and the red oxide (Cu_2O). The latter is employed in coloring glass of a ruby-red tint. The *green rust* which forms on the surface of a copper-sheeted ship, and on copper coins and vessels which lie in moist places for some time, is a carbonate of copper, and is due to the carbonic acid and oxygen of the air acting upon the copper in the presence of moisture. It is very poisonous, and hence any barnacles which may attach themselves to the copper sheathing are poisoned. The carbonate of copper, under the name of *blue verditer*, is largely prepared and sold as a pigment. The subchloride of copper, moistened and exposed to the air, yields the pigment known as *Brunswick green*. There are several compounds obtained by allowing acetic acid to act upon oxide of copper which are commercially called *blue* and *green verdigris*. The sulphate of copper, or *blue vitriol* ($CuO,SO_3 + 5HO$), is prepared by dissolving the black oxide in sulphuric acid, and allowing the salt to crystallize out. The crystals are large and present a fine blue color. It is soluble in water, and is extensively used by the dyer for the production of several blue and green colors. The solution of blue vitriol is also employed in the preservation of timber from dry-rot, and it forms a constituent of some writing-inks. See *Bronze* and *Cannon-metals*.

COPPER SCISSEL.—The clippings of copper left after the formation of percussion-caps, friction-tubes, coinage, etc.

COPTIC LEGION.—In 1799 the French troops in Egypt, not receiving any reinforcements, grew weaker every day through loss in combat and disease, when General Kleber, who commanded after the departure of Napoleon, organized a Corps of Copts, or native Christians, about 600 strong, which was known as the Coptic Legion. They were armed the same as the French soldiers.

COPYING.—A term applied in photography to the reproduction of paintings, engravings, manuscripts, maps, etc. The kinds of camera and lens most suitable for the purpose will be found described under their respective heads; the quality and condition of chemicals necessary are based upon the facts, that long exposure is almost invariably required, and that, in the majority of cases, it is desired to copy black marks upon a white ground, as in a sheet of music, for example. Where it is obvious that nothing that can be called a middle tint is required, but simply pure black and white, recourse should be had to organic matter in the bath; a little acetate of soda and an extra amount of acetic acid may be also added, and an old collodion containing free iodine employed. It is important that the work or surface to be copied should be placed in a strong light, and exactly at right angles to the axis of the lens, which should be furnished with a *small* stop. These three conditions, it will be seen, are such as are calculated to insure density in the blacks of the negative, freedom from distortion, and sharpness at the edges of the picture. The copying of oil-paintings seems to the amateur, at first sight, to present almost insuperable difficulties, on account of the reflected light from the varnish passing through the lens, and producing black patches on the negative. This may, however, be completely avoided by the employment of a lens of long focus, which admits of the oblique pencils of light passing off without entering the camera. Attention to the laws of the reflection of light will suggest to the reader the importance also of avoiding a bright light immediately behind the camera, as the rays of light would then fall on the varnished surface, nearly at right angles, and be reflected into the camera. The oil-painting, therefore, though placed in strong sunshine, for the purpose of giving vigor to the more obscure parts, should be so arranged as to allow the light to fall on it at an angle of about 35° or 40°.

COPYING MACHINES.—The various contrivances for procuring duplicates of writings without the labor of transcribing them may be reduced to two classes. In the one the writing is first made and then copied; in the other the copy and the original are produced at the same time. The essence of the first method is this: In writing the original, an ink is used that is made for the purpose, or common ink thickened by the addition of a little sugar. When the writing is dry, a damped sheet of thin unsized paper is laid upon it, and over this a piece of oiled paper. The whole is then subjected to pressure, and the damped paper is found to have taken off an impression of the writing. It is of course the reverse of the original, but the nature of the paper allows it to be read right on the other side. The machines for communicating the pressure are of various kinds. Some pass the sheets between rollers like the copper plate press; others act on the principle of the common printing-press. A simple plan is to wrap the sheets round a wooden roller of about an inch diameter, lay this upon a table, and roll it under a flat board, pressing all the while. Another very common method of copying is by means of prepared blackened paper laid between two sheets of thin writing-paper. The writing is traced firmly on the upper sheet with a steel or agate point or common black-lead pencil, and the lines are found transferred in black from the blackened sheet to the paper adjacent. By having several of these blackened leaves, a number of copies may be produced at once. The blackened paper is prepared by saturating it with a mixture of lard and lamp-black, and cleaning it so far that it will not soil paper unless pressed against it.

CORBIE.—A word obsolete in English except as a heraldic term for a raven. See *Heraldry*.

CORDAGE.—*A rope* is composed of threads of hemp or other fibrous material. These threads are called *yarns*. A number of these yarns twisted together form a *strand*, and three or more strands twisted together form a rope. The ropes in ordinary use are composed of three strands laid *right-handed*, or, as it is called, *with the sun*. Occasionally a large rope will be found laid up in four strands, also *with the sun*. This is generally used for stationary rigging, such as shrouds, guys, heavy gun-slings, etc., and is sometimes called *shroud-laid*. Small halyards are sometimes laid with four strands and a core; this kind of rope runs more smoothly and wears longer. *Cable-laid rope* is composed of nine strands, and is made by first laying up three ropes of three strands each, with the sun, and then laying the three ropes up together into one, against the sun. Right-hand rope must be coiled *with* the sun, and cable-laid rope *against* the sun. *The size* of rope is always given in inches and fractions, and is measured on the *circumference*, for the reason that it is seldom possible to get a squarely-cut end in order to measure the diameter. In making requisitions for rope, it should be clearly indicated that this measure is the one considered. *Spun-yarn* is made by twisting together very loosely two or more well-tarred yarns, and is designated by the number of its yarns; as, two-yarn, three-yarn, etc. It is used for serving, seizings, stops, etc., and is very pliable. *Marline* is also made of tarred yarns, but is tightly twisted, and is much harder and smoother than spun yarn. It is not fit for serving when the rope served is to be bent up, as it is not pliable enough to cover the rope in such cases. *The bight* of a rope is any part not an end. A *bight* is formed by bending or doubling the rope so as to form a loop. This distinction should be particularly noted, and the two terms should not be confounded. The interstices between the strands of a rope are called the *jaw*, and rope is called long or short jawed as it is loosely or tightly laid up together. Those ropes which are stationary are called *standing* rigging; as, guys for a gin, gun-slings, etc. Those which run through blocks or pulleys, such as gin-falls, trace-ropes, etc., are *running* rigging.

Worming a rope is filling up the divisions between the strands by passing spun-yarn along them, to render the surface smooth for parceling and serving. *Parceling* a rope is wrapping narrow strips of canvas about it, well tarred, in order to secure it from being injured by rain-water lodging between the parts of the service when worn. The parceling is put on *with* the lay of the rope. Parceling is also used to prevent chafing or cutting of a rope when a strain is brought against a rough surface or sharp edge. For this purpose old rope or canvas wound around is sufficient. *Serving* is the laying on of spun-yarn or other small stuff in turns round the rope, close together, and hove taut by the use of a serving-board for small rope and serving-mallet for large rope. Small ropes are sometimes served without being wormed, as the crevices between the strands are not large enough to make the surface very uneven; but a large rope is always wormed and parceled before being served. The service is put on *against* the lay of the rope. *Whipping* is securing the end of a rope with twine to prevent it from fraying out. For temporary use it may be done by winding twine about the end of the rope and securing the end of the twine by passing it under two or more turns of the twine and pulling it tight. It is better, however, to secure the ends by sewing them through the rope, so that each stitch may lie in the division between two strands. This is called a *sewed* whipping.

Splicing is putting the ends of ropes together by opening the strands and placing them into one another, or by putting the strands of the ends of a rope between those of the bight. (Fig. 1.)

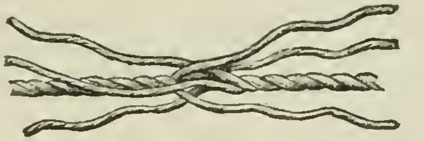

Fig. 1.

A Short Splice.—Unlay the strands for a convenient length; then take an end in each hand, place them one within the other, and draw them close. Hold the end of one rope and the three strands which come from the opposite rope fast in the left hand, or if the rope be large, stop them down to it with a rope-yarn. Take the middle strand, which is free, pass it *over* the strand which is first next to it, and then through *under* the second and out between the second and third from it, then haul it taut. Pass each of the six strands in the same manner; first those of one end and then those of the other. The same operation may be repeated with each strand, passing each *over* the third strand from it, *under* the fourth, and through; or, as is more usual, after the ends have been stuck once, untwist each strand, divide the yarns, pass one half as above described, and cut off the other half. This tapers the splice.

A Long Splice.—Unlay the ends of two ropes to a distance three or four times greater than for a short splice, and place them within one another as for a short splice. Unlay one strand for a considerable distance and fill up the interval which it leaves with the opposite strand from the other rope. Twist the ends of these two together, then do the same with two more strands. The two remaining strands are twisted together in the place where they were first crossed. Open the two last-named strands, divide in two, take an overhand knot with the opposite halves, and lead the ends over the next strand and through the second as the whole strands were passed for the short splice. Cut off the other two halves. Do the same with the others that are placed together,

Fig. 2.

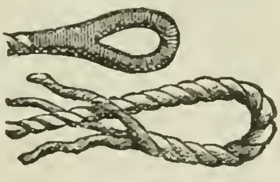

Fig. 3.

dividing, knotting, and passing them in the same manner. (Fig. 2.) *Before cutting off any of the half strands the rope should be got well upon a stretch.* Sometimes the whole strands are knotted, then divided, and the half strands passed as above described. This splice does not increase the diameter of the rope, and is used for splicing a fall or other rope that runs through blocks or pulleys.

An Eye-splice.—Unlay the end of a rope for a short distance and lay the three strands upon the standing part, so as to form an eye. Put the first end through the strand next to it. Put the second end over that strand and through the second, and put the remaining end through the third strand on the other side of the rope. (Fig. 3.) Taper them, as in the short splice, by dividing the strands and sticking them again. This splice is used to form a permanent loop in the end of a rope.

A Grommet.—Take a strand just unlaid from a rope, with all its turns in it, and form a ring of the size you wish by putting the end over the standing part. Then take the long end and carry it twice round the ring in the crevices, following the lay until the ring is complete; then take an overhand knot with the two ends, divide the yarns, and stick them as in the long splice. Used for a trunnion-loop for rolling or slewing a gun. See *Blocks*, *Mechanical Maneuvers*, and *Rope*.

CORDON.—1. In military operations, a line of sentries inclosing or guarding any particular space of ground, to prevent the passage of persons other than those belonging to the army. The sentries are placed within sight of each other. If intended to guard against contagious diseases, it is called a *Cordon Sanitaire*.

2. The coping of the escarp or inner wall of the ditch, sometimes called the magistral line, as from it the works in permanent fortification are traced. It is usually rounded in front, and projects about one foot over the masonry: while it protects the top of the revetment from being saturated with water, it also offers, from projection, an obstacle to an enemy in escalading the wall.

CORDUROY-ROAD.—A roadway formed of logs laid side by side across it, as in marshy places; so called from its rough or ribbed surface, resembling corduroy.

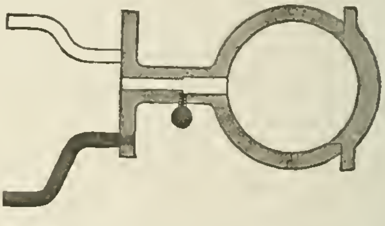
CORE-BARREL.—The core-barrel, as represented in the engraving, consists of a water-tight iron tube, AD, about fifteen feet long and three fourths of an inch thick, its exterior diameter at the head being twelve inches, and tapering one fourth of an inch, at the lower extremity, to facilitate its withdrawal after the cast. It is rounded at its lower end, D, and fluted throughout the cylindrical part, to allow the escape of gas generated by the burning of the composition with which it is covered. To prepare the core for casting, journals are first fitted, at either extremity of the barrel; it is then placed in a horizontal position upon an iron truck, being supported by the journals, which rest in bearings. While so supported it is easily turned by means of a crank attached to one of the journals, and is first wrapped or served with white-hemp stuff (18-thread), covering that portion of the barrel which comes in contact with the molten iron. Over this a coating of molding-composition is applied quite wet, which is wrapped with twine, to insure its adhering. When about half dry the outer or last layer of composition is applied, which, being made quite sticky, adheres readily. Great care is taken to have the surface of the core perfectly smooth, and the composition of uniform thickness. The diameter of the core-barrel for a 15-inch gun, when complete, is 13.75 inches at the top, and slightly tapered at the bottom. When ready, the truck supporting the core-barrel is rolled into the drying-oven, and when perfectly dry removed; the usual time required being eighteen hours. The composition then receives a coating of coke-wash, when it is again placed in the oven, where it remains until thoroughly dry. Upon its final removal the journals at either extremity are removed, being replaced by the regular cap on top, and a tight-fitting screw-plug at the bottom, which is covered with molding-composition, and dried by a fire built under it.

The gauge for centering the core consists of a long wooden rod, on the end of which a piece of board is fixed at right angles, and on this board a light is placed. The length of this projecting board, previously determined, is the distance the core should be from the mold when in the center. Having adjusted the core in the mold by means of the screws fitted in the legs of the spider, it is secured firmly by clamps, made to fit over the top of the frame and under the flange of the flask.

The core-barrel is withdrawn about eighteen hours after the casting, as soon as the metal becomes sufficiently cool to permit of its removal. The withdrawal causes no delay or trouble, as the rope with which it is wrapped is consumed, and therefore leaves the barrel detached from the composition surrounding it, the latter adhering to the bore of the gun. See *Molding*.

CORE-BOX.—The core-box, employed in the fabrication of hollow projectiles and shown in the drawing, consists of two hemispherical cups. The lower one is made in two sections, which are so constructed as, when united, to receive and hold the spindle in place, and also to form a base for the core-box to rest upon while being filled. The core is formed by pouring the composition into the opening at the top of the upper cup and ramming it down until the interior space is filled. The surface at the opening is then rounded off with a former, and the core-box is removed. The core is then thoroughly dried in an oven and afterward painted with coke-wash.

The requisite compression being given by screws, the core is by means of a gauge placed exactly in the



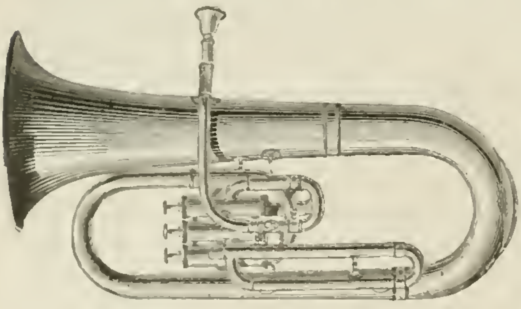
center of the mold and supported in that position by the stem which forms the fuse-hole. The stem is perforated with small holes to allow of the escape of steam and gas generated by the heat of the melted metal; that part of it which comes in contact with the melted iron and forms the fuse-hole is coated with sand. In pouring the melted iron into the mold with the ladle care should be taken to prevent scoria and dirt from entering with it, and for this purpose the surface should be skimmed with a wooden stick. After the iron has become sufficiently hardened, the flasks are opened and the sand knocked from the casting. Then the core is broken up and removed, and the interior surface cleaned by a scraper. The greatest care is to be taken to remove every particle of sand or fragment of iron from the interior. The sinking-head or projecting portion at the gate, and around the base where the two halves join, is taken off with a file or chisel if necessary. A number of the balls are now placed in a large revolving iron cylinder, which by friction polishes and makes the surface more uniform. See *Fabrication of Projectiles*.

CORED SHOT.—An elongated projectile having a cavity in the body of it. This cavity is for the purpose of throwing the center of gravity towards the front end of the projectile, thus insuring greater steadiness of flight. The hollow projectiles are either shells or case-shot, both of which, in their construction and use, are similar to those described for smooth-bore guns. Rifle-projectiles have a length of two to three times their diameter, depending upon the pattern, and whether solid or hollow, the latter being generally the longer. See *Projectiles*.

CORMONTAIGNE SYSTEM OF FORTIFICATION.—Cormontaigne, the immediate successor of Vauban, holds a place only second to this master of the art in the estimation of the engineers of the French school. In planning the front which has received his name, Cormontaigne seems to have applied himself rather to remedy the defects noticeable in the methods of Vauban than to produce any radical change in the combinations which had thus far received the sanction of engineers generally. Observing that from the great height given by Vauban to his scarp-walls they might be easily breached from a distance, Cormontaigne suppressed the small wall supporting the parapet and diminished the height of the scarp-wall, placing the top of it on a level with the crest of the glacis. He adopted as a principle *that all masonry should be masked from the fire of the enemy's batteries at a distance*, and to obtain this point he has so arranged the height of his principal scarps, and the command given to the glacis crest in front of them, that the top of the scarp shall not lie above the level of the crest, thus masking from view the entire scarp, by the earth forming the glacis, from all positions in advance of the glacis crest. Cormontaigne was the first to develop clearly the influence of large demi-lunes on the progress of the attack, by their forming deep re-enterings between them in front of the bastion salients. Also the increased strength gained by fortifying on a right line, or on polygons with a great number of sides. In both of these cases the fronts assailed cannot be enveloped by the assailant's works, and the demi-lunes from their salient position intercept the prolongations of the bastion-faces, thus masking them from the positions from which alone an enfilading fire could be brought upon them. The modifications of Vauban's trace are different in the various works of Cormontaigne; but the following he indicates in his memoirs as the one preferred by him. The exterior side is 360 yards; the perpendicular, $\frac{1}{6}$; the faces of the bastions, $\frac{1}{3}$ of the exterior side; the flanks are 40 yards, and are so placed that the curtain shall be 120 yards. This combination makes the lines of defense somewhat less, and the bastions larger, than in Vauban's method. The dimensions of the enceinte-ditch are so regulated by Cormontaigne as to furnish earth sufficient for the embankments. It is 28 yards wide at the salient, and from 2 to 4 yards wider opposite the tenaille; this admits the entire fire of the flanks to sweep the ditch. The tenaille is made with a curtain and wings; a ditch 10 yards wide being left between it, the curtain, and the flanks. Cormontaigne placed little value on small demi-lunes, as they form but slight and therefore weak re-enterings before the bastions, and consequently retard but little the enemy's attack upon them; besides this, a small demi-lune covers but very imperfectly the shoulder-angles of the bastions. To remedy these defects, his demi-lune is so laid out that the prolongations of the magistrals of its faces will intersect the bastion-faces at 30 yards from the shoulder-angles; the lengths of its faces being 120 yards. To circumscribe as much as practicable the space in the demi lune which the enemy, after he gains it, requires for his works, the extremity of the demi-lune terre-plein, which is also the top of the counterscarp of the redoubt, is drawn at 20 yards from the magistral of the face; the ditch of the redoubt is 10 yards wide, and the magistral of its face is parallel with the counterscarp. By this arrangement the ditch is well flanked by the face of the bastion near the shoulder-angle. The general width of the covered-way is 10 yards. Cormontaigne enlarged considerably the re-entering place-of-arms, to which he added a redoubt with a revetted scarp and counterscarp. The addition of this work is a great improvement upon the covered-way of Vauban, who indicates in his works small redoubts of earth, or tambours of wood, for the same purpose. Cormontaigne's redoubt increases the strength of the covered-way; the troops assembled in the covered-way for sorties are secure under its fires; it sees in reverse, and protects any breach made in the face of the demi-lune; finally, it serves, in connection with the extremity of the demi-lune, to cover the opening left between the flanks of the bastion and the wings of the tenaille, through which, if a breach was made in the curtain, the interior retrenchments, resting upon either the flanks or faces of the bastion, could be turned. Traverses are placed along the covered-way, to close the places-of-arms, defend the covered-way, and intercept projectiles fired in ricochet. The crest of the glacis is broken into a cremaillère line, to allow room for the defiles of the traverses. The short branches of the cremaillère throw a fire on the salients of the covered-way; the positions of the long branches are so taken that the defiles may be seen and swept by the fire of the works in their rear. Cormontaigne, after a series of trials, whose object was to give the ditches such dimensions that they should furnish the earth required for the embankments, regulated the command of the different works as follows: The lowest work, which is the demi-lune covered-way, he lays down as a rule, shall command the exterior ground by not less than 7½ feet; and the works most advanced shall be commanded by those in the rear. It was found that, for the purpose of equalizing the excavations and embankments of the front, the crest of the demi-lune covered-way should have a command of 10½ feet above the natural ground. The crest of the bastion covered-way, and of the re-entering place-of-arms, commands the crest of the demi-lune covered-way by 2 feet. The magistral of the enceinte is horizontal, its elevation being the same as the mean elevation of the crest of the bastion covered-way. The scarp-wall is 30 feet high. This dimension has since been generally adopted by engineers. The relief of the tenaille is determined as in Vauban's method, so as not to mask the fire of the flanks upon the ditch opposite the extremity of the demi-lune; as it is here that a breach may be made in the bastion-face, through the ditch of the demi-lune. The demi-lune is commanded by the enceinte 3 feet, and by its own redoubt 1½ feet. The demi-lune, therefore, commands its covered-way 7 feet. The redoubt of the re-entering place-of-arms commands the crest of the glacis only 4½ feet; its interior crest is so placed as not to mask the fire of the bastion faces on the glacis in advance of it. The interior crests of all the works are 7½ feet above their terre-pleins, except that of the tenaille, which is 6½ feet; and of the redoubt of the re-entering place-of-arms, which is 9 feet. The interior crests of the faces of all the works exposed to enfilading fires are one foot higher at the salients than at the extremities. The profile of the parapet of the principal outworks is the same as that of the enceinte. The communications are generally of the same nature, and placed about in the same positions, as in Vauban's method. The planes of the glacis are so determined that they may be swept by the fire of the works in the rear; their inclination is usually about twenty-four base to one perpendicular. When a greater command of the site than that afforded by the enceinte is requisite on any front, Cormontaigne places a cavalier within the bastion. To this work he gives the same form as that of the bastion; placing the faces and flanks of the two parallel to each other. The faces of the cavalier are alone revetted, as well as the counterscarp of their ditch, which is cut within the bastion. This ditch is broken off at the shoulder-angles of the cavalier, and directed upon the faces of the bastion; these portions also having a revetted scarp and counterscarp. A parapet is thrown up behind the scarp, and between the flank of the cavalier and the bastion faces; thus isolating the anterior portion of the bastion, and furnishing an interior retrenchment which, when the shoulders and flanks of the bastions are masked from the assailant's view, can only be carried by a breach made either in the cavalier-face, or in the portions resting on the cavalier and bastion faces. From the preceding it appears that the most important modifications made by Cormontaigne in Vauban's first method consist—1. In the means taken to cover the *masonry* from distant batteries. 2. In more capacious bastions susceptible of receiving efficient permanent interior retrenchments. 3. In an enlarged demi-lune, which places the bastions in strong re-enterings, covers the shoulder-angles, and admits of a redoubt in its interior, which work strengthens the demi-lune, and sees in reverse the breach made in the bastion-face. 4. In an enlarged re-entering place-of-arms, containing a redoubt which strengthens the entire covered-way, and covers the movement of the troops in sorties. These modifications, although of great value, and constituting an important step in the art, still leave much to be desired; and engineers since Cormontaigne's time have sought to remedy the defects of his method, of which the following are the principal: 1. The enceinte has rather too slight a command, and is without any bomb-proof shelters. 2. The inclination of the superior slope of its parapet, which is ⅙, is too small to have the ditches well flanked. 3. A breach can be made in the bastion-face through the ditch of the demi-lune. 4. There are dead spaces in the ditch of the demi-lune, near the extremities of its faces. 5. The redoubt of the re entering place-of-arms is not tenable after the demi-lune is taken. 6. The traverses of the covered-way do not afford the requisite protection to that work. 7. Finally, the communications are mostly inconvenient, and not well covered from the assailant's fire. See *Fortification* and *System of Fortification*.

CORNET.—1. A metallic wind-instrument resembling a trumpet, and used in bands. The *cornu* of the Romans, like the instruments mentioned in Leviticus (xxv. 9), was curved and formed from a horn. It was afterwards of metal, probably copper. Its invention is credited by Athenæus to the Etruscans. It differed from the *tibia* in being larger, and from the *tuba* in being curved. It had no keys or stopples.

The cornet-à piston, represented in the drawing, is a



modern wind-instrument of the trumpet kind, is generally made of brass, has two or three valves, and in brass bands takes the soprano and contralto parts. It was first introduced in France as an orchestral instrument. Its tones are less powerful, but far more easily manageable, than those of the trumpet. See *Band*.

2. In the British service, the lowest grade of commissioned officer in the cavalry, equivalent to *Ensign* in the infantry, his duty being to bear the standard. With the Lieutenant, he assisted the Captain in the daily duties connected with the troop to which he belonged. There were as many Cornets in a cavalry regiment as there were troops. A Cornet's commission used, in the days of "purchase," to cost £450; but much larger sums were habitually paid, varying according to the celebrity, or rather the fashionable character, of the Corps. The pay was 8*s*. per day, with 1*s*. or 1*s*. 6*d*. extra for field-allowance. The half-pay varied from 2*s*. 6*d*. to 3*s*. 6*d*. The pay being utterly inconsistent with the price paid for the commission, none but wealthy men could enter the cavalry. In 1871 the rank was abolished, Sub-Lieutenants (who are merely probationary Lieutenants) being substituted.

CORNETTE-BLANCHE.—An ornament which in ancient times served to distinguish French officers who were high in command. It was worn by them on the tops of their helmets. It likewise meant a Royal Standard, and was substituted in the room of the Royal Pennon. The Cornette-blanche was only unfurled when the King joined the army; and the persons who served under it were Princes, Noblemen, Marshals of France, and old Captains, whose orders came direct from the King.

CORNING.—That process in the manufacture of gunpowder which takes place after the cake is removed from the hydraulic press—having been previously broken down—to the granulating-house, when it is passed through rollers and sieves, until the different-sized grains are formed. Corning is another term for granulating. See *Gunpowder*.

CORONA.—An upper saddle-blanket used in packing. Next to the skin of the animal is placed a piece of clean cloth, or an ordinary woolen blanket neatly folded; over this is placed the *corona*. It is made of woolen cloth, with worked ornamental borders, and consists of two or three folds stitched together. The number or name of the animal to which it belongs is generally stitched upon it in colored cloth. In taking the corona off, grasp it in the center, front and back, let the sides come together, and place it across the aparejo, back to the rear. The corona should be the same size as the saddle-blanket, and should neatly cover it, on the animal. See *Packing*.

CORPORAL.—The rank below that of Sergeant. In the British army, at present, Corporal is the grade next below non-commissioned officers. When the regiment is formed as a corps, he has no function different from the private soldier. In barracks or camp, however, he exercises certain disciplinary control over the privates. At present, in the British army, there are 32 Corporals to each regiment of cavalry, and 40 for each infantry battalion. They receive pay varying from 1*s*. 3*d*. to 2*s*. 5*d*. per day. The Lance Corporal is an assistant Corporal, who remains, however, on private's pay; he wears one *chevron* on his arm, and two when he rises to the rank of Corporal. In the United States army, a Corporal is the lowest officer in a company, standing between a private and Sergeant, and does duty in the ranks as a private, except that he places and relieves sentinels, and at drill has charge of a squad.

CORPORAL MAJOR.—In the British service, a troop Corporal Major is the non-commissioned officer of the highest rank in a troop of the Household Cavalry; his position and authority are the same as those of a Color-sergeant of infantry. A regimental Corporal Major is the non-commissioned officer of the highest rank in each of the three regiments of Household Cavalry, and corresponds to a Sergeant Major of infantry.

CORPORAL PUNISHMENT.—The infliction on the bare back, by means of a cat-o'-nine-tails, of a certain number of lashes for crimes committed by soldiers. Except for very grave offenses, such punishment is seldom resorted to in the army, and then only during war-time or on board ship. The number of lashes is limited to 50.

CORPORAL'S GUARD.—An expression used to indicate a detachment of several men under arms. It may be applied to a squad equal to that usually placed under the charge of a Corporal for drill, police, guard-duty, etc. Generally made use of in a derisive manner.

CORPS.—The Articles of War use the word *corps* in the sense of a portion of the army organized by law with a head and members; or any other military body having such organization, as the Marine Corps. A regiment is a corps; an independent company is a corps; a body of officers with one head is a corps, as the Topographical Engineers. Detachments of parts of regiments, or of whole regiments, united for a particular object, whether for a campaign or a part of a campaign, are not corps in the sense of the Rules and Articles of War, for such bodies have neither head nor members commissioned in the particular body temporarily so united; but the officers with such detachment hold commissions either in the corps composing the detachment, in the army at large, in the Marine Corps, or Militia.

A corps operating with an army should consist of three divisions of the line, a brigade of artillery, and a regiment of cavalry. If the corps is to operate independently, the cavalry force should be increased to a division. The same principles which govern the evolutions of a division are applicable to a corps. The commands of the General are communicated through his Staff-officers; they are general in their nature; embrace the particular formation he may desire for each division; the direction the line is to extend; the point where its right or left is to rest; and such further instructions as may be necessary to carry out his views. Orderlies for the Corps, Division, and Brigade Commanders are detailed from the infantry, and are mounted.

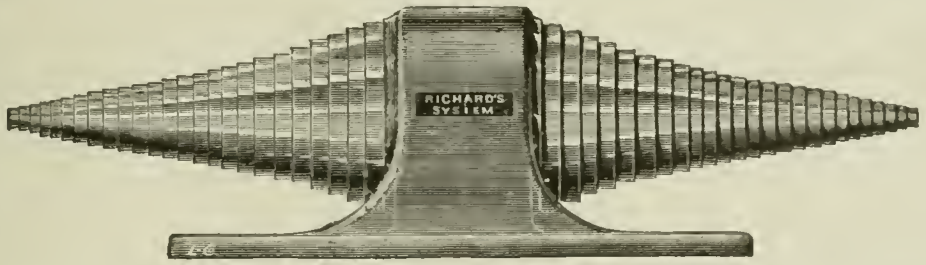
CORPS ARTILLERY.—A portion of the field-artillery left at the entire disposal of the Officer Commanding the Artillery, to employ in any manner required by the Corps Commander. It is sometimes termed *reserve-artillery*, and should consist of both light and heavy batteries. It fulfills two purposes—one to support the *divisional* guns, and the other to give the means of combining a large number of pieces as an *artillery mass* for a decisive effort either offensive or defensive.

CORPS D'ARMEE.—In the military system of the greater Continental European States, an organization of the forces in the time of peace. The whole military strength is divided into several corps, each complete in itself as an army, with everything needful for service, Staff and Artillery-park included. The English army is now distributed into eight army corps, stationed in eight territorial centers. The French army had in 1879 nineteen *corps d'armée;* which have been increased in strength by the recent military reorganization. Germany had in the same year eighteen *corps d'armée.* In the Austrian service the normal number of *corps d'armée* is thirteen. The military strength of Russia, as finally settled in 1876, is distributed over fourteen military districts. See *Army Corps.*

CORPS DES GUIDES.—A body originally formed in France in 1756, consisting of one Captain, one First Lieutenant, two Second Lieutenants, two Sergeants, two Corporals, one Anspessade, and twenty Privates, called the *Fusilier-guides.* Another Corps of Guides was also formed in 1796. This corps now forms part of the Imperial Guard.

CORPS OF ENGINEERS.—A Corps organized in the United States in 1802, to consist of one Colonel, one Lieutenant Colonel, two Majors, four Captains, four First and Second Lieutenants, and Cadets,—the whole number not to exceed twenty,—to be stationed at West Point, and to constitute a Military Academy. In 1838 the Corps was increased to forty-seven officers, and a Corps of Topographical Engineers in addition was organized, In 1846, Sappers, Miners, and Pontoniers (bridge-builders) were added. In 1861, at the beginning of the Rebellion, three additional companies were provided for, and one of Topographical Engineers was added. This company was disbanded in 1863, and its officers sent to the Corps of Engineers. At present the Corps has one Chief, six Colonels, twelve Lieutenants, twenty-four Majors, thirty Captains, twenty-six First Lieutenants, and ten Second Lieutenants; also the Battalion. The Corps is a special arm of the service, charged with the reconnoitering and surveying for military purposes; the selection of sites, the formation of plans, projects, and estimates for military defenses of every kind; the construction and repair of fortifications and defensible works of every description, whether temporary or permanent; the planning, laying out, and superintending all military works, defensive or offensive, of troops in the field, camp, or cantonment; the examination of all routes of communication by land or by water, both for supplies and for military movements; the planning and construction of military roads and bridges; the planning and execution of such works of river or harbor improvement, including sea-walls, breakwaters, and light houses, as may be assigned to it by law, or by the President of the United States; the collection, arrangement, and preservation of all reports, memoirs, estimates, plans, drawings, and models relating to the several duties above enumerated. All quarters for officers and soldiers, all workshops and storehouses required within the lines of permanent fortifications, are constructed by the Corps of Engineers as a part of the work. Until 1866 the Engineer Corps had the superintendence of the United States Military Academy at West Point, but since that year all branches of the service are admitted to their share of supervision. See *Engineering* and *Royal Corps of Engineers.*

CORRECTIVE GAUGES.—A device for testing and correcting fixed caliper-gauges, and also as a reference in any case to prove dimensions within its range; the disks are not constructed on what is termed the pyramid plan; each one is separate, ground independently to standard size, and tested by the measuring machine. The usual set, as shown in the drawing, is made to embrace forty-nine sizes, advancing by sixteenths from one fourth of an inch to two and one half inches, and by eighths to four inches, but can be furnished with any number of sizes up to any required diameter. See *Gauge, Measuring-machine,* and *Standard Scale.*



Corrective Gauges.

CORRESPONDENCE.—All official correspondence between the Heads of the different Departments of the Staff of any command and its Commander passes through the Adjutant General, Assistant Adjutant General, or Adjutant of the command, as the case may be. Communications to or from a Commander and those under his command pass through the Adjutant General, Assistant Adjutant General, or Adjutant on duty with it, excepting only such communications between a Disbursing Officer and the Chief of the Bureau in which he serves as relate exclusively to the ordinary routine of business in their own Department. All communications, reports, estimates, etc., from officers serving at a military post, as well as communications of every nature addressed to them relating to affairs at the post, pass through the Post Commander. All communications, whether from an inferior to a superior, or *vice versa*, are, as a general rule, to pass through the intermediate Commanders.

In cases of pressing necessity, which leave no time for regular communication, the necessity is stated. The same rule governs in verbal applications. A Lieutenant seeking an indulgence applies through his Captain, a Captain through the Adjutant, and so on. This, however, is not interpreted as including matters in relation to which the intermediate Commanders can have no knowledge, and over which they are not expected to exercise control or to express opinion. All communications from superior to inferior officers are answered through the same channel as received.

Officers cannot apply to the Secretary of War or General of the Army for personal favors, or address them on official matters in any other manner than is prescribed by Regulations and military usage. All such communications must be in writing, and addressed to the Adjutant General of the Army, through the intermediate Commanders. Applications made in any other mode than that above prescribed are not entertained, but are construed as a breach of discipline, subjecting the writer to arrest and trial for disobedience of orders. Generally officers who forward communications indorse on them their remarks or opinion, without other letters of transmittal. Official letters should generally refer to one matter only. Those transmitting rolls and returns should refer to no other subject. Applications for opinions or decisions upon questions relating to official business are not made by persons in the military service to the Judge Advocate General, or to officers connected with other branches of the Government, as the Attorney General, or officers of the Treasury Department, without first submitting such question to the Secretary of War through the regular channels. No officer is addressed in orders or official communications by any title other than that of his actual rank. All communications on public service are marked on the envelope "Official Business."

Whenever more than three pages of the sheet used are required for the body of the communication, an additional half-sheet, or more if necessary, is neatly pasted to the first sheet, so that the outer page may be left entirely blank. Letter-paper is folded in three, foolscap in four, equal folds, parallel with the writing. The inner edge of the sheet is the top when folded. The left-hand fold of the outer page is the first fold. The first fold is used exclusively for a brief analysis of the contents of the original communication, the office marks, and noting of inclosures. Indorsements commence at top of the second fold, and follow each other in regular order of date on successive folds, leaving room after each for office marks. In no case should a loose wrapper be placed around an official paper, except as a mere covering, on which nothing is to be written; but additional space for indorsements should be provided by neatly pasting slips of paper on the under side of the last fold—right-hand edge of the original paper—each slip to correspond in length and width (when pasted on) with the length and width of the original fold, and to turn back upon the last fold like the leaves of a book. By this arrangement the first fold on which the office marks and brief are made is always outside. Printed labels, by way of indorsement, are not pasted on the papers; they cause the folds to crack, and increase the bulk of the papers. All inclosures are numbered, and bear the proper office marks. Inclosures of the original communication are noted on the first fold, just below the brief. If others are added when an indorsement is made, the number of them is noted at the foot of their appropriate indorsement, and also on the first fold of the original communication, and to the latter notation is added the number of the indorsement to which they belong, thus: *One inclosure—Fifth indorsement*. Inclosures to indorsements are numbered in the same series as those to the original paper, and the number of the indorsement to which they belong is added below. If few in number and not bulky, inclosures may be kept inside the original paper. If otherwise, they will be folded together in a wrapper marked "Inclosures," as an accompanying package.

CORRIDOR.—The covered-way lying around the whole compass of the fortifications of a place.

CORROSION.—A species of dissolution of metallic bodies either by an acid or a saline menstruum. Cannon-metals should be able to resist the corroding action of the atmosphere, and the heat and the products of combustion of the powder; should be susceptible of being easily bored and turned; and should not be too costly, on account of the very great number and weight of cannon required for the military service.

CORROSIVE SUBLIMATE.—A laboratory substance described as the bichloride of mercury. It is formed by introducing hot mercury into chlorine gas; the mercury inflames and the bichloride is formed. There are other ways of preparing it. What is termed kyanizing is applying this substance to the preservation of timber, cordage, sails, tent-cloths, and other fabrics from decay by mold, or by the ravages of insects. This mode of preserving the articles mentioned is the invention of Mr. Kyan.

CORRUGATED IRON.—Common sheet-iron, and what is improperly called "galvanized-iron" (i.e., sheet-iron coated with zinc by immersion in a bath of the fused metal), have of late been made available for many useful purposes, by virtue of the great additional strength imparted to the sheets by corrugation, which is merely an application to metallic substances of the old contrivance of "goffering or crimping," by means of which the frills of the olden time were made to keep their shape. The sheets of metal are passed between rollers, the surfaces of which are formed into rounded grooves and ridges, the ridges of one roller filling the grooves of the other. The metal in passing between these is compressed into a waving form, or corrugated. It will be easily understood that a piece of sheet-metal, of given size and thickness, if rolled up to form a tube, will resist a much greater bending strain than when flat. Now the curves of the corrugation may be regarded as a series of half-tubes, and the additional strength is due to the application of the same principle. Walls and roofs of temporary buildings are now extensively made of this material. Railway-sheds, emigrants' houses, temporary churches, store-rooms, and sheds for dock-yards, etc., are among the common applications. Mr. Francis, of New York, has applied the principle to the construction of light boats, the strength of which, and their power of resisting violent blows, such as boats are subject to on landing through a surge, is said to be remarkably great. On this account they are proposed to be used for life-boats, ships' boats, etc. They are made by stamping the metal in enormous dies, of the shape and size of the boat, and grooved for the required corrugations. Small boats thus constructed require no internal bracings, the requisite rigidity and strength being given entirely by the corrugations.

CORSELET.—A small cuirass, or piece of armor to cover the front of the body, worn formerly by pikemen. See *Armor*.

CORSEQUE.—The common name of the *ranseur* in France. See *Ranseur*.

CORSESCA.—A kind of spear used in the sixteenth century. Now obsolete.

CORSO.—An Italian word used to express not only the racing of horses (without riders), but also the slow driving in procession of handsome equipages through the principal streets of a town, such as almost always takes place in Italy on festivals. This custom has given a name to many streets in almost all the larger towns of Italy. The best known of these is the Corso in Rome, which is the scene of the celebrated diversions of the carnival.

CORTEGE.—The official staff, civil or military; a train of attendants. See *Triumph*.

CORUNDUM.—A hard mineral consisting of crystalline alumina. The sapphire and ruby are allied substances of different colors. Corundum is used in powder of varying fineness; is made up into wheels and laps with gums, resins, glue, etc.; and is employed in the armory in the form of cones, cups, files, slabs, wheels, laps, bobs, points, and tapes.

COSIGNE.—The French expression commonly used for the parole or countersign.

COSSACKS.—A people inhabiting those parts of the Russian Empire which border on the northern dominions of Turkey, Poland, and the southern confines of Siberia. Both the name and origin of this people are involved in great uncertainty. They seem to have none of the national characteristics of the Russians, and are probably a mixed Caucasian and Tartar race. They form a sort of independent republic, paying no taxes to Russia, but cheerfully contributing their numerous and valuable contingent of men, who are well known as the most harassing light troops that ever exercised a predatory warfare in the train of any army.

COSTON SIGNAL-LIGHTS.—These consist of red, green, and white lights and their various combinations, representing the different numbers and pendants. The colors assimilate as far as possible with those of the day-flags. The case is made of fuse-paper 3 inches long and 1¼ inch in diameter. A cylindrical block of soft wood ½ inch long forms the bottom, with a wooden nipple attached to fit into the signal-holder or firing-pistol. Through the center of the bottom is a small hole with a thin copper tube $\frac{3}{16}$ inch in diameter, extending through the middle of the case to within ¼ inch of the top. Hollow drifts are used in filling, which are struck fifteen moderate blows with a half-pound mallet for each charge. The case is filled to the top of the copper tube; the last charge being ¼ ounce of mealed powder. A small strand of quick-match is put through the copper tube and wooden bottom, the upper end stitched to the side of the paper case above the mealed powder, and the lower end split to make sure of its ignition by the cap from the pistol. The top of the case is covered with a thin wafer of brown paper immediately over the quick-match and mealed powder; then over all is a pasteboard top with a rim secured to the body of the case by a strip of paper pasted on the two. The wooden bottom is covered with shellacked paper. The signal is finally covered with white, red, or green paper, according to the color of the composition, and packed in laboratory-boxes for issue.

The several colors in the Coston signals are intended to burn from 8 to 10 seconds. In a signal composed of three colors 1½ charges of the composition of the last color to be burned are put in first and driven; a thin circular disk of paper is put in the case on top of this composition, then 1½ charges of the second color are put in and driven, a piece of paper put on, and then 1½ charges of the first color to be burned are put in and driven.

When a signal is composed of but two colors, the lower third of the paper case is filled with powdered clay, and driven the same as the composition, then on top of this clay the second colored composition is driven, and on that the first. When but one color forms a signal, two thirds of the case is first filled with clay, and the composition driven in the upper third. The following compositions are used for Coston signals:

For the white signals—5 parts sublimate of sulphur; 5 parts sulphuret of antimony; 2 parts red oxide of lead; 3 parts sulphuret of arsenic; ½ part bleached shellac; 24 parts nitrate of potash.

For the red light—16 parts chlorate of potash; 6 parts oxalate of strontium; 2 parts bleached shellac; 2 parts sugar of lead; ½ part desiccated lamp-black.

For the green light—4 parts chlorate of mercury; 2 parts bleached shellac; 12 parts chlorate of barium. See *Signal-rocket*.

COTICE.—In Heraldry, one of the diminutives of the bend. It is a fourth part of the bend, and is usually borne in couples with a head between. Sometimes written *Cost*. See *Heraldry*.

COTTON WASTE.—The refuse cotton collected in cotton-mills. It is used for wiping machinery, and should be put away with care in some out-of-the-way place when the work of the day is over, or saturated in water with a solution of soda and boiled, when the oil will be extracted. In its oily state with particular oils, such as vegetable-oils, it is liable to spontaneous combustion, and should not therefore be left about. It is very dangerous, as will be realized, to leave it in houses where gunpowder is manufactured. It is not at all unlikely that the explosion in many gunpowder-houses, the reason of which has been unknown, has been caused from cotton waste containing oil having been left in the houses at night, and thus ignited the building or buildings. In some cotton waste itself there are the elements of fire.

COUCHANT.—In Heraldry, a beast lying down, and with his head up, is *couchant*. If the head is down, he is *dormant*. See *Heraldry*.

COUDIERES.—Small plates of metal, of various shapes, fixed together by straps and buckles, over the mail, in order to give an increased security to the elbows.

COULLART.—A military instrument of war used in the early part of the fifteenth century for the purpose of casting great stones.

COUNCIL OF ADMINISTRATION.—A Board of Officers periodically assembled for the administration of certain business matters. In the United States service, the Commanding Officer of every post, at least once in every two months, on muster-days, convenes a *Post Council of Administration*, to consist of the *three* regimental or company officers next in rank to himself; or, if there be but two, then the *two* next; if but one, the *one* next; and if there be none other than himself, then he himself acts. Regimental Councils of Administration consist of the three officers of the regiment on duty at headquarters next in rank to the Commander. The junior member records the proceedings of the Council in a book, and submits the same to the Commanding Officer. If he disapprove the proceedings, and the Council, after a reconsideration, adhere to its decision, a copy of the whole is sent by the Officer Commanding to the next higher Commander, whose decision is final, and entered in the Council-book, and the whole is published in Orders for the information and government of all concerned. The proceedings of Councils of Administration are signed by the President and Recorder, and the Recorder of each meeting, after entering the whole proceedings, together with the final order thereon, deposits the book with the Commanding Officer. In like manner, the approval or objections of the Officer ordering the Council are signed with his own hand. The Post Council prescribes the quantity and kind of clothing, small equipments, and soldiers' necessaries, groceries, and all articles which the Post Traders may be required to keep on hand; examines the Post Traders' books and papers, and fixes the tariff of prices of the said goods or commodities; inspects the Post Traders' weights and measures; fixes the laundress' charges, and makes regulations for the Post School. Councils of Administration at posts occupied by companies of the same regiment, at regular meetings, set aside and cause to be paid over to the regimental treasurer fifty per cent of the amount accruing to the post fund during the preceding two months after deducting the expenses of the bakery. This amount is carried by the Regimental Treasurer to the credit of, and will constitute, the regimental fund. When a post is garrisoned by companies of different regiments, the Council makes an equitable division of the sum allotted to the regimental fund, and causes the sum belonging to each regiment or corps to be paid over to its Treasurer. In case of the loss of regimental, post, or company funds, the circumstances of the loss are carefully investigated by the Council of

Administration, and reported with a recommendation as to the responsibility, through the proper channels, to the Adjutant General, for decision by the Secretary of War.

COUNCIL OF WAR. A conference of officers, in military or naval warfare, on some matter in which the Commander wishes to fortify his judgment by an appeal to that of others. The French make a special provision for a Council of Defense in a garrison. The Governor or Commandant may summon the Heads of Departments to meet him in consultation whenever he may think such a step desirable; and the opinions expressed at such meetings are placed upon record. The Commandant of a garrison generally solicits the opinion of a Council of War before surrendering to besiegers. The English Military Code leaves these matters to the discretion of the Commander.

COUNTER-APPROACHES.—With a strong, well-disciplined garrison, skillfully commanded, one of the most efficient auxiliary means of defense is to be found in counter-approaches from the main defensive works on the point of attack, towards the position of the besieger's lines. These consist of simple trenches pushed forward from the most advanced works as far as can be safely done with a view of obtaining enfilading and reverse fires, both of artillery and infantry, on the trenches and batteries of the besiegers. The front to be occupied by the counter-approaches, the distance to which they should be pushed forward in advance of the main works, and the direction they should receive will depend upon the natural features of the site, the positions and strength of the besieger's works, and the bearing of the main defensive works upon the ground over which the counter-approaches must be run.

The portions of the besieger's works that the counter-approaches can be made most effective against are his batteries and his boyaux of approach. Positions, therefore, should be given to the counter-approaches, and a sufficient front to obtain enfilading and slant reverse views on the boyaux with artillery and musketry, and a fire of Sharp-shooters on the batteries, with a complete view of the ground in advance of them, not obstructing, however, the fire of the main defenses. The trenches by which they are connected with the defensive works should be enfiladed by these, and should be so run that the retreat of the troops through them shall not be liable to be cut off, whilst they should offer a convenient and short line of communication. To prevent them from being of immediate use to the besiegers, if carried by open assault, the reverse of the trenches, even of those which are enfiladed from the main defensive line, should receive a gentle slope to the rear to enable the trench to be swept by a slant or even direct fire from the works in the rear. If good positions can be found for them, the counter-approaches should be supported by strong field-works; otherwise stockaded keeps for small detachments may be made at suitable points to assist in repelling any open assault of the besiegers.

From the most advanced line of the counter approaches, picked men may be sent forward to occupy good positions to annoy the artillerists and working parties of the besiegers by taking shelter behind any cover from fire or by digging holes, from which, by throwing the earth in front, they can speedily gain cover. These holes may be gradually enlarged so as to contain three or four men each, who can be readily rallied for mutual support against open assaults by small detachments of the besiegers, or for small sorties against their workmen. The counter-approaches will also be used for positions for movable batteries of light rifled guns, which can be shifted from point to point during the day, wherever they can best annoy the besieger's works and find cover, and be withdrawn at night to secure them from the danger of capture. During this period the Engineer Officers and workmen are employed in organizing the point of attack for a vigorous defense. The covered-ways are palisaded with care. Tambours, or block-houses, are established in the salients of the most advanced and exposed outworks, and also in the re-enterings, where guards are constantly posted. See *Approaches.*

COUNTER-ARCH.—In fortification, a vertical arch connecting the tops of the counterforts.

COUNTER-BATTERY.—A battery employed to dismount or silence, by direct fire, the guns of an enemy's works. In such a battery the interior crest should be nearly parallel to the line to be counter-battered. A position somewhat oblique to the line, so that the shot of the battery may enter the embrasures obliquely, is also a good one for tearing away the cheeks of the embrasures and exposing the guns of the defenses. Whenever a position has to be taken up for an enfilading or a counter-battery, in which the direction that can be given to the interior crest is very oblique to that which it ought to receive, it will be necessary to make the embrasures of the battery with a corresponding obliquity to the direction of the parapet; but to avoid the inconvenience of these embrasures when very oblique, it will be necessary to break the interior crest into a serrated line, to allow the muzzles of the guns to be run the requisite distance into the embrasures; placing one side of the indent perpendicular to the axis of the embrasure, and the other parallel to it.

For ricochet, the batteries are best armed with smooth-bore 18- and 24-pounders and 8-inch howitzers. The fire of the guns is mainly directed against the artillery of the defenses; that of the howitzers to sweep the covered-ways and ditches, to destroy the palisadings and the traverses by the explosion of the shells that may lodge in them. As a general rule, there need not be more than seven pieces, nor should there usually be less than three in any one battery; the number depending upon the bearing which the artillery of the part to be silenced may have upon the ground on which the works of the besiegers must be placed. The batteries should be as far asunder as practicable, so as not to invite a concentration of the fire of the defenses upon any point, by the accumulation of a large number of pieces on it, and thus multiply the chances of the loss both to the troops and *matériel.*

The greater part of these batteries will occupy fixed positions during the time they are in use, and which, as has been stated, will depend upon the positions occupied by the artillery of the besieged. Other batteries of lighter caliber, which can be easily shifted from point to point, as the exigency may require, can be used in combination with these, by taking advantage of any natural covers, or by throwing up slight parapets like those in ordinary field-works. For batteries of rifled guns, with long ranges, the guns may safely and advantageously be placed in barbette. For positions within more certain range of the besieged works, the guns should be placed in embrasures more or less open according to the field of fire desired. See *Batteries* and *Enfilading Battery.*

COUNTER-CHANGED.—In Heraldry, when several metals and colors are intermixed, one being set against the other, they are said to be counter-changed.

COUNTERFORT.—In fortification, a mass of stone or brick work added to the revetment of a rampart, in such a way as to form a buttress for resisting the pressure of the mass of earth. Counterforts occur at intervals of about twenty feet, and assist in preventing the earth from pushing down the revetment-wall into the ditch. When properly constructed, counterforts very effectually enable the walls to resist the shock of distant artillery. They have been made *dovetailed, rectangular,* and *diminished.*

COUNTER-GUARD.—1. An outwork designed to defend the two faces of a bastion or ravelin from a direct fire, so as to retard a breach being made. The counter-guard consists of two lines of rampart parallel to the faces of the bastion or ravelin, and separated from them by a narrow ditch. The crest of the counter-guard must be some three feet lower than that of the works it covers, in order not to obstruct the defense. Lest the enemy should establish a battery on the counter-guard, the terre-plein, or flat space behind its parapet, is made very narrow. Noizet speaks of the counter-guard as a valuable, and sometimes a necessary, element of a front; preferring it in some cases to the demi-lune. Like all other outworks, when used, it should be flanked by the enceinte flanks, be swept on the interior by the fire of its faces, and not intercept their fire on the ground in advance of it. Vauban, in his third method, forms his enceinte with a high scarp-wall, of the same dimensions and form as in his first method; and he procures his flanking arrangements for the enceinte by small bastioned towers of masonry, which are casemated in the lower story, and have an open battery in the upper, covered by a masonry parapet. This enceinte he covers with spacious counter-guards of the form of lunettes, the faces, flanks, and gorges of which are revetted, and which cover the bastioned towers of the enceinte; and between the flanks of these counter-guards, and covering the curtain of the enceinte between the bastioned towers, he places a tenaille. A demi-lune, in the form of a lunette, is placed in front of the counter-guards and tenaille; within which he has placed a redoubt with a revetted scarp and counterscarp. The whole of this combination of outworks he incloses with a covered-way arranged in the usual manner. Cormontaigne uses the counter-guard only as an exceptional outwork; and has applied it, in some of the works constructed by him, to strengthen a point that would otherwise have been too weak; but not, as by Vauban, as a constituent part of his method. Two of the most eminent modern Engineers, Coehorn and Carnot, in their methods, use earthen counter-guards to cover their enceintes, giving them only sufficient thickness at the top for a parapet and a banquette for infantry; so that, being taken by the assailant, he will not find sufficient room to place a breach-battery upon their terre-pleins against the enceinte. In this way they serve chiefly as masks or face-covers to the enceinte-faces. Haxo forms of the counter-guard a constituent element of his method, giving it, like Vauban, the form of a lunette. See *Outworks*.

2. A plate of metal, flat or concave, plain as in open work, found on the side of the barrel (and perpendicular to its axis) in swords of the sixteenth century.

COUNTER-HURTERS.—In gunnery, pieces of iron bolted to the rails on which the gun-carriage moves to check it in front and rear.

COUNTERMAND.—To revoke, as a former command; to direct or order in opposition to an order previously given, thereby annulling it or prohibiting its execution.

COUNTERMARCH.—An evolution by which a body of men change front, and at the same time retain the same men in the front rank. On the same principle, a whole army will sometimes change front. If after the countermarch the order *about face* be given, the same front will be preserved, with the rear rank in front, and what was previously the right now serving as the left. A rear rank may also become a front rank by merely countermarching round the end of the latter, which remains stationary.

To place a piece of artillery and its caisson in the same relative positions on the ground they occupied before, but facing in the opposite direction, the Instructor commands: 1. *Countermarch*, 2. MARCH. At the command *march*, the leading carriage reverses, and moves at once to the position occupied by the rear carriage at the beginning of the movement; the rear carriage follows the track of the leading one, reverses on the same ground, and preserves its distance. On the completion of the countermarch, the section moves forward in the new direction. To halt the section upon the completion of the countermarch, the Instructor commands: 1. *Section*, 2. HALT. The command *halt* is given when the heads of the lead-horses of the leading carriage reach the position occupied by the hind part of the rear carriage at the beginning of the movement.

COUNTERMINES.—Galleries or chambers excavated under the glacis or some other part of a defense-work of a fortress. Their purpose is to foil a besieger. In a fortress on a large scale there are enveloping-galleries, counterscarp-galleries, listening-galleries, galleries of communication, and other subterranean passages, under various parts of the outworks, all for the purpose of assisting the defenders in discovering and frustrating plans laid by the besiegers. Listening-galleries are sometimes pushed forward even to the foot of the glacis. In such places selected men put their ear to the ground, and listen for the approach of the enemy, as denoted by the sound of tools used in driving a mine or gallery of attack. The sound of a pickaxe so employed can be heard through the ground at a distance of 60 feet. As there are no openings above, these galleries cannot be driven beyond a certain distance, as the sappers would be stifled for want of air. If a mine be driven to blow up the defense-works, a countermine is driven to blow up the besiegers; and sometimes the two parties carry their works so far as to meet in the subterranean passages, and there fight. If there be only a thin wall of earth left between them, they will fire pistols through bored holes, or drive in cartridges or smoke-balls. This terrible work is mostly carried on by sappers and miners.

The systems of countermines proposed by most writers on this branch of the defense are generally of too complicated a character to admit of being executed at a reasonable cost, and they require for their service not only a large amount of powder, but also a great number of miners. The following arrangement has been proposed to meet in a simple and satisfactory manner the requisites of a subterranean defense: Parallel to the capital of an assailable salient of the work, four listening-galleries may run out to a distance from 50 to 80 yards beyond the salient; the interval between these galleries being twice the line of least resistance of the heaviest charged mines. If we take this line at 7 yards, or 21 feet, which is about the greatest for common mines, the interval of the galleries will be 15 yards. The dimensions of the listening-galleries for about the first 20 yards may be those of a grand gallery, and the remaining part may be a common gallery. These galleries will depart from a transversal grand gallery about 6 yards in advance of the counterscarp at the salient, which will serve as a communication between them, and also as a depot. Other transversals of the size of half-galleries, or branches, will be made at different intervals for the purpose of ventilation. This group of galleries will have their outlet into the ditch, through two galleries, one leading from each extremity of the transversal grand gallery.

To flank this group, other listening-galleries may extend obliquely outwards from the two outside parallel galleries. To serve the mines of this group, a series of ascending branches may lead from the galleries to chambers, placed midway between the galleries, and having a line of least resistance of 4 yards. This will place these chambers at about 8 yards from the two adjacent galleries. Smaller branches may lead, if necessary, from these last branches to other groups of chambers having a line of least resistance of 2 or 3 yards. A series of chambers with lines of least resistance of 7 yards will be established in juxtaposition with each listening-gallery. From this arrangement it will be readily seen that ground over the mines can be entirely broken up, and that the successive explosions of the mines of one group will destroy the branches and galleries which lead to them, without injuring those of other groups. The object of this disposition is to blow up by repeated explosions the ground over which the enemy must approach upon the assailed salient. Groups of galleries and mines similar to the one in advance of the salient may be arranged for the defense of the interior of the work at the salient. As the air in the galleries of mines is liable to become foul from various causes, some mechanical contrivances and chemical methods by which the vitiated air can be removed and fresh air introduced have to be resorted to for the purpose of enabling the miners to circulate through them with safety. Air-pumps, bellows, and artificial draughts, procured by kindling a fire at one of the outlets of a system of galleries, are the ordinary expedients by which this object is attained.

The great pecuniary outlay requisite in establishing a system of galleries, the time and labor for their construction, besides the large corps of experienced miners and the extra provision of powder demanded for their efficient service when the system embraces any considerable extent of surface, has led Engineers to consider whether the end proposed by subterranean means of defense might not be attained by some more simple expedients. Since the application of galvanic currents to exploding mines, and the facilities which it affords to effect this at very considerable distances, it has been proposed to substitute isolated shafts for

Countermining Operations at Siege of Sebastopol.

galleries, placing them in positions most suitable to attain the besieger's works. The shafts, to give them a character of permanency, may be lined with masonry and receive a stone or iron cover, which may be concealed from view by placing it several feet below the surface. When wanted for service, the shafts are charged and tamped in the usual manner, and connected with a galvanic battery by insulated wire conductors, laid sufficiently far below the surface of the ground to be without the sphere of the besieger's excavations and of other accidents.

We find remarkable countermining operations at the siege of Sebastopol. There the French had to work under far more unfavorable circumstances than the Russians; the system of countermines of the latter being well ventilated by shafts sunk in the ditch of bastion No. 4, and others in the glacis, and also being below strata of a hard limestone rock, and the French, moreover, having a greater distance to push their galleries to reach the Russian countermines than these were from their defensive works in their rear. With these disadvantages, the French resolved, about March 14, 1855, to break up sufficient ground between their third parallel and the ditch of bastion No. 4, by a connected series of mines, to give them front enough for a fourth parallel, which was to contain troops to cover their further mining operations. All of their subsequent mining labors on this point, up to the close of the siege, tended to this object; and at this period the effect of their arduous labors is shown in the drawing. A is the salient of bastion; B, bottom of ditch and entrance to countermines, C, C; D, D, crater formed by explosions of French and Russian mines; E, E, French galleries of attack; F, third parallel from which French attack was made; G and H, communications between third parallel and French trenches in and around the borders of crater, D, D, D. During these operations the French executed about 100 feet of ramps and shafts, and about 4000 feet of galleries and branches. They exploded six undercharged mines and camoutlets; twenty stone fougasses; thirty-five over-charged mines; and sixty-four over-charged shafts: making a total of one hundred and twenty-five explosions; using in all about 130,000 pounds of powder. Their losses in killed, in wounded from momentary suffocations, and in those rescued after having been buried alive, among their own miners and some auxiliary force from the infantry of the line, were two hundred and twenty-eight in all; of which eight were officers, killed either in the mines or trenches by explosions, and eight by the Russian fire. Not only did the French use their mines to gain a footing for their fourth parallel, but they were obliged to resort to the same means to open, in the rock, communications between these two parallels. See *Blower*, *Gallery*, and *Mines*.

COUNTER-PAROLE.—A word given in any time of alarm, as a signal. See *Parole*.

COUNTER-PASSANT.—In Heraldry, a term for two beasts passing each other the contrary way.

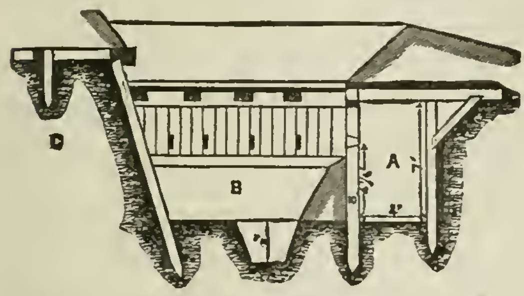
COUNTERPOISE-CARRIAGE.—A sort of carriage which, applied to a gun mounted in *barbette*, allows it to recoil behind the parapet or other shelter, and by means of a counterpoise brings it, or assists in bringing it, again into *battery* after it has been loaded. In the Moncrieff carriage the counterpoise is a heavy weight between the cheeks of the top carriage. In the King carriage the weight is in a well under the pintle block, and is attached to the carriage by a wire cable.

COUNTER-ROUND.—A body of officers whose duty it is to frequently visit and inspect the rounds and sentinels.

COUNTERSCARP.—The side of the ditch opposite to the parapet. The slopes of the scarp and counterscarp will depend on the nature of the soil, and the action on it of frost and rain. The scarp is less steep than the counterscarp, because it has to sustain the weight of the parapet. It is usual to give the slope of the scarp a base equal to *two thirds* of the base of the natural slope of a mound of fresh earth whose altitude is equal to the depth of the ditch; the base of the counterscarp-slope is made equal to *one half* the same base.

To determine the exact dimensions of the ditch for a given parapet requires a mathematical calculation. On the field a result may be obtained approximating sufficiently near the truth for practice, by assuming the depth of the ditch and dividing the surface of the profile of the parapet by it to obtain the width. In excavating the ditch it will be found that more earth will be furnished at the salients than is required there for the parapet; and that the re-enterings will not always furnish enough. On this account the width of the ditch should not be uniform, but narrower at the salients than at the re-enterings. See *Scarp*.

COUNTERSCARP-GALLERY.—The counterscarp-gallery consists of a framework, covered on top with a sheeting, which is placed within the counterscarp at the salients. The front of the gallery is made of nine- or ten-inch scantling, placed upright, and arranged with loop-hole defenses; these pieces are connected at top by a cap-sill. Cross-pieces are notched on the cap-sill about three feet apart; they are supported by shores placed four feet from the front piece. The cross-pieces may project three feet beyond the shores, and, if necessary, be braced from the shores. The gallery is covered on top by 1½-inch sheeting; and behind in a similar manner, but only to the height of five feet above the bottom.



A, Section; B, Elevation of a Counterscarp-gallery for a Work with a Revetted Scarp, C.

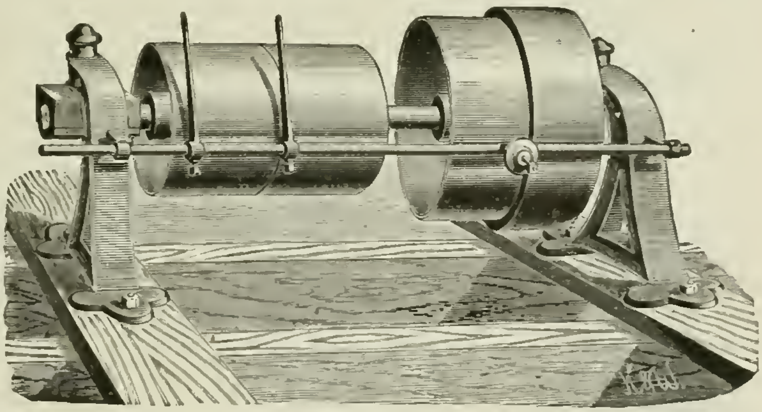
This arrangement gives a free space behind the back sheeting for the play of the rammer in loading. The height of gallery may be only seven feet; its width, according to the foregoing arrangements, is four feet. It should be covered on top by at least three feet of earth. The level of the gallery should be the same as the ditch; and there should be a small ditch in front of it, to prevent the enemy from closing on the loop-holes, or obstructing their fire by filling the ditch in front of them by means of sand-bags, fascines, etc. The entrance to the gallery is by a narrow door. See *Scarp-gallery*.

COUNTERSCARP-WALL.—A revetted counterscarp is regarded as adding to the difficulty of descending into the ditch, and as offering greater security against an open assault. For this purpose the wall should not be less than 12 or 15 feet in height to offer a serious impediment; in any case, where motives of economy do not imperiously demand it, the counterscarp-wall of the enceinte should be from 18 to 24 feet in height. This height will not only give great security to the ditch, but, as will be seen in the description of the siege-works of the assailant, it will delay considerably his progress, as the gallery by which he must generally reach the bottom of the ditch from the level of the covered-way terreplein is one of the slowest and most laborious of his operations.

Besides giving greater security against a surprise, a revetted counterscarp enables the assailed to circulate through their ditches even when the assailant has established his trenches along the glacis-crest, as the top of the counterscarp-wall will screen the troops passing along the bottom of the ditch. It also affords facilities for forming a counterscarp-gallery behind it, loop-holed for the defense of the ditch in an open assault, which, for small works without thorough flanking arrangements, will be found very serviceable. Besides, this gallery will be found of great utility where a system of defensive mines is to form a part of the defenses. But as counterscarp-galleries, if seized by the assailant, may be turned against the defenses, it is important that they should be placed in positions where they will be of little value to the assailant if seized by him.

The necessity for revetting with a wall of masonry the scarp and counterscarp of a wet ditch in which the water can be retained at a level of six feet in depth is not so obvious; as when the ditch is wide the obstacle of the water alone would seem to be sufficient to secure the place from a surprise. Many works under this condition have been built with simple earthen scarps and counterscarps; in some instances a chemin-de-ronde being formed by leaving a wide berm between the foot of the exterior slope and the crest of the scarp, and planting a loop-holed stockade near the crest. But in rigorous climates, where the water freezes quickly, a wet ditch is no longer a security in winter; and a revetted scarp of at least 24 feet in height, with a steep earthen counterscarp, is a better security against a surprise than the expedients proposed of keeping an open channel along the middle of the ditch of 12 feet in width, piling up on each side of it the ice taken from the channel, and throwing water over the exterior slopes to freeze and form a slippery surface to an assaulting column. See *Scarp-gallery*.

COUNTER-SHAFT.—An opposite and parallel shaft driven by band or gearing from the former one. The drawing shows the counter-shaft which accompanies the Tanite Company's large No. 5 wheel emery-grinder, much used in armories. The counter-shaft may be overhead, or it may receive the impulse from below. The Pratt clutch is generally applied to the counter-shaft. This clutch is unsurpassed in ease of working, freedom from binding, durability, and readiness of adjustment. The shipper-slide has no transverse strain; the clutch-jaws cannot become bound; the contact of the surfaces to produce motion is perfect; there is no shock in starting or reversing—no sudden tension of the belts, or undue strain upon the shipper-handle. Counter-shafts with this clutch may or may not be provided with cones. The Pratt friction-pulleys are furnished with sleeves and collars for adaptation to many machines where instantaneous starting and stopping is desirable. A threaded shoe is furnished with the collar, by means of which the attachment may be made to an ordinary straight shaft, by threading the shaft a length slightly exceeding the thickness of the collar.



Counter-shaft.

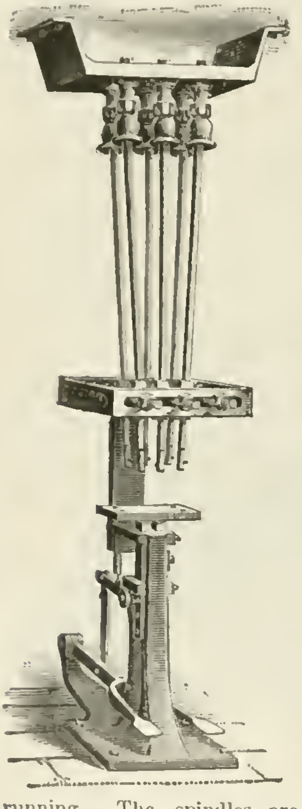
Supposing we have a main shaft running 110 revolutions, and a 12-inch hand-lathe counter-shaft with 8-inch tight and loose pulleys running 220 revolutions, we can find the following elements in a very simple manner: 1. To find the size of the pulley on the main shaft, multiply the diameter of the pulley on the counter-shaft by its number of revolutions and divide the product by the number of revolutions of the main shaft. The quotient will be its diameter:

$8 \times 220 = 1760, \frac{1760}{110} = 16$ inches diameter. 2. To find the number of revolutions of the counter-shaft, multiply the diameter of the pulley on the main shaft by its number of revolutions and divide the product by the diameter of the pulley on the counter-shaft:

$16 \times 110 = 1760$, $\frac{1760}{8} = 220$ revolutions. 3. To find the size of the pulley on the counter-shaft, multiply the diameter of the pulley on the main shaft by its number of revolutions and divide the product by the number of revolutions of the counter-shaft: $16 \times 110 = 1760$, $\frac{1760}{220} = 8$ inches diameter.

COUNTERSIGN.—A watchword or number given daily in time of war by the Commander of an army to the force under his command, in order that friends may be distinguished from foes; it is exchanged between guards, and intrusted to those employed on duty in guarding the camp or garrison. Before the enemy, the countersign must be given by every one who approaches a sentry's post, otherwise he will not be permitted to pass. See *Parole*.

COUNTERSINK.—An enlargement of a hole to receive the head of a screw or bolt. The sides of the hole are merely chamfered if the hole is to receive the head of an ordinary wooden screw. When a flat-headed screw or the head of a bolt is to be let in flush with or below the surface, a flat bottom is required. The countersinking-machine is quite a useful one in the arsenal and armory on general work such as strap- and T-irons, metal plates, harness, books, etc., where several holes are to be made, on a regular or irregular line, as each piece can be drilled and countersunk at one operation. The engraving represents six spindles; but the apparatus may be provided with any number required, according to the work to be done. The drills can be adjusted very close to each other, or several inches apart, even while the machine is running. The spindles are suspended from a frame fastened to the ceiling, and power is applied to the upper ends by means of belts from horizontal counter-shafts. The engraving shows but one table-slide; some countersinking-machines have two tables, with which the operator can do two different kinds of work at once if desired, or he can use all the spindles on one table.



A very convenient countersink and drill combined is so constructed that the countersink follows the drill, and the job is finished at one operation, saving the adjusting of work and tools twice. The countersink is so shaped that it may be readily ground when dull, and is finished with round shanks either ½ or $\frac{41}{64}$ inch diameter.

COUNTER-SWALLOWTAIL.—In fortification, a kind of outwork very much resembling a single tenaille. See *Swallowtail*.

COUNTER-TRENCHES.—Trenches made against the besiegers, which consequently have their parapets turned against the enemy's approaches, and are enfiladed from several parts of the place on purpose to render them useless to the enemy if he should chance to come into possession of them. See *Counter-approaches*.

COUNTER-VAIR.—An heraldic fur. It differs from *vair* by having its cups or bells of the same tinctures placed base against base and point against point. The tinctures are *or* and *azure*. See *Heraldry*.

COUNTERVALLATION.—In military engineering, a chain of posts constructed by the besiegers of a fortified place; it completely surrounds the place at a certain distance, and is intended to prevent sorties of the besieged. The posts are generally small redoubts, either isolated or connected by a line of earthworks. It is only during very protracted sieges that countervallations are constructed. They bear a certain relation to circumvallation.

COUNTER-WORKS.—Works undertaken for the purpose of destroying or rendering useless those of an enemy. See *Counter-mines*.

COUNTRY.—The region outside of a fort down to which the glacis slopes. See *Site*.

COUP DE MAIN.—A sudden and vigorous attack for the purpose of instantaneously capturing a position. See *Charge*.

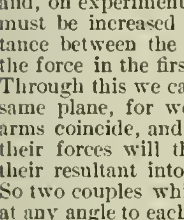
COUP DE POING.—A small pistol with a wheel-lock, invented in the sixteenth century. It is made entirely of iron, and the barrel is about 6½ inches in length. It is called *terzerol* in Germany.

COUP D'ŒIL.—The art of distinguishing by a rapid glance the weak points of an enemy's position, and of discerning the advantages and disadvantages offered by any given space of country, or selecting with judgment the most advantageous position for a camp or battle-field. Experience is a great aid in the acquisition of this necessary military faculty, but experience and science alone will not give it.

COUPED.—A term in Heraldry, used to describe the head or any limb of an animal cut off from the trunk, and smooth. It is distinguished from *erased*, i.e., forcibly torn off, and therefore ragged and uneven. A distinction is also made between *couped* and *couped close*, the latter signifying that the head or limb is cut off close, leaving no part of the neck or trunk attached to it. When crosses, bars, bends, and the like, are cut so as not to touch the sides of the escutcheon, they are also said to be couped. See *Heraldry*.

COUPE-GORGE.—This term, literally meaning *cut-throat*, is used in a military sense to signify any spot or position which affords an enemy so many advantages that the troops who occupy it must either surrender or be cut to pieces.

COUPLES.—The name given in statics to pairs of equal parallel forces acting in opposite directions, and at different points of a body. It is shown in the article PARALLEL FORCES that when two parallel forces act in opposite directions on a body, they may be replaced by one equal to their difference acting parallel to them in the direction of the greater, at a point *not* between but *beyond* the points where they are applied; and which point recedes the further from their points of application the nearer they approach equality, getting to an infinite distance when they become equal, and when their resultant accordingly is zero. In this limiting case the forces constitute a couple; they have no tendency to *translate* the body; their action goes wholly to make it rotate about an axis passing through its center of gravity, and perpendicular to the plane in which the couple acts. Such being the case, a couple cannot be replaced or counteracted by any single force, for such a force would produce translation; it can only be replaced or balanced by other couples. The length of the straight line which meets the lines of action of the forces at right angles is called the "arm" of a couple, and the product of the force into its arm is called its "moment." Most of the leading propositions in the theory of couples are readily seen to be true, as soon as they are stated. For instance, as the axis round which a couple tends to make a body rotate passes through the body's center of gravity perpendicularly to the plane of the couple, it does not matter what position the couple occupies in its own plane. Also, supposing the body to be rigid, the couple may be moved into any plane parallel to its own, provided its new position be rigidly connected with the original position. It is also obvious, on the principle of the lever, that the efficiency of the couple depends on its moment simply, so that its arm may be shortened or lengthened at pleasure, provided the force be increased or diminished as the case may require, so as always to make the product of the force and arm the same. Suppose ropes fastened at the bow and stern of a ship pulling with equal force in opposite directions; they will make the ship turn round an axis through its center of gravity, at a rate depending on the force applied to the ropes. If the ropes be fastened to opposite points of the vessel nearer midships, it will only turn round at the *same* rate, provided the force applied to the ropes be *increased;* and, on experiment, it would be found that the force must be increased so that its product into the distance between the ropes shall equal the product of the force in the first case into the length of the ship. Through this we can compound couples acting in the same plane, for we can turn them round till their arms coincide, and then give them a common arm; their forces will then act in the same lines, when their resultant into the arm will be the new couple. So two couples which are situated in planes inclined at any angle to each other may be replaced by a single couple. Suppose the couples both to be moved in their respective planes till their arms coincide with the line of intersection of the planes, CD. Bring them then to a common arm in this line, AB. At



each end of this arm we shall have a pair of forces, say P and Q, inclined to one another at the angle of inclination of the planes. Their resultant, by the composition of forces, will be a force R, acting in a line between the planes. We shall have then forces R acting at each end of the arm, and evidently in directions parallel and opposite. R × arm AB, then, is the moment of the resultant couple. Having seen how to compound couples whose planes are inclined to one another, the theory of the composition of couples may be said to be complete; for if they are in parallel planes, we know we can bring them into the same plane and to a common arm, and so into a common couple. In statical theory, any number of forces acting on a body, and not in equilibrium, may be reduced to a single force, a single couple, or a single force and a single couple. We have shown that the couples may all be reduced to one, as well as those forces which do not produce couples. If the single force do not act perpendicularly to the plane of the couple, it can always be compounded with the forces of the couple, so as to reduce the whole to a single force; if it act perpendicularly, then it cannot be compounded with the couple, and the body will have at once a motion of translation and motion of rotation. See *Force* and *Rotation*.

COUPLING-STRAP.—A strap connected to the off bit-ring of the off horse, thence through the near bit-ring, and leading back to the harness of the near horse. Used with artillery-horses, and also for restive horses in ordinary service.

COUPURE.—A passage, about twelve or fifteen feet broad, cut through the glacis in the re-entering angle of the covered-way, to facilitate sallies by the besieged. They are sometimes made through the lower curtain to let boats into a little haven built in the re-entering of the counterscarp of the outworks.

COURCON.—A long piece of iron which is used in the artillery and which serves to constrain or tighten cannon.

COURIERS. — Government servants employed for carrying, securely and expeditiously, important dispatches. Active and accustomed to travel, speaking several languages, and with a sufficient idea of their own consequence, they will set out at a moment's notice, pursue their way by steamer, by rail, by hired voiture, or on horseback, with little intermission by night and by day, until they reach their destination. Acquainted with routes, officials, and methods of clearing the way, and provided with all proper credentials, including a requisite supply of cash, nothing interrupts them in their eager course.

COURONEMENT.—In fortification, this term signifies the most exterior part of a work when besieged. Sometimes written *Couronnement.*

COURTEL.—An ancient military implement which served both for a knife and a dagger.

COURT-MARTIAL.—A Court for the trial of any one belonging to the army or navy for some breach of military or naval law. The members of the Court fill the functions both of Judge and Jury. In the British army, Courts-Martial are *General*, *District*, or *Regimental*. The first is the only one of the three empowered to award death or transportation for life as a punishment to the offending person. It consists of thirteen Commissioned Officers, if so many can be obtained at the time and place; and a Deputy Judge Advocate is specially appointed to conduct the prosecution. A Non-commissioned Officer, or a Private, may be tried by any one of the three kinds of Court, but a Commissioned Officer only by a General Court-Martial. A *District* or *Garrison* Court-Martial may be convened by a Field-officer commanding a district or corps, without requiring the Sovereign's sign-manual. It consists of a number of members, varying from three to seven, with a Captain or higher officer to act as Deputy Judge Advocate. Such a Court tries Warrant Officers, Non-commissioned Officers, and Rank and File, and can only treat such offenses, or alleged offenses, as meet with secondary punishment. A *Regimental* Court-Martial may be convened by the Commanding Officer of a regiment or detachment; it consists of three or more members; it treats of minor offenses, and can award only minor punishments. In all these kinds of Court-Martial the members are sworn in; the Court is an open or public one; the vote or sentence is decided by majority, the junior members voting first; but two thirds of the whole number, in a General Court-Martial, are necessary to give validity to a sentence of death. Before execution, the sentence of every military Court-Martial has to be approved and confirmed by the Convening Authority. Sometimes *Courts of Inquiry* are held instead of a Court-Martial, not to try or to punish, but to make an investigation; the members not being on oath. Such a Court occasionally precedes a Court-Martial. In the United States the Court is composed of from five to thirteen Commissioned Officers of suitable rank. Regimental Courts-Martial, having jurisdiction of minor offenses, consist of not less than three Commissioned Officers; Garrison Courts-Martial are similarly constituted. A General Court-Martial for the army can be held only on the order of the President, or of the Commander of the Army, or an officer commanding a separate Department.

The following is the form of the order appointing a General Court-Martial, the last paragraph being omitted when the Court can be kept up with thirteen members:

HEADQUARTERS, ——, etc.

A General Court-Martial is appointed to meet at ——, on the —— day of ——, or as soon thereafter as practicable, for the trial of —— ——, and such other prisoners as may be brought before it.

DETAIL FOR THE COURT.

1. —— ——	8. —— ——
2. —— ——	9. —— ——
3. —— ——	10. —— ——
4. —— ——	11. —— ——
5. —— ——	12. —— ——
6. —— ——	13. —— ——
7. —— ——	—— —— *J. A.*

A greater number of officers than those named cannot be assembled without manifest injury to the service.

By order of ——— ———.

——— ———,
Assistant Adjutant General.

Under the provisions of the 74th Article of War, officers who may appoint a Court-Martial are competent to appoint a Judge Advocate for the same. Accordingly, a Judge Advocate must be appointed for a Regimental or a Garrison Court-Martial in like manner as for a General Court. The President of a Court-Martial, besides his duties and privileges as member, is the organ of the Court to keep order and conduct its business. He speaks and acts for the Court in each case where the rule has been prescribed by law, regulation, or its own resolution. In all their deliberations the law secures the equality of the members. The 86th Article of War does not confer on a Court-Martial the power to punish its own members. For disorderly conduct a member is liable as in other offenses against military discipline; improper words are to be taken down, and any disorderly conduct of a member reported to the Authority convening the Court. Application for delay or postponement of trial must, when practicable, be made to the Authority convening the Court. When made to the Court, it must be before plea, and will then, if in the opinion of the Court well founded, be referred to the Authority convening the Court, to decide whether the Court should be adjourned or dissolved, and the charges reserved for another Court. Upon application by the accused for postponement on the ground of the absence of a witness, it ought distinctly to appear on his oath—1st, that the witness is material, and how; 2d, that the accused has used due diligence to procure his attendance; and, 3d, that he has reasonable ground to believe, and does believe, that he will be able to procure such attendance within a reasonable time stated. Prisoners are tried on joint charges only for offenses necessarily involving concert of action. In all other cases the charges must be separate. Whenever the same Court-Martial tries more prisoners than one, and they are arraigned on separate and distinct charges, the Court is sworn at the commencement of each trial, and the proceedings in each case are made up separately.

The Judge Advocate summons the necessary witnesses for the trial; but he does not summon any witness at the expense of the United States, nor any officer of the army, without the order of the Court, unless satisfied that his testimony is material and necessary to the ends of justice. Officers or enlisted men who receive a summons to attend as witnesses before any Military Court, Board, or any Civil Court, or other Tribunal competent to issue subpœnas to witnesses, outside the limits of the Department where they may be serving, before starting to obey the summons, forward it through the proper channels to the Commanding General of the Department, that the necessary orders may be issued. Orders from competent military authority are required for the movements of all officers and enlisted men in such cases. In cases of extreme urgency, and when the public interest would be liable to suffer by delay, Post Commanders may authorize immediate departure in obedience to the summons. In such cases special reports are made of the facts and reasons to the Department Commander for his approval of the action taken. A Post Commander who may be summoned is governed by the foregoing. The Judge Advocates of Military Courts, in issuing process under section 1202, Revised Statutes, to compel the attendance as witnesses of persons not in the military service, formally direct the same to some officer designated by the Department Commander as available for the service. The nearest Military Commander will thereupon furnish the necessary military force for the execution of the process whenever such force shall be actually required. The preliminary summons or subpœna may be served upon a witness by any person whatsoever. Cases of habitual drunkenness and utter worthlessness, which have not already been made the occasion of a trial by Court-Martial, may be tried under the charge of "Conduct to the prejudice of good order and military discipline," with separate specifications for each one of the acts of drunkenness. Civil employés of the War Department serving with, or other persons properly attached to, an army in the field in time of war, may be understood as agreeing that they will submit themselves for the time being to military control. Accordingly, under the 63d Article of War, such persons are within military jurisdiction, as provided for in said article, when their treachery, defection, or insubordination might endanger or embarrass the army to which they belong in its operations against what is known in military phrase as "an enemy." To enable the officers of an army to preserve good order and discipline is the object of this paragraph, and these may be as necessary in the face of hostile savages as in front of any other enemy. When an army is engaged in offensive or defensive operations against a public enemy, it may be said to be "in the field." The fact that troops are operating in a region of country chiefly inhabited by hostile Indians, and remote from the exercise of civil authority, may enter into the description of "an army in the field." Under other circumstances, these civil employés do not belong to the military establishment in a sense making them amenable to trial by Court-Martial. The legal punishments for soldiers by sentence of Court-Martial, according to the offense and the jurisdiction of the Court, under the law, are: death; confinement; confinement on bread-and-water diet; solitary confinement; hard labor; ball and chain; forfeiture of pay and allowances; discharges from service, and reprimands; and, for Non-commissioned Officers, reduction to the ranks. The idea of punishment or degradation is not associated with the honorable and important duty of guards by imposing sentences of extra tours of guard-duty. Solitary confinement, or confinement on bread and water, cannot exceed fourteen days at a time, with intervals between the periods of such confinement not less than such periods, and not exceeding eighty-four days in any one year.

When the sentence of a Court-Martial is imprisonment, the Court indicates whether the prisoner shall be confined in a penitentiary or a military prison, according to law and the nature of the offense. When the Court has sentenced a prisoner to a *military prison* for any offense, no power is competent to increase the punishment by designating a *penitentiary* as the place of confinement. In order to keep men who are confined for purely military offenses apart from the moral influence of such as are convicted of penal offenses, it is desirable that Courts-Martial should designate confinement in a penitentiary instead of a military prison, when it can be done legally under the 97th Article of War. The sentence of a Court-Martial involving confinement for a definite period of time is considered as beginning from the date of the promulgation of the sentence in Orders, if the person sentenced is in custody at that time, unless the time of its commencement is otherwise expressly fixed by the sentence of the Court or in the Order promulgating the proceedings. When soldiers under sentence, or awaiting sentence, commit other offenses for which they are tried and sentenced, the second or cumulative sentence may be executed upon the expiration of the first, whether the Court or Reviewing Authority so specify or not. A sentence to confinement, with or without forfeiture of pay, cannot, in terms, be made to commence at a date prior to the confirmation of the proceedings of the Court. If it is proper to take into consideration the length of confinement to which the prisoner has been subjected previous to such confirmation, it may be done by the mitigation of the sentence, so that its term from the date of approval shall not extend beyond the period contemplated by the Court or by the Reviewing Officer When a sentence imposes forfeiture of the monthly pay, or of a stated portion of the monthly pay, for a certain number of months, the force of the sentence is to stop *for each month* the amount stated. Thus, *ten dollars of monthly pay for one year* would be a stoppage of one hundred and twenty dollars. When the sentence is silent as to the date of commencement of the forfeiture of pay, it begins with the date of promulgation of the sentence in Orders, and does not apply to pay accrued previous to that date. This holds good whether the sentence imposes a forfeiture of a specified sum or one of a certain amount per month. Where the same time is covered by two or more forfeitures, they must, as to such time, apply together, until all are satisfied. The rate of forfeiture for a given time will then be the aggregate of the rates of the several forfeitures applicable thereto, whether the actual rate of pay for the time be greater or less.

A Court-Martial cannot assign and make over the pay of a soldier to any other person, and the receipt of such person is not a sufficient voucher for the Disbursing Officer. Nor can a soldier be required to receipt for money paid without his consent to another person. The Authority which has designated the place of confinement, or Higher Authority, can change the place of confinement, except in case of prisoners confined in the Leavenworth Military Prison, who are subject only to the orders of the Secretary of War. Ordnance Sergeants, Commissary Sergeants, and Hospital Stewards, though liable to discharge, may not be reduced. Nor are they tried by Regimental or Garrison Courts-Martial, unless by special permission of the Department Commander. Every Court-Martial keeps a complete and accurate record of its proceedings, to be authenticated by the signatures of the President and Judge Advocate, who also certify, in like manner, the sentence pronounced by the Court in each case. The record must show that the Court was organized as the law requires; that the Court and Judge Advocate were duly sworn in the presence of the prisoner; that he was previously asked whether he had any objection to any member, and his answer thereto. A copy of the Order appointing the Court is entered on the record in each case. The record is clearly and legibly written, as far as practicable, without erasures or interlineations. The pages are numbered, with a margin of one inch on the left side of each page, and at the top of the odd and bottom of the even pages; through this last margin the sheets are stitched together; the documents accompanying the proceedings are noted and marked in such manner as to afford an easy reference. No recommendation is embraced in the body of the sentence. Those members only who concur in the recommendation sign it.

The record of the proceedings of a Court-Martial is indorsed on the first fold, by the Judge Advocate or Recorder of the Court, with the name of the place where the Court is held; the date when the proceedings were signed; the designation of Order convening the Court; the names of the Presiding Officer, the Judge Advocate, and of the Prisoner tried.

Judge Advocate.

CASE TRIED.
Private E—— F——,
—— Artillery.

The Judge Advocate transmits the proceedings without delay to the officer having authority to confirm the sentence, who states at the end of the proceedings in each case his decision and orders thereon.

When a Military Court adjourns for three days or more, the members belonging to the command where it assembles, or to adjacent posts (to which, with the sanction of the Department Commander, they return on the daily adjournments), will be liable to duty with their respective commands during the time of such adjournment, and the adjournment should be reported by the Judge Advocate or Recorder to the Commanders concerned. When the Court adjourns for less than three days, its members will ordinarily be exempt from other duty during that time. This paragraph is directory only, and may be modified by Department Commanders, according to the exigencies of the service. When a Court adjourns without day, the members return to their posts and duties unless otherwise ordered by the President or Competent Authority.

When General Courts-Martial try cases requiring the decision of the President of the United States, they should not be dissolved until his action is promulgated; but upon the completion of the trial the members should be ordered to resume their respective duties. When a Court-Martial appears to have erred in any respect, the Reviewing Authority may reconvene the Court for a reconsideration of its action, with suggestions for its guidance. The Court may thereupon, should it concur in the views submitted, proceed to remedy the errors pointed out, and may modify or completely change its findings. The object of reconvening the Court in such a case is to afford it an opportunity to reconsider the record, for the purpose of correcting or modifying any conclusions thereon, and, also, to make any amendments of the record necessary to perfect it. Anything like a reopening of the case, by calling new witnesses, or recalling those already examined, is wholly foreign to the proceeding. The power to pardon or mitigate the punishment ordered by a Court-Martial is vested in the Authority confirming the proceedings (except in case of prisoners confined in the Leavenworth Military Prison), and in the President of the United States. An abatement of five days upon each month of consecutive good conduct may be allowed to military prisoners upon each sentence to confinement for over six months. For the Leavenworth Military Prison the orders are issued by the Commander of the Military Department of the Missouri. All other orders for pardon, mitigation, or discharge of prisoners confined in the Leavenworth Military Prison must emanate from the War Department. An order remitting forfeiture of pay operates only as to time subsequent to its date. The forfeiture continues operative for the time between date of promulgation of sentence and date of order of remission, and at the rate fixed in the sentence if the forfeiture be one of a certain amount per month; or, if it be of a specified sum, at the rate of the soldier's current pay, less deduction for Soldiers' Home. To this extent a remitted forfeiture must stand as a charge against the soldier's pay until satisfied. In case of a sentence contemplating payment of a stated sum to a soldier upon his release from confinement, such payment is made only when there is sufficient balance to his credit after deducting all authorized stoppages.

Company Commanders should be careful in noting sentences upon muster-rolls to give all of the data affecting pay, including the dates of the several orders of sentence and remission. Where one or more payments have been made to the soldier for time subsequent to date of an order of sentence, the muster-roll should be made to show the amount that has been deducted on account of the forfeiture. The data required by this regulation should continue to be borne on successive muster-rolls until the entire amount of the forfeiture for the time between dates of orders of sentence and remission shall have been deducted.

Whenever prisoners are sent to the Leavenworth Military Prison to serve out their sentences, the order promulgating the sentence, and the descriptive list (to which will be appended a statement of conduct), are forwarded with them.

The employment of a Reporter, under section 1203, Revised Statutes, is only authorized for General Courts-Martial in cases where the Authority convening the Court may consider such an officer necessary. When Reporters are employed, they are allowed not to exceed ten dollars a day, to cover the whole period of absence from their residence, traveling, or on duty. If the place of meeting of the Court be changed, transportation in kind is allowed. They are paid by the Pay Department on the usual certificate of the Judge Advocate.

Under the Rules and Articles of War, it is made the duty of Commanding Officers to see reparation made to the party or parties injured, from the pay of soldiers who are guilty of abuses or disorders committed against citizens. Upon proper representation by any citizen of wanton injury to his person or property, accompanied by satisfactory proof, the Commanding Officer of the troops causes the damage to be assessed by a Board of Officers, the amounts stopped against the pay of the offenders, and reparation made to the injured party. This proceeding is independent of any trial or sentence by Court-Martial for the criminal offense. See *Field-officer's Court, Garrison Court-Martial, General Court-Martial*, and *Regimental Court-Martial*.

COURT OF CHIVALRY.—A Military Court established by Edward III., of which the Earl Marshal and the Lord High Constable were joint Judges. When held before the Earl Marshal alone it was merely a Court of Honor; but when both were present it was also a Criminal Court. Having encroached on the common law, its jurisdiction was defined by an Act under which the Court claimed power to give relief to such of the nobility and gentry as thought themselves aggrieved in matters of honor, and to keep up the distinctions of degrees and quality. In criminal cases a jury was sworn; but in general the proceedings of the Court were summary matters, being brought under its cognizance by complaint or petition. An attempt was made to revive the functions of the Court in Queen Anne's time; but, except as represented by the Earl Marshal's Court (see *College of Arms*), it has now gone into abeyance.

COURT OF HONOR.—A Military Court authorized by the regulations of the Prussian service, convened for the purpose of sustaining the honor of the service and of individuals, and of punishing officers who may be found guilty of conduct deviating even in the least from the principles which actuate military men as men of honor. The Court of Honor of a regiment consists of all Commissioned Officers in it except the prosecutor, the defendant, near relations, officers appearing as witnesses in the case, officers on leave, detached service, under arrest, or awaiting trial before any Court; and has for its regular business management a Council of Honor, consisting of the Senior Captain, Senior First Lieutenant, and Senior Second Lieutenant. The Court has jurisdiction over all acts or omissions (not provided for by any fixed laws) which are unofficer-like or ungentlemanly in their nature, particularly such as contracting debts, improper choice of society, excessive use of intoxicating liquors, gambling, quarrels, carelessness or neglect of duty, and scandal. With the exception of General Officers, all officers of the Standing Army, the Reserve, the Landwehr, and those of the Retired List are subject to the laws of the Court of Honor. The Court to investigate the conduct of a Field-officer is made up of the Field-officers of the division to which the officer belongs.

COURT OF INQUIRY.—In cases where the General or Commanding Officer may order a Court of Inquiry to examine into the nature of any transaction, accusation, or imputation against any officer or soldier, the said Court shall consist of one or more officers, not exceeding three, and a Judge Advocate, or other suitable person as a Recorder, to reduce the proceedings and evidence to writing, all of whom shall be sworn to the faithful performance of duty. This Court shall have the same power to summon witnesses as a Court-Martial, and to examine them on oath. But they shall not give their opinion on the merits of the case excepting they shall be thereto specially required. The parties accused shall also be permitted to cross-examine and interrogate the witnesses so as to investigate fully the circumstances in the question. The proceedings of a Court of Inquiry must be authenticated by the signature of the Recorder and the President, and delivered to the Commanding Officer, and the said proceedings may be admitted as evidence by a Court-Martial, in cases not capital or extending to the dismission of an officer, provided that the circumstances are such that oral testimony cannot be obtained. But Courts of Inquiry are prohibited unless directed by the President of the United States or demanded by the accused. The Court may be ordered to report the *facts* of the case with or without an opinion thereon. Such an order will not be complied with by merely reporting the evidence or testimony; facts being the result, or conclusion established by weighing all the testimony, oral and documentary, before the Court.

When a Court of Inquiry is directed to be assembled, the order should state whether the Court is to report the facts or not, and also whether or not it is to give an opinion on the merits. The Court should also be instructed whether its attention is to be extended to a general investigation, or to be confined to the examination of particular points only, as the case may seem to require, in the judgment of the officer under whose authority it is assembled. Where the subject is multifarious, the Court should be instructed to state its opinion on each point separately, that the proper authority may be able to form his judgment.

The Court may sit with open or closed doors, according to the nature of the transaction to be investigated. The Court generally sits with open doors; but there may be delicate matters to be examined into that might render it proper to sit with doors closed. The form of proceeding in Courts of Inquiry is nearly the same as that in Courts-Martial: the members being assembled, and the parties interested called into Court, the Judge Advocate or Recorder, by direction of the President, reads the order by which the Court is constituted, and then administers to the members the following oath: "You shall well and truly examine and inquire, according to your evidence, into the matter now before you, without partiality, favor, affection, prejudice, or hope of reward: so help you God." The accusation is then read, and the witnesses are examined by the Court; and the parties accused are also permitted to cross-examine and interrogate the witnesses so as to investigate fully the circumstances in question. The examination of witnesses being finished, the parties before the Court may address the Court should they see fit to do so; after which the President orders the Court to be cleared. The Recorder then reads over the whole of the proceedings, as well for the purpose of correcting the record as for aiding the memory of the members of the Court. After mature deliberation on the evidence adduced, they proceed to find a state of facts, if so directed by the order constituting the Court, and to declare whether or not the grounds of accusation are sufficient to bring the matter before a General Court-Martial; and also to give their opinion of the merits of the case if so required. The Court should be careful to examine the order by which it is constituted, and be particular in conforming to the directions contained therein, either by giving a general opinion on the whole matter, a statement of facts only, or an opinion on such facts. The proceedings of Courts of Inquiry have been returned to be reconsidered when the Court has been unmindful of these points. It has been settled that a member of a Court of Inquiry may be objected to for cause. The proceedings must be authenticated by the signatures of the President and Recorder, and delivered to the Commanding Officer or Authority which ordered the Court; and the said proceedings may be admitted in evidence by a Court-Martial, in cases not capital nor extending to the dismission of an officer, provided oral testimony cannot be obtained. Transactions may become the subject of investigation by Courts of Inquiry after the lapse of any number of years, on the application of the party accused or by order of the President of the United States; the limitation mentioned in the Articles of War being applicable only to General Courts-Martial. It is not necessary to publish the proceedings or opinion of the Court, although it is usually done in General Orders. The Court is dissolved by the Authority that ordered it to convene.

COUSSINET A MOUSQUETAIRE.—A bag formerly worn by a French soldier on his left side beneath the cross-belt. It hung on a hook near the butt of his musket. The expression likewise signifies a wedge used to support the mortar in its frame.

COUSTIL A CROC.—A short sword of Italian origin used in the fifteenth century, and very much like the *anelace*.

COUTERE.—An ancient piece of armor which covered the elbow. At present but little used.

COUVRE-BASSINET.—A plate that moves on a hinge and covers the priming after it has been placed above the pan or bassinet.

COVER.—1. Natural or artificial protection from the fire of the enemy, the former being afforded by hills, woods, banks, walls, etc., the latter by fortifications constructed for the purpose. 2. To stand exactly in front or in rear of another man or object.

COVERED COMMUNICATIONS.— Shelter-trenches are much used to afford covered communications along a given front; to connect the works in a "line with intervals;" to bring a musketry-fire upon ground which cannot be swept by the fire from a particular work, etc. A trench, when used as a communication for infantry only, should be made three feet deep, and four feet wide at the bottom. The earth should be thrown on the side towards the enemy, and then leveled off in the form of the superior slope of a parapet, so that the men in the trench can fire over this mass of earth. If the trench is to be used for the passage of artillery, or to be used by bodies of troops passing from one point to another along the front, the least width at bottom should be made eight feet, and the height of the top of the mound of earth should be at least six feet and a half above the bottom of the trench. The side of the trench toward the enemy should be cut into offsets, and arranged so as to allow a fire of musketry over the parapet. Shelter-trenches are rarely made to follow a straight line, but usually conform to the contour of the ground. The trace should be marked on the ground if there is time to do it. It will economize the labor of the troops, and avoid an unnecessary waste of time. The trace should be governed by the general rules laid down for field-works, and great care should be taken that it cannot be enfiladed by a fire of the enemy. Profiles are not necessary. The points which would be occupied by them may be marked by men standing upon the edge of the proposed trench towards the enemy. A line would then be marked on the ground, by a pick, passing through the points selected. Parallel to this line, and twelve or fifteen feet in rear of it, the line of troops should be formed The front rank, furnished with intrenching-tools, would begin the digging; the rear rank would lie down. Reliefs should be formed, and the trench rapidly executed. The shelters for artillery or cavalry may be made in a very short time, in a way similar to that shown for the shelter-trench for infantry. On undulating ground the shelter-trench for infantry is frequently on the slope; the shelter for artillery would generally be on or behind the crest. A piece of artillery on the crest of undulating ground can be quickly run under cover, if it be desirable. This cover can be quickly and easily improved, by making a slight excavation and arranging a mass of earth in front of the gun. Slopes of this kind could be used for infantry as well as for artillery; and where a simple screen is the main object to be had, the communication would be along the reverse slope. See *Communications*.

COVERED DEFENSES.—To this class belong those constructions and arrangements intended to shelter the troops and *matériel* from vertical fire. Scarp and counterscarp galleries, casemates, casemated caponieres, bomb-proof barracks, etc., are examples. In the permanent works of more recent construction in our own country and in Europe, revetment-walls with relieving arches have in most cases been introduced instead of the ordinary thick walls with counterforts, which had been hitherto the usual mode of retaining the earth of the rampart and parapet. The piers of the relieving arches, which also serve as counterforts to the revetment-wall, are rectangular in plan, and usually run back from 12 to 16 feet. They are from 4 to 6 feet thick, and placed from 12 to 18 feet apart between their center lines. The arches are usually full center and two feet thick, with a rough shaped capping which adds an additional thickness from 9 to 12 inches over the crown of the arch. When the scarp-walls are entirely detached, leaving an open corridor between them and the rampart, they are pierced with one or two tiers of loop-holes, from which a fire can be brought upon the ditch and upon the terre-plein of the covered-way, or any work in front of the enceinte. To give cover to the men at the loop-holes, arched recesses are made in the thickness of wall, or else short counterforts are built back from the wall, which serve as the piers of covering arches. The width of the recesses should admit of three or four loop-holes at the usual distance apart, their height and depth being sufficient to give the men shelter from vertical fire and allow them to handle their arms with convenience. The most simple method of arranging a gallery behind a counterscarp-wall for the defense of a ditch is to build another wall parallel to that of the counterscarp, and to throw an arch over between the two to cover the top of the gallery. The counterscarp-wall is pierced with loop-holes arranged in the same way as in scarp-galleries.

Caponiere defenses for the ditches are classed under the head of what are termed *defensive casemates*, which are bomb-proof arched structures for receiving cannon, firing through embrasures pierced in the front or mask wall of the casemates. Defenses of this class, when used to flank the ditch, are termed *casemated caponieres*. These defenses are usually placed in the ditch at the middle point of the side or front to be flanked. The outline of their plan is mostly that of a lunette, the flanks being perpendicular to the line of the scarp, and the two faces making a salient angle of 60 . The caponiere is either built in juxtaposition with the enceinte, or else detached from it. In the latter case an inclosure is formed between the two by a loop-holed wall which connects the flanks with the scarp-wall. Each flank consists of one or two tiers of arched chambers, the piers of the arches being perpendicular to the back of the walls of the flank. Each chamber is of sufficient dimensions for the service of a single gun with a contracted field of fire. In some cases loop-holes are pierced for small-arms on each side of the embrasure; in others the casemates of one story are pierced for cannon, and the other for small-arms. The casemates are closed in rear by a thin wall, which is provided with windows for light and ventilation; and the piers are pierced with doorways to form a communication between the chambers and to assist the ventilation. Flues or vents are made in the front wall, just under the arches, for a like purpose. Where it may be necessary, the lower floor is drained by a conduit through the front wall.

It should be observed that whatever advantages covered defenses afford as shelter from the assailant's fire, they present the inconveniences of a comparatively narrow and obstructed field of view to the assailed, which is further obscured by the smoke which may gather within the gallery, and in front of the loop-holes. From these causes the assailed having to aim at a venture, his fire is likely to be less effective than in open defenses, where the smoke disperses rapidly and leaves a clear field of view. The same may be said of loop-holed walls covering exterior corridors where the space to the rear is confined. Owing to these considerations, loop-holed and covered defenses of the kind in question should be restricted to special defensive purposes, where an object within the field of fire can be attained with some certainty whether seen or not by the assailed; as, for example, the protection of a ditch, or a scarp-wall which cannot be flanked from within the work; for sweeping a covered-way, or the interior of any outwork which cannot be brought well under the fire of the parapet of the main work. As the main object of covered defenses is protection against shells, it is essential that the arches of the galleries should be bomb-proof. As the span of these arches is usually small, a thickness of 2 feet given to the masonry, and a covering from 4 to 6 feet of earth above it, are ordinarily considered sufficient for the object in view. With regard to the front walls of these constructions, as they are too thin to withstand the direct action of artillery, they must either be covered by earthen masks, as a glacis raised beyond the counterscarp, for example, or be used only in positions where they are not exposed to this fire. See *Casemates*.

COVERED FLANK.—The platform of the casemate, which lies hid in the bastion. These retired flanks are a great defense to the opposite bastion and passage of the ditch, because the besiegers can neither see nor easily dismount their guns.

COVERED-WAY—COVERT-WAY.—In fortification, an open corridor or passage bordering the ditches of the enceinte and outworks, if there be any, forming a continuous line of communication around the fortification, masked from the view of the enemy by an embankment of sufficient height to cover the troops in it. The covering embankment is arranged towards the covered-way like an ordinary parapet, and receives on the exterior a gentle slope or *glacis*. This outwork is indispensable to a garrison determined on an active and vigorous defense. By means of it the garrison have a covered position beyond the ditch where they can assemble with safety, either for the purpose of making a sortie, or to guard the ditches and the communications across them; and it affords them also a secure point of retreat if repulsed in a sortie, as a reserve left in the covered-way will be at hand to check the pursuit by their fire, and enable the retreating party to gain the enceinte. The covered-way prevents all access to the ditch by a strong fire of musketry, which sweeps all the exterior ground, and affords facilities for posting beyond the ditch sentinels and small detachments to guard the ditches and the communications across them. It is the most indispensable of all the outworks, and it is only in rare cases that we can do without it. Vauban placed a high value on this work, which, to use his own words, "costs less to the defense and more to the assault than any other work." See *Outworks*.

COVERING FASCINES.—Fascines made of stout picket stuff, not less than one inch thick, without any mixture of small brushwood. They may be used in place of planks for the superstructure of wooden bridges; and may also be used, if no stout planks or spars are to be had, for the roofs of field powder-magazines. They may be made of the usual diameter of nine inches. Their length will depend upon the particular purpose for which they are intended

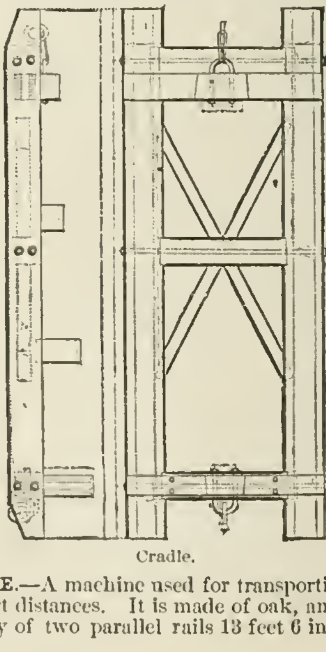
COVINARII.—The soldiers who fought on the *covinus*, a kind of war-chariot used by the ancient Britons and Belgians.

COWARDICE.—Want of courage to face danger. The Articles of War declare that any officer or soldier who misbehaves himself before the enemy, runs away, or shamefully abandons any fort, post, or guard, which he is commanded to defend, or speaks words inducing others to do the like, or casts away his arms or ammunition, or quits his post or colors to plunder or pillage, shall suffer death, or such other punishment as a Court-Martial may direct.

COW-BOYS.—A band of marauders in the time of the American Revolution, consisting mostly of refugees who adhered to the British side, and who infested the so-called *neutral ground* lying between the American and British lines, plundering all those who had taken the Oath of Allegiance to the Continental Congress. The term has recently been applied to marauding parties in the Western States and Territories.

CRAB.—A winch on a movable frame with power-gearing, used in connection with derricks and other non-permanent hoisting-machines. The larger gear-wheel is on the shaft of the roller, and is rotated by the spur-pinion and hand-cranks. The crab or geared capstan used in mechanical maneuvers consists of a strong frame of oak timber firmly fastened to the ground by stakes, or tied by rings in the ends of the side pieces. The bottom side pieces are joined by two cross-braces, between the tenons of which, and through from end to end of each, passes a bolt, firmly fastening the frames together. The bottom and top side pieces are joined by four upright and eight inclined braces. A bolt passes through the upright braces from top to bottom, binding the parts together. Extending across the frame are two shafts, which rest in cast-iron boxes fastened to the top pieces. Upon one is fastened a cast-iron drum and a large geared wheel, having 110 teeth; on the other a small geared wheel with 14 teeth and the cranks for turning, which are held in place by nuts. This axle has a motion in the direction of its length to disengage the geared wheels when desired. See *Mechanical Maneuvers*.

CRACKED HEELS.—From careless grooming, washing horses' legs and imperfectly drying them, permitting them to stand in accumulations of filth or exposed to draughts, the skin becomes inflamed, tender, itchy, thickened, and by and by cracked. An ichorous noisome discharge exudes, and lameness often results. In animals with round, *gummy* legs it is sometimes constitutional; underbred horses with rough hairy fetlocks present the majority of cases; white heels, being more delicate, are especially affected; whilst the hind limbs, exposed as they are to filth and cold, suffer most frequently.



Cradle.

CRADLE.—A machine used for transporting heavy guns short distances. It is made of oak, and consists essentially of two parallel rails 13 feet 6 inches long and 10 by 12 inches thick. These rails are united by a transom near each end and one in the middle; these transoms have such length as to make the entire width of the cradle 60 inches. A bolster is placed over each end-transom; the ends of these bolsters are flush with the exterior sides of the rails. The bolsters for the support of the breech are 6 inches high and 8 inches thick; that for the chase, 15 inches high and 6 inches thick; the middle part of the top of each is slightly hollowed out to form seats for the piece. A movable bolster, having notches at each end to fit upon the rails, is intended to be placed tight up against the middle part of the gun after it has been placed on the cradle. Diagonal braces are fitted inside between the rails and transoms. The under part of the ends of the rails, both front and rear, is beveled off, so that, in moving in either direction, the rollers can be caught under the cradle with facility. The under surfaces of the rails are shod with iron to prevent them from splintering out. A ring is attached by a link and eye-bolt to each end-transom for the purpose of attaching blocks and tackle when moving the cradle and piece. The cradle moves on wooden rollers; each roller is 78 inches long and 7 inches in diameter. From six to ten rollers are required; they rest and move on way-planks laid on the ground. See *Mechanical Maneuvers.*

CRAKERS.—A term applied to the choice soldiers of various organizations in the time of Henry VIII.

CRAKYS.—An ancient term commonly applied to great guns. It is now quite obsolete.

CRAMPETS.—A term very frequently applied to the cramp-rings of a sword-scabbard.

CRAMPTON ROTARY PUDDLING - FURNACE.—This furnace, used in the Royal Gun Factory, is designed to accomplish the following points: (*a*) The utilization of slack or small coal without the production of smoke; (*b*) the automatic feeding of fuel and air in proper proportions, by which only perfect combustion can be effected; (*c*) the production of heat of the highest intensities with perfect regularity both as regard intensity and quality; (*d*) the construction of puddling-furnaces without brick-work, composed of a single chamber, in which the gas is produced, consumed, and the material treated; (*e*) the reduction of wear and tear both of the lining and of the furnace by the prevention of unequal contraction and expansion; (*f*) also to effect the fettling of the revolving furnace in a quick, simple, and effective manner; (*g*) and, lastly, to eliminate phosphorus and sulphur from common pig to such an extent as to enable good steel to be produced from it.

This puddling-furnace consists of a cylindrical casing of wrought-iron, the casing being made double, so that a water-space is formed both at the sides and at the ends. To the center of one end is attached a two-way cock, which communicates with two pipes. Through one pipe the incoming water is conducted direct to the front of the furnace, while through the other heated water escapes at a temperature of 90 degrees. The main body of the furnace is hooped at two points by steel tires, these tires each taking a bearing upon a pair of carrying-wheels. These carrying-wheels or rollers turn on bearings supported by plummer-blocks fixed to the large cast-iron base-plate which carries the whole furnace. The turning-gear of the furnace is very simple, and consists of a pinion engaging a toothed segment bolted to the casing, and worked by a small engine with diagonal cylinders. The supply of the powdered fuel is arranged by means of a revolving worm or creeper, which carries the dust along the duct, where it is deposited in front of the extremity of an air-pipe leading from the fan, the blast from which delivers the coal-dust into the furnace and assists in its combustion. It may be here stated that at the time the trial of this furnace was proposed coal was at an enormous price, and any economy of fuel was of the highest importance. The results of experiments with this furnace showed that the iron produced from it was defective in the following important qualifications: 1. It could not be often reheated; 2. It was not free from blister; 3. It was often red-short. These defects render it unsuitable for the manufacture of ordnance. See *Furnace* and *Iron*.

CRANE-DREDGE.—A variety of dredging-machine formerly used, but now, in a great measure, superseded by the boom-dredge. The crane-dredge, as commonly built, is provided with a set of three-threaded blocks, for multiplying the hoisting-power; but since these augment the prejudicial resistance of friction, and increase the time of hoisting and discharging the filled dipper, we have assumed the drum-strain to be transmitted directly to the dipper-bail. This is fair for comparative purposes, since it reduces both dredges to the same relative conditions—the new dredge being generally worked with a single chain, although the threaded blocks might be applied to it if deemed expedient. It is apparent that at commencement of work the greater the angle included between the hoisting or excavating chain and the dipper-handles, the greater will be the force in the direction of the bank, and the smaller in the line of the dipper-handle. Experiments have been conducted with a view to making this angle as large as possible without impairing the efficiency of action, and the first step in this direction was the invention of the "extension-crane," which remedied the matter a trifle; then followed the arm pivoted to the long side of the crane, and bearing, at its outer end, sheaves, over which the hoisting-chain was worked. This invention, while fulfilling its mission, was yet so annoying in its action that it was abandoned.

In the common form of the crane-dredge, the angle included between the excavating-chain and the dipper-handles is about 8°. After much study and extensive experiments, Mr. Ralph R. Osgood invented his boom-dredge, in which the angle in question is almost 30 . Since the component of force in the direction of the bank is almost directly proportional to the size of this angle, the boom-dredge will have a bank force nearly 3.5 times as great as given by the crane-dredge. The boom-dredge, by dispensing with fall-blocks, is enabled to raise its load quicker, and with less loss of power by friction, than the crane-dredge; and also requires a shorter dipper-handle, from the fact that its uppermost point of support — the friction-clutch or brake—is brought, by means of the falling or movable boom, 10 feet or more nearer the dipper. It is also strained less, thus requiring less material for its construction and being less liable to bend or break. See *Boom-dredge*, *Dredging-machine*, and *Excavator*.

CRANES.—Cranes are employed for moving ordnance, molds, and other heavy masses about a foundry. They are fitted with cog-wheel gearing to obtain power at the expense of time, and are often worked by steam. Care must be taken to give great strength to this machine, and to cause its motion to be easy on its pivot. When properly adjusted a weight may be lifted and transported from one point to another, anywhere within the limits of the circle described by the arm.

Cranes are most clearly classified by reference to their modes of transferring their loads horizontally; and, thus considered, are found to divide themselves into the following groups, viz.: 1. *Rotary*—In which the load is revolved around a fixed center, such as a mast or column. 2. *Rectilinear*—In which the load is moved in straight lines, in one or more directions. Both types of cranes are subdivided into two general classes as to their movements, viz.: (*A*) *Fixed*—When their supporting members are fixed in some permanent location. (*B*) *Movable*—When the crane as a whole can be moved about. And into four other general classes as to their source of motive power, viz.: (*a*) *Hand*—When the motions, either vertical or horizontal, are effected by manual power. (*b*) *Power*—When the motions are effected by power derived from line shafting driven by a stationary engine or other fixed motor. (*c*) *Steam*—When the motive power is derived from a steam-engine attached directly to the crane itself and moving with it. (*d*) *Hydraulic*—When the motive power consists of hydraulic pressure obtained from a pump or accumulator, and carried to the crane by pipes.

A further distinction is covered by the term *locomotive*, which is applied to cranes (usually of the rotary type) which are capable of propelling themselves upon a roadway or track. Rotary cranes comprise the following principal types, viz.: 1. *Swing-cranes*—In which the central mast is pivoted to the floor and roof of the building, and the load is suspended from a block fixed at the outer end of an arm projecting horizontally from the mast, the only horizontal motion being one of rotation. 2. *Jib-cranes*—In which the central mast is pivoted to the floor and roof of the building, and the load is suspended from a trolley traveling in and out upon an arm or jib projecting laterally from the mast. 3. *Column-cranes*—Which consist of a jib-crane constructed to revolve around or upon a fixed column forming the support of a building or floor. 4. *Pillar-cranes*—In which the central column or pillar is entirely supported by a heavy foundation built at its base, and the load is suspended from a boom projecting from the pillar and revolving with it or around it. 5. *Derrick-cranes*—Which consist of a jib-crane for yard use, the upper end or pivot of the mast being held in position by guy-rods or stays, instead of by attachment to a roof or ceiling. 6. *Walking-cranes*—Which consist of a pillar- or jib-crane mounted on wheels, and arranged to travel by power or by hand upon one or more rails. 7. *Locomotive-cranes*—Which consist of a pillar-crane mounted on wheels, and provided with a steam-engine and boiler, the power of which is available for operating the crane and for propelling it upon its tracks.

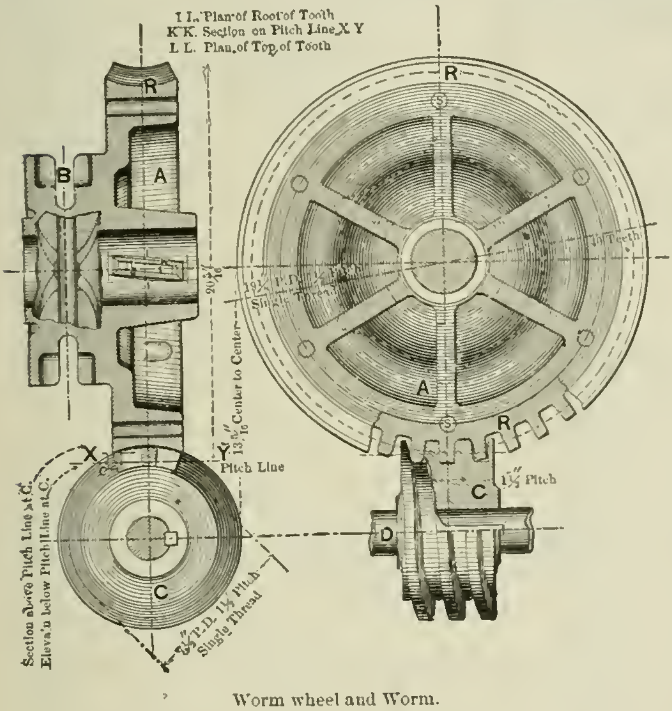
Rectilinear Cranes comprise the following principal types, viz.: 1. *Bridge-cranes*—In which a fixed bridge spans an opening, and the load is suspended from a truck or trolley capable of moving across the bridge. 2. *Tram-cranes*—In which a truck or short bridge, from which the load is suspended, is arranged to travel longitudinally upon a pair of overhead-rails, but is without capacity for transverse motion. 3. *Traveling-cranes*—In which a rectangular space is provided with overhead-tracks upon two of its opposite sides, and is spanned by a bridge arranged to travel longitudinally upon these tracks, the load being suspended from a truck or trolley capable of moving transversely across the bridge, so that the load may be moved to or from any point within the entire rectangle. 4. *Gantries*—In which an overhead-bridge is supported at each end by a frame, or trestle, extending downwards, and having wheels in its base to permit of travel upon two longitudinal tracks laid upon the ground, so that the entire structure can move endwise upon the latter, and the load, which is suspended from a truck or trolley on the bridge, can be moved transversely across the bridge. 5. *Rotary Bridge-cranes*—Which combine a rotary with a rectilinear movement, and consist of a bridge having one end pivoted to a central pier or post, while the other or outer end travels on a circular overhead-track, or is supported by a gantry-frame traveling upon a circular track upon the ground, the load being suspended from a truck or trolley traveling transversely across the bridge.

The most important factor in the economy and convenience of a crane is the mechanism by which the load is lifted and lowered, as it must necessarily come into action every time the crane is used. In all applications of power, from whatever source derived, it must be remembered that the gearing of a machine can only modify the power applied in one of two ways, viz.: (1) By reducing its velocity, and proportionately increasing its force or "pull." (2) By increasing the velocity, and proportionately decreasing the intensity of the power transmitted. Under no circumstances, unless the motive force is increased, can power be gained except by a sacrifice in speed, or can speed be increased except by a sacrifice in power. If either or both must be increased without diminishing the other, it can only be accomplished by supplying more motive power. The function of gearing, then, is to change the force or direction of the power applied. If it is well designed and constructed, this may be done with only a small loss from friction; while if badly made, the gearing may absorb much power in wasteful friction of its moving parts. In machinery for hoisting, the "purchase," or conversion of velocity into lifting power, is usually effected partly by a multiplication of the ropes or chains of the tackle through which the load is suspended, and partly by gearing within the machine, which latter thus becomes an important feature in crane-work. The gearing ordinarily used for this purpose consists either of spur-wheels and pinions or of worm-wheels and worms, or both combined, and the smoothness and economy of power of the machine depend largely upon the manner in which the gearing is made.

A second feature of prime importance in the hoisting-gear of a crane is the mode of sustaining the load, and guarding against its "running down" when the application of the motive power is discontinued. This has heretofore been accomplished, in machines having spur-gearing, by a ratchet-wheel, the pawl of which has to be entirely disengaged to permit lowering to occur, or by a brake, which, when on, prevents all motion of the machine, and which requires to be held or thrown off, both in hoisting and lowering. In machines having worm-gearing the end is attained by a construction of the worm-wheels such that the friction between the worm and the wheel is sufficient to prevent the backward rotation of the worm under the pressure of the teeth of the worm-wheel caused by the load, the resistance thus generated sufficing to prevent the running down of the load. There is a current opinion among machinists in general that worm-gearing offers so disastrous a frictional resistance in wear, that its use, except for purposes where little power is to be transmitted, and where certain slow movements are to be effected, is not permissible in good mechanism. This view is supported by most of the text-books, which invariably represent the laying out of the teeth by considering the worm as a rack with inclined teeth where the pitch-lines of the worm and wheel are taken on a plane passing through the axis of the worm. Now, the fact is that the use of worm-gearing for hoists, cranes, boring-bars, lathes, etc., has been growing in favor and it is found that neither excessive loss of power nor excessive wear of gearing ensues. In regard to friction, it is established that for the ordinary ratio of wheel to worm, say not to exceed 60 or 80 to 1, well fitted worm-gear will transmit motion backward through the worm, exhibiting a lower coefficient of friction than is found in any other description of running machinery.

In order to reach this result the following method of laying out a worm-gear and worm is employed. Assume the teeth on the worm to be .65 of the pitch radially, of which .60P is to be the line of contact with the teeth of the wheel (on the radius and also on the plane through the middle of the teeth), and that .05P be for clearances between the roots and points of worm and wheel teeth. Let the teeth of the wheel follow the circle of the worm throughout the arc, which ought not to exceed 60°. Let R = outside radius of worm; Rp = radius of pitch of worm; F = face of wheel at root of teeth; and P = pitch of teeth: then $Rp = \frac{1}{2}\{R + (R - .6P)\cos a\}$, and $F = 2(R + .05\,P)\sin a$. To simplify the process of laying out worm-wheels, it has been usual to make the outside radius of the worm $R = 2P$, and the angle $a = 60°$, when $Rp = 1.606P$, and $F = 2.05P$. The effect of this method of setting out pitch-lines for the teeth of screw-gearing is to bring the bearing, or working lines of contact, for both orders of teeth more nearly on the true pitch-line, and not to throw much effort or work on the points of the teeth of the worm-wheel outside of the true pitch-line. The following illustration represents a worm-wheel and worm constructed in accordance with the above system, and of the proportions employed in the Weston cranes.

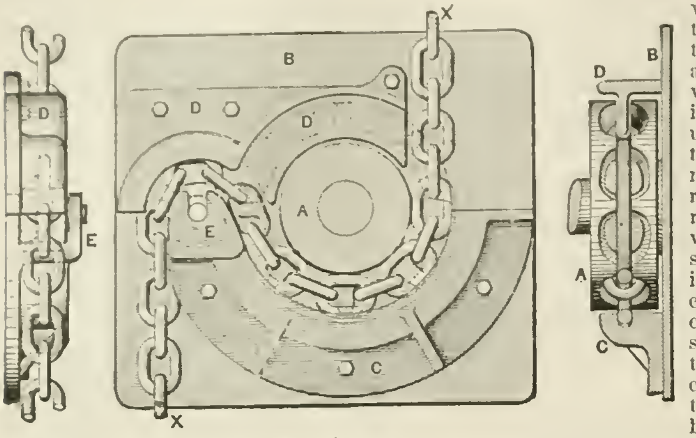
In all cranes, except those of small size, provision should be made for one or more changes of speed in hoisting and lowering, so that the speed may be varied according to the load and the nature of the work to be done. Cranes operated by power *may* be so constructed that the maximum load can be lifted at the quickest speed; but they are usually so proportioned that this can be done only at a slow speed. By this plan much economy of gearing, space, and cost is effected, and the practical efficiency of the crane for all ordinary uses is not impaired. The most perfect construction is one that permits a change of speeds to be made whether the hoisting-gear is in motion or at rest, and which sustains the load automatically while a change of speed is being made. The hoisting-gear of a crane should therefore attain the following results, viz.: (1) Such changes in direction and velocity



Worm wheel and Worm.

of the power applied as will give the desired motions to the load. (2) The accomplishment of this with a minimum loss of power through friction. (3) The safety, both of the operator and the load, under all conditions; to insure which the load must be always self-sustained and incapable of "running down." (4) Capacity for changes of speed and for convenient transition from one of these to another at will, whether the gearing is in motion or at rest, and for the automatic support of the load during the act of changing speeds.

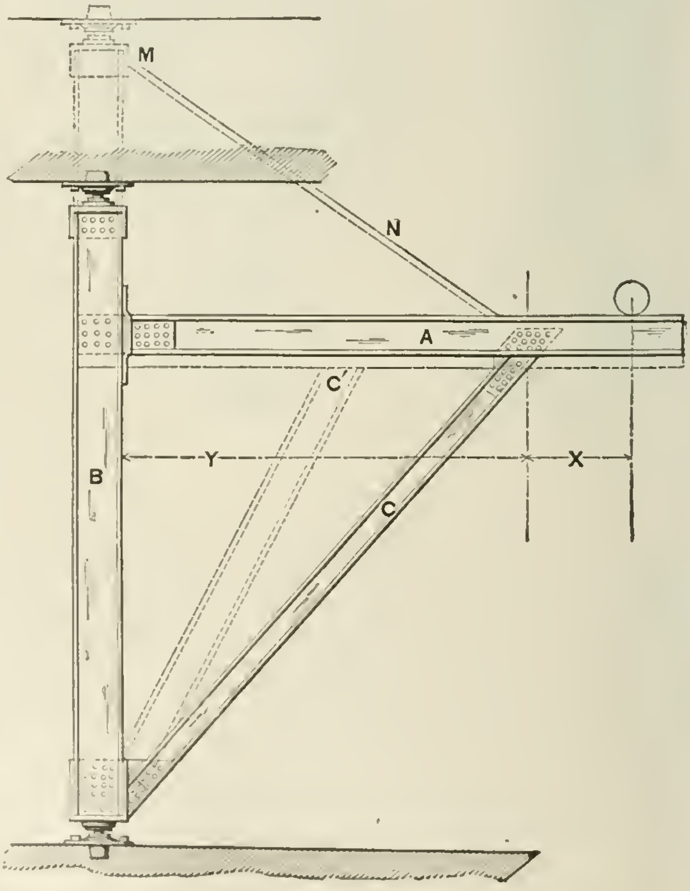
In some types of rotary cranes no traverse mechanism exists, except an arrangement of parts which provides for the rotation of the crane. In others, such as jib- and derrick-cranes, provision must also be made for moving the truck or trolley horizontally on the jib, and the same provision is required for moving the trolley of bridge- and traveling-cranes transversely on the bridge. In all such cases a separate mechanism, distinct from the hoisting-gear, has heretofore been employed, and is still sometimes desirable or convenient. When employed, its parts should be as few and simple as possible, and it should be so far independent of the hoisting-gear as to permit either to be used at any time separately or conjointly. In power-cranes provision should be made for accelerating the speed of the trolley-travel whenever the nature of the work admits of it. The best possible result is attained when travel of the trolley is effected without varying the vertical position of the load, and without causing useless movement of the hoisting-chain or rope over the sheaves through which it supports the load, which movement would involve much additional friction, and cause rapid wear of the chain or rope. In traveling-cranes a point of great importance is the parallelism of the bridge-travel with the longitudinal tracks. Any defect here results in increased resistance to traction, and any considerable error might cause derailment. In traveling-cranes, as heretofore built, the use of flanged wheels has been relied upon to prevent derailment, and the propulsion of the bridge has been effected by a transverse shaft extending the whole length of the bridge, and connected by gearing with the truck-wheels supporting each end of the bridge, so that, by revolving the shaft, the truck-wheels would be rotated, and the bridge be thereby propelled, provided the adhesion between the wheels and the rails was sufficient. In some instances, where the adhesion has not been sufficient to prevent slipping, a cast-iron rack has been laid adjacent to the longitudinal tracks, and extending their whole length, and pinions, gearing into this rack, attached to the axles of the truck-wheels, so that propulsion is effected independently of the adhesion of the truck-wheels to the track. If the load were always central on the bridge, and the motive power always applied to this shaft at the center of its length, this plan would answer well, although it is somewhat clumsy; but in practice the load is constantly varying in position, and the motive power is applied at one end of the long transverse shaft, so that torsion of the shaft induces a considerable variation in the travel of the opposite ends of the bridge. This error is a constantly varying one, according to the portion of the load resting upon each truck, as determined by the position of the trolley, the load being never equally distributed between the two trucks except when it is exactly in the center. It follows, therefore, that this system of bridge-travel, although operative, is radically defective, and that its use involves a constant loss of power by needless friction, and entails a proportionate amount of wear and tear of rails, wheels, and driving-gear. A better and more simple method of bridge-propulsion has lately been introduced, by means of which the longitudinal motions of the bridge are effected by *pulling* each of its ends, simultaneously and at equal speed, in the desired direction. For this purpose light wire cables are used, which, by a very simple and ingenious arrangement of guide-sheaves, are made to act as a "squaring device" to hold the bridge at all times perpendicular, or square, to the tracks upon which it travels. By this system the friction of traction is reduced to a minimum, and the danger of derailment from unequal travel of the opposite ends of the bridge entirely obviated. From the above facts it becomes evident that a perfect system of bridge-propulsion must hold the bridge always absolutely square with its tracks, and must propel the opposite ends of the bridge in the same direction, at the same time, and at the same speed, however unequally the load may be distributed. It is desirable also that, in large cranes at least, provision be made for starting the bridge slowly from a state of rest, and then increasing the speed, and also for varying the speed while the bridge is in motion.



Chain-wheel, Guide, and Stripper.

In almost every type of crane the load is primarily carried upon a flexible cord of some kind. This usually consists of rope, either hemp or wire, or of chain. Each of these has distinctive merits and objections. Ropes have the advantage of being formed of many parts or fibers, so that no splicing or welding is necessary in their manufacture, and they thus have an assured and practically uniform strength throughout their length. Chains, on the contrary, consist of a series of independent links, each of which is formed from a straight bar, and welded, so that a single imperfect weld injures the whole, the strength of a chain being obviously limited by the strength of its weakest link. By care and good workmanship, however, this danger can be avoided, in which case the chain becomes as safe as the rope, and much more durable. Where a rope is used, the hoisting-gear must necessarily include a drum or barrel upon which the rope is wound up when hoisting takes place. Chain may also be thus wound up on a barrel, and this has heretofore been the common practice when chains have been employed in crane-construction, and a prominent feature in cranes of large capacity has usually been a proportionately large "winding-barrel" to receive the chain. A chain, however, admits of another mode of construction, which consists in substituting for the wide barrel or drum a pocketed "chain-wheel," consisting of a narrow wheel or sheave, of a width only slightly greater than that of the chain, and having formed upon its periphery a series of indentations or "pockets," exactly corresponding in size and shape with the links of the chain, so that the chain and the pockets fit together accurately, and slipping of the chain upon the chain-wheel becomes impossible. It thus follows that rotation of the chain-wheel causes positive motion of the chain at a speed equal to the circumferential velocity of the wheel, in a manner precisely similar to the motion of a rack driven by a pinion, or of one spur-wheel driven by another.

The best material for the chain-wheel has been found, by experience, to be soft cast-iron, as this causes the least wear upon the chain, and as it is of course best to have the wear come upon the wheel (which is easily and cheaply replaced) than upon the chain. In all of the several types of cranes, the chain-wheels are made and inserted so as to be easily replaced. This, however, does not require to be frequently done, as the wheels will usually endure five or six years of constant use before wearing out. To further insure the proper engagement of the chain-wheel and chain, a chain-guide is provided as shown in the drawing. The functions of this chain-guide are (1) to cause the chain to enter properly into engagement with the wheel; (2) to hold it in engagement with several of the pockets of the wheel, so that the strain upon the chain is distributed over these several pockets, and "stripping" of the wheel prevented; and (3) to permit the lower half of the wheel to be used for engagement with the chain and yet cause the slack side of the chain to follow the wheel up to the horizontal center line again.



Jib-crane Frame.

The construction by which these results are obtained is clearly illustrated in the drawing, in which A represents a pocketed chain-wheel mounted upon the plate or frame B. C is the "chain-guide," enveloping the lower half of the chain-wheel A, and bolted securely to the plate B. The inner curved surface of the chain-guide is grooved, and is of such shape as to leave a space between it and the periphery of the chain-wheel merely sufficient to admit the chain. The latter is thus compelled to enter properly, and is held securely in engagement with the pocketed chain-wheel throughout the arc of contact. At E the chain-guide carries a small roller, over which the slack chain passes downward into a suitable box or receptacle. To insure the proper separation of the chain from the chain-wheel at the point of disengagement there is provided a "chain-stripper." This piece, marked D in the drawing, is also bolted to the plate B, and is provided with a projecting tongue or rib, D', the point of which lies deep in the center groove of the wheel, and thus strips or separates the chain from the wheel as it reaches the proper point, and prevents any clinging of the chain to the wheel. A prolongation of the "stripper" D covers the guidesheave at E and insures the proper passing downward of the chain. The construction of the chain-wheel and its adjuncts, which is above illustrated and described, constitutes a perfect device for hauling in and paying out chain, whether fully loaded or empty, and is moreover easier upon the chain, and more conducive to its endurance, than any ordinary form of winding barrel or drum. With slight modifications, to adapt it to the varying conditions, this construction is embodied in all of the various types of the Weston cranes.

Construction in iron has been adopted almost exclusively for the frames, girders, etc., of the Weston cranes. The great variety of structural shapes of iron which are now obtainable, and the increasing capacity of our rolling-mills to produce shapes of large area and of great length, have greatly simplified and cheapened the building of iron crane frames and girders of moderate sizes. Wherever the dimensions of the work admit, these irons are employed. In machines of larger size resort is had to plate-girders, as described below, while for the columns of large pillar-cranes and similar machines cast-iron in single pieces is employed. The frames of small jib-cranes may frequently be constructed by using a single iron for each of the principal members, in which case the I-beam section is found best. For larger sizes, say from 3 tons upwards, a double frame, each of the principal members being composed of two channel-irons, is found better. The latter construction is shown in outline in the drawing, in which the jib, A, mast, B, and brace, C, are each composed of two channel-irons, separated sufficiently to give proper room for the attachment of the mechanism and to permit the main chains, depending from the trolley, to pass between the two irons forming the jib. The best and most economic construction requires that the brace, C, shall intersect the jib, A, at a distance from the mast equal to four fifths of the extreme effective radius of the crane; that is, that the distance X should be one fourth as great as the distance Y. When for any reason it is necessary that the brace intersect the jib at a point nearer to the mast, as, for instance, at C', as shown by the dotted lines, a much greater depth is necessary in the irons forming the jib, and frequently also in those composing the mast. Where it is possible to obtain greater height of mast above the jib, as indicated by dotted lines at M, a suspension-rod, N, may be substituted for the brace, C, and the latter omitted, thus giving entire freedom below the jib. The intersections of the several members of jib-cranes thus constructed are best united by the overlapping of the web of one part upon the other, and by gusset-plates, all firmly fastened by proper riveting.

In proportioning the frames and girders, such dimensions are adopted as will insure a factor of safety of *six* throughout; that is, such that the strains developed, with the maximum load suspended at the center, or point of greatest strain, shall not exceed one sixth of the breaking strength of the material employed. We state the case in this way for the reason that it is still customary with most engineers to make such calculations upon the basis of an assumed "factor of safety." The best and latest practice, however, is to proportion the parts with reference to the elastic strength of the material employed, and it is the present practice, so far as possible, to give such dimensions to the frames and girders that under no condition shall any of their members be strained to within 50 per cent of the elastic limit of the material. At all intersections of members, and at points of attachment with wrought or cast-iron parts, an excess of strength is always provided to allow for the weakening of bolt and rivet holes and other contingencies. Special attention is given to securing unusual strength and safety in these details of the Weston cranes, all of which are based upon exact and careful calculation. A comparison of one of these cranes with most others of equal nominal capacity will show much difference in the amount and disposition of material employed, so that, although the latter may possibly lift their full nominal load without breaking down, the former may be relied upon to do so always with absolute safety. Doubtless a load of 10 tons could be lifted with a 5-ton crane without disabling it; but in executing a contract to furnish a Weston crane of 10 tons capacity, the builders furnish one proportioned as above explained, and of a strength such as to make it absolutely safe for its intended work. See *Bridge-crane, Column-crane, Derrick-crane, Differential Pulley-block, Hooks, Jib-crane, Locomotive-crane, Pillar-crane, Rotary Bridge-crane, Swing-crane, Take-ups, Traveling-crane, Trolleys,* and *Walking-crane.*

CRANEQUENIERS.—A surname given to the foot-troops who, in ancient times, were armed with the *cranequin.*

CRANEQUIN.—The *windlass crossbow* anciently used by foot-soldiers who were surnamed *cranequeniers.*

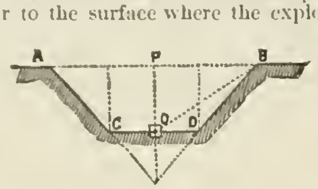
CRANK.—In machinery, an arm or a bend on an axle or shaft which may be driven by a connecting-rod or by the hand, its use being to convert an alternating straight motion into a continuous revolution. A crank may have part of the shaft on both sides, so that one rod may drive two wheels. There are two positions in a crank in which the connecting-rod exercises no power whatever; viz., when the arm of the crank is parallel to the connecting-rod, and again when the crank is at the opposite point of its course. A push or pull of the rod in such circumstances can only press the shaft against its bearings. The effect is greatest when the rod and the crank-arm are at right angles, and it decreases gradually on both sides of that position, until at the top and bottom it is reduced to nothing. In order to carry the crank over these *dead points,* as they are called, a fly-wheel is fixed on the shaft; this receives part of the force of the rod while at its best, acts as a reservoir, and by its stored-up momentum carries the shaft round when the rod is powerless.

CRANNOGES.—The name given in Ireland and in Scotland to the fortified islands in lakes which were in common use as dwelling-places and places of refuge among the Celtic inhabitants. The etymology of the word is uncertain, but it is believed to refer to the timber which was employed either in the fortification of the island, or in the construction of the houses which were placed upon it.

CRAPE.—A thin fabric made of raw silk, which has been tightly twisted, without removing the viscous matter with which it is covered when spun by the worm. It is simply woven as a thin gauze, then dressed with a thick solution of gum, which in drying causes the threads partially to untwist, and thus gives a wrinkled and rough appearance to the fabric.

It is usually dyed black, and is used for mourning-apparel.

CRATER.—The form of the crater in ordinary soils has not been accurately ascertained. The only use of the exact determination of this form would be to calculate precisely the quantity of earth thrown from the crater, and by that means to proportion the charge to the effect to be produced. Different figures have been assigned by Engineers to the solids constituting the crater; some assuming it to be a cone, the center of the powder being taken as the vertex; others, a paraboloid, the center of the powder being the focus, etc. To afford a uniform and simple rule for calculating the volume of the crater, the solid will be assumed as a truncated cone, the radius, O D, of the lower circle, being also assumed at one half the radius, P B, of the upper circle. The radius, P B, of the upper circle is termed the *crater radius;* the line, O P, drawn from the center of the powder perpendicular to the surface where the explosion takes



Section of Crater.

place, the *line of least resistance;* and the line, O B, drawn from the same center to any point in the circumference of the upper circle, *the radius of explosion.*

It was for a long time supposed by miners that a crater could not be formed with a radius greater than twice the line of least resistance with any charge; but the experiments of Belidor have shown that, by successive augmentations of the charge, the crater radius may be increased to six times this line, but not much beyond; that within this limit the ratio of the diameters of the craters is nearly that of the square root of the charges; and that galleries can be destroyed by such mines at distances of four times their line of least resistance. The physico-mathematical theory of mines is still very imperfect, owing to the impracticability of ascertaining the exact effects of the explosion of powder in a medium which is seldom homogeneous, and the resistance of which, arising from its tenacity, compressibility, etc., to the expansion of the gases, can only be arrived at by a wide range of experiments made with minute care. From the want of these elementary data, the formulæ at present in use, to determine the charges for different media, are necessarily empirical, and their results are to be relied on only within the limits in which they coincide with experiments. For most cases in practice these approximations are near enough, and valuable as the only guides that the miner has to refer to. See *Mines.*

CRAVAT.—A part of the uniform prescribed for officers in the United States army. The cravat is black, and the tie is not permitted to be visible at the opening of the collar. Neither cravats nor stocks are worn by the enlisted men when on duty.

CREEDMOOR RIFLE-RANGE.—The largest and most complete rifle-range in the United States. It is a station on the Long Island Railroad, about 10½ miles east of New York, was established in 1871, and is much frequented by riflemen for target practice.

CREESE.—A Malay dagger, generally with a wavy or *flaming* blade, which the Malay tribes render still more fatal by dipping into poison. Sometimes written *Crease, Cressit, Cris, Krees,* and *Kris.*

CREMAILLE.—In field-fortification, the term *cremaille* is employed when the inside line of the parapet is broken in such a manner as to resemble the teeth of a saw. This advantage is gained by the measure that a greater fire can be brought to bear upon the defile than if only a simple face was opposed to it; and consequently the passage is rendered more difficult.

CREMAILLERE LINE.—An indented line, consisting of long and short branches, which may be arranged as shown in the drawing. The long branches are usually made 70 yards long, or more, and are directed towards ground which cannot be occupied

Crémaillère Line.

by an enemy. The short branches are made about 30 yards long, and are used to flank the long branches. Instead of giving the long branches directions parallel to each other, they may all be directed upon a single point, which the enemy cannot reach. See *Lines.*

CRENAUX.—In fortification, small openings or loop-holes, made through the walls of a fortified town or place. They are extremely narrow towards the enemy, and wide within; so that the balls from the besiegers can scarcely even enter, whereas two or three soldiers may fire from within.

CRENEL—CRENELLE.—A term sometimes used for a battlement, but more frequently for the embrasures in a battlement. The adjective *crenellated* is in frequent use to signify that a building is supplied with crenelles. See *Battlement.*

CRENELLE.—In Heraldry, a term meaning embattled, and used to signify that any ordinary is drawn like the battlements of a wall. See *Heraldry.*

CREPIDA.—The iron-shod shoe worn by the early Greek philosophers and soldiers. It did not cover the whole of the foot.

CRESCENT.—1. A musical instrument consisting of a staff with arms and suspended bells, used in a band.—2. In Heraldry, the crescent is used both as a bearing or charge, and as a difference, or mark of cadency. In the latter case it designates the second son and those that descend from him.—3. A representation of the half-moon with the horns turned upwards, called a crescent, is often used as an emblem of progress and success. It is generally spoken of as "The Arms" of the Turkish Empire, but is more properly the emblem of the Empire and people—not a very appropriate one in our day. It was, however, the emblem of the Greek before it became that of the Turkish rule; and at the present day is frequently to be seen on churches in Moscow and elsewhere in Russia, generally surmounted with the cross, marking unquestionably the Byzantine origin of the Russian Church.—4. The name of three orders of knighthood. In 1799, after the battle of Aboukir, the Sultan Selim III. testified his gratitude to Nelson by sending him a crescent richly adorned with diamonds. It was not intended as an order, but Nelson wore it on his coat, and on several occasions called himself the Knight of the Crescent. Selim was flattered by the value which the English Admiral, already decorated with so many orders, seemed to attach to his gift; and it was this circumstance which determined him, in 1801, to found the Order of the Crescent. Mohammedans being forbidden, in the Koran, to carry such marks of distinction, the order is conferred only on Christians who have done service to the State. The second person on whom it was conferred was General Sebastiani, for his defense of Constantinople against the English fleet in 1807. The insurrection of the Janissaries suspended the efforts at Europeanizing which Selim had begun; and when they were resumed by Mahmud, he instituted several other decorations. There was an old Order of the Crescent instituted at Algiers by René, Duke of Anjou, brother and heir of Louis III., King of Naples, in 1464. Its objects were those common to the religious military orders of those days: the honor of God, the defense of the Church, the encouragement of noble actions, and the glory of the founder. The Dukes of Anjou and

Kings of Sicily were sovereigns of the order. The badge was a crescent of gold, on which was the word Loz, enameled in red letters, the import being Loz (laus) en Croissant—Praise by Increasing. Like many other orders founded by the smaller sovereigns, the Order of the Crescent did not survive the founder. See *Cadency*.

CREST.—1. In fortification, the intersection of surfaces making a salient angle with the plane of site. 2. Though popularly regarded as the most important feature in heraldic emblems, the crest, in the eyes of heralds, is an external adjunct to the shield, without which the bearing is complete, and which may consequently be altered without materially affecting its significance. Occupying the highest place on the helmet, it is the member of the bearing by which the knight was commonly known in battle; and from this circumstance it is to it that the term *cognizance* (from *cognosco*, to know) is properly given. Its claim to a classical origin is probably better than that of any other portion of coat-armor. Jupiter Ammon is represented as having borne a ram's head on his helmet, and Mars the figure of a lion or a tiger. Alexander the Great, on the pretense that he was sprung from Jupiter, assumed the ram's head; and Julius Cæsar bore a star, to denote that he was descended from Venus. The helmet, as we see it represented on ancient statues and gems, was frequently adorned with a crest. Sometimes it was of horse-hair; at other times a lion or other animal was placed on the helmet, either erect or couchant. Newton, in his *Display of Heraldry*, says that the first crest to be met with in the monuments of English chivalry is that on the great seal of Richard Cœur de Lion. The helmets in this instance, and in that of Roger de Quincy, Earl of Winchester, differ in form from those afterwards used, the crest occupying a much larger space. Crests are said to have come into general use about the time of Henry III., and to have been used as marks of distinction by Commanders in the Holy Wars, as they had formerly been by the Roman Centurions. For lightness they were often made of stuffed leather, which was gilt, silvered over, or painted — a circumstance which explains their greater size then than in later times, when they were made either of wood or metal. The earliest example of the wreath on which the crest is now invariably placed is that on the monument of Sir John Harsick. It consisted of two pieces of silk, of the colors of the armorial bearings of the wearer, twisted together by the lady who had chosen him for her knight. Though crests are now invariable appendages to shields, and many of them are appropriated to particular families by hereditary descent, they are believed to have been originally assumed at the pleasure of the wearers; and they are even now less strictly under the cognizance of the heralds than the devices on the shield, which must always be assigned by competent authority. Crests are so various that a classification of them is scarcely possible. The following is an abridgment of that given by Newton, who has written very fully on the subject. The most ancient class of crests he believes to have consisted of ferocious animals, which were regarded as figuratively representing the bearer and his pursuits. Secondly, they were devices assumed as memorials of feats of chivalry, and for the purpose of perpetuating traditions and family legends, either in addition to or differing from those represented on the shield. Thirdly, they served only to give a more prominent place to objects already represented on the shield. Fourthly, they commemorated religious vows, or expressed the religious or knightly aspirations of the bearer. Fifthly, they were mere whims, and were adopted for no very definite reason, and served no very definite purpose. As many of them belonged to persons not only unconnected by family, but having different names, they no longer served the purpose of distinction when separated from the shield. To this latter class belong the vast majority of modern crests assumed at the suggestion of seal-engravers and coach-painters.

Helmet and crest of Roger de Quincy, Earl of Winchester.

CRESTED.—In Heraldry, when a cock or other bird has its comb of a different tincture from its body, it is said to be *crested* of such a tincture, naming the tincture. See *Heraldry*.

CRETE.—The earth thrown out of a ditch in a fortification, trench, etc. The most elevated part of a parapet or glacis.

CRIB-BITING.—A bad habit met with especially in the lighter breeds of horses and those spending a considerable amount of leisure in the stable. The act consists in the animal seizing with his teeth the manger, rack, or any other such object, and taking in at the same time a deep inspiration, technically called *wind-sucking*. Crib-biting springs often from idle play, may be first indulged in during grooming, especially if the operation is conducted in the stall, and the animal be needlessly teased or tickled; is occasionally learned, apparently, by imitation from a neighbor; and in the first instance is frequently a symptom of some form of indigestion. Its indulgence may be suspected where the outer margins of the front teeth are worn and rugged, and will soon be proved by turning the animal loose where he can find suitable objects to lay hold of. It usually interferes with thriving and condition, and leads to attacks of indigestion. It can be prevented only by the use of a muzzle or throat-strap; but in those newly acquired cases resulting from gastric derangement, means must further be taken to remove the acidity or other such disorder. See *Veterinary Art*.

CRIB-STRAP.—A neck-throttler for crib-biting and wind-sucking horses.

CRIME.—In its legal as opposed to its moral or ethical sense crime is an act done in violation of those duties for the breach of which the law has provided that the offender, in addition to repairing, if it be possible, the injury done to the individual, shall make satisfaction to the community. A private wrong or civil injury, on the other hand, is an infringement on the rights of an individual merely, for which compensation to him is held, in law, to be a complete atonement. From this definition, which is that generally adopted by lawyers, it is obvious that legal criminality is not a permanent characteristic attaching to an action, but one fixed upon it arbitrarily, from considerations of expediency. Without changing its moral character, the same action may, and very often is, a crime in one country or in one generation, and no crime in another country or a succeeding generation. Malice, or evil intention, however, is in all cases essential to the character of crime, for, though there may be an immoral act which it is inexpedient to punish as a crime, it can never be expedient to punish as a crime what is not an immoral act. But it is not necessary that the evil intention shall have had reference to the party injured. If the offender acted in defiance of social duty, and regardless of order, a crime has been committed, though it may not have been the particular crime which he intended. For example, it is murder if A kill B by mistake for C, unless the killing of C would have been justifiable or excusable. The law can take no cognizance of a bare intention which has not ripened into any sort of act. How far *attempts* to commit crime are punishable is always a question of difficulty. The general rule seems to be, that if such acts can be unequivocally connected with the criminal intention, they are punishable, though not to the same extent as the completed crime. Pupils under seven years of age, and insane persons, as being incapable of design or intention, are regarded in the eye of the law as incapable of crime; but questions as to the responsibiity of persons laboring under partial insanity are often surrounded with practical difficulties, which are positively insoluble. The defense of *compulsion*, or *vis major*, as it is called by lawyers, if completely established in fact, is generally sufficient in law. The subjection of a servant to a master, or of a wife or child to a husband or parent, will be no defense for the commission of an act of the criminality of which the offender was aware, unless it amount to compulsion. Magistrates acting *bona fide*, and soldiers acting under their officers in the ordinary line of duty, are not liable to a criminal charge. Extreme want is no excuse for a crime in law, though it furnishes a ground for an application for mercy.

In the technical language of the law of England, the term *offense* has a wider signification than crime, the latter including only such of the former as are punishable by *indictment*. Crimes are divided into *misdemeanors* and *felonies*, the latter being a higher species of offense than the former. For the specifications of crimes, capital and military, see *Articles of War*.

CRIMPING-HOUSES.—Houses in which persons were entrapped into the army; hence the name of "Crimp Sergeant." In a riot in London some of these receptacles were destroyed by the populace, in consequence of a young man who had been enticed into one being killed in endeavoring to escape, September 16, 1794.

CRINED.—A term in Heraldry. When the hair of a man or woman, or the mane of a horse, differs in tincture from the rest of the charge, the object is said to be *crined*, of such a metal or color. See *Heraldry*.

CRINIERE.—Small plates of armor used in the Middle Ages to defend the necks of war-horses. Also written *Manifère*. Sometimes written *Crinet*.

CRIQUES.—Small ditches which are made in different parts of a ground for the purpose of inundating a country, in order to obstruct the approaches of an enemy.

CROATS.—In military history, the light, irregular troops; generally people of Croatia. They were ordered upon all desperate services, and their method of fighting was the same as that of the Pandours.

CROCHERT.—A hagbut or hand-cannon anciently in use. Now obsolete.

CROCUS.—A polishing-powder composed of peroxide of iron. It is prepared from crystals of sulphate of iron, calcined in crucibles. The portion at the bottom, which has been exposed to the greatest heat, is the hardest, is purplish in color, and is called *crocus*. It is used for polishing brass or steel. The upper portion is of a scarlet color, and is called *rouge*. It is used for polishing gold, silver, and speculum metal. *Rouge*, the cosmetic, is made from safflower, or from carmine, which is a preparation of cochineal.

CROOK.—A circular tube belonging to band-instruments, such as the French horn or trumpet, which fits into the end of the instrument next the mouthpiece, for the purpose of making the pitch of the instrument suit the key of the music; the notes of the parts for these instruments being always written in the natural key of C, with the name of the key of the piece marked in letters.

CROSS.—1. The Order of the Cross was originally a spiritual order of knighthood, which sprang up in Palestine in the time of the Crusades, and was then called the *Bethlehemite Order*. After the commencement of the thirteenth century, the knights of this Order adopted the monastic life, settling chiefly in Austria, Bohemia, Moravia, Poland, and Silesia. Pope Gregory IX. confirmed the Order in 1328. Its principal seat is now in Bohemia, and its members generally hold ecclesiastical preferments or professorships in the University of Prague. They are distinguished by a cross of red satin, with a six-pointed star under it, and are sometimes called *Stellieri*.

2. A term in Heraldry. If we assume the art of blazon to have originated in connection with the Crusades, it will not surprise us to find the symbol of the Christian faith so frequently introduced into the escutcheons of ancient and noble families everywhere in Europe. It is one of the honorable ordinaries, and indeed, from its sacred character, is esteemed by heralds as the most honorable charge. Its form varies so much that Ménestrier counts 42 crosses; La Colombière, 72; and Guillim, 39. Most of the architectural crosses occur in Heraldry, along with many others. See *Victoria Cross*.

CROSS-BAR SHOT.—A shot which is folded into a sphere for loading, but on parting from the muzzle is expanded into a cross with sections of the shot at the extremities of the arms.

CROSS-BELTS.—Belts worn over both shoulders and crossing the breast, usually worn by Sergeants.

CROSS-BOW.—An ancient weapon of offense of the eleventh century. The cross-bows of the cavalry were lighter than those of the infantry, and the string was stretched by means of a simple lever, called a *goat's-foot*. There are seven different sorts of this weapon, viz., the *goat's-foot cross-bow*, the *windlass cross-bow*, the *latch cross-bow*, the *German cross-bow*, the *cross-bow à galet*, the *ramrod cross-bow*, and the *Chinese cross-bow*. The wood most sought after in France for the making of bows was the yew; and in Charles VII.'s time (1422–1463) a law was passed for the planting of yew-trees in all the Norman churchyards, so that wood might never fail for the new weapon, which was then in great favor. The bow was used until the introduction of fire-arms and guns; even later it was still popular, and preferred to the cross-bow. The Scythians, Cretans, Parthians, and Thracians were as much celebrated in ancient times for their skill in the handling of this weapon as the English archers were during the Christian Middle Ages. See *Archers*.

CROSS-BOW A GALET.—A cross-bow of the sixteenth century, so called from the round pebbles, leaden bullets, and earthenware balls that were shot from it instead of bolts. It was called *balestre* by the Germans.

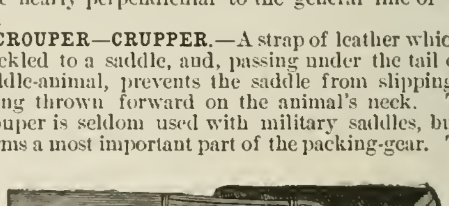
CROSS-FIRE.—The crossing of lines of fire from two or more points or places. See *Fire*.

CROSS-GUARD.—The transverse bar that forms a cross with the blade and the barrel of a sword, at their point of junction.

CROSS-LIFT.—To cross-lift a piece or other object is to cross handspikes under it from opposite sides; the butt end of the handspike is on the ground, and the power is applied by lifting at the other end. By cross-lifting, the piece is moved in a direction nearly at right angles to its axis. See *Mechanical Maneuvers*.

CROTCHET. 1. In fortification, an indentation in the glacis of the covered-way at a point where a traverse is placed. 2. The arrangement of a body of troops, either forward or rearward, so as to form a line nearly perpendicular to the general line of battle.

CROUPER—CRUPPER.—A strap of leather which is buckled to a saddle, and, passing under the tail of a saddle-animal, prevents the saddle from slipping or being thrown forward on the animal's neck. The crouper is seldom used with military saddles, but it forms a most important part of the packing-gear. The



tendency of the aparejo to work forward is overcome by a wide crouper (the dock-rest being of soft and round leather to avoid galling) attached to its outside and passing back over the hips. It should be carefully adjusted and always kept clean. See *Packing*.

CROUPIERES.—Armor placed on the buttocks and haunches of war-horses in the Middle Ages, to protect them against the arms of the adversary.

CROWBAR.—An iron bar used as a lever to move heavy weights in mechanical maneuvers, drills, etc.

CROWN.—As the emblem of sovereignty in modern Europe, the crown was borrowed rather from the diadem than the crowns of antiquity. This decoration was originally Oriental. Alexander the Great adopted it from the Kings of Persia; and Antony assumed it during his luxurious intercourse with Cleopatra. According to some, its adoption for the gods originated in the fillet, which was assigned to Bacchus for the purpose mentioned as that which led to the use of the convivial crown. In modern States, crowns were of very various forms, till heralds devised a regular series of them to mark the various gradations of sovereignty, from that of the Emperor down to what are now called the coronets of counts and barons. The Pope also had his triple crown. So entirely was the crown regarded as the symbol of sovereignty that the word came often to be used as synonymous with the Monarchy—a sense in which we will still speak of the Crown of England, and the domains and possessions of the Crown.

The crowns of kings and emperors are closed above, whilst the coronet of a noble is merely an open circle surrounding the head; hence *to close the crown* has been the ambition of princes desirous of shaking off the authority of feudal superiors and assuming a complete sovereignty.

CROWNING OF THE COVERED-WAY.—Having reached, during the *third period* of the siege, to within some six yards of the crest of the covered-way bordering the ditches, and from which the scarps of the works to be breached can be seen, and their ditches commanded and enfiladed, a trench is pushed forward from each of the direct approaches parallel to and within five or six yards of the crest. As this trench necessarily leads towards the retired parts, it will be more or less exposed to a commanding enfilading fire from points nearly in its line of direction, and to a slant and more or less reverse fire, from each of which it will be necessary to cover it by ordinary and wing traverses; besides which it will be well in some cases to run out to the rear flanking ends of trenches, and when the re-entering itself is deep it may be found necessary to connect these trenches, making a continuous line or secondary parallel within the salient points gained. This trench, when bordering the crest of the covered-way, is termed the *crowning of the covered-way*, and, as has been shown, it may be effected either under an open assault or by a systematic approach by sap.

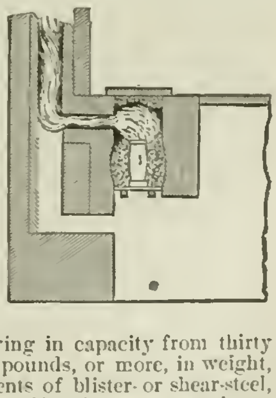
When the crowning of the covered-way is completed, or whilst in progress, preparations are made for constructing batteries to open breaches in the main works, and for counter-batteries to control the fire of any guns which the besieged, taking advantage of the paralyzed state of the batteries in front of the first and second parallels, from the obstruction offered by the approaches in advance of the third parallel, and even by the parallel itself, may now put in position. The positions given to the counter-batteries are usually such as to fire in the directions of the ditches and against the portions of the main work by which these are swept, and those of the breach-batteries will be as nearly opposite as practicable to the points where it is deemed best to open breaches. The counter-batteries are thus usually thrown around the salients, and the breach-batteries are placed further in, but still near the counter-batteries, as they are less exposed here to plunging or reverse fire than if placed further in. The principal point to be observed is that the breach when made shall be wide enough for the front of the assaulting column, be practicable or of easy ascent, and open the interior of the work throughout the entire width of the breech. The wider the breach, of course the better, but one of thirty yards width is considered a formidable gap for the besieged to attempt to close, with troops alone, to oppose an assaulting column. See *Siege*.

CROWN-WORK.—The crown-work, in a permanent fortification, consists of two or more bastioned fronts, with their outworks, placed in front of some portion of the enceinte, to give it additional strength. It is terminated like the horn-work by two wings, which rest either upon the enceinte, or upon two demi-lunes. Its covered-way, like that of the horn-work, forms a continuous communication with that of the enceinte. Certain arrangements of the bastioned lines give rise to the bridge-heads known as *horn-works* and *crown-works*. Let a point be taken in front of the bridge and some distance from it. Through this point let a right line be drawn perpendicular to the general direction of the bridge. On this line thus drawn as an exterior side let a bastioned front be constructed, and its salients be joined with the banks of the river by straight lines, which are so directed that they can be swept by a fire from the opposite bank. The resulting trace is known as a horn-work. It is plain that this work will only be used when the main approach to the bridge lies in the prolongation of its length.

If through a point assumed in front of the bridge two right lines were drawn making an angle with each other, and prolonged until they reached the banks of the river, and on these two lines, as exterior sides, bastioned fronts were constructed, the resulting trace would be that of a crown-work. It is plain that this trace will be employed when the approaches to the bridge are oblique to the direction of the bridge, and that the enemy would use one as quickly as the other. If there are several approaches, and the entire front is exposed to attack, a continued bastioned line might be used, inclosing the space in front of the bridge from bank to bank. In this case, if a salient occupies the central position, the line is known as a crown-work. In the latter case it is called a *complex crown-work*, to distinguish it from one constructed on two sides only, which is called *simple* crown-work. See *Horn-work*.

CROW'S-FEET.—Obstacles placed on the ground over which cavalry may be expected to pass. They are formed of four points of iron, each spike about two and a half inches long, and so arranged that when thrown on the ground one of the points will be upwards. Boards, with sharp nails driven through them, may supply the place of crow's-feet. The boards are imbedded in the ground, with the sharp points projecting a little above it. See *Accessory Means of Defense* and *Calthorp*.

CRUCIBLE-STEEL.—The best and most uniform quality of steel can only be obtained by fusion. That obtained by cementation is, as a rule, very unequal in quality; and uniformity can only be attained by repeated fagoting and welding, steps which are necessarily attended with a loss of carbon and consequent reduction of hardness. The requisite uniformity of composition may, however, be obtained by breaking up the crude bars produced in the forge or by cementation, and exposing them to a high degree of heat in crucibles out of contact with the air. The product, when melted, is poured out into cast-iron molds forming ingots of *crucible-steel*, which are very much more regular in both composition and texture than the original material.



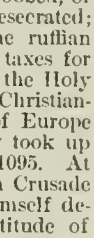
Crucibles of very refractory fire-clay, mixed with plumbago, varying in capacity from thirty to fifty and a hundred pounds, or more, in weight, are charged with fragments of blister- or shear-steel, and placed in furnaces. The furnaces, as shown in the drawing, are furnished with covers, and a chimney which increases the draught of air, and the crucibles are furnished with lids of clay to exclude the air. The furnaces containing the crucibles are filled with fuel; and for the perfect fusion of the steel the most intense heat is kept up for two or three hours. When the steel is thoroughly melted the crucibles are removed either by hand or machinery, and their contents poured, in the liquid state, into ingot-molds of the shape and size required. When the crucibles are emptied, if sound, they are returned to the mixing-room again, and charged.

Although steel may be cast into ingots, it is too imperfectly fluid to be cast into very small articles. The ingots of steel are taken to the forge or rolling-mill, and prepared by hammering or rolling into shape in the same manner as other steel, but with less heat and with more precaution. The great secret of the manufacture is in the selection and mixture of irons, and in the pouring of sound ingots. Large castings are made by emptying a sufficient number of large crucibles into an immense ladle placed over the mold; the ladle is then tapped from the bottom. Great skill in melting and pouring the metal, and particularly in heating and forging such great masses, without burning them on the outside or failing to condense them to the core, is of obvious importance. Steel, like iron, is improved by hammering and rolling; consequently when a large cast-steel block is required of great tenacity for a particular purpose, the metal is not run into a mold of the shape and size of the required finished dimensions, but it is cast into a short, thick ingot, and then hammered and drawn to the required finished dimensions, or it is rolled to the required shape between the rollers.

The drawing down of a heavy ingot requires, first a uniform heat throughout the mass; and, to soften the center of such a casting without burning the outside, a moderate and steady temperature maintained for several days; secondly, the effect of the hammer must be felt at the center of the mass, instead of being confined to the outside. A light blow would be absorbed in changing the figure of the surface-metal, and in breaking and distorting the grain, while a great weight falling from a moderate height would be resisted by the whole mass of the forging, and thus felt at its center. See *Cast-steel* and *Steel*.

CRUSADES.—The name given to the Religious Wars carried on during the Middle Ages between the Christian Nations of the West and the Mohammedans. The first of these was undertaken simply to vindicate the *right* of Christian pilgrims to visit the Holy Sepulcher. On the conquest of Palestine, however, the *object* of the Crusades changed, or at least enlarged, and the efforts of the subsequent Crusaders were directed to the rescue of the whole land from the Saracens, who had repossessed themselves of it. From an early period in the history of the Church, it was considered a pious act to make a pilgrimage to the Holy Sepulcher, and to visit the various spots which the Saviour had consecrated by his presence. When Palestine was conquered by the Arabs in the seventh century, that fierce but generous people respected the religious spirit of the pilgrims, and allowed them to build a church and hospital in Jerusalem. Under the Fatimides of Egypt, who conquered Syria about 980 A.D., the position both of the native Christian residents and of the pilgrims became less favorable; but the subjugation of the country, in 1065, by brutal hordes of Seljuk Turks from the Caucasus rendered it intolerable. These barbarians, but recently converted to Mohammedanism, were nearly as ignorant of the Koran as of the Scriptures. They hardly knew their fellow-religionists, and are said to have wreaked their vengeance on the Mussulmans of Syria, as well as on the Christians. The news of their atrocities produced a deep sensation over the whole of Christendom. The first to take alarm were, naturally enough, the Byzantine Monarchs. In 1073, the Greek Emperor Manuel VII., sent to supplicate the assistance of the great Pope, Gregory VII., against the Turks, accompanying his petition with many expressions of profound respect for His Holiness and the Latin Church. Gregory—who beheld in the supplication of Manuel a grand opportunity for realizing the Catholic unity of Christendom—cordially responded; but circumstances prevented him from ever carrying the vast designs which he entertained into execution, and the idea of a Crusade died gradually away. It was, however, revived by his successor, Urban II., an able and humane man, whose sympathies were kindled by the burning zeal of Peter the Hermit, a native of Amiens, in France, who had made a pilgrimage to the Holy Land, witnessed the cruelties perpetrated by the Turks, and was now traversing Europe, preaching everywhere to crowds in the open air, and producing the most extraordinary enthusiasm by his impassioned descriptions of how Pilgrims were murdered, robbed, or beaten; how shrines and holy places were desecrated; and how nothing but greed restrained the ruffian Turks (who made the Christians pay heavy taxes for their visits to Jerusalem) from destroying the Holy Sepulcher and extirpating every vestige of Christianity in the land. As soon as the feelings of Europe had been sufficiently heated, Urban openly took up the question. Two Councils were held in 1095. At the second, held at Clermont, in France, a Crusade was definitely resolved on. The Pope himself delivered a stirring address to a vast multitude of clergy and laymen, and as he proceeded the pent-up emotions of the crowd burst forth, and cries of *Deus vult* (God wills it) rose simultaneously from the whole audience. These words, *Deus vult*, by the injunction of Urban, were made the war-cry of the enterprise, and every one that embarked in it wore, as a badge, the sign of the cross; hence the name *Crusade*.

CRUSHER-GAUGE.—An instrument employed for determining the pressure of the powder in the bore of a gun. It is so constructed as to register the maximum pressure of the powder-gas at the particular point in the bore where the apparatus is placed. As used in England, it consists of a screw-plug of steel with a movable base, which admits a copper cylinder; one end of the cylinder rests against an anvil, while the other is pressed by a movable piston, kept against the cylinder by an annular spring; the cylinder is centered in the chamber by a small watch-spring, to prevent the escape of gas to the chamber; the head of the piston and body of the anvil are fluted; four small holes communicate with the main vent through the upper part of the plug; a gas-check is placed against the lower end of the piston. The action of the gauge is as follows: The gas, acting on the piston, crushes the copper cylinder against the anvil; the amount of compression it sustains indicates the pressure. The area of the copper cylinder for 8-inch guns is $\frac{1}{12}$ of a square inch; that of the piston being $\frac{1}{4}$ of a square inch. A table of results to produce definite amounts of pressure by the testing-machine affords a means of comparison of the results produced in the gun at different points of the bore. See *Pressure-gauge*.



CRUSHING-FORCE.—The samples submitted to the test of compression are small cylinders, the lengths of which are generally two and a half times their diameters. Bars of greater length than these diameters are liable to bend under the pressure before the fracture occurs; and if the lengths be less than two diameters, the fracture in its regular form may not be fully developed, and a portion of the sample may be pulverized or reduced to small grains. The ends of each sample are made perfectly parallel and perpendicular to the axis, so that all parts of the sample will be equally pressed. The dimensions of the sample are carefully measured before placing it. The depression or permanent set at every 5000 pounds, for instance, is then carefully noted. The breaking-weight is recorded, as well as the angle of fracture of the specimen. The strength per square inch will be

$$S = \frac{\text{weight}}{\text{area}}.$$

See *Rodman Testing-machine.*

CRUST.—In a horse, the internal part of his foot which covers the more sensitive parts, and to which the shoe is immediately attached.

CRYPTOGRAPHY.—Secret writing, or writing to understand which the recipient must know the key. Such modes of communication have been in use from the earliest times. The Lacedæmonians, according to Plutarch, had a method which has been called the *scytale*, from the staff employed in constructing and deciphering the message. When the Spartan Ephors wished to forward their orders to their Commander abroad, they wound slantwise a narrow slip of parchment upon the staff so that the edges met close together, and the message was then added in such a way that the center of the line of writing was on the edge of parchment. When unwound, the scroll consisted of broken letters; and in that condition it was dispatched to its destination; the General to whose hands it came deciphering it by means of a staff exactly corresponding to that used by the Ephors. Polybius has enumerated other methods of cryptography. The art was in use also among the Romans. Upon the revival of letters, methods of secret correspondence were introduced into private business, diplomacy, plots, etc.; and as the study of this art has always presented attractions to the ingenious, a curious body of literature has been the result. John Trithemius, the Abbot of Spanheim, was the first important writer on cryptography. His *Poligraphia*, published in 1500, has passed through many editions, and has supplied the basis upon which subsequent writers have worked. It was begun at the desire of the Duke of Bavaria; but Trithemius did not at first intend to publish it, on the ground that it would be injurious to public interests. The next treatises of importance were those of John Baptist Porta, a Neapolitan mathematician, who wrote *De Furtivis Literarum Notis*, 1563; and of Blaise de Vigenere, whose *Traité des Chiffres* appeared in Paris in 1587. Lord Verulam proposed an ingenious system of cryptography on the plan of what is called the double cipher; but while thus lending to the art the influence of his great name, he gave an intimation as to the general opinion formed of it and as to the classes of men who used it; for when prosecuting the Earl of Somerset in the matter of the poisoning of Overbury, he urged it as an aggravation of the crime that the Earl and Overbury "had ciphers and jargons for the King and Queen and all the great men—things seldom used but either by Princes and their Ambassadors and Ministers, or by such as work or practice against or, at least, upon Princes." Other eminent Englishmen were afterwards connected with the art. John Wilkins, subsequently Bishop of Chester, published in 1641 an anonymous treatise entitled *Mercury, or The Secret and Swift Messenger*, a small but comprehensive work on the subject, and a timely gift to the diplomatists and leaders of the Civil War. The deciphering of many of the Royalist Papers of that period, such as the letters that fell into the hands of the Parliament at the battle of Naseby, has by Henry Stubbe been charged on the celebrated mathematician, Dr. John Wallis, whose connection with the subject of cipher-writing is referred to in the Oxford edition of his mathematical works, 1689; as also by John Davys. Dr. Wallis states that this art, formerly scarcely known to any but the Secretaries of Princes, etc., had grown very common and familiar during the civil commotion, "so that now there is scarcely a person of quality but is more or less acquainted with it, and doth, as there is occasion, make use of it."

Schemes of cryptography are endless in their variety. Bacon lays down the following as the "virtues" to be looked for in them: "that they be not laborious to write and read; that they be impossible to decipher; and, in some cases, that they be without suspicion." The principles are more or less disregarded by all the modes that have been advanced, including that of Bacon himself, which has been unduly extolled by his admirers as "one of the most ingenious methods of writing in cipher, and the most difficult to be deciphered, of any yet contrived." The simplest and commonest of all ciphers is that in which the writer selects in place of the proper letters certain other letters in regular advance. This method of transposition was used by Julius Cæsar. He, "per quartam elementorum literam," wrote *d* for *a*, *e* for *b*, and so on. There are instances of this arrangement in the Jewish rabbis, and even in the sacred writers. An illustration of it occurs, Jeremiah xxv. 26, where the Prophet, to conceal the meaning of his prediction from all but the initiated, writes Shehach instead of Babel (Babylon), the place meant; i.e., in place of using the second and twelfth letters of the Hebrew alphabet (*B*, *b*, *l*), counting from the beginning, he wrote the second and twelfth (*sh*, *sh*, *ch*), counting from the end. To this kind of cipher-writing Buxtorf gives the name Athbash (from *a*, the first letter of the Hebrew alphabet, and *th*, the last; *b*, the second from the beginning, and *h*, the second from the end). Another Jewish cabalism of like nature was called Albam; of which an example is in Isaiah vii. 6, where Tabeal is written for Remaliah. In its adaptation to English this method of transposition, of which there are many modifications, is comparatively easy to decipher. A rough key may be derived from an examination of the respective quantities of letters in a type-founder's bill or a printer's "case." The decipherer's first business is to classify the letters of the secret message in the order of their frequency. The letter that occurs oftenest is *e;* and the next in order of frequency is *t*. The following groups come after these, separated from each other by degrees of decreasing recurrence: *a, o, n, i, r, s, h; d, l; c, w, u, m; f, y, g, p, b; v, k, x, q, j, z.* All the single letters must be *a*, *I*, or *O*. Letters occurring together are *ee, oo, ff, ll, ss*, etc. The commonest words of two letters are (roughly arranged in the order of their frequency) *of, to, in, it, is, be, he, by, or, as, at, an, so*, etc. The commonest words of three letters are *the* and *and* (in great excess), *for, are, but, not*, etc.; and of four letters, *that, with, from, have, this, they*, etc. Familiarity with the composition of the language will suggest numerous other points of value to the decipherer.

Bacon remarks that though ciphers were commonly in letters and alphabets, yet they might be in words. Upon this basis codes have been constructed, classified with words taken from dictionaries being made to represent complete ideas. In recent years such codes have been adapted by merchants and others to communications by telegraph, and have served the purpose not only of keeping business affairs private, but also of reducing the excessive cost of telegraphic messages to distant markets. Obviously this class of ciphers present greater difficulties to the skill of the decipherer. Figures and other characters have been also used as letters; and with them ranges of numerals have been combined as the representatives of syllables, parts of words, words themselves, and complete phrases. Under this head must be placed the dispatches of Giovanni Michael, the Venetian Ambassador to England in the reign of Queen Mary, documents which have only of late years been deciphered. Many of the private letters and papers from the pen of Charles I. and his Queen, who were adepts in the use of ciphers, are of the same description. One of that Monarch's letters, a document of considerable interest, consisting entirely of numerals, purposely complicated, was in 1858 deciphered by Prof. Wheatstone, the inventor of the ingenious crypto-machine, and printed by the Philobiblon Society. Shorthand marks and other arbitrary characters have also been largely imported into cryptographic systems to represent both letters and words—commonly the latter. This plan is said to have been first put into use by the old Roman poet Ennius. It forms the basis of the method of Cicero's freedman, Tiro, who seems to have systematized the labors of his predecessors. A large quantity of these characters have been engraved in Gruter's *Inscriptiones*. A correspondence of Charlemagne was in part made upon marks of this nature.

A favorite system of Charles I., used by him during the year 1646, was made up of an alphabet of twenty-four letters, which were represented by four simple strokes varied in length, slope, and position. This alphabet is engraved in Clive's *Linear System of Short-hand*, 1830, having been found amongst the Royal manuscripts in the British Museum. An interest attached to this cipher from the fact that it was employed in the well-known letter addressed by the King to the Earl of Glamorgan, in which the former made concessions to the Roman Catholics of Ireland.

Complications have been introduced into ciphers by the employment of "dummy" letters—"nulls and insignificants," as Bacon terms them. Other devices have been introduced to perplex the decipherer, such as spelling words backwards, making false divisions between words, etc. The greatest security against the decipherer has been found in the use of elaborate tables of letters arranged in the form of the multiplication-table, the message being constructed by the aid of preconcerted key-words. In a letter dated 20th February, 1659-60, Hyde, alluding to the skill of his political opponents in deciphering, says that "nobody needs to fear them if they write carefully in good ciphers." In his next he allays his correspondent's apprehensions as to the deciphering of their letter: "I confess to you, as I am sure no copy could be gotten of any of my ciphers from hence, so I did not think it probable that they could be got on your side of the water. But I was as confident, till you tell me you believe it, that the devil himself cannot decipher a letter that is well written, or find that 100 stands for Sir H. Vane. I have heard of many of the pretenders to that skill, and have spoken with some of them, but have found them all to be mountebanks; nor did I ever hear that more of the King's letters that were found at Naseby, than those which they found deciphered, or found the ciphers in which they were writ were deciphered. And I very well remember that in the volume they published there was much left in cipher which could not be understood, and which I believe they would have explained if it had been in their power." An excellent modification of the key-word principle was constructed by the late Admiral Sir Francis Beaufort; it has been recently published in view of its adaptation to telegrams and post-cards. Ciphers have been constructed on the principle of altering the places of the letters without changing their powers. The message is first written Chinese-wise upward and downward, and the letters are then combined in given rows from left to right. In the celebrated cipher used by the Earl of Argyle when plotting against James II., he altered the position of the words. Sentences of an indifferent nature were constructed, but the real meaning of the message was to be gathered from words placed at certain intervals. This method, which is connected with the name of Cardan, is sometimes called the trellis or card-board cipher. The wheel-cipher, which is an Italian invention, the string-cipher, the circle-cipher, and many others, are fully explained, with the necessary diagrams, in the authorities named above—more particularly by Kluber in his *Kryptographik*.

CRYSTALLIZATION. — Of the various circumstances which affect the strength of cannon-metal, the most important appear to be those which connect themselves with crystallization. It is a law of the molecular aggregation of crystalline solids, that when their particles consolidate under the influence of heat in motion, their crystals arrange and group themselves with their principal axes in lines perpendicular to the cooling or heating surfaces of the solid; that is, in the lines of direction of the heat-wave in motion, which is the direction of least pressure within the mass; and this is true, whether in the case of heat passing from a previously fused solid in the act of cooling and crystallizing on consolidation, or of a solid not having a crystalline structure, but capable of assuming one upon its temperature being sufficiently raised by heat applied to its external surfaces, and so passing into it.

The metals used in gun-construction are crystallizing bodies, which in consolidating obey more or less perfectly, according to their conditions, this law; so that in castings of these metals the planes of crystallization group themselves perpendicularly to the surfaces of external contour; that is, in the directions in which the heat of the fluid metal has passed outwards from the body in cooling and solidifying. Because the crystals of these metals are always small and are never very well pronounced, these directions are seldom very apparent to the eye, but they are not the less real. Their development depends upon—

First—The character of the metal itself; all irons that present a coarse, large-grained, dark, or spangled fracture contain a large proportion of uncombined carbon or graphite, and form in castings of equal size the largest crystals.

Second—The size or mass of the castings; the largest castings presenting for any given variety of metal the largest and coarsest aggregation of crystals, but by no means the most regular arrangement of them, which depends chiefly upon—

Third—The rate at which the mass of the casting has cooled, and the regularity with which heat has been carried off by conduction from its surfaces to that of the mold adjacent to them.

Those castings in which the fluid iron is poured into a nearly cold and very thick mold of cast-iron, whose high conducting power rapidly carries off the heat, present the most complete and perfect development of the crystalline structure perpendicular to the chilled surfaces of the casting. In such, crystals are often found penetrating more than an inch into the substance of the metal, clear and well defined. These prevailing directions of crystalline arrangement may be made more clear to the eye by the accompanying drawings, which show sections of a round and a square bar of cast-iron where the crystallization is well developed. In the round bar the crystals all

radiate from the center; in the square bar they are arranged perpendicularly to the four sides, and hence have four lines in the diagonals of the square—in which the terminal planes of the crystals abut or interlock, and about which the crystallization is always confused and irregular. The result of this arrangement is to create *planes of weakness* where the different systems of crystals intersect.

The size and arrangement of the crystals of a metal have an important influence on its strength. This arises from the fact that the adhesion of the crystals by the contact of their faces is less than the cohesion of the particles of the crystals themselves, and that consequently rupture takes place along the larger or principal crystalline faces. See *Cast-iron Guns*.

CUBICAL POWDER.—This powder is of a regular cubical grain, being formed by cutting the press-cake in two directions at right angles to each other by means of saws. A sample was tested in 1876 with the following results:

Nature of Gun.	Kind of Powder.	Weight of charge.	Weight of projectile.	Velocity.	Pressure.
		Lbs	*Lbs*	*Feet.*	*Lbs.*
8-inch rifle.	Cubical, D = 1.765. G = 56.	35	176	1 446	46,500
9-inch rifle	Cubical, D = 1.765. G = 56.	40	229	1,436	24,750

As tested in the 11-inch rifle, this powder proved "high," a pressure of 28,000 pounds resulting with a charge of only 50 pounds. Each grain of this powder is about .75 inch in size, and the granulation is about 72 to the pound. See *Gunpowder*.

CUBIC EQUATIONS.—A cubic equation containing but one unknown quantity is one in which the highest exponent of the quantity in any term is 3. Every such equation can be reduced to the general form $x^3 + px + q = 0$, in which the coefficient of x^3 is 1, and that of x^2 is zero. Every cubic equation of this form has three roots, all of which may be real, or one only may be real and the other two imaginary. The roots will all be real when p is essentially negative and $\frac{p^3}{27} > \frac{q^2}{4}$ numerically. One root only will be real when p is essentially positive, or when it is negative and $\frac{p^3}{27} < \frac{q^2}{4}$ numerically. If p is essentially negative and $\frac{p^3}{27} = \frac{q^2}{4}$, two of the roots are equal. When one of the roots only is real, the equation may be solved by the following formula, known as Cardan's formula:

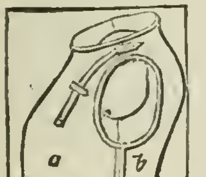
$$x = \sqrt[3]{-\frac{q}{2} + \sqrt{\left(\frac{q^2}{4} + \frac{p^3}{27}\right)}} + \sqrt[3]{-\frac{q}{2} - \sqrt{\left(\frac{q^2}{4} + \frac{p^3}{27}\right)}}.$$

When the roots are all real, this formula fails to give their values. The solving of cubic equations is of frequent necessity in the investigation of the problems of gunnery.

CUBIT.—A measure employed by the ancients, equal to the length of the arm from the elbow to the tip of the middle finger. The cubit of the Romans was about 17⅖ inches, and that of the Hebrews 22 inches, but its length is now generally stated at 18 English inches.

CUGNOT SYSTEM OF FORTIFICATION.—A system having a circular tracing and dispensing with outworks. The revetment of the escarp contains a loop-holed gallery, with machicoulis for the defense of the ditch and the counterscarp. See *Fortification*.

CUIRASS.—The cuirass, as its name implies, was originally a jerkin, or garment of leather for soldiers, so thick and strong as to be pistol-proof, and even musket-proof. The name was afterwards applied to a portion of armor made of metal, consisting of a back-plate and breast-plate hooked or buckled together; with a piece jointed to the back called a *culet* or *garde de reines*. The French cuirass, represented in the drawing, is composed of a breast-plate, *a*, and a back-plate, *b*, joined together by straps. The thickness and form of the breast-plate are such as to ward off small-arm projectiles beyond a distance of forty yards; this distance is assumed under the supposition that within it the infantry soldier will be too busily engaged preparing to defend himself against the cavalry soldier, with his bayonet, to fire his piece. The back-piece is only made of sufficient thickness to resist the stroke of a sword; it is presumed this will induce the wearer to present his front rather than his back, when he arrives within a short distance of his enemy. The middle of the breast-plate is formed into a ridge, and the sides slope off to deflect projectiles coming from the front. The thickness at the ridge is .23 inch; from this it tapers to the edges, where it is .078 inch. The back-piece is .047 inch thick throughout, and the weight of the entire cuirass is about 16.75 lbs. The edges are turned up to prevent the point of a sword from slipping off against the body. The cuirass and helmet worn by the leading sapper in digging a siege-trench are thick enough in all their parts to resist a bullet at the distance of 40 yards. See *Armor*.



CUIRASSIERS.—Heavy horsemen, in the time of Queen Mary, wearing body-armor over buff coats. They carried swords and pistols, and the reins were strengthened with iron chains. In modern armies the name is often given to the heaviest cavalry. Napoleon's twelve regiments of cuirassiers attracted much attention during his wars. The first rank of Russian cuirassiers are armed with lances. The only cuirassiers in the British army (wearing the cuirass) are the Life-guards (red) and Horse-guards (blue); and in these the cuirass is now regarded rather as a matter of show than of use. See *Cuirass*.

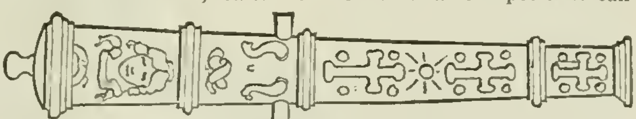
CUISSART.—Among ancient armor, cuissarts were worn by troopers. They consisted of small strips of iron plate laid horizontally over each other round the thigh, and riveted together. Also written *Cuish*, *Cuissard*, *Cuisse*, and *Cuissot*.

CUL-DE-SAC.—A street or alley with an opening at only one end, easy therefore of entrance, but not for exit; thence any very close, confined, uncomfortable place. The expression is applied to a position in which an army finds itself with no way of exit except to the front.

CULLEN RIFLE.—A magazine-gun carrying a great number of cartridges, as many as 40 or 50. This arm has been used to some extent in the United States, but has not met with any considerable success. See *Magazine-gun*.

CULOT.—An iron cup inserted in the conical opening of the Minié and other early projectiles. This *culot*, moving before the inertia of the lead is overcome, forces the ball into the grooves. It has since been discovered that the ball is forced as well without as with the culot, and it has accordingly been suppressed.

CULVERIN.—The introduction of cast-iron projectiles, which are much stronger and denser than those of stone, led to the invention of a new species of cannon called culverins, which very nearly correspond in construction and appearance to the guns of the present day. The great strength of these pieces and their projectiles permitted the use of a large charge of powder; and their introduction proved an important step in the improvement of artillery. The idea was entertained by ancient artillerists—founded on the relation which cannon were erroneously supposed to bear to small-arms—that the range increased with the length of the piece; and in consequence many culverins were made of enormous length. A remarkable piece of this description still exists at Dover, England, familiarly known as "Queen Anne's pocket-piece." While it carries a ball weighing only 18 pounds, it is more than 25 feet long. See *Cannon*.

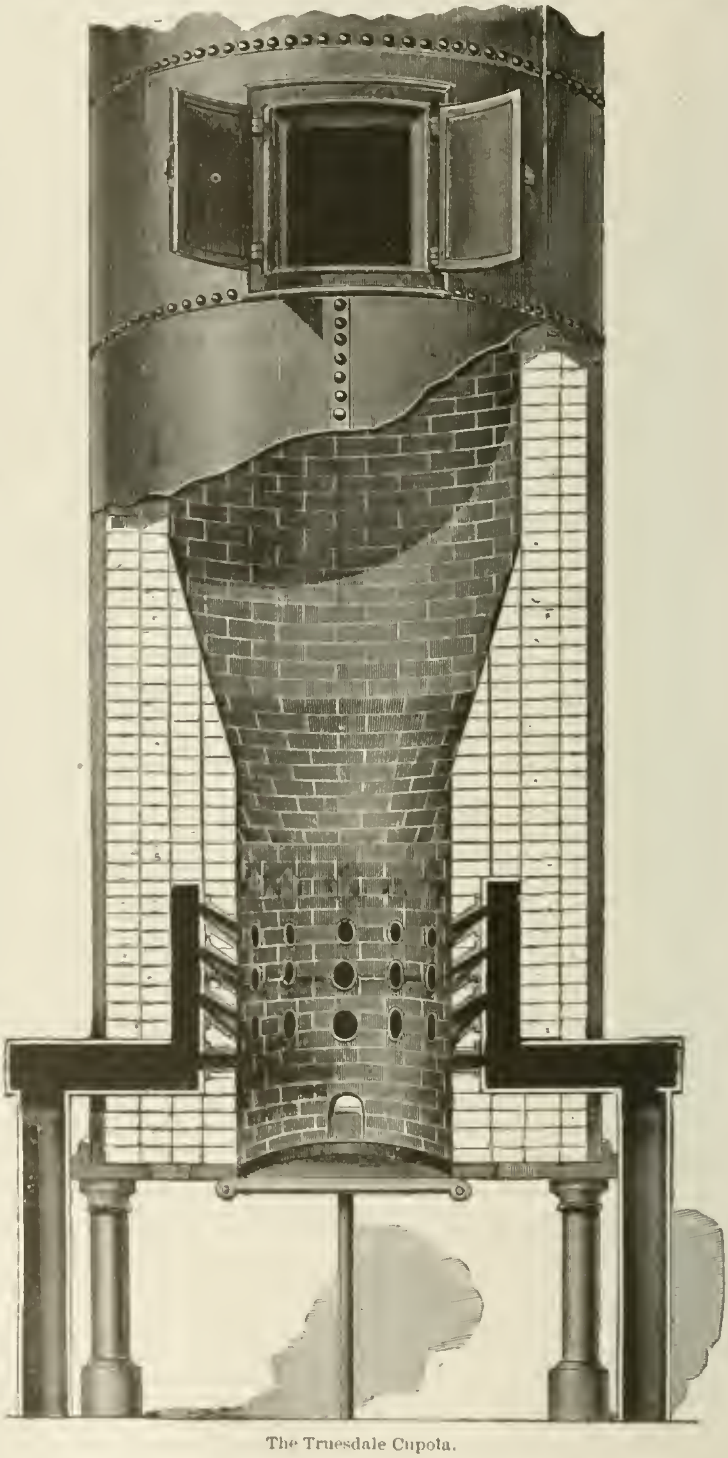


Culverin—"Queen Anne's Pocket-piece."

CUNETTE.—In fortification, the bottom of the ditch, when dry, usually receives a slight slope from the foot of the scarp and counterscarp to its center, where a small drain, termed a *cunette*, is dug to receive the surface-water and keep the ditch dry. In some cases, from motives of economy, the difference of level between the cunette and the foot of the counterscarp-wall is increased, thus giving a less height of wall. This practice, however, can only be followed where the foundations of the wall will be secure, from the soil of the bottom of the ditch being of such a nature as not to yield from the effects of the weather upon it. Also written *Cuvette*. See *Ditch*.

CUPOLA.—A revolving shot-proof turret, formed of strong timbers, and eased with massive iron plates of 12 and 14 inches thick. In some systems of cupolas the tower is erected on a base which is made to turn on its center by means of steam-power. Within the turret heavy ordnance is placed, and fired through openings made in the sides.—The term *cupola* is also applied to a blast-furnace in which iron is melted. See *Cupola-furnace*.

CUPOLA FURNACE.—Many costly experiments have been tried of late years in order to determine, along with other related questions, the best form of blast-furnace in which iron is smelted. Which is the most serviceable form is as yet a very much disputed point; but, according to the published accounts, furnaces of the unusual height of 80 to 100 feet give, as a rule, the best results. To this end it is indispensable that the following conditions are fulfilled: 1. Rapid melting, that the iron may be gotten under the slag as soon as possible, to prevent exposure to the blast, which, at the high temperature in the cupola, rapidly decarbonizes the iron. 2. Uniform combustion in the melting part of the cupola. It is evident that iron melted at different temperatures will vary both in quality and in temperature, and castings poured from such iron will not be uniform in quality or shrinkage. 3. Such an arrangement of the cupola and method of introducing the blast as will maintain the fluidity of all the slag in the cupola, so that it may be drawn off when necessary. It is apparent that when the slag has chilled around and above the tuyeres, drawing off the melted slag below does no good whatever. In most cupolas the blast is introduced at two opposite points; in some cases four and six tuyeres are used, but in the same plane. In very large cupolas from 5000 to 10,000 cubic feet of air per minute are required. This large amount of air introduced at these few points cannot instantly be elevated to the high temperature in the cupola (over 3000° Fahrenheit), consequently combustion is arrested at the entrance, and the slag is chilled by the cold air around the mouth of the tuyere. These obstructions are constantly increased by the melting slag, which cools as it falls, and adheres to those already formed as soon as struck by the blast. If the melting is continued sufficiently long, the entire opening above the tuyeres is bridged over, melting ceases, and the bottom must be dropped. The combustion, under these circumstances, has necessarily been very imperfect. In some parts (as above the chilled slag at the mouth of the tuyeres) the fuel has scarcely been ignited, while in other



The Truesdale Cupola.

parts the heat has been so intense that when the current is forced by the accumulated mass of chilled slag against the lining of the cupola, it is often melted out nearly to the shell. The result is bad iron, great loss in castings, a low percentage of effect for fuel used, and a bad condition of cupola. Another style of cupola is made with continuous tuyeres, in which the blast enters all around the cupola in a sheet. It is well known that neither water nor air can be projected in this way to any considerable distance. To attempt to throw water from a flat nozzle would be simply ridiculous. In cupolas constructed on this plan the blast has but little power to penetrate the stock, but turns upward near its entrance, leaving the stock in the center unsupplied with air. On this account cupolas using sheet-blast are constructed of an oval or oblong shape, bringing their opposite walls closer together, in order that thus the blast may reach the center. It is well known that cupolas, with walls straight or nearly straight, are much weaker and more difficult to keep in repair than the cylindrical form, and require special arrangements to keep the brick in place. If the difficulties encountered in the old-style cupola were obviated by this plan, these evils might be borne; but they are not: the walls being brought nearer together, the liability of bridging over is increased without any compensating benefit. The majority of foundrymen who have tried this construction have gone back to the old style, or have lined them in cylindrical form and substituted the round tuyeres for the sheet-blast.

The drawing shows the Truesdale cupola, in section. In this furnace we find—1. A very considerable contraction of the lower part of the cupola, or that part containing the tuyeres. The blast is thus introduced nearer the center, lessening the distance necessary to force the air, and also the amount of fuel required to make the bed. The boshes or inclines partially support the descending stock, rendering it more open below than above, and on this account the blast is more easily diffused through the entire mass. 2. An important feature is a largely increased number of tuyeres, distributed over a much larger surface. By this arrangement the blast is enabled to penetrate and diffuse itself through every part of the stock, and at the same time is so subdivided that the amount entering at any one place is not so great as to arrest combustion or chill the slag before being elevated to the temperature necessary to enter into combustion. A further advantage is that the cold air entering through the tuyeres protects a certain area of surface about each tuyere, and when placed sufficiently contiguous to each other, as shown in the drawing, the whole interior melting surface is protected. 3. Another important feature in this cupola is the arrangement of graduated tuyeres, each tuyere having the orifice admitting the blast diminished as they ascend in the series. By this means the gas generated by the heat evolved in combustion at the lowest series of tuyeres (a considerable portion of which in its rapid ascent would pass out of the cupola unconsumed) is met by a fresh supply of oxygen and utilized. The same operation is repeated by each tuyere in the series for the one below it. The saving thus effected amounts to ten per cent of the entire amount of fuel burned. An examination of the drawing will give, perhaps, a clear idea of the interior of this cupola during the process of melting. The lower tuyeres in the series having larger openings, and consequently more volume and strength, the blast penetrates further into the stock before ascending than the blast from the next series, which, being somewhat diminished and having less force, ascends before reaching as far inward as the blast from the tuyere below it, and so on through the entire series, the upper set supplying the blast nearest the circumference. It will readily be seen that this arrangement secures the perfect distribution and diffusion of the blast throughout the entire cupola, effecting uniform, rapid, and perfect combustion, with the complete consumption of all the gases generated, without chilling the slag, which, in a fluid state, floats on the melted iron, protecting it from decarbonization. The effects are rapid melting and sharp, with hot iron of a uniformly good quality throughout the entire heat. See *Foundry*, *Iron*, and *Mackenzie Cupola-furnace*.

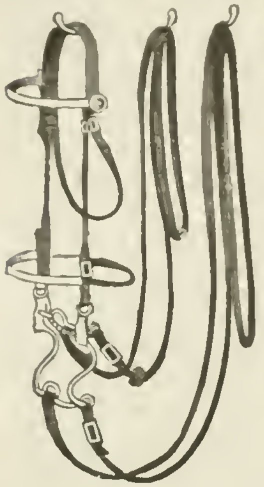
CURARI.—A celebrated poison used by some tribes of South American Indians for poisoning their arrows. It is by means of this poison that the small arrows shot from the blow-pipe become so deadly. The nature and source of this poison remained long unknown, the Indians being very unwilling to reveal the secret, which seems, however, to have been at last obtained from them by Sir Robert Schomburgk, and it is now regarded as pretty certain that the principal ingredient is the juice of the *Strychnos toxifera*, a tree or shrub of the same genus with that which yields nux vomica. It has a climbing stem, thickly covered with long spreading reddish hairs; rough, ovate, pointed leaves, and large, round fruit. The poison, when introduced into the blood, acts on the nervous system, and produces paralysis, with convulsive movements, and death ensues. It is supposed to be the most powerful sedative in nature. Artificial respiration is the most efficacious means of preventing its effects. It has been proposed to employ it in the cure of lockjaw and hydrophobia, and it has recently been asserted, as the result of experiment, that it can be very beneficially employed in the former disease. Like snake-poison, it is comparatively inert when taken into the stomach. Also written *Ourari*, *Woorali*, and *Woorara*. See *Arrow-poisons*.

CURB.—1. A strain of the straight ligament which runs down the back of the hock of a horse. It is most common in animals with straight small hocks and that conformation known as *sickle-hams;* whilst like other strains it occurs from sudden and violent exertion, often proceeding in the lighter breeds from leaping or galloping in heavy ground, and in the heavier from the effort of keeping back a load whilst going down a steep incline. Swelling appears on the inner and back part of the joint, generally causing lameness, which is most apparent in trotting, and, in slight cases, usually wears off after the animal has been out for ten minutes. Fomentations must first be used to allay the irritation and inflammation; when heat and tenderness disappear, cold applications will be advisable; when, after ten days, the enlargement still continues, a blister is generally necessary; whilst, from the first, all work must be forbidden.

2. A funnel-shaped iron border standing out from the incorporating bed of a gunpowder-mill at an angle of 45 degrees, and 2 feet high, serving to keep the charge in the bed, and all extraneous matter out of it.

CURB-BIT.—A stiff bit having *branches* by which a leverage is obtained upon the jaws of a horse. The lower end has rings or loops for the reins, and the upper end has loops for the *curb-chain* and the *cheek-straps* of the head-stall. The curb-chain has usually twisted links, and is fast by one end to the loop of the *off* branch, and is hooked to the loop of the *near* branch. It forms the fulcrum for the leverage of the branches.

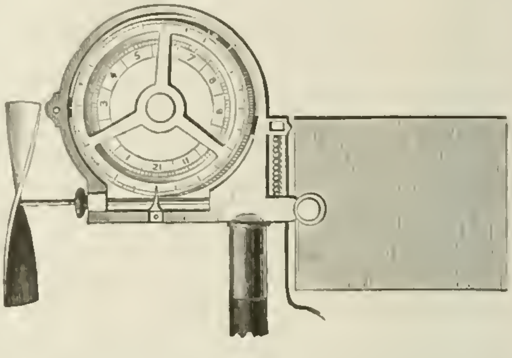
CURB-BRIDLE.—A bridle used in the military service, and having a curb. To put on the curb-bridle, take the reins in the right, the crown-piece in the left hand, approach the horse on the near side, passing the right hand along his neck; slip the reins over his head, and let them rest on his neck; take the crown-piece in the right hand, the left side of the bar of the bit resting on the first two fingers of the left hand; bring the crownpiece in front of and slightly below its proper position, insert the thumb of the left hand into the side of the mouth above the tushes; press open the lower jaw; insert the bit by raising the crown-piece, pass the left hand under the brow-band, draw the ears gently under the crown-piece, beginning with the right ear; arrange the forelock, secure the throat-lash, and then the curb-strap, taking care not to make them set too closely. There should be at least three fingers' breadth between the throat-lash and the jaw, and one finger's breadth between the curb-strap and jaw. The bit should hang so as to touch, but not draw up, the corners of the mouth. In no case should the top of the mouth-piece touch the palate. The halter may be taken off before bridling, the reins being first passed over the neck; if the bridle be put on over the head stall, the hitching-strap, if not left at the manger or picket-line, should be tied round the neck or attached to the left saddle-ring. The hitching-strap may be also arranged as follows: loop it two or three times through the ring, so that the loop may be about eight inches long; wind the strap several times around the loop, and draw the end of the strap tightly through it. See *Bridle* and *Unbridle*.



CURIET.—A breastplate made of leather. The *surcoat* or *jupon*, which usually covered the former styles of armor, was laid aside about the time the cuirass was adopted, say the reign of Edward III. The early cuirass of the Greeks was of linen, which was afterwards covered with plates of horn or scales of horse-hoofs. The Roxalani wore leather with thin plates of iron. The Persians wore a similar cuirass. The Romans introduced flexible bands of steel, folding over one another during the flexure of the body. The Roman *hastati* wore chain-mail (hauberks). The same nation, as well as the Greeks, used the back- and breast plate. See *Armor*.

CURRACH.—The name given in the British Islands to a canoe or boat made of a slender frame of wood covered with skins. Skiffs of this sort, as well as canoes hollowed out of the trunks of oaks, were in use among the Britons in the earliest times of which we have record. Julius Cæsar, who built some of them after the British model, tells us that the keel and gunwales were of light wood, and the sides of wicker, covered with hides. Similar descriptions of the currach are given by Pliny, Lucan, Solinus, Festus Avienus, Sidonius Apollinaris, and others. The first occurrence of the name seems to be in Gildas, who wrote in the sixth century; he speaks of the currach as in use among the Scots and the Picts. A long voyage in the North Sea, made in a currach during the same century, by one of the companions of St. Columba, is commemorated by Adamnan, who died in 704. In 878 three Irish missionaries sailed in a currach from Ireland to Cornwall; the voyage occupied seven days; and the size of the currach is indicated by the remark that it was one of two skins and a half. An old Life of St. Patrick speaks of a currach "of one skin, with neither helm nor oar." The currach of a larger size had a mast and sail. The currach still continues to be used on the Severn, and on many parts of the Irish coast, especially on the shores of Clare and Donegal. The last currach known to have been used in Scotland is in the Museum at Elgin. It was employed on the Spey, towards the end of last century. A boat of bison-skin, essentially the same with the British coracle, is in use among some of the Indians of North America.

CURRENT-METER.—An instrument for measuring the velocity of currents. One form, the *pilot-tube*, acts by the ascension of water in a vent-pipe whose lower orifice is presented squarely to the current, the indication being read by a float or graduation in or upon the vertical part of the tube. Another form acts as a dynamometer, by opposing a resisting body to the action of the current, and indicating the force of the action by a dial or graduated bar. The dynamometer current-gauge of Woltmann (1790) is a light water-wheel operated by the current, and having on its axis an endless screw, which operates toothed wheels and a register, the rate or force being deduced from the rotations in a given time. The drawing



shows this instrument adapted for use in small rivers and streams, or to show the number of gallons flowing from any reservoir or vessel. The mean velocity of water in rivers equals $\frac{(\sqrt{v}-1)^2+v}{2}$, when v is the surface velocity expressed in inches. In the absence of a meter, the surface-velocity may be determined by carefully noting the time required for a chip or any small substance to float a measured distance. The following are the usual expressions applied to river-velocities:

Sluggish,	about 1½ ft.	per second, or	1	mile	per hour.
Ordinary,	" 3	"	2	"	"
Rapid,	" 5	"	3	"	"
Very rapid,	" 8	"	5	"	"
Torrent,	" 9 or more	"	6	"	"

CURRENT SERIES.—In military administration, orders issued from Established Commands, such as Divisions, Departments, etc., being numbered in regular order for each year. This expression is frequently used when referring to orders issued in the year passing or current.

CURRICLE-GUN.—A very small piece of ordnance, mounted upon a carriage of two wheels, and drawn by two horses. The artilleryman is seated on a box, and the whole can be moved forward into action with astonishing rapidity The tumbrils belonging to curricle-guns carry 60 rounds of ball-cartridges. This gun is no longer in general use.

CURRIER.—A very small musketoon with a swivel mounting; but little used at present.

CURRY-COMB.—A kind of scraper used for dressing horses. It consists of a number of iron plates notched on one edge to form rough teeth. These plates are fastened in parallel lines to an iron back, to which a handle is attached, and the horse is "curried" by scrubbing with the teeth.

CURTAIN.—The curtain, in a fortification, is the portion of rampart or wall between two bastions or two gates. In a regular siege, to batter down the curtain is one of the main operations depended on, and many of the external works constructed by the defenders are intended to frustrate, or at least embarrass, this operation See *Bastioned Forts*.

CURTAIN-ANGLE.—The angle of a fortification between the flank and curtain. See *Bastioned Forts* and *Curtain*.

CURTAL-AXE.—A short sword with a curved blade. The name has been modified from time to time: *coutal-hache*, *coutal-axe*, *curtle-axe*, *curtal-axe*, *coutelace*, *curte-lasse*, and *cutlass*.

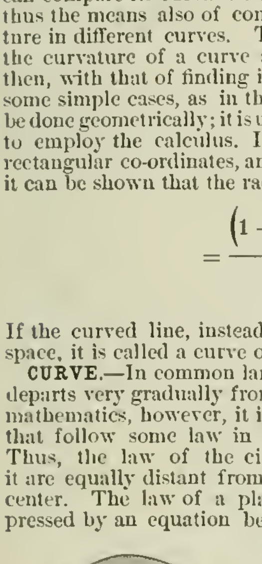
CURTALL.—An ancient piece of ordnance, peculiar for its shortness. Sometimes written *Curtald*.

CURVATURE.—The curvature of a plane curve at a point is its tendency to depart from a tangent to the curve at that point. In the circle this tendency is the same throughout, for the curve is perfectly symmetrical round its center; in other words, the curvature of a circle is constant. In different circles the curvature is inversely as the radius—i.e., it diminishes as the radius increases. The reciprocal of the radius is accordingly assumed as the measure of curvature of a circle. A straight line which has no curvature may be considered part of a circle whose radius equals infinity as the reciprocal of infinity, measures the curvature, and is $= 0$. The constancy of curvature in the circle suggests an absolute measure of curvature at any point in any other curve; for whatever be the curvature at that point, we can always find a circle of the same curvature. The radius of the circle which has the same curvature at any point in a curve as the curve itself at that point is called the radius of curvature of the curve for that point; and the circle itself is called the *osculating* circle. If we know the radius of curvature of a curve at different points, we can compare its curvature at those points. We have thus the means also of comparing degrees of curvature in different curves. The problem of measuring the curvature of a curve at any point is the same, then, with that of finding its radius of curvature. In some simple cases, as in the conic sections, this may be done geometrically; it is usually necessary, however, to employ the calculus. If the curve be referred to rectangular co-ordinates, and x, y be a point in it, then it can be shown that the radius of curvature

$$= \frac{\left(1+\frac{dy^2}{dx^2}\right)^{\frac{3}{2}}}{\frac{d^2y}{dx^2}}.$$

If the curved line, instead of being plane, twists in space, it is called a curve of double curvature.

CURVE.—In common language, a crooked line that departs very gradually from the straight direction; in mathematics, however, it is usually restricted to lines that follow some law in their change of direction. Thus, the law of the circle is that all points of it are equally distant from a fixed point, called the center. The law of a plane curve is generally expressed by an equation between the co-ordinates of any point in it referred to a fixed point. When the equation of a curve contains only powers of x and y, the curve is algebraic; when the equation contains other functions, logarithms for instance, of x and y, the curve is called transcendental. The cycloid, e.g., is a transcendental curve.



There are also curves, like the spiral, that do not continue in one plane; these are called curves of double curvature. To express the law of such a curve requires three co ordinates and two equations. Curves are said to be of the first, second, third, etc., order, according as their equations involve the first, second, third powers of x or y. The circle, ellipse, parabola, and hyperbola are of the second order of curves. There is only one line of the first order, namely, the straight line, which is also reckoned amond the curves. The higher geometry investigates the amount of curvature of curves, their length, the surface they inclose, etc.

The number of curves that might be drawn is, of course, infinite. Quite a large number have received names, and are objects of great interest to the mathematician—in some cases, for their beauty; in others, for their remarkable properties. Among the most interesting are the following: 1, circle; 2, ellipse; 3, hyperbola; 4, parabola; 5, cissoid of Diocles; 6, conchoid of Nicomedes; 7, lemniscata; 8, cycloid; 9, harmonic curve; 10, trochoid; 11, the witch; 12, cardiode, 13, curves of circular functions—e.g., curve of sines; 14, the logarithmic curve; 15, the spiral of Archimedes; 16, the catenary; 17, the tractory; 18, the tractrix; 19, the ovals of Cassini; 20, the reciprocal spiral.

The term *curve* is also applied to a draughtsman's instrument having one or a variety of curves of various characters other than arcs, which may be struck by a compass. Such a combination of curves is shown in the drawing. They are frequently constructed for specific purposes, such as *shipwright's curves, radii-curves*, etc.

CURVED FIRE.—When a projectile is fired so as just to clear an interposing cover, and then descend upon the object, the line of fire being perpendicular or nearly so to the front of troops or works to be destroyed, such practice is termed *curved fire* in order to distinguish it from ricochet. This kind of fire has been long employed to dislodge troops posted behind cover by firing common shells from guns or howitzers. Smaller charges and higher angles would, as in ricochet, be required than for ordinary direct fire. The employment of curved fire at the siege of Strasburg by the Prussians, during the Franco-Prussian War, was very successful, a hidden escarp at a range of 910 yards having been breached with a 6-inch B. L. R. gun, with a charge of powder $\frac{1}{10}$ the weight of the projectile fired, which was 60 lbs. Under curved fire it is necessary that a projectile should strike the revetment at a considerable angle of descent, with sufficient energy to destroy the masonry. Now, in order that a considerable angle of descent may be obtained at a moderate range (from 1000 to 1500 yards) it is necessary that the remaining velocity should be low; and this may be obtained in two ways —by a projectile that has been fired originally with a comparatively high velocity, and has lost it rapidly; or by a projectile that has been fired originally with a lower velocity and a higher elevation, but has not lost its velocity so quickly. If the projectile has the same weight in both cases, the first result would be obtained by a short shell of large caliber, the second by a long shell of smaller caliber, the resistance of the air having a greater effect on the former than the latter. The question is, which of the two systems would be preferable ?

CURVE OF RESISTANCE.—When the velocities of a projectile at two points in the trajectory near together are known, the amount of resistance, R, offered by the air at the mean velocity can be formed from the formula $R = \frac{w(v^2 - v'^2)}{2gS}$; in which $w =$ weight of the projectile; v and $v' =$ the velocities at the two points; and $S =$ the space in which the velocity is reduced from v to v'. If several resistances are determined in this manner from velocities obtained in practice, a *curve of resistance*, which will give the resistances at all intermediate velocities, may be constructed.

CUSHMAN COMBINATION-CHUCK.—A variety of chuck much employed in the armory and ordnance-shops. The drawings show the construction and action of the device. That portion of the jaws which enters the body of the chuck is cut into a half nut (A, Fig. 3) that engages with a screw (B), the square head of which projects through the face or rim of the chuck to receive a wrench. Below this projecting head is a bevel pinion inside the rim that engages with a circular rack or toothed ring (C C). Turning any one of these screws will actuate the rack and every other screw, and so far it is simply a concentric-jawed chuck. The toothed ring rests upon a plain ring (D D), the periphery of which is a screw-thread that engages with a similar thread on the inside of the shell, so that by turning the ring in one direction it is moved forward towards the face of the chuck, and by turning it the other way it is carried towards the back of the chuck. By this means the circular rack may be meshed in gear with the pinions on the screws, or disengaged from them (Figs. 1 and 2). When in and out of gear the ring (D D) is held in position by a spring catch. Should it be required to move one or more of the jaws further from the center than the others, the spring catch is released by thumb-pressure, the supporting ring is turned out by a knob at the back of the chuck, and the circular rack unmeshed. In this condition it has the characteristics of an independent jaw-chuck. See *Chuck*.

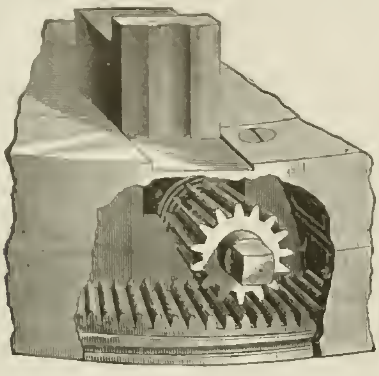


Fig. 1.

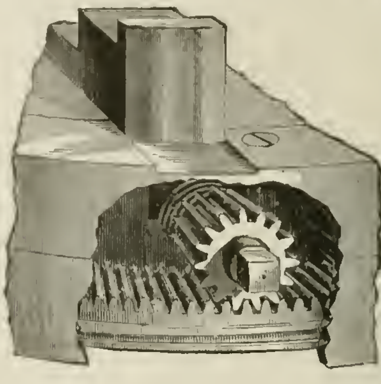

Fig. 2.

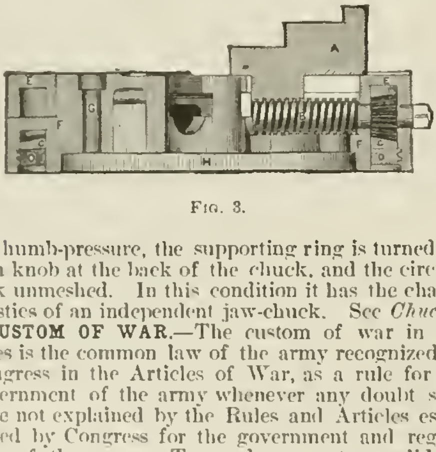

Fig. 3.

CUSTOM OF WAR.—The custom of war in like cases is the common law of the army recognized by Congress in the Articles of War, as a rule for the government of the army whenever any doubt shall arise not explained by the Rules and Articles established by Congress for the government and regulation of the army. To render a custom valid the following qualities are requisite: 1. Antiquity; 2. Continuance without interruption; 3. Have been acquiesced in without dispute; 4. It must be reasonable; 5. Certain; 6. *Compulsory*—that is, not left to the option of every man whether he will use it or not; 7. Customs must be consistent with each other.

CUT.—A term employed in mechanical maneuvers signifying to move the object horizontally, without rolling, by moving each end alternately in the required direction. See *Cuts* and *Mechanical Maneuvers*.

CUT-AND-THRUST SWORD.—An ancient offensive weapon used for cutting and thrusting. It was straight-bladed, at first short and broad, afterwards longer and double-edged, sharp pointed, with a rectangular sheath, and always worn on the right side.

CUTLASS.—A short, heavy, curving sword; especially used by seamen in boarding or repelling boarders. The term is abbreviated from *curtal-axe*. Rosalind calls it a *curtle-axe*. It is usually about 3 feet long, with a japanned hilt.

CUT OFF.—In a military sense, this phrase is variously applicable. *To cut off an enemy's retreat* is to maneuver in such a manner as to prevent an opposing army or body of men from retiring when closely pressed either to their intrenchments or into a fortified town from which they had marched or sallied.

CUTS.—1. Movements in saber-exercise, executed as follows:

Front Cut.—Being at guard, raise the saber, the arm half extended, the hand in front of the right shoulder, and a little higher than the head, the edge upward, the point to the rear, and higher than the hand. (Two.) Cut, extending the arm to its full length. (Three.) Resume the guard. The first position of *front cut* is the position of *raise saber*.

Left Cut.—Being at guard, turn the head and shoulders to the left, raise the saber, the arm extended to the right, the hand in quarte and as high as the head, the point higher than the hand. (Two.) Cut diagonally to the left. (Three.) Resume the guard.

Right Cut.—Being at guard, turn the head to the right, carry the hand opposite the left breast, the point of the saber upward, the edge to the left. (Two.) Extend the arm quickly to its full length, and give a back-handed cut horizontally. (Three.) Resume the guard. The *left* and *right cuts* are used against infantry, inclining the body forward, and cutting at the necessary angle.

Rear Cut.—Being at guard, throw the right shoulder well back, and execute the first motion of *right cut*. (Two.) Extend the arm quickly to its full length, and give a back-handed cut horizontally to the rear. (Three.) Resume the guard.

Left in Quarte and Tierce Cut.—Being at guard, execute the first motion of *left cut*. (Two.) Execute the second motion of *left cut*. (Three.) Turn the hand in tierce and cut horizontally. (Four.) Resume the guard.

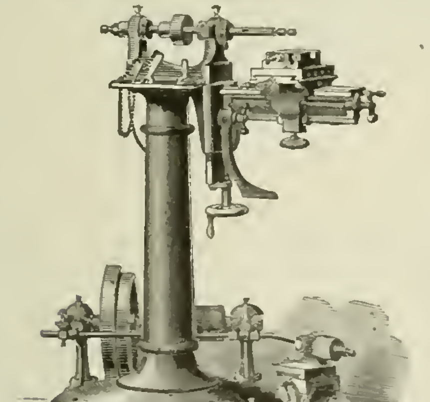
Right in Tierce and Quarte Cut.—Being at guard, execute the first motion of *right cut*. (Two.) Execute the second motion of *right cut*. (Three.) Turn the hand in quarte, and cut horizontally. (Four.) Resume the guard.

Rear in Tierce and Quarte Cut.—Being at guard, execute the first motion of *rear cut*. (Two.) Execute the second motion of *rear cut*. (Three.) Turn the hand in quarte, and cut horizontally. (Four.) Resume the guard. See *Saber-exercise*.

2. When breaching walls, it is necessary to separate that part of the masonry or revetment to be overthrown from the adjoining portion, in such a manner that it may soon be brought down by its own weight and by the fire directed upon it. The best method of effecting this is to cut the wall first in a horizontal direction, and then vertically at such distances as the strength of the masonry may require. In general, the height of the horizontal cut should be about one third the total height of the scarp-wall from the bottom, though in some cases it may be preferable to make it as high as the middle line of this wall. This will depend greatly upon the thickness of the wall, and should be determined in each case at such a height that the breach may be practicable. If too

high, the ramp composed of the débris will be intercepted by a portion of the wall; if too low, the opening will be masked by the débris itself. The length of the cut will be regulated by the width of passage required for the assaulting party, generally from 20 to 30 yards. Each gun has a certain space allotted to it, and commences firing at one extremity, spacing the shots at regular intervals depending upon the caliber of the gun. Returning, it fires at points exactly between the former, and finishes by destroying any salient parts of the masonry left uninjured throughout the line. The completion of the cut will be known by the earth falling through. By marking on the platform the direction of the stock and wheels at each fire, on returning the proper direction can easily be given to the piece. The elevation will remain unchanged. The number of vertical cuts having been determined so that no section of the wall shall be sustained by more than one counterfort, the cuts are formed by first firing a shot at a certain distance above the horizontal line and then another in the center of this interval; the intermediate salient points are destroyed as before. A second equal length of cutting is effected in the same manner, and so on until the length is sufficient. Care must be taken that the extreme vertical cuts progress as rapidly as the others. These vertical cuttings need not, in general, be carried to a greater height than one half the distance between the horizontal line and the cordon, nor is it always necessary that they should penetrate quite through the revetment as in the case of the horizontal cut. If the wall does not fall on the completion of the cuts, a few volleys are fired at the middle of the spaces thus outlined. After the wall has fallen, the counterforts are battered down, and, if necessary, the fire continued upon the backing of earth in order to make the slope easy of ascent. See *Breaching*.

CUTTER-GRINDER.—A grindstone or emery-wheel specially constructed for grinding the sections of cutter-bars. In the machine commonly employed in the United States arsenals, the platen to which the holder and guide are attached is adjusted in height to suit the diameter of the cutter to be operated upon. The guide rests against the tooth that is being ground, thus gauging the work perfectly, even though there may be irregularity in the size of the teeth. The machine is adapted to cutters of all sizes and styles of teeth, whether straight, beveled, or spiral. Either small grindstones or emery-wheels may be attached to the spindle.



The drawing shows a very efficient machine of this class, made by E. E. Garvin and Company. The construction has been simplified by substituting a planed knee for the heavy stud in former use. A sliding platform, made to move more freely than in the old-style machine, is fitted to this knee and is bound in any desired position by tightening a gib by means of a hand-screw shown beneath. A special attachment is also provided for this machine when required for surface-grinding. The drawing shows it in position on the machine, with the cutter grinding-head on the floor. The machine can be changed from a cutter-grinder to a surface-grinder in a few minutes. Upon the sliding platform is a stand capable of being held by a cam binder at any desired angle. This stand is used for the mandrel-stud, and has a graduated arc of 90 degrees for setting the stud at any angle. The centers shown in the drawing enable the operator to sharpen reamers and taps of almost any shape. With this machine all sizes and shapes of cutters can be handled from ½ inch to 8½ inches diameter, and face mills, by using platform shown at foot of machine, up to 12 inches diameter. The arrangement is such that plenty of space is allowed for the hands in sliding the work upon the mandrel. The slide and spindle bearings are sheathed and covered with cap-nuts for the exclusion of dust and emery. The spindle-boxes have adjustment for wear, and the sliding surfaces are substantially gibbed. The surface-grinder will grind a piece 10 inches long and 8 inches wide. The slide is operated by a rack and pinion movement, making it very sensitive and quickly handled. The cross-feed is operated by a screw attached to the end of the knee. This attachment is very useful in grinding small hardened work, such as straight edges, cutting dies, calipers, gauges, etc. Small pieces can be held in a vise made fast to the slide for that purpose. The countershaft-hangers are adjustable and self-oiling. The following are the general dimensions:

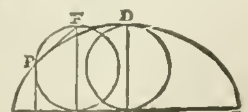
Tight and loose pulleys on countershaft 4½ by 2 in. face
Speed of countershaft ....400 rev.
Weight of machine, complete..............300 lbs.

CUTTING-OFF MACHINE.—This most useful machine is essential to the proper equipment of the foundry, arsenal, and other places where shafts, rods, bars, or pipes are to be cut to length. Cutting off constitutes a large share of the blacksmith-work of a machine-shop, and when performed in the usual manner costs three times as much as if done by a machine. The ordinary mode of cutting off consists of three operations—heating, cutting with chisels, and finishing the ends afterwards; either of these operations costs as much as to cut off by a machine which performs all at once. The Betts machine can be operated by unskilled workmen, and can be set in an iron-room to save space in the machine-shop; the tools require no dressing, and can be ground by any one. Such a machine can be profitably employed where five or more machinists are at work, and is found to be a very important machine tool. The angle and movement of the tools are wholly different from those of a lathe, which cannot be used to advantage for such work; the tools have uniform section, and are supported to the end at their bottom edge in a special tool-clamp, having a new adjustment to alter the angle of the cutting edge of the tool, in operating on soft or hard material. In rolling-mills and iron-works, where large numbers of pieces are to be cut, one attendant can operate two machines if both are arranged with power-feed.

CUTTING-SHOE.—A horseshoe with nails on only one side, for horses that *cut* or *interfere*. See *Horseshoeing*.

CYANE.—An ancient metallic composition used for the ornamentation of cuirasses and for the embellishment of the bosses of shields.

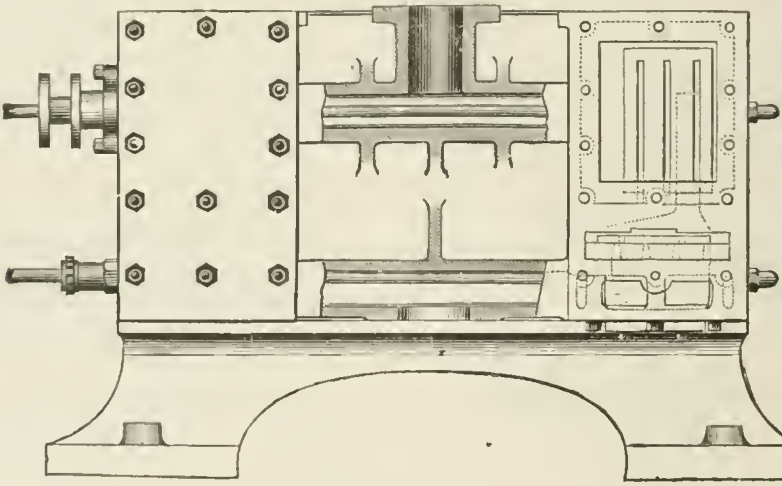
CYCLOID.—If a circle roll along a straight line on its own plane, a point on the circumference describes a curve which is called the cycloid. The curve is one of the most interesting we know in respect both of its geometri-



cal properties and connection with dynamics. One of its most interesting properties is this: The time of a body's descending from rest from any point in the arc of an inverted cycloid to the lowest point is the same, from whatever point of the curve the body begins to descend. This is sometimes expressed by saying that the cycloid is the *isochronous curve.* The body having reached the lowest point will, through the impetus received in the fall, ascend the opposite branch of the curve to a height equal to that from which it fell, losing velocity in its ascent by the same degrees as those by which it acquired it in its descent, and it will employ precisely the same time in ascending as it did in descending. It is clear that if a surface could be procured that would be perfectly smooth and hard, the cycloid would thus present a solution of the problem of perpetual motion. The curve was discovered by Galileo in 1615.

CYLINDER.—1. The name of a genus of geometrical solid figures, of which there may be an endless species. The most common kind of cylinder is that which is generated by the revolution of a rectangular parallelogram about one of its sides, which line is called the axis of the cylinder. But in order to embrace all varieties of cylinders, we must generalize the mode of generation. A cylinder, then, is a solid generated by a line which moves parallel to itself while one end traces upon a plane any curve whatever. When the position of the generating line is at right angles to the plane, the cylinder is *right;* when not, it is *oblique.* If the curve traced is a circle, and the line perpendicular to the plane, the cylinder is a *right circular cylinder*, etc. In all cases the content of the cylinder is found by multiplying the number of square units in the base by the number of linear units in the altitude, which is the perpendicular distance between the two ends. The area of the convex surface is equal to a rectangular parallelogram whose base is the circumference of the end, and its height the length of the generating line. To this must be added the areas of the two ends, to get the entire surface of the cylinder.

2. That chamber of a steam-engine in which the force of steam is utilized upon the piston. The cylinder is generally designed to meet the requirements of the valve-construction. The drawing shows an elevation of the Cummer cylinder, in which is seen, in part section, the steam-passage with a short length of pipe, and below it the exhaust-passage. On either side are the steam- and exhaust-chests; that on the right has the cover removed, showing steam- and exhaust-valves. The valve-stems are also shown; they pass through the steam- and exhaust-passages and connect the valves at one end with those at the other. The exhaust valve-seat is removable for greater convenience of construction, and to allow for refacing. Below the exhaust-valve is the exhaust-passage. The steam enters the cylinder through a three-ported seat, afterwards uniting to form but one opening into the cylinder, and is exhausted through the lower part of this same port, which then by one large opening communicates with the chest in which the exhaust-valve is located. There is no real connection between the two, however; each valve within its own chest controls its own ports, and live steam cannot enter the exhaust. The valves are carefully scraped to an accurate bearing, and being flat are easily fitted and remain tight for a long time. Both steam- and exhaust-valves have a constant travel under all conditions, and this conduces to equal wear, while from the simple construction, whenever repairs are needed, they may be easily made in an ordinary shop with ordinary tools. This is a very desirable point. The valve and valve-stems as well, as the eccentrics, are provided with means of adjustment so that the desired amount of lead and cut-off may be given the steam-valves, and the exhaust-valves set for the desired release and degree of compression. Each valve can be adjusted independently of the others so as to act in the most efficient manner. See *Steam-engine.*



Cummer Cylinder.

CYLINDER-GAUGE.—An instrument employed in the inspection of cannon. It is a hollow cylinder of iron, turned to the least allowed diameter of the bore, and one caliber in length. It has a cross-head at each end, one of which has a smooth hole through its axis to fit the staff, and the other is tapped to receive the screw in the end of it. The cylinder-gauge is introduced into the bore of the gun, and must pass freely to the bottom of the bore. The instrument shows that the bore is not too small. See *Inspection of Ordnance.*

CYLINDER-MILL.—One form of a mill for pulverizing the ingredients of gunpowder, having a cylindrical runner traversing on a bed-stone. See *Gunpowder.*

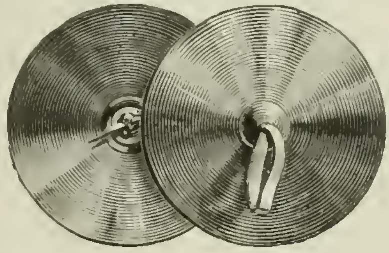
CYLINDER-POWDER.—That of which the charcoal is made in iron cylinders. See *Gunpowder.*

CYLINDER-STAFF.—An instrument used, in the inspection of ordnance, to measure the length of the bore. It is supported by a rest of a T-form at the muzzle, and the extremity inserted in the gun is armed with a *measuring-point* and a *guide-plate.*

CYLINDRICAL CHAMBER.—In the 8-inch siege-mortar, and in the eprouvette-mortar, the bottom of the bore at the mouth of the chamber is formed of a portion of a sphere, so that the projectile closes the mouth of the chamber. In other howitzers the chamber is connected by means of a conical surface, the junctions being rounded off to prevent being worn away by the action of the powder. Cylindrical chambers when narrow and deep give greater ranges than shallow wide ones, which do not confine the powder so much; but as in the former the gas acts on but a small segment of the projectile (usually hollow), it sometimes breaks it; and for this reason too great a depth in cylindrical chamber must be avoided.

CYLINDRICAL INCH.—A term employed in ordnance. It is a cylinder whose base is one inch in diameter and whose altitude is one inch.

CYMBALS.—Military instruments of percussion, which, when struck one against the other, produce a loud harsh sound of no fixed pitch. The best cymbals are those made in Turkey and in China. Attempts to discover and imitate the composition of the metal have all failed. The notes in music for this instrument are all placed on the same line or space, in rhythmical succession. Cymbals, although military instruments, are now much used in the orchestra by modern composers. Cymbals are among the most ancient instruments, being represented in different forms upon the sepulchral monuments. They were used by the Levites in the Temple Ordinances, and the sons of Asaph excelled in their use. They are



mentioned among other instruments, 1043 B.C., when David brought the ark home,—*harps, psalteries, timbrels, cornets, cymbals* (2 Sam. vi. 5). The *loud-sounding* and *high-sounding* cymbals mentioned in Psalms cl. 5 were probably the clashing cymbals and rattling castanets. See *Band.*

D

DAG.—A thick clumsy pistol used in the fifteenth and sixteenth centuries. In the *Spanish Tragedy*, published in 1603, one of the characters shoots the dag.

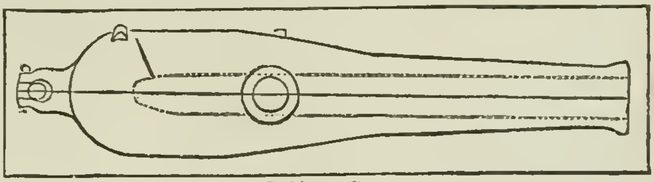
DAGEN.—A peculiar kind of poniard used in very ancient times. Now obsolete.

DAGGER.—A weapon resembling a sword, but considerably smaller, being used for stabbing at close quarters. Daggers are generally two-edged, and very sharp towards the point. Originally it had no guard for the hand, and was worn at the girdle in a sheath. It is now regarded as a general military weapon in European countries. The dagger was a part of the equipment of the Frank warrior, who probably called it a *coutel*, or something like that. It does not differ materially from the *dirk* of the Gadhelic branches of the Celts, or the *poniard* of the nations who acknowledge Latin as the base of their mother-tongues. In the fourteenth century it was carried by citizens, yeomen, sailors, and ladies. It survives in England in the midshipman's *dirk*, and in other places as a *stiletto*, a *bowie-knife*, etc. Some ingenuity has been expended on this weapon in the mode of attaching it to the handle and providing the latter with a pistol.

DAGUE.—A short thick poniard which was formerly much used when individuals engaged in single combat.

DAHLGREN BREECH-STRAP.—A strap connecting the breech with a separate trunnion-ring, in order to avoid longitudinal weakness in a gun, without disturbing the usual and convenient preponderance. The strap is made of bronze, and cast in two pieces: one piece constituting the strap, half the trunnion-ring, and the greater part of the trunnions; the other constituting the opposite half of the trunnion-ring and the remainder of the trunnions. The two parts are riveted together at the trunnions. This strap remedies another and greater defect of cast-iron guns than longitudinal weakness—the unsoundness of the casting around the trunnions.

DAHLGREN GUN.—The Dahlgren guns of large caliber are made of cast-iron, solid, and cooled from the exterior. To produce uniformity in the cooling, the piece is cast nearly cylindrical, and then turned down to the required shape, which is shown in the drawing. The thickness of metal around the seat of the charge is a little more than the diameter of the bore, which rule holds good for nearly all cast-iron guns. The chase, however, tapers more rapidly than in other cast-iron guns, which gives the appearance of greater thickness of metal at the reinforce.



Dahlgren Gun.

The chamber is of the Gomer form. The principal guns of this system are of 9- and 11-inch caliber. A piece of 10-inch caliber has, however, been introduced into the Navy, on Admiral Dahlgren's plan, for firing solid shot with 40 lbs. of powder. The 15-inch and 20-inch naval guns are shaped exteriorly after the Dahlgren pattern, but are cast hollow and have the elliptical chamber of the Rodman system. The following table shows the principal dimensions, etc., of Dahlgren guns:

Gun.	Length of Bore.	Maximum D m.	Weight.	Service-charge.	Maximum Charge.	Weight of Shot.	Weight of Shell.
	Inch.	Inch.	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.
20-inch	163	64	100,000	100		1,080	
15-inch	130	48	42,000	35	60	400	330
13-inch	130	41.7	36,000	40		280	224
11-inch.	132	32	16,000	15	20	170	130
10-inch.	119¼	29.1	12,000	12¼	16	125	100
9-inch.	107	22.2	9,200	10	13	93	70
125-pdr..	117¾	33.25	16,500	40		125	100

See *Cast-iron Guns* and *Ordnance.*

DAM.—A barrier for raising the level of water in a stream, for the purpose of forming a reservoir, inundating, or for turning the water in another direction. Several dams are sometimes placed upon a water-course for the purpose of preventing too rapid an escape of water where it is needed for irrigation or for moving machinery. There is also a variety of dam called a coffer-dam, in which an inclosure is bounded by a barrier which prevents exterior water from entering, used generally for the purpose of excavation. Dams constructed for raising the level of water have an important use in the slack-water navigation of rivers. The materials which enter into the construction of dams differ according to circumstances. If the structure be required to bar a narrow gorge and a considerable stream, it must be made very strong, not only to withstand the hydrostatic pressure, but also the force of the current, which often, during freshets, becomes very great. The materials are then generally composed of a combination of wood-work and masonry. Masonry may be principally used when the gorge is so narrow as to allow of the construction of a sufficiently small horizontal arc to resist the pressure. When the dam is very long (across a wide stream), unless a vast amount of stone is used, wooden braces must be employed. When the body of water to be restrained is not more than four or five feet deep and the bottom is firm, a clay or stiff loam embankment nine or ten feet thick, well compacted, will answer the purpose if a gate be provided to keep the water from flowing over the top of the embankment, which would cause it to wear away. It is not always economy to build the dam in the narrowest part of the stream, or where the opposite banks nearest approach each other. This will often cause, during a freshet, too great a depth of running water over the dam, by which it may be endangered. A point should be selected where the dam can be made of sufficient width to allow the water to pour over it without piling up too much, and where the foundation is good. The line of a dam may be transverse or diagonal to the flow of water. The diagonal is sometimes of advantage in increasing the width of flow, but is liable to interfere with the bed of the stream below more than the transverse line. Where practicable, the form of an arc, the convexity fronting up stream, is the best; but a broken line may sometimes be employed to advantage, the angles pointing up stream acting as braces, while the angles pointing down stream may be held by natural rock-formation or heavy masonry strengthened by bracing.

DAMAGES.—The costs of repairs of *damage* done to arms, equipments, or implements, in the use of the armies of the United States, are to be deducted from the pay of any officer or soldier in whose care or use the said arms, equipments, or implements were when the said damages occurred: provided, the damage was occasioned by the abuse or negligence of said officer or soldier. Every officer commanding a regiment, corps, garrison, or detachment is required to make once every three months, or oftener if required, a written report to the Chief of Ordnance stating all damages to arms so belonging to his command, and naming the officers and soldiers by whose negligence or abuse the damages were occasioned.

Barrack damages, in the British army, is the term applied to injuries done to barracks, barrack-furniture, etc., by soldiers, when the actual perpetrator cannot be discovered.

DAMASCENING—DAMASKEENING.—The art of producing upon ordinary steel certain ornamental appearances resembling those observed on the famous Damascus blades. Attention was first drawn to this branch of industry by the Crusaders, who brought from Damascus to Europe many articles made of superior steel, such as sword-blades and daggers. These were found to possess not only great elasticity, united with considerable hardness, but their surfaces were covered with beautiful designs, formed by a tissue of dark lines on a light ground, or light lines upon a dark ground, and occasionally by the inlaying of gold on the steel-blue ground. These Damascus blades appear to have been constructed of steel and iron welded together; and the elegant designs were brought out by immersing the blades in dilute acids, which, eating away unequally the surface, gave rise to the mottled appearance. In genuine Damascus blades the designs run through the substance of the blade, and the watering, or regular, almost symmetrical figuring, is not worn off by friction, or even grinding. Imitations of the watering of Damascus steel are produced on common steel by etching with acids; and in this way landscapes, inscriptions, and ornaments, and decorations in general, are imprinted on the steel-blue ground. Gold and silver are also inlaid in the higher class of sword-blades and other articles. Gun-barrels are occasionally subjected to the process of damascening. Attempts have been lately made in France to accomplish damascening by means of photography, but as yet with very imperfect results.

DAMASKIN.—A certain variety of saber; so called from the manufacture of Damascus.

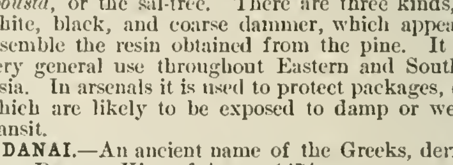
DAME.—Among miners, any portion of the earth which may remain after the explosion of a mine has taken place. It likewise means a piece of wood with two handles used to press down turf or dirt in a mortar.

DAMMER.—A resinous substance found in many parts of India; it exudes from different kinds of trees. That used in Bengal is yielded by the *Shorea robusta*, or the sâl-tree. There are three kinds, the white, black, and coarse dammer, which appear to resemble the resin obtained from the pine. It is in very general use throughout Eastern and Southern Asia. In arsenals it is used to protect packages, etc., which are likely to be exposed to damp or wet in transit.

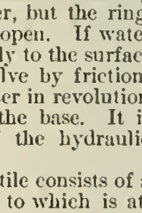
DANAI.—An ancient name of the Greeks, derived from Danaus, King of Argos, 1474 B.C.

DANAIDE.—An hydraulic machine made of two cylinders, one within the other, turning easily on a vertical axis, and having a small space between them. The smaller one is closed at the bottom, and the other has a hole in the middle of its base. The bottoms of the two are separated by partitions reaching from the circumference to the center, but the ring-like space between the cylinders is open. If water be turned into this space horizontally to the surface of the cylinders, they begin to revolve by friction, which motion is increased by the water in revolution acting on the radial partitions in the base. It is found that nearly three quarters of the hydraulic power can thus be utilized.

DANA PROJECTILE.—This projectile consists of a cast-iron body having a conical base, to which is attached a cup-shaped ring of brass. Upon discharge,



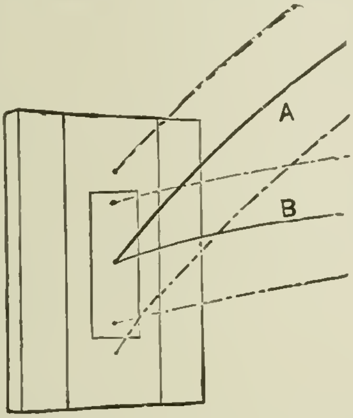
the ring is driven forward upon the base, and by this movement the soft metal expanded into the grooves and rotation communicated to the projectile. As the front end of the sabot passes the shoulder it is crowded down into the groove cut round the body of the shot, and thus "clinched," as it were. The same end is sought in the arrangement at the bottom of the sabot, where the gas, acting in the cannelure, presses the lip into the groove cut in the cast-iron. Such is the provision designed to secure the sabot from stripping. Turning upon the projectile is prevented by wedge-shaped projections and recesses upon the base of the projectile and the under surface of the sabot. See *Expanding Projectiles.*



Dancette.

DANCETTE.—One of the lines of partition in Heraldry, which differs from indented only in the greater size of the notches. The indentations where the division is *per fess* dancette never exceed three in number. See *Heraldry.*

DANGEROUS SPACE.—That zone, partly before and partly beyond the object fired at (the sights having been correctly elevated), which is *covered* by the trajectory. The object may be displaced to the front or rear of its correct range-point a distance equal, in the aggregate, to the depth of this zone, and still be hit by the projectile. The *dangerous space* will, of course, be increased by the firer lying down and aiming at his adversary's feet. A part of the *dangerous space* is near the muzzle of the gun in the rising branch of the trajectory; the rest of it is in the falling branch. These two parts are continuous up to and including the *battle-range*. The *dangerous space* varies considerably with the weapon used. It is readily seen in the drawing how, with



an equal divergence of the bullets in both cases, those having flat trajectories hit the target, while those having highly-curved trajectories miss it, the one striking above and the other below it. It also varies with the object fired at, and for the same arm diminishes as the range increases beyond *battle-range;* up to this point it increases with the range.

The *dangerous spaces* corresponding to different distances are generally for a height of 63 inches for a foot-soldier and 8 feet 2½ inches for a mounted man. The following table shows the *dangerous spaces* for both a foot-soldier and a cavalryman, corresponding to the different graduations of the rear sights of the muskets of different nations:

DANIELL BATTERY.—A constant battery, much used in mining operations. The containing vessel of the Daniell cell is of copper, which serves likewise as the negative element of the pair. Inside of this is another vessel of porous unglazed earthenware containing a rod of zinc. The space between the copper and the porous cell is filled with a solution of the sulphate of copper, which is kept concentrated by crystals of the salt lying on a projecting shelf, near the surface of the solution, and dilute sulphuric acid is placed with the zinc in the porous cell. When a tangent galvanometer is included in the circuit, the needle keeps steadily at the same point for hours. The rationale of its action is given as follows: The porous cell which keeps the fluids from mingling does not hinder the passage of the current; when the atoms of hydrogen that would ultimately be freed at the copper reach the porous cell, they displace the copper in the sulphate of copper, and copper instead of hydrogen is thrown on the copper plate. To give a graphic representation of this action, it is necessary to suppose that the sulphate of copper is $CuSO_4$, the direct combination of the metal (Cu) with a salt radical (SO_4) called sulphion, and that the dissolution of the zinc arises from the decomposition of sulphuric acid, regarded as the sulphionide of hydrogen (H_2SO_4), the SO_4 directly attacking the metal. This view of the composition of oxygen salts, though new in Daniell's time, is now universally admitted. Taking these letters to represent the molecules, and beginning with the copper (Cu) of the outer vessel, and ending with the zinc (Zn) of the rod, we have the arrangement before discharge, $Cu,\overline{CuSO_4}.\overline{CuSO_4}.^{cl}\overline{H_2SO_4}\ \overline{H_2SO_4}\ Zn$; and after it, $\overline{CuCu}\ \overline{SO_4Cu}\ \overline{SO_4}^{cl}H\ \overline{SO_4},H\ \overline{SO_4Zn}$. The discharge, therefore, effects a deposition of copper at the copper, and the formation of sulphionide of hydrogen at the porous cell, and of sulphionide of zinc at the zinc rod. Instead of hydrogen in its nascent state being deposited at the copper, we have copper in the same condition; but the galvanic polarization caused by the latter is very much inferior to that resulting from the former, and hence the superior electro-motive force of Daniell's cell. The porous cell keeps the sulphate of zinc from reaching the copper, and thus obviates another source of diminished force in the one-fluid battery. The sulphate of zinc once formed is itself subjected to the decomposing action of the pile, and zinc is deposited on the copper plate, thus tending to give a zinc-zinc instead of a copper-

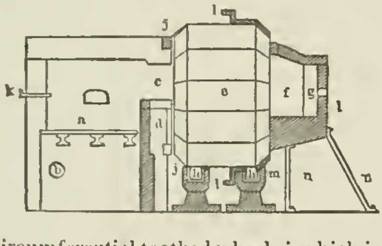
See *Battle-range.*

zinc pair. The constancy of Daniell's battery is not unlimited, for the sulphate of zinc which results from the action, being a bad conductor of electricity, enfeebles the current. In the Daniell cell used for telegraphs, the containing vessel is of glass, and no sulphuric acid is added to the water round the zinc, as, in the course of the action, sufficient acid comes through from the sulphate cell. See *Galvanism*.

DANK ROTARY FURNACE.—In order to lessen the great amount of labor involved in working the charge, various mechanical appliances have been proposed in substitution for manual puddling. They may be generally classified under two heads: namely, those imitating the motions of hand-stirring, and those using rotating or oscillating hearths. The drawing shows Dank's rotary furnace, which has a fire grate, *a*, like an ordinary puddling-furnace, with a blast, *b*, under the grate, and also, *k*, over the fire. The ash-pit and fire-hole are closed. The fire-bridge, *d*, is of iron, and has a water-pipe cast into it to cool it, and a lining of fire-brick next to the fire, and on top, and a covering of *fettling* next to the charge. A ring of hard metal is placed on the bridge-plate for the bearing of the chamber, and forms a butt-joint. The revolving chamber, *e*, is an open-ended cylinder, one end of which butts against the ring on the bridge, where the gases are admitted from the fire at *c;* and the other end serves as a door for the reception and removal of the charges, and also for the escape of the products of combustion. The chamber rests on rollers, *h h*, and



has a circumferential toothed wheel, *i*, which is geared to an engine. The chamber is lined with a mortar of pulverized ore and lime, which is laid on the inside quite thick and dried. The lining is completed by "fettling," which consists in charging a small quantity of fine ore and melting it while the chamber is revolving. When it is melted the revolution is stopped, and the molten metal settles in a pool at the bottom. Small and large lumps of ore are thrown into the pool, which is allowed to solidify. A fresh quantity of fine ore is again charged, and the process repeated, the chamber being stopped at a different place each time. This is continued until the whole chamber is lined with the ore, or "fettled," when it is ready for charging. At the opposite end or front of the furnace is a movable piece, *f g d*, which answers the purpose both of door and flue. It can be moved by means of suitable apparatus overhead, and when in its place the escaping gases pass through at *f* into the flue and chimney. When it is removed for the introduction or removal of the charge, the end of the chamber is open. The operation of the furnace is as follows: A quantity of mill-cinder is first charged, and on this the iron in a molten or heated condition. A partial rotation is given to the furnace from time to time to expose all portions of the charge to the action of the gases. When the whole of the charge is melted, the chamber is revolved once or twice a minute to obtain the most perfect action of the cinder on the iron. After five or ten minutes the iron begins to thicken, and the rotation is stopped. The heat is raised, and the cinder liquefies, and floats over the iron, containing all the impurities of the iron. The cinder is tapped off by the tap-hole, *m*, and the tap-hole closed. The heat is again raised, and the chamber revolved six or eight times a minute, by which means the charge is dashed about violently in the furnace. A high temperature being kept up, and the charge continually turned over, the particles begin to adhere when the rotations are reduced to two or three in a minute, and the ball speedily forms. The props, *n n*, of the movable piece are removed, and the flue and front of the furnace are moved away, and the ball withdrawn and carried to the hammer or squeezer, where it is formed into a *bloom*. See *Furnace*.

DANNEBROG.—An ancient battle-standard of the Danes, bearing the figures of a cross and crown, and alleged to have fallen from heaven at the battle of Volmar, 1219 A.D. Like the palladium, it was supposed to insure victory, but it was twice captured and twice retaken. The Order of the Dannebrog ranks second in the Danish orders of knighthood.

DANNEVIRKE.—A wall of defense against the Franks built by the Danes in 808 A.D., reaching from the North Sea to the Baltic. During the troubles of 1848 the line of the old wall was strongly fortified, but the works were destroyed in 1864.

DARA BOOKA.—A form of kettle-drum of ancient and modern Egypt, and the connecting-link between the *drum* proper and the *tambourine*. It is more generally called *tam-tam*. See *Tom-tom*.

DART.—A missile spear or javelin much in use among the ancients, and yet seen among many of the more barbarous nations. The Caffres of South Africa and the original inhabitants of Australia are very expert in the use of the *assegai*. The darts in use among the ancients were of two kinds, namely, spear-headed (that is, without barbs) and bearded. The former were often attached to a long cord, enabling the thrower to recover his weapon after having thrown it. Dart-heads are usually made of iron, but among savage nations flints, sea shells, fish-bones, and other hard substances have been employed; and among some of the aboriginal inhabitants of Africa and America the dart was merely a sharp-pointed stick, the end of which was carbonized by fire. The weapon is always very simple in its construction, and is usually from 3 to 5 feet long.

DATERAM.—The Bornu name for a most excellent African contrivance, used in some parts of the Sahara Desert, by means of which tent-ropes may be secured or horses picketed in sand of the driest description, as in that of a sand-dune, whence a tent-peg would be drawn out by a strain so slight as to be almost imperceptible. The plan is to tie to the end of the tent-rope or tether a small object of any description by its middle, as a short stick, a stone, a bundle of twigs, or a bag of sand, and to bury it from 1 to 2 feet in the loose sand. It will be found, if it has been buried 1 foot deep, that a strain equal to about 50 pounds weight is necessary to draw it up; if 1½ feet deep, that a much more considerable strain is necessary; and that if 2 feet deep, it is quite impossible for a single man to pull it up. Theoretically this is obvious; for, supposing the earth to consist of smooth, spherical grains of one size, and granting that these grains cannot move horizontally at the moment of drawing, and that they *must* move vertically upwards, it is plain that the substance attached to the rope when moved upwards must start before it an inverted pyramidal pile of grains. Take the most unfavorable case, supposing it to be a triangular pile; then the number of grains to be started (and consequently their weight) varies as $\frac{n(n+1)(n+2)}{1 \,.\, 2 \,.\, 3}$, or in a ratio greater than n^3 (n being the number of layers of grains above). In practice the grains of sand are capable of a small but variable amount of lateral displacement, which gives relief to the movement of sand caused by the *dateram*. On the other hand, the friction of the grains of sand tends to increase the difficulty of movement. Of course the resistance varies under different circumstances; but it is no exaggeration to estimate its increase as seldom less than as the square of the depth.

DAUPHINS.—Ornamental handles on brass guns over the trunnions, so called from their resemblance to the fish of that name.

DAUPHIN'S CROWN.—A circle of gold set round with eight fleurs-de-lis, closed at the top with four dolphins, their tails conjoined in a fleur-de-lis.

DAWK.—A method of traveling in India which consists in posting by palanquin from station to station, or for any distance. The traveler must first purchase a strong palanquin, which he can have for from 40 to 100 rupees (£4 to £10), but which he can always dispose of when his journey has been completed, and generally at a profit. His clothes, together with whatever articles he may not immediately need, are carried in tin boxes or wicker baskets called *pettarahs*, by separate bearers, who precede or accompany the palanquin; whatever he considers necessary, however, he keeps beside himself inside. At all the stages, which are from 9 to 11 miles apart, there are relays of bearers, previously provided by the Postmaster, the usual number for one palanquin being eleven. All arrangements as to cost are made with the Postmaster of each presidency before starting, but the traveler is also expected to give some small sum to his bearers at the end of each stage: eight annas (one shilling) among the entire set of bearers is as much as is expected in the way of gratuity. The horse-dawk, a kind of carriage with seats for four, and capable of being used as a bed in which two can sleep, the baggage being conveyed on the top, set on wheels, and drawn by horses, is in use on the great trunk road from Calcutta to the upper provinces, but has not been established throughout the country generally Frequently written *Dak*.

DAY.—Originally the space of time during which it is light, in opposition to the space of darkness or night; it now more usually denotes a complete alternation of light and darkness. It is the earth's rotation that causes the vicissitude of day and night. The earth being a globe, only one half of it can be in the sun's light at once; to that half it is day, while the other half is in its own shadow, or in night. But by the earth's rotation the several portions of the surface have each their turn of light and of darkness. This happens because the position of the earth is such that the equator is on the whole presented towards the sun; had either pole been towards the sun, that hemisphere would have revolved in continual light, the other in continual darkness. One complete rotation of the earth does not make a day, in the usual sense. If the time is noted when a particular fixed star is exactly south or on the meridian, when the same star comes again to the meridian the next day, the earth has made exactly one rotation, and the time that has elapsed is called a *sidereal day*. This portion of time is always of the same length; for the motion of the earth on its axis is strictly uniform, and is, in fact, the only strictly uniform motion that nature presents us with. Sidereal time, or star-time, from its unvarying uniformity, is much used by astronomers. But the passage of a star across the meridian is not a conspicuous enough event for regulating the movements of men in general. It is not a complete rotation of the earth, but a complete alternation of light and darkness that constitutes their day. This, which is called the *civil* or the *solar* day, is measured between two meridian passages of the sun, and is about four minutes longer than the sidereal day. The cause of the greater length is this: When the earth has made one complete turn, so as to bring the meridian of the place to the same position among the fixed stars as when it was noon the day before, the sun has in the mean time (apparently) moved eastward nearly one degree among the stars, and it takes the earth about four minutes more to move round so as to overtake him. If this eastward motion of the sun were uniform, the length of the solar day would be as simple and as easily determined as that of the sidereal. But the ecliptic or sun's path crosses the earth's equator, and is therefore more oblique to the direction of the earth's rotation at one time than another; and besides, as the earth moves in her orbit with varying speed, the rate of the sun's apparent motion in the ecliptic, which is caused by that of the earth, must also vary. The consequence is that the length of the solar day is constantly fluctuating; and to get a fixed measure of solar time, astronomers have to imagine a sun moving uniformly in the celestial equator, and completing its circuit in the same time as the real sun. The time marked by this imaginary sun is called *mean solar time;* when the imaginary sun is on the meridian, it is *mean noon;* when the real sun is on the meridian, it is *apparent* noon. It is obvious that a sun-dial must show apparent time, while clocks and watches keep mean time. Only in four days of the year do these two kinds of time coincide. In the intervals the sun is always either too fast or too slow; and the difference is called *the equation of time*, because, when added to or subtracted from apparent time, it makes it equal to mean time. The mean solar day is divided into twenty-four hours, the hours into minutes and seconds. A sidereal day, we have seen, is shorter; its exact length is 23 hours, 56 minutes, 4 seconds of mean solar or common time. Astronomers divide the sidereal day also into twenty-four hours, which are of course shorter than common hours. In the course of a civil year of 365 days, the earth turns on its axis 366 times, or there are 366 sidereal days. Astronomers reckon the day as beginning at noon, and count the hours from 1 to 24. The civil day begins at midnight, and the hours are counted in two divisions of twelve each. The ecclesiastical day was reckoned from sunset to sunset. See *International Date-line*.

DAY-BOOK.—In the British service, a sort of private memorandum-book in which the Pay-sergeant enters all details of expenditure other than pay under each man's head. These entries are made at the moment, and afterwards transferred to the ledger.

DAY'S MARCH.—The length of a day's march for troops of any army depends, to a great extent, upon the condition of the roads, the supply of water, forage, etc.; also upon the advantages to be gained over the enemy. Under ordinary circumstances infantry should march from 15 to 20 miles a day, halting about 10 minutes every hour. Cavalry should march about 20 miles a day, and be kept at a walk, halting several times during the day. The march of artillery should be governed by the movements of the arms of the service to which it is assigned for duty.

DEAD-ANGLE.—Any ground over which the defenders' fire may pass, but so high above the assailant that he cannot be injured by it, is called a *dead-space*, or a *dead-angle*. Thus, in a redan or a lunette, if the enemy gets into the ditch, he is safe from any fire coming over the parapet. The ditch in each of these cases has the defect known as a dead-space. It was to remedy these defects, which exist in all works where the angles are all salients, that parts of a work were drawn back, or made to form re-entering angles, for the purpose of arranging lines from which direct fires could be brought to bear upon the ground not defended by the lines adjacent to it.

DEAD-HEAD.—1. An extra length of metal cast on the muzzle-end of a gun in order to contain the dross and porous metal which floats on the sounder metal beneath. When cooled and solid the *dead-head* is cut off. It is called also the *sprue*. 2. The tail-stock of a lathe containing both the *dead-spindle* and *back-center*. See *Lathe*.

DEAD-MARCH.—A piece of solemn music intended to be played as an accompaniment to a funeral procession.

DEAD-PAY.—Pay drawn for dead soldiers, whose names are kept on the rolls, and which is appropriated by dishonest officers.

DEAD-SHOT.—An unerring marksman: one whose scores are always high. The term is frequently applied to the best shot in a company or regiment.

DEAD-SPINDLE.—The non-rotating spindle in the *tail-stock* or *dead-head* of a lathe. See *Lathe*.

DEAN FIELD-GUN.—A 3½-inch bronze muzzle-loading field-piece, constructed on the plan of the 3½-

inch Rodman muzzle-loading rifle, model 1870. It is without preponderance. Its length and weight are very nearly the same as those of the light 12-pounder, and it is adapted to the same carriage. The main peculiarity in its construction consists in the application of Mr. Dean's patent process for condensing and hardening the metal of the bore. The rifling consists of seven lands and grooves each. The lands are .50 inch in width. The grooves are 1.07 inch in width and .075 inch in depth. The twist is uniform, making one turn in 12 feet. The vent is in the normal position, on the top of the gun. The gun was cast solid in a cast-iron flask or "chill" about 3½ inches thick, the interior surface being covered with a slight coating of clay and sand. The metal used consisted of three old bronze 6-pounders furnished by the Ordnance Department and a part of a bronze 12-pounder on hand at the foundry. At the second casting the metal of the rejected piece was returned to the furnace, with the exception of a section reserved for tests, and another part of the 12-pounder was added to supply the deficiency. The weight of the charge of metal was 3364 pounds, the time of melting 1 hour 50 minutes, and time of fusion 1 hour 10 minutes. The gun was removed from the flask 18 hours after casting, and when thoroughly cooled was placed in a lathe and the sinking-head cut off. It was next bored out in a boring-machine to a diameter of 3.37 inches.

To condense the metal of the bore the gun was then inclosed in the iron flask in which it was cast, and was placed in the condensing-machine and firmly secured by heavy iron rods. Six mandrels, varying in diameter from 3.42 inches to 3.50 inches, were used in the operation. These, by means of a hydraulic press of 10-inch bore, were in the order of their size successively forced down the bore of the piece and withdrawn, and the operation was repeated until the most of the resilience of the metal had been overcome and the bore enlarged to very nearly 3.50 inches in diameter. The pressures used varied from 500 to 2400 pounds per square inch—making a total pressure of from 19½ to 94 tons. After condensing the bore the gun was removed to the rifling-machine and rifled, the grooves being planed out to a little less than the required depth. It was then put back in the condensing-machine and the bore still further enlarged by means of an expanding mandrel so constructed as to follow the opposite lands and grooves. On account of a slight error in the width of the rifling-tool, the grooves were left too narrow for the ribs of the mandrel, and consequently the edges of the lands were slightly abraded in the operation. A little grinding with fine emery removed much of the rough edge left upon the lands, but did not wholly restore the smoothness desired. In this connection it should be stated that the condensing process was only applied to the cylindrical portion of the bore, and consequently the metal at the bottom was left in its ordinary condition. The gun was next turned down in lathes to its prescribed exterior dimensions and a copper vent-piece inserted. The following are the principal dimensions of the gun:

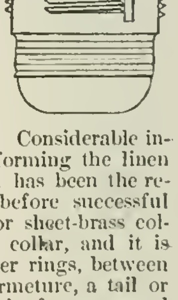
	Inches.
Exterior diameter at the muzzle	6.70
Exterior diameter 62 inches from muzzle (maximum)	11.22
Exterior diameter 65 inches from muzzle	11.05
Diameter of knob of cascabel	3.75
Diameter of trunnions	4.2
Diameter of rimbases	5.68
Length of trunnions, right	3.23
Length of trunnions, left	3.24
Distance between rimbases	11.050
Width of grooves	1.07
Depth of grooves	.075
Width of lands	.5
Twist of rifling	144
Length of bore	65.03
Length of rifling	60.378
Axis of vent from bottom of bore	1.46
Total length of piece	73.86

Weight, 1322 pounds.

See *Bronze Guns* and *Ordnance*.

DEAN MAGAZINE-GUN.—The breech-block of this gun is operated by a small lever, through the intervention of two links, the latter of which causes the recoil-block to descend while the former forces the breech-block to the rear, when the lever is thrown to the front. The lock is of the usual outside pattern and needs no extended description. Two magazines are provided, one in the butt and one in the tip-stock, either of which may be used by locking off, by means of a cut-off, the other. The carrier, which is open at both ends to receive cartridges from either magazine, has a vertical motion at right angles to the axis of the piece. It is operated by the lever in the same general manner as the Winchester repeater, so well known in this country. This gun carries ten cartridges in the tip-stock magazine, six in the butt-stock, and one in the chamber. See *Magazine gun*.

DE BANGE FERMETURE.—This fermeture is noticed at length in the article SCHULTZ WIRE GUN, and only a general description of the mode of checking the escape of gas is intended to be given in this connection. Its general features are shown in the drawing. It recommends itself prominently by effectiveness, its extreme simplicity,



and its not requiring the surface of the bore to be recessed. Its success has warranted its adoption in the land-service of France, and it is applied to all calibers. The gas-check is composed of a fillet or collar made of a linen-cloth disk with a proper-sized circular hole, central with the circumference, set up into the form of a collar to receive its filling. This latter consists of a mixture of two thirds of shredded asbestos and one third of mutton-suet, packed into the collar, which is then closed and completed by a seam formed on the inside surface of the body. Any seams outside would be fatal to the construction. Considerable ingenuity has to be exercised in so forming the linen disk; and the present arrangement has been the result of considerable experiment before successful results were secured. Two zinc or sheet-brass collars cover at top and bottom this collar, and it is placed, in addition with two copper rings, between the rondelle and the face of the fermeture, a tail or rod to the rondelle passing through the fermeture and being keyed to keep the system in position in the block. The vent, lined with copper, finds place in the axis of the breech-block, thus affording central fire. See *Broadwell Ring* and *Schultz Wire Gun*.

DEBLAI.—In fortification, any hollow space or excavation in the ground made during the construction of fortifications or siege-works. The cavity itself is the *deblai*, while the earth taken from it is called the *remblai*.

DEBOUCHING.—In military tactics or evolutions, the marching out of a body of troops from a wood, defile, or other confined spot into open ground.

Debruised.

DEBRIS.—Ruins of a building or town which has been sacked; the broken remains of an army after a defeat.

DEBRUISED.—A term peculiar to English Heraldry, used to indicate the grievous restraint of an animal, and its being debarred of its natural freedom by having any of the ordinaries laid over it. See *Heraldry*.

DECAGON.—In fortification and plane geometry, a figure of ten sides. When the sides are equal, the figure is called a regular decagon. A decagon may be formed from a pentagon by forming any irregular triangles on its sides in such a way that no two of them shall have their sides in the same straight line. A regular decagon is got from a regular pentagon by describing a circle round the latter, bisecting the arcs between its angular points, and drawing lines joining the angular points to the points of section.

DECAMP.—To quit any place or position in an unexpected manner. It likewise signifies to march an army or body of men from the ground where it before lay encamped.

DECANUS.—In Roman military history, a petty officer who presided over the ten soldiers of his contubernium, or those living in the same tent.

DECARBONIZED STEEL.—Since 1873 all small-arm barrels turned out at the National Armory have been made of decarbonized steel (Bessemer), and about one in six hundred only have been found to burst in proof. The principal defects of decarbonized steel as a material for gun-barrels are fine seams running in the direction of the length of the barrel. These seams are sometimes so fine as to escape the numerous inspections to which the barrels are subjected in the course of manufacture, and are only detected by the browning process. Though such barrels have strength to resist the proof-firing, they are rejected for service. A good decarbonized steel for rifle or carbine barrels has sufficient strength to resist a charge composed of one proof-bullet and sufficient musket-powder to fill the bore to the muzzle. A wrought-iron rifle or carbine barrel will only endure about one half of this charge. The breech-loading system after it is finished and assembled to the barrel is subjected to a "finished-proof" charge of a single service-bullet and a charge of 85 grains of musket-powder, which is all that can be crowded into the cartridge-shell. Numerous trials have shown that the Springfield system will stand at least 120 grains of powder and three service-bullets, weighing altogether 1265 grains. The fact that a small-arm barrel seldom or never bursts or swells at the muzzle in proof shows conclusively that when such defects are found in service the cause is some obstruction in the bore. Obstructions arise generally from the improper stopping up of the muzzle to keep out moisture. It may arise from dirt introduced by resting the muzzle of the piece on the ground. Instances have occurred of the bursting of service-barrels by a bullet in the bore—the result of a charge insufficient to expel it. Very accurate and delicate machines are now used to weigh each finished cartridge and reject any that may be deficient in powder. The barrel of a rifle will endure at least 10,000 service-fires before its accuracy is sensibly impaired; and its exterior dimensions may be very much reduced by wear without impairing its strength for service. See *Small-arms* and *Steel*.

DECEASED OFFICERS AND SOLDIERS.—In the United States service, the death of an officer, with cause, date, and place, is reported without delay by his immediate Commander direct to the Adjutant General. When the death occurs away from the officer's station, in hospital or on leave, it is the duty of the Army Medical Officer, if there be one in charge, or of any officer having cognizance of the fact, to make the report. A duplicate of the report is sent to Department Headquarters. Inventories of the effects of deceased officers, as required by the 125th Article of War, are transmitted to the Adjutant General of the Army. If legal representatives take possession of the effects, it is so stated on the inventory and the report of death. If there be no legal representative present to receive the effects, a list of them is sent to the nearest relative of the deceased officer. At the end of two months, if not called for, they are sold at auction and accounted for as in the case of deceased soldiers; except that swords, watches, trinkets, and such articles are labeled with the name, rank, regiment, and date of death of the owner, and sent through the Adjutant General to the Second Auditor of the Treasury for the heirs. On the death of any officer in charge of public property or money, the Commanding Officer appoints a Board of Survey to take an inventory of the same, which he forwards to the proper Bureau of the War Department; and he designates an officer to take charge of the said property or money till orders in the case are received from the proper authority. Funeral expenses of officers who die at a military post or station are ordinarily not a proper charge against the Appropriations for the Army. Expenses "of the interment of officers killed in action, or who die when on duty in the field, or at posts on the frontiers, or when traveling on orders," may, under certain circumstances, be ordered paid by the Secretary of War. But, except when emergency requires that the Commanding Officer of the Department or District shall order the body to be transported from the battle-field to a suitable place of interment at the nearest town, post, or station, before the approval of the Secretary can be obtained, such approval must be had in advance. No accounts are paid for any such expenditure until the approval of the Secretary of War in writing is obtained. The unclaimed remains of officers or soldiers who may die at temporary camps, or on detached service, are decently inclosed in coffins and transported by the Quartermaster's Department for burial at the nearest military post or national cemetery, unless the Commanding Officer deem burial at the place of death to be proper.

Inventories of the effects of deceased soldiers required by the 126th Article of War are prepared in triplicate, two copies to be forwarded to the Adjutant General by the Commanding Officer of the company to which the deceased belonged, together with final statements of pay, clothing, etc.; the other copy to be retained with the company records. Each inventory is indorsed, "Inventory of the effects of ——— ———, late of company (—), ——— regiment of ———, who died at ———, the ——— day of ———, 18—." When a soldier, absent from his company, dies at any post or station, it is the duty of his immediate Commander to furnish direct to the Adjutant General the required inventories and final statements, and at the same time to forward to the Commanding Officer of the company to which deceased belonged a report of his death, specifying the date, place, and cause; to what time he was last paid, and the money or other effects in his possession at the time of his decease; and if a legal representative receive the effects, it is so stated in the report. If the soldier leave no effects, that fact is reported. This report is noted on the next muster-roll of his company. Should the effects of a deceased soldier not be administered upon within a short period after his decease, they are disposed of by a Council of Administration, under the authority of the Commanding Officer of the post, and the proceeds deposited with a Paymaster to the credit of the United States until they are claimed by the legal representatives of the deceased. In all such cases of sales by the Council of Administration a statement in detail or account of the proceeds, duly certified by the Council and Commanding Officer, accompanied by the Paymaster's receipt for the proceeds, are forwarded by the Commanding Officer to the Adjutant General. The statement is indorsed, "Report of the proceeds of the effects of ——— ———, late of company (—), ——— regiment of ———, who died at ———, the ——— day of ———, 18—." The effects in all cases are turned over, when called for, to the legal representatives without further authority from the Adjutant General. When the effects are turned over to the relatives of the deceased, before these inventories are sent to the Adjutant General, their receipts therefor are attached to the inventories. In all other cases one copy of the receipt is sent with a letter of transmittal to the Adjutant General, and a duplicate retained with the company. Receipts in duplicate are taken from the Paymaster for funds turned over to him—one copy to be sent direct to the Adjutant General, and one retained with the company.

DECHARGEURS.—Men appointed to attend the park of artillery, and to assist the non-commissioned officers, etc., who are employed on that service. It is the duty of the former to keep a specific account of articles received and consumed, in order to enable the latter to furnish their officers with accurate statements.

DECIMATION.—A military punishment, rarely inflicted in the present day. When a considerable body of troops committed some grave military offense, which would be punished with death if committed by an individual, the punishment was awarded to one tenth of them by lot, instead of to the whole number, in order that the army might not be too much weakened.

DECISIONS.—In Courts-Martial, the majority of the votes decides all questions as to the admission or rejection of evidence, and on other points involving law or custom. If equally divided, the doubt is in favor of the prisoner or accused.

DECLARATION OF INDEPENDENCE.—The American Declaration of Independence was agreed upon July 4, 1776, by the thirteen American Colonies then in revolt against England. Its history is brief but important. Early in 1776 the Delegates in Congress from Massachusetts were directed to vote for independence of England. Soon afterwards several other Colonies sent similar instructions. Washington wrote: "A reconciliation with Great Britain is impossible. When I took command of the army I abhorred the idea of independence; but I am now fully satisfied that nothing else will save us." Pennsylvania and New York were the last to acquiesce in the demand for a declaration. The tenor of these instructions to the Delegates from their constituents was in favor of cutting loose from Great Britain entirely and forming an independent government. June 7, 1776, Richard Henry Lee moved in Congress that "These United Colonies are and of right ought to be free and independent States." Four days later the motion was adopted, and two Committees were raised to present a Declaration and the Plan of a Confederation. On the Declaration Committee were Jefferson, Franklin, John Adams, and Roger Sherman. They reported June 28, but action was delayed, as the New York and Pennsylvania Delegates, having received no special instruction, thought they had no authority to vote for the Declaration. The Declaration of Independence was drafted by Thomas Jefferson, and but very slightly changed from his copy. When it came up for final action it received the vote of every Delegate. The vote was taken by Colonies, and every Colony gave unanimous approval. It was immediately signed by the names of 56 members present, and as soon as the slow means of printing and circulating in those days could spread it, it went forth not only as the defiant answer of the Colonies to the demands of the mother-country, but as a claim for the political emancipation of mankind. It ought to be known by heart by every boy and girl in America. Not many years ago the reading in full of the Declaration of Independence was considered as necessary in any social celebration of the 4th of July as a prayer in religious services; but in these days, partly from carelessness, but more from the large infusion of foreigners whose habits and ideas have greatly modified the primitive notions of our own people, the custom has fallen into disuse.

DECLARATION OF WAR.—The formal announcement by a government of its intention to wage war against another is a proceeding which is observed among all civilized nations. In the United States the declaration of war is a power exercised by Congress alone. During the Age of Chivalry, a Herald made declaration of war at the enemy's Court, his tabard on his arm.

DECLINATION-NEEDLE. — When a magnetic needle is suspended or made to rest on a point so as to be free to move in a horizontal plane, it finds its position of rest in a line joining two fixed points on the horizon; and when made to leave that position, after several oscillations, it returns to it again. At certain places on the earth's surface these two points are the north and south points of the horizon; but generally, though near, they do not coincide with these. A vertical plane passing through the points on the horizon indicated by the needle is called the magnetic meridian, in the same way that a similar plane, passing through the north and south points, is known as the astronomical meridian of the place. The angle between the magnetic and astronomical meridian is termed the declination or variation of the needle. The declination is east or west according as the magnetic north lies east or west of the true north. Instruments for determining magnetic declination are called declination-needles, or declinometers. In this instrument there are two things essential—the means of ascertaining the astronomical meridian, and a needle for showing the magnetic meridian. The common form of declinometer consists of a tripod provided with leveling-screws, and supporting a pillar, to which is fixed a graduated azimuthal circle. A compass-box, with vernier attached, moves on the azimuthal circle by means of a pivot at the top of the pillar. Two uprights are fixed to the side of the compass-box, on which rests the axis of a telescope. A graduated arc is fixed to the bottom of one of the uprights, and the angle of elevation of the telescope is marked by a vernier on the arm attached to the axis of the telescope. A level is also hung on the axis of the telescope for adjusting the instrument. Inside the compass-box is another graduated circle, the line joining the zero-points of which is parallel to the axis of the telescope. All the fittings are in brass or copper, iron, of course, being unsuitable. The compass-box and telescope move round as one piece on an axis passing through the center of the azimuthal circle. When an observation is made, the telescope is pointed to a star whose position with regard to the astronomical meridian is known at the time of observation. The telescope with the compass-box is then brought the proper number of degrees on the azimuthal circle, until its axis is in the meridian of the place. If, when the telescope is in this position, the north end of the needle stand at the zero-point of the inner circle, the declination would be 0 ; but if it lie east or west of this point, the declination is shown by the degree at which the needle stands. It is difficult to construct a needle so that the line joining its poles exactly coincides with the line joining its visible extremities. If this coincidence be not perfect, the geometrical axis of the needle according to which the reading is made lies to the right or left of the magnetic axis, and consequently of the true reading. To remedy this, the needle is so made that it can rest either on its lower or upper surface. In finding the true reading, the position of the needle is marked, and then it is turned upside down and again marked, the mean of the two readings giving the true one. The declination of the needle may be also ascertained by the dipping-needle. The ordinary compass which must be used by making allowance for declination is a declination-compass. See *Dipping-needle* and *Magnetism.*

DECOMPTE.—A liquidation or balance which from time to time was made, in the old French service, between the Captain of a company and each private soldier for money advanced or in hand.

DECORATION-DAY.—The anniversary, in the United States, on which flowers are placed on soldiers' graves, and which is observed on May 30th. This day was set apart for the purpose mentioned soon after the War of the Rebellion.

DECORATIONS.—In pyrotechny, the compositions which are placed in the heads of rockets, in paper shells, etc., to make a brilliant display when the receptacle is burst. See *Pyrotechny.*

DECOUPLE.—In Heraldry, a term signifying severed or disjoined, so that the ends stand at a distance from one another; as, a *chevron decouplé.*

DECOY.—To lead or to entice into a snare; to lead into danger by artifice; to entrap. An enemy is said to be decoyed when a small body of troops draws them into action, while the main body lies in ambush ready to act with the greatest effect.

DECREMENT.—An heraldic term by which the wane of the moon is indicated. A *moon decrescent* is a half-moon with her horns turned to the sinister. The terms *decrescent* and *decours* are likewise used.

DECURIO—DECURION.—A Roman cavalry officer, commanding ten men. Decuriones Municipales were Roman provincial magistrates who had the same power in free and corporate towns as the Senate had in Rome. At first numbering 10, as their name implies, they frequently numbered 100 in later times. Their duty was to watch over the interests of their fellow-citizens, and increase the revenues of the commonwealth. They were required to be 25 years of age, and to possess a certain income. The legion was officered by six *Tribunes*, sixty *Centurions*, with an equal number of officers who served as file-closers for the infantry; and twenty *Decurions* of cavalry; besides these there were the officers of the velites, who fought out of the ranks.

DEEP.—A term used in the disposition or the arrangement of soldiers placed in ranks before each other; hence two deep, three deep, etc. *Deep line of operations*, a long line.

DEFAULT.—The common expression for a military offense in the British service.

DEFAULTER-BOOK.—A book in which the record of crimes committed by soldiers is entered. There are two defaulter-books in a regiment, the *company* and the *regimental*. In the former all offenses of whatever description committed by non-commissioned officers and soldiers, whether punishment may have been awarded or not, and every act of drunkenness committed by a soldier, are inserted. Cases of absence, which may be considered equivalent to drunkenness, are not to be so numbered, but in lieu thereof the letter D is to be inserted in *red ink* opposite every such case, by the officer commanding the company. All offenses are to be inserted in the officer's own handwriting. In the latter, or regimental defaulter-book, all punishments awarded by the Commanding Officer of the regiment, or by Courts-Martial, are inserted. In this book also all offenses are to be entered for which a punishment exceeding seven days' confinement to barracks has been awarded.

DEFAULTERS.—1. Soldiers who have been guilty of military offenses. The term is generally applied to men sentenced to confinement to barracks, and attaches to them until the completion of their punishment. 2. If any officer employed or who has heretofore been employed in the Civil, Military, or Naval Departments of the Government to disburse the public money appropriated for the service of those Departments, respectively, shall fail to render his account or pay over, in the manner and in the times required by law, or the regulations of the Department to which he is accountable, any sum of money remaining in the hands of such officer, the First or Second Comptroller of the Treasury, as the case may be, shall cause to be stated and certify the account of such delinquent officer to the Solicitor of the Treasury, who shall immediately proceed to issue a warrant of distress against such delinquent officer and his sureties, directed to the Marshal or Marshals of the district or districts where they reside; and the Marshal shall proceed to levy and collect the sum remaining due by distress and sale of goods and chattels of such delinquent officer; and, if the goods are not sufficient, the same may be levied upon the person of such officer, who may be committed to prison, there to remain until discharged by due course of law. But the Solicitor of the Treasury, with the approbation of the Secretary of the Treasury, may postpone for a reasonable time such proceedings where, in his opinion, the public interest will sustain no injury by such postponement. If any person shall consider himself aggrieved by any warrant issued as above, he may prefer a bill of complaint to any District Judge of the United States, and thereupon the Judge may, if in his opinion the case requires it, grant an injunction to stay proceedings. If any person shall consider himself aggrieved by the decision of such Judge either in refusing to issue the injunction, or, if granted, on its dissolution, such person may lay a copy of the proceedings had before the District Judge, before a Judge of the Supreme Court, who may either grant the injunction or permit an appeal, as the case may be if, in his opinion, the equity of the case requires it. The judgment on a warrant of distress under this Act, and the proceedings under the judgment, are a bar to any subsequent action for the same cause. No money appropriated shall be paid to any person for his compensation who is in arrears to the United States, until such person shall have accounted for and paid into the Treasury all sums for which he may be liable: provided, that nothing herein contained shall be construed to extend to balances arising solely from depreciation of treasury notes received by such person to be expended in the public service; but in all cases where the pay or salary of any person is withheld, in pursuance of this Act, it shall be the duty of the Accounting Officers, if demanded by the party, his agent or attorney, to report forthwith to the agent of the Treasury Department the balance due; and it shall be the duty of the said agent, within sixty days thereafter, to order suit to be commenced against such delinquent and his sureties.

DEFEAT.—The rout or destruction of an army by an enemy. Strictly the word expresses the complete want of success of an army; a repulse signifying less, and a rout more, than defeat. It is also used to mean resistance with success; as, to defeat an assault.

DEFECTION.—The act of abandoning a person or cause to which one is bound by allegiance or duty, or to which one has attached himself. See *Abandon*.

DEFENCE—DEFENSE.—1. In military law, the defendant's answer to the plea, or the method of proceeding adopted by the defendant to protect himself against the plaintiff's action.

In point both of law and reason, a Court-Martial has as much power over the evidence introduced by the prisoner as over that of the prosecutor, and can reject the witnesses of the one as well as the other, or any part of such witnesses' testimony. Courts-Martial are particularly guarded in adhering to the custom which obtains of resisting every attempt on the part of counsel to address them; but cases have occurred in which professional gentlemen in attendance have been permitted to read the defense prepared for the prisoner. A Court will prevent a prisoner from adverting to parties not before the Court, or only alluded to in evidence, further than may be actually necessary. All coarse and insulting language should be avoided in any part of the defense.

2. In fortification, all sorts of works that cover and defend the opposite posts. The parapets of all coast and harbor defenses should be constructed of earth, where favorable sites can be found; but for low sites that can be approached within grape-shot range such batteries must give place to masonry defenses; and where masonry-casemated castles with three tiers of guns in casemates, and with guns and mortars on the roofs, are resorted to, embrasures of wrought-iron will be found applicable. With such batteries well constructed, the direct fire of ships has little effect. Movable columns of troops in numbers, depending on the probable object of the enemy, must be held in some central position. If railroads are to convey the troops, a central point within a radius of sixty miles will be within good supporting distance. If railroads are not relied on, the distance should not be greater than fifteen miles. The columns should be at least seven tenths infantry, one tenth cavalry, and two tenths field-artillery; the latter being useful to oppose the debarkation of troops. The French charge both the fleet and the army with the movable defense of coasts. Steamers and flotillas, armed with howitzers, are particularly suited to that object. Corps of troops assembled at some central position are held ready to be thrown upon a threatened point. Batteries of howitzers give

their aid to these corps. Concerted signals are carefully arranged.

The defense of works attacked by regular approaches calls for the most active and vigilant exertions on the part of the besieged, especially so from the artillery. So soon as the operations of the besieger indicate what work of a line, or the particular part of a work, is his objective, every effort must be made to restrict the extent of his lines of envelopment. To this end, adjacent and collateral works must be armed with pieces of the heaviest caliber, so situated as to take the lines of approaches as much as possible in flank. These batteries will give special attention to the long-range batteries of the besiegers. Every available piece of artillery must be brought forward and placed in battery so as to strike the besiegers at some point or other. Unremitted fire must be maintained against the heads of the approaches; these, from their open character, are peculiarly vulnerable to mortar-fire. As many mortars as possible should be placed in batteries established for this special purpose. It is not advisable to crowd artillery into the objective point of the enemy, but rather to the right and left of it; this secures a cross-fire, and at the same time withdraws the pieces from the points upon which the besieger concentrates his fire. If an assault is to be apprehended, batteries, especially of machine-guns, should be established so as to sweep the ditch and prevent the enemy from making a lodgment by digging into the scarp and parapet. These batteries must be well secured by means of bomb-proof covers and gun-shields. Traverses must be thrown up to protect the guns, and bomb- and splinter-proofs constructed to shelter the cannoneers. An interior line of intrenchments should be constructed in rear of that part of the main work attacked. This should be well supplied with light pieces of artillery, which may be kept under cover until the proper moment and then run up to drive the enemy from his lodgment on the main work. The supply of ammunition must be closely attended to, and under no circumstances, where it is possible to avoid it, should it be allowed to fall below the probable needs. All of the operations of the artillery in the defense, as well as in the attack, should be directed by one head. See *Harbor Defenses.*

DEFENSIVE BATTLE.—In a purely defensive battle, an army chooses a position in which to await the enemy and there to give battle with no other end in view than to hold this position and repulse the enemy. The fact that a party acts on the defensive supposes something wanting either in the numbers or efficiency of his troops; either of which defects can only be remedied by resorting to aids, offered either by nature or art, for restoring the equilibrium between the opposing forces. There is one point that needs to be strongly inculcated, which is that a position should not only be strong tactically, but good strategically. It should not only lend itself to the maneuvers of our troops and to the efficacy of their fire; but, if forced, should favor a safe retreat. The advantages offered by heights for the defensive may induce into serious disaster a General who takes a position of this kind from purely tactical considerations, without regard to their strategical bearing; or, when this latter consideration does not come up, who looks simply at the defensive properties without examining also the advantages that a skillful enemy, operating offensively, might derive from them.

Suppose an army to occupy a ridge of heights, crossing obliquely its line of retreat; its right resting on an inaccessible obstacle. Now, an army advancing to the assault of this position might look upon it in two aspects. First, strategically, seeing that by making the attack on the right, although the ground there is the most difficult, it will force the assailed back, so as to expose his line of retreat, and may therefore be well worth the effort and cost. Second, tactically, to assail vigorously the more exposed left wing, and, throwing it back on the right, necessarily produce a disaster; as the character of the ground, a narrow plateau, is supposed to be such that it will not admit of a change of position of the assailed to meet this attack in front. However otherwise advantageous, it would evidently be imprudent then for a General to take up a position of this kind, unless so superior to the enemy that he will be able to foil an attack on either wing. There remains, however, one more resource to the General, in a similar case, when he has ample time to employ it, and that is fortification. This is one that every great General has, at one time or another, availed himself of, and, in every case, with advantage. Military history is full of examples where the scale of great and decisive battles has turned on the taking or holding a mere field-work that had occupied but a few hours' time to throw up. This, however, belongs to the domain of fortification, one of the most difficult as most important branches of the military art, and which demands for its proper exercise military qualifications of a high order. There probably has existed no great engineer who, when called upon, has not shown himself a superior General; nor a great General who did not fully acknowledge and appreciate the art of fortification.

Where an army is forced to accept a defensive battle in an open position, which affords no points on which its flanks can rest with security, there is but one disposition of combat open to it, and that is to secure the wings by such an accumulation and distribution of troops upon them that the assailant will run a greater risk in an attack on one of them than on the front. The center in this case will be deployed in the first line, so as to bring all its fire to bear, both direct and cross, over the approaches to it. The troops to support the wings will be massed, so as to be ready to act promptly, as the phases of the action may demand; and the reserve will occupy a central position in the rear, from which it can promptly be thrown upon any point pressed by the assailant.

It is in such positions that the formation of the order of battle by squares is resorted to when the assailant is very superior in cavalry. This is done either by a formation of small squares by single battalions, or by resorting to larger ones, as to those formed of four or more battalions. The first have the advantage of being very promptly formed, but they afford hardly more interior space than is wanted for their own staff, leaving whatever cavalry and artillery we have to find shelter between the squares. The large squares demand more complication of maneuver, and more time in their formation, but afford a large interior space, where the caissons of the artillery, and even the cavalry, if in small numbers, may find shelter. In this last disposition some of the artillery would be in battery in front of those angles of the squares where its fires can best sweep the approaches on the two adjacent sides of the square; other portions will be in the intervals of the squares, so as to throw a flank and cross fire over the approaches to them. The sharp-shooters may be advanced a little on those angles which are not occupied by the artillery so as to strengthen these weak points. The cavalry, if in sufficient force to charge opportunely, will take post between the squares, where it will be least exposed to the enemy's artillery, and be ready to seize the proper moment for entering into action. See *Battles, Mixed Battle,* and *Offensive Battle.*

DEFENSIVE PATROLS. — That class of patrols made with a view of insuring greater security from the enemy's attempts to pass or force the line of outposts. They consist usually of three or four men, who go the rounds, along the chain of sentinels and between the posts; seldom venturing farther than a few hundred paces beyond the sentinel's chain; the object being to search points which might present a cover to the enemy's scouts, and to keep the sentinels on the alert.

DEFENSIVE WAR.—A war undertaken to repel invasion or the attacks of an enemy. Defensive war may be divided into three kinds. It is either a war sustained by a nation which is suddenly attacked by another who is superior in troops and in means; or a nation makes this sort of war by choice on one side of its frontiers; or it is a war become defensive by the loss of a battle. See *War*.

DEFERRED PAY.—An increase of 2*d*. per diem granted by Parliament to the non-commissioned officers and soldiers of the British army and Reserve, under the following conditions: The 2*d*. per diem for the Army with the Colors to be payable on the discharge or death of every non-commissioned officer or man, in respect of all service (previously to the completion of 12 years' service) from April 1, 1876. The 2*d*. per diem for the Army Reserve to be paid annually in arrear to all men in it. Any sum earned by a man dying during the year to be paid to his representatives. £1 per man, now paid for necessaries, not to be payable to men accepting the new terms.

DEFILADING.—That part of the art of fortification which consists in determining the directions and heights of the lines of rampart, so that the interior may not be commanded by the fire of any works which the enemy may raise. Defilading is divided into horizontal and vertical. The object of the first is to prevent the lines being commanded in the direction of their length, or enfiladed; the prolongations of the lines, therefore, must avoid all points where hostile works could be erected. Vertical defilading determines the height of rampart necessary to protect the interior from direct fire. See *Defilement*.

DEFILE.—In a military sense, any narrow place the passage of which can be made by troops only when undeployed. Mountain-passes, river-crossings, narrow isthmuses, and roads through close forests represent the usual forms of defiles. They necessarily imply obstacles in the way to the free movement of armies, and are therefore important features in a theater of war, and consequently points demanding special attention by way of defensive arrangements. For these no precise rules can be laid down; nevertheless some general principles may be stated. The chief advantage offered by a defile is, that with but comparatively slight intrenchments a small force is able to hold a position against a much greater; this for the reason that, owing to the essential nature of a defile, the attacking force must operate in a constrained position, not admitting of much development of fire. The main object, therefore, is to secure such a column of fire over the defile as to make it impossible for the enemy to stem it; this is best accomplished by selecting such points as will give an enfilade fire. They should be selected with a view to mutual support, and intrenched in such manner as to be secure against capture by *coup de main*. The enemy must be compelled to make his attacks with divided forces and inferior numbers. This is best accomplished by occupying several positions within flanking distance of each other. He will, probably, not be able to attack all simultaneously, and it will be a costly operation for him to attack them in detail.

The positions should be so chosen as to allow them to concentrate their artillery-fire upon any point where it might be advantageous for the enemy to establish batteries, and the artillery of the defense should be of such power as to preclude all possibility of his doing so. All hollow approaches, such as would be formed by ravines in a mountain-pass, must be searched by the fire of artillery. This, as a rule, will require pieces to be placed in open batteries exterior to the inclosed works. Such batteries must be well supported by infantry sheltered in rifle-trenches. The whole system should be so connected as to leave no part isolated or without the support of other parts, and the defense of each point must be stubborn in the extreme to prevent the enemy from gaining possession of advantageous positions. All parts of the line or group of works must be in communication by telegraph, telephone, or signaling, or by all three. This is a matter of the greatest moment in securing not only the physical but also the moral support of the parts. In every case artillery should form a chief feature in the means of defense; the kind of pieces for the different parts of the system will depend upon the character of the ground and of the nature of the attacks that may be expected. As a rule, all approaches must be covered by fire; wherever horizontal fire cannot be made to reach, mortars must be used. However much the pieces may be scattered, they must be capable of concentrating their fire upon any position the enemy may assume.

If a defile is to be held for the purposes of an army either advancing or retiring in front of an enemy, the head of it towards the enemy must be secured by a line similar to a *tête-de-pont;* this for the purpose, if advancing, of giving room for the army to deploy after passing the defile, and to prevent the enemy from striking it while defenseless in column; if retreating, the same disposition is necessary to hold the pursuing army in check while the troops are defiling to the rear. In both cases, as the object is to keep the enemy from closing in for a pitched battle, artillery must be freely used. In the attack upon a defile, intrenched, armed, and defended as it should be, artillery will be the most important weapon; this for the reason that, from the very nature of defiles, other arms can act but feebly, while artillery possesses the power of reaching its object beyond intermediate obstacles. As much artillery should be brought to act as possible, and, although it may be widely dispersed, its fire must be concentrated upon some particular work in the system of defenses. The work must be attacked with such vigor and persistency as to insure its destruction and easy capture. Other works are successively attacked in the same manner. The operations upon both sides thus partake of the nature of a siege, and are governed by the same principles.

DEFILEMENT.—Where the site of a field-work is sensibly horizontal and there are no commanding points within cannon-range from which an assailant can get such a view into it as to regulate his fire with some certainty, there is no controlling motive for making the relief other than uniform; though it lessens, to some extent, the effects of an enfilading fire, by making a face higher at the salient, giving it a uniform slope back, as the higher the covering mass over which the fire of the assailant must pass to reach the interior of a work, the greater will be the portion of the work screened. The extent of the cover thus gained will depend upon the angle of elevation and the charges with which the assailant's fire is maintained. With great angles and heavy charges from considerable distances, and great angles and light charges when near to the work, the projectile may receive a great plunge in the descending branch of its trajectory, so as to fall quite close behind the covering object; but these great plunges are unfavorable to ricochet, so that if the assailant wishes to preserve this fire, which is generally regarded as the most effective in enfilading the interior of a parapet, he must sacrifice the effect of great plunges, and submit to the advantage of better cover which the assailed gains by raising his salients, or using traverses for the same end. When the site is not horizontal and there are commanding heights from which the interior of the work can be plunged into, by firing under small angles of depression, or ground lower than the work from which a reverse fire can be obtained, on the more elevated portions, over the parapet of the lower portions, the parts thus exposed must be screened either by raising the parapet to a suitable height, or by interposing a covering mass within the work for the same object. The operation by which this is effected is termed *defilement*, and when a work is thus screened it is said to be *defiled*.

Defilement is seldom practicable, nor in fact is it necessary for lines of any considerable extent. The most that can be attempted is so to vary the plan, when it can be done and not impair the efficiency of the fire of the different parts on the approaches, as to prevent the prolongation of any important face or flank from falling on any point where the assailed would have a commanding position to enfilade; rather giving those parts a direction such that their prolongation outwards shall fall on low ground, or on points inaccessible to the artillery of the assailed. No specific rules can be laid down further than of a general character. Taking, for example, a line of works to be thrown up within cannon-shot of a range of heights the crests of which lie in the same direction and are sensibly horizontal, the best cover that could be obtained in this case would be a simple right line of uniform relief, the direction of which should be parallel to that of the crests. If the site on which the line is placed is horizontal, by giving a good height to the parapet a sheltered zone for the troops and *matériel* of more or less extent will in this way be obtained. If the site slopes much from the range of heights, then the same height of parapet will mask a broader zone of shelter, and the more so as the declivity of the surface is the more decided. But if the site slopes towards the crests, then the difficulty of obtaining shelter will be the greater as this counter-slope is the greater. If instead of a right line a broken line is used, as a redan or a serrated line, then it will be well to make the face of each redan or tenaille as short as practicable, and to make the salient angles very obtuse. In this manner but short lines will be presented to an enfilading fire, and the prolongations of these lines be brought to intersect the crest of the range at more distant points, thus forcing the assailant to use higher angles of elevation to reach them from his enfilading position. When the line of the crests descends in a right line towards the site, then supposing the general direction of the parapet to be a right line, the most favorable position for the defilement, by a uniform relief given to the line, will be to give the line of the parapet a direction upon the point where the line of the crests prolonged would meet the site. The zone of shelter covered by the parapet in this case will be so much the greater, and the defilement the better, as the general direction of the parapet makes a greater angle with that of the crest. The same remarks apply to a sloping or counter-sloping site. As the position of the works become the less restricted, there will be freer play for the skill and eye of the engineer to obtain a good solution of the question. For works open at the gorge and inclosed works defilement becomes more important, as, the force being small, every means should be employed for its safety. In such works there is also much less freedom to vary the plans. The most that can be done is to avoid enfilading or reverse views, by opening more or less the salient angles so as to bring the more prominent dangerous points within the angle of the adjacent faces prolonged, or to bring those prolongations upon dangerous points as distant as practicable. In the first case a reverse fire on either face will be avoided, and in the second the enfilading position of the assailant will be thrown to a further distance. The *defilement* of field-works is not indispensable to a good defense; nor is it always practicable. It is, however, not only a conservative means, but it also inspires the assailed with confidence; for the soldier regards with much distrust the strength of his position when he finds himself exposed to the plain view of the enemy from an elevated point.

For the solution of all problems of the defilement of permanent works the engineer requires: 1. The limit exterior to the defenses beyond which the effect of the enemy's fire may be regarded as so uncertain as to be neglected. 2. The presumed positions within this limit that the enemy may take up to bring his artillery to bear upon the works. 3. An accurate topographical map of all the ground within the above limits, as given by its horizontal curves referred to a plane of comparison. 4. The magistrals and interior crests of the works, as either definitely or proximately arranged, referred to the same plane. The limits beyond which the enemy's fire, from the usual *smooth-bore siege-guns*, may be disregarded, owing to the uncertainty of long ranges, are 1500 yards, where the work is exposed only to a direct or front fire, and 2000 yards when open to a reverse fire. For *rifled guns*, which will hereafter be used in all siege-operations, these limits should embrace all the exterior ground within the accurate range of the heaviest guns of this class. When the terre-pleins, therefore, are covered, either by their parapets or other means, from batteries at these distances, they may be considered as offering shelters sufficiently secure for the troops, etc., upon them. It may happen that there are points beyond these limits, but within the extreme range of siege-guns, which, from their positions, it would not be safe to disregard; but these will form exceptional cases, and, when they occur, will be treated in the same manner as those within the limits. The surface of the site embraced within the exterior limits and the line of defenses may be divided into *three* zones; *one* lying between the limits and the position of the first parallel of the attack; the *second* between the positions of the first and second parallels; the *third* between the positions of the second and third parallels. In any position that the assailant can take up for his batteries, within the first zone, it is usually estimated that he will not throw up any parapet with a greater command than 10 feet over the ground on which it is placed. Granting this, the muzzles of his guns, behind the parapets, will not be raised higher than 6 feet above the natural surface; so that assuming the surface of this first zone to be raised 6 feet above its true position, this may be regarded as the limit, vertically, within which the assailant's lines of fire will be restricted; and therefore if the interior of the defenses is covered from the fire within this limit, the troops, etc., will be secure. That the assailant will not in all likelihood elevate his guns above this limit will seem probable, when it is taken into consideration that any advantage he might derive from doing so would not be commensurate with the labor it would cost him. For suppose the enemy to have taken up a position for an enfilading battery at 1000 yards from any salient, to enfilade one of its faces of the length of 100 yards, and that he should decide upon raising his guns 3 feet, or 1 yard, above the limit just laid down; a simple proportion will show that by this increase in the height of his battery he will be able to attain a point at the farther end of the face only 3.6 inches lower than he would have done in the position of the assigned limit—an advantage which, considering the uncertainty of the fire at the assumed ranges, would hardly compensate the additional labor of giving to his works the additional command. In the zone between the first and second parallels the limit may be reduced to 4½ feet; for at this distance from the defenses their fire is so destructive and certain that the enemy cannot, without great loss of life and time, raise the parapet of his batteries higher than 8 feet above the natural surface. From the third zone the musketry of the enemy may be brought to bear upon the defenses; and from this position, during sorties from the defenses, or at any other opportune moment when their fire is not active, the enemy might mount on the parapet of his trenches, and from there deliver his fire. This would bring his line of fire about 10 feet above the natural surface. The limit, vertically, of this zone may therefore be safely assumed at 10 feet above the natural surface.

In the defilement of each part separately of the line of defenses, those portions alone of these zones should be regarded as dangerous which are embraced within arcs, or other lines drawn at the foregoing distances from the salients, or the faces of the part to be defiled. It may also happen that, within the limits of dangerous ground for one portion of the line of defenses, there may be other portions which, from their position, may mask the portion to be defiled from all the dangerous points beyond them; in which case the points thus shut off need not be regarded, in effecting the operations of defilement. Within the limits of the zones of danger, positions may be determined for front, for reverse, and for enfilading fire. If the two faces, for example, of a work be prolonged to intersect the extreme limit of dangerous ground, the sector which they embrace may be termed *the limits of direct* or *front fire;* since, from every position that can be taken up within this sector, a direct fire alone can be brought to bear upon the two faces. The two sectors which lie adjacent to this may be termed *the limits of lateral* or *reverse fire*, since they afford positions from which a reverse fire can be obtained against one of the faces, and a front fire upon the other. It is also only within these last limits that positions for enfilading the terre-pleins of the faces can be obtained. The problems of defilement which present themselves for solution may embrace one or more of these cases in any example; depending upon the relative positions of the interior crest of the work to be defiled, and of the dangerous ground embraced within the foregoing limits. In the case of direct fire alone, the terre-pleins can be screened by their parapets. In that of a reverse fire on one face alone, its terre-plein, in some cases, may be screened by a suitable position assigned to the parapet of the other. Where both are exposed to this fire, one or more traverses must be resorted to as a screen. Against an enfilading fire on one face alone, a portion of the parapet of the other, near the salient, may be a sufficient protection in some cases; but, for the most part, traverses, placed across the terre-plein, will be the only remedy. See *Direct Defilement* and *Reverse Defilement.*

DEFLAGRATION.—A term applied to the rapid combustion of ignited charcoal when a nitrate (such as nitrate of potash) or a chlorate (such as chlorate of potash) is thrown thereon. As chlorates do not occur naturally, it follows that deflagration with a natural salt indicates a nitrate; and if the deflagration be accompanied by a violet flame, it is characteristic of nitrate of potash (ordinary niter or saltpeter); and if by a strong yellow flame, it is indicative of nitrate of soda (cubical niter).

DEFORMER.—In a military sense, this word signifies to break; as, *deformer une colonne,* to break a column.

DEGAT.—The laying waste an enemy's country, particularly in the neighborhood of a town which an army attempts to reduce by famine, or which refuses to pay military exactions.

DEGORGEOIR.—A sort of steel pricker used in examining the vent of a cannon; a priming-wire.

DEGRADATION.—In military life, the act of depriving an officer forever of his commission, rank, dignity, or degree of honor, and taking away at the same time every title, badge, or privilege he may possess.

DEGRADED.—A term in Heraldry signifying placed upon steps or degrees, as in a *cross Calvary.*

DEGREE OF LATITUDE.—A space along the meridian through which an observer must pass to alter his latitude by one degree—i.e., in order to see the same star one degree nearer to or further from the zenith. The space must be found by actual measurement; and owing to the earth being an oblate spheroid, and not a sphere, it varies with the place of observation—the degrees being generally longer towards the poles, where the earth is flatter, and shorter at the equator, where the earth is more curved. If the earth were a sphere, a degree would be exactly a 360th part of the meridian. As it is, the length of a degree of latitude depends on the latitude of the place. From a variety of observations conducted at various times and places, from as far back as the time of Eratosthenes (250 B.C.), tables have been constructed showing the length of degrees at different latitudes. The length of "the middle degree," as it is called, or that of places in latitude 45 , may be taken approximately at $69\frac{1}{10}$ English miles. The ascertained differences between degrees of latitude is one of the proofs of the earth's spheroidicity.

DEGREE OF LONGITUDE.—The space between two meridians that make an angle of 1 at the poles, measured by the arc of a circle parallel to the equator passing between them. It is clear that this space is greatest at the equator, and vanishes at the poles; and it can be shown that it varies with the cosine of the angle of latitude. The annexed table shows the lengths of a degree of longitude for places at every degree of latitude from 0° to 90 . It is computed on the supposition that the earth is a sphere.

Deg. lat.	English miles.	Deg. lat.	English miles.	Deg. lat.	English miles.	Deg. lat.	English miles.

DEHORS.—In the military art, all sorts of outworks in general, placed at some distance from the walls of a fortification, the better to secure the main places, and to protect the siege, etc.

DELF.—An heraldic charge, representing a square sod or turf, the term being derived, it is supposed, from the verb to *delve* or dig. A *delf tenné* is the appropriate abatement for him who revokes his challenge, or otherwise goes from his word. See *Abatement.*

DELINEATOR.—A perambulator, or geodetical instrument on wheels, with registering devices for recording distances between points; a pendulum arrangement by which a profile line is inscribed on a traveling strip; and certain other data, according to construction.

DELIQUESCENCE.—The power that certain salts have of attracting moisture and dissolving into water. Saltpeter has generally many deliquescent and impure salts in it, which in the process of refining it is freed from before being used for gunpowder purposes.

DELIVER BATTLE.—A term taken from the French *livrer bataille*, meaning to enter practically upon a contest; the opposing armies being in sight of each other.

DELIVERY.—The draught or allowance by which a pattern is made to free itself from close lateral contact with the sand of the mold as it is lifted. Also called *draw-taper.*

DELLIS.—The Bosnian and Albanian horsemen, who served without pay in the Turkish armies.

DELVIGNE LIFE-SAVING GUN.—This piece of ordnance weighs 20 kilos, is made of gun-metal, about 18 inches long, and has an iron tail-piece screwed into the breech and jointed, so that in firing it is simply thrust into the soil until the square breech brings up. The elevation is regulated by a quadrant and plummet put into the muzzle. The bore is about 1¼ inch, and the piece carries wooden arrows, fitted with iron tails to reach the charge; and at the muzzle these are much larger than the tail-piece, so that the shock of explosion operates on the square bases of the arrows, which are protected by rings of metal.

In loading this piece, a vacant space is left and the cartridge is fired near its outer end; the piece being very short, this brings the vent about in the center of the length. The iron arrows are about one third longer than the gun, and about half the length of the arrow is in the gun when ready to fire. The advantages claimed by Delvigne in this little piece are its cheapness and portability, while with sufficient charge it gives an equal or better range; besides the wooden and iron arrows he fires a wooden arrow out of the *perrier* or almost any gun, which has cross-bars of round iron made malleable to resist the shock. These cross-pieces are fixed at right angles to the arrow, near the outer end, and are about as long as three diameters of the arrow. It is found that in firing this the cross-pieces are bent to an angle of about forty-five degrees with the plane of the arrow, and thus form an anchor or grapnel, useful for many purposes. Arrows of wood have the advantage of floating if they drop near the wreck, and of being readily recovered when they go beyond or fall short. The iron flèche is intended for long ranges or strong contrary winds. The distance depends much on weather, on the amount of charge, elevation, and the line running clear.

In 1872 Delvigne's new gun, weighing 20 kilos (44.09 pounds), gave a range of 300 meters (328.09 yards), with a wooden flèche weighing 8 kilos (17.63 pounds), and a shot-line 8 millimeters (.315 inch) in diameter. See *Life-saving Rockets*.

DELVIGNE RIFLE.—A rifle having a chamber screwed into the breech at the bottom of the bore, which supplies an apartment for the powder. The shoulder of the chamber provides a place on which the ball rests, and thus preserves the powder. The ball enters freely, and is rammed and made to take the grooves. A sabot was subsequently attached to the under side of the ball, and attached to it was a patch of greased serge, which served to prevent fouling in the bore.

DEMEMBRE.—An heraldic term signifying that the members of an animal are cut from its body. Also written *Dismembered*.

DEMI—DEMY.—In Heraldry, an animal is said to be *demi* when only the upper or fore half of it is represented. In inanimate objects the dexter half per pale is usually intended, when it is said to be demi, though a *demi-fleur-de-lis*, for example, may be a *fleur-de-lis* divided per fess. See *Heraldry*.

DEMI-BASTION.—In fortification, a kind of half-bastion which frequently terminates the branches of a crown-work or horn-work, and which is also occasionally used in other places. See *Bastion*.

DEMI-CANNON.—A variety of ordnance, anciently used, carrying a ball ranging from 30 to 36 pounds in weight.

DEMI-CULVERIN.—An ancient piece of ordnance, carrying a ball weighing 9 or 10 pounds.

DEMI-FILE.—That rank in a French battalion which immediately succeeds to the *serre-demi-file*, and is at the head of the remaining half of its depth.

DEMI-GORGE.—In fortification, half the gorge or entrance into the bastion, not taken directly from angle to angle, where the bastion joins the curtain, but from the angle of the flank to the center of the bastion, or the angle which the two curtains would make by their prolongation.

DEMIHAG.—A very small arquebuse, of which the stock was bent or hooked, in order that it might be held more readily. It was much used in the sixteenth century.

DEMI-LANCE.—A light lance or half-pike; also the term for a light horseman who carried a lance.

DEMI-LUNE.—The object of this work is to secure the gates of the place from a surprise; to mask from the enemy's batteries the flanks and curtain of the enceinte; to give cross-fires on the salients of the bastions; and to favor sorties. The fire from the demi-lune is very effective on the enemy's works along the bastion capitals. Finally, it is a work of which the enemy can only obtain possession after great labor and loss of time; and when carried, it is with great difficulty that he can render it tenable, as it is exposed to the fire of the enceinte, within a short range. Engineers since Cormontaigne, finding that the demi-lune still admitted of being enlarged with advantage, have accordingly so determined its dimensions that it may be thrown so far to the front as will still place the breach which an enemy may make in its face within the range of the musketry of the bastion-face. In large fronts, like Noizet's, the demi-lune may be thus made to cover about 30 yards of the bastion-faces from the shoulder-angle, and thus secure retrenchments resting against this part from being turned by a breach made near the shoulder-angle. These considerations limit the salient angle of the demi-lune to 60°, and place the salient at not more than 210 yards from the bastion-face, as this distance will bring the breach at about 180 yards from this face, or within the effective range of musketry. The demi-lune thus arranged places the bastions, in all cases, in strong re-enterings; but when the angles of the polygon are very obtuse, the faces of the bastions prolonged also fall within the salients of the demi-lunes, and are therefore not easily enfiladed. The demi-lune, with numerous advantages, is not without defects. Its faces, from their position, are exposed to an enfilading fire; it deprives the curtain of all action on the exterior ground; and it is only when the angles of the bastion are very open that the re-enterings formed by the demi-lunes become of a formidable character. The glacis of the demi-lune covered-way forms a ridge, which is serviceable to the enemy by masking his works on one side of the ridge from the fire of the collateral works on the other. Various devices have been proposed by engineers to remedy this defect of exposure to enfilading fire. Some have proposed raising a very high bonnet at the salient, to act as a traverse and limit the effect of a plunging enfilade. Others have proposed a curved pan-coupé in the salient, of sufficient size to mount several guns to fire in the direction of the capital. Others suggest breaking the faces into several crochets, like the covered-way, and with like purpose. Others propose to draw the salient of the parapet so far inwards that the faces prolonged will fall without the limits of the assailant's enfilading positions. Others propose to occupy the salient with a high casemated traverse, to cover from enfilade and to give a strong fire from the casemates on the assailant's approaches in advance of the salients of the adjacent works. See *Outworks* and *Ravelin*.

DEMI-LUNE CUT.—This cut isolates the part of the demi-lune near the extremity of the face from the salient portion; this part, being arranged with a parapet behind the cut, can be defended after the enemy has effected a lodgment on the demi-lune salient. The cut thus prevents the enemy from driving the besieged from the redoubt of the re-entering place-of-arms; which he might do were the whole demi-lune to fall at once into his possession. By placing the interior line of the bottom of the cut sufficiently above the bottom of the ditch, the scarp of the demi-lune redoubt may be partly covered, and at the same time an obstacle may be placed in the way of an enemy who might attempt to carry the work behind the cut by first getting into the cut. The slope given to the bottom of the cut still leaves a height between the exterior line and the bottom of the demi-lune ditch which will secure the cut from an assault on that side. The object of this slope is chiefly so to diminish the height of the demi-lune scarp that it may not be exposed to a battery, which can be placed on the glacis of the re-entering place-of-arms. As to the interior crest, it is placed as low as possible, and is arranged to cover the interior from the plunging fire of the enemy when established on the demi-lune salient. See *Bastion-face Cut*.

DEMI-LUNE REDOUBT.—The essential object of this redoubt is to sweep at close range the terre-plein of the demi-lune and to render its defense more obstinate by the support it receives from the redoubt. The enemy having possession of the demi-lune will be obliged to carry its redoubt before he can assault the breach he may have made in the bastion-face, as this breach is seen in reverse by the fire of the flanks of this work. The redoubt should be as advanced as possible, to see in reverse the lodgments of the enemy on the glacis of the collateral works. The face of the redoubt is directed on the interior shoulder-angle of the bastion to have its ditch flanked by the bastion-face. In placing the salient of the magistral below the salient of the demi-lune, the top of the scarp-wall will be nearly on the level with the demi-lune terre-plein. This arrangement will force an enemy, lodged on the demi-lune terre-plein, either to lower his battery to effect a breach in the redoubt, or else to employ a mine for this purpose; either of which operations will cost him much labor and loss of time. The least command should be given to the redoubt over the demi-lune, to enable the fire of the redoubt to sweep the demi-lune terre plein. The flanks of the redoubt are principally to procure a reverse fire on the breach in the bastion-faces; their length is estimated for three guns. The piece nearest the extremity of one flank should be covered by the extremity of the opposite flank from the reverse fire which might come through the redoubt-gorge from the enemy's lodgment on the bastion covered-way. The terre-plein of the flank is made 11 yards, as it is habitually armed with cannon. The scarp-wall of the redoubt may be reduced to the minimum dimensions of 12 feet. But on account of its importance, and also not to diminish too much the interior space, it has been found that the dimensions adopted, 16.50 feet, best satisfy the requisite conditions. The top of the wall slopes towards the gorge, so that at the shoulder-angle it may be about 4 feet lower than at the salient; the object of this is to expose as small a portion of the wall as possible to the enemy's fire through the demi-lune cut; which from its width might admit of a breach being made in the redoubt, through it, from the enemy's lodgment on the re-entering place-of-arms. The dimensions named are employed in the Noizet system of fortification. See *Demi-lune.*

DEMI-PARALLELS.—In siege operations it is usual to place the third parallel so near to the defenses as to bring the covered-ways, or other most advanced defenses which may be assaulted openly, within range of stone mortars, placed in batteries either within or in front of this parallel; its position, for this object, should be some 60 yards from the salient points of the most advanced portions of the defenses, so as to bring their interior within the range of the stones and other missiles thrown from the mortars. In giving the third parallel this position, there will be a wide zone of ground between it and the second parallel, over which the approaches connecting these two parallels must be run, which would be very much exposed to the sorties of the besieged, as well as the third parallel, were its protection left to troops stationed as a guard in the second parallel. To provide protection for these approaches and for the third parallel whilst in process of construction, ends of trenches, termed *demi-parallels*, are run out on the right and left of the lines of the approaches, far enough to contain sufficient bodies of troops to protect the men working on the trenches in advance of them from sorties. The positions of the demi-parallels will be regulated by the same tactical considerations as those which regulate the positions of the parallels. The length to which they should be extended on the flanks of the approach will be regulated by the number of troops that it may be deemed necessary to post within them, and also from the consideration that they shall not obstruct or be endangered by the fire of any batteries to their rear.

DEMI-PIKE.—A kind of spontoon, seven feet long, used by the infantry or for boarding.

DEMI-PLACE D'ARMES.—In fortification, a circular trench constructed upon the prolongation of the lines of the covered-way, to the right and left of the zigzags, to cover the troops employed in their defense.

DEMI-REVETMENT.—A revetment of the scarf only to the height protected by the glacis.

DEMOLITION.—In military operations it sometimes becomes necessary to destroy buildings, bridges, etc. Wooden structures are very readily and effectually destroyed by burning. Ordinary dwelling-houses of stone or brick may be blown down by placing against the walls charges of from 25 to 50 pounds of powder, each contained in a bag, box, or any convenient vessel, and exploded by means of an electric primer, a slow-burning time-fuse, or a piece of slow-match. The effect of the explosion is to blow away a portion of the foot of the wall, that above settling down without, as a rule, toppling over. An inside angle or corner of the building is the most advantageous place for the charge, for the reason that, being confined on two sides, the explosive force acts more powerfully than when against a plain surface, and also because the angle or corner of the building, being a point of greatest support, when blown away leaves the remaining parts greatly weakened. Against strong and massive walls, such as are generally found in large public edifices, charges of powder, unless very heavy, have but little effect when simply exploded against the wall without tamping. Inside angles should, if possible, be taken, or when the building has buttresses, the angles formed by them are advantageous for confining the explosive force and causing it to take effect on the wall. The powder is placed in a box or keg and covered with earth and stones. When placed five or six feet above the foot of the wall the effect is greatly increased. In all cases where demolition is to be produced, dynamite may well be used instead of gunpowder. Its destructive effect is more than thirty times that of powder, weight for weight.

To destroy the arches of a masonry bridge, excavate a hole down to the crown or haunch of the arch, place in it a charge of one or two hundred pounds of powder, according to the thickness of the arch, tamp it well with earth and stones, and explode it. The amount of powder is determined from the formula $X = \frac{3}{4}A^2 \times B$: in which X is the charge in pounds, A the line of least resistance through the arch, and B the breadth of the bridge, both in feet. When the width of the arch is over 25 feet, two charges should be placed, to prevent the chance of blowing a hole through the middle without bringing down the sides. These should be exploded simultaneously, if possible. When the side walls are lightly built, it is better to pull enough of the stone away to allow a tunnel being run on top of the arch to the middle of the roadway. This does not interfere with the use of the bridge during the operation, and if it is not desired to destroy the bridge immediately, the charge may be kept in its place ready for use at any moment. In this case the charge should be in a tight box or barrel, well pitched to protect it against moisture. The charge may be exploded by means of an electric primer, the ordinary fuse used in blasting, or with a powder-hose. This latter is made of canvas or any stuff that will hold fine-grained powder, and is inclosed in a trough to protect it from the moisture of the earth.

Wooden bridges are easily burnt; but if great secrecy is necessary, a hole may be bored with an auger in a main-brace and a charge of powder or dynamite exploded therein, blowing it to pieces. Charges should be placed in several of the braces and exploded as near simultaneously as possible. During the War of the Rebellion a small torpedo was devised for this purpose. It consisted of a tin cylinder 1.75 inch in diameter and about 7 inches long. Both ends of the cylinder were open, and through it passed a bolt of .75-inch iron, with a stout head at one end and a nut at the other, each having a diameter of 2 inches. A washer of the same size as the head was placed under the nut; through a hole in the washer passed a strand of slow-match to communicate fire to the powder with which the cylinder was filled. A coat of varnish protected the powder from moisture. To use it, a hole 2 inches in diameter was bored in the timber; into this the torpedo was driven, head downwards, and the fuse ignited. The most effectual way of destroying an iron bridge is to attack the abutments by mining down so as to get behind the masonry a large charge of powder or dynamite, which being exploded destroys the supports of the superstructure. When time and means permit, remove as many bolts as possible, so as to weaken the parts, after which build a strong fire and heat the main-braces to make the bridge sag and warp out of shape, or to come down entirely.

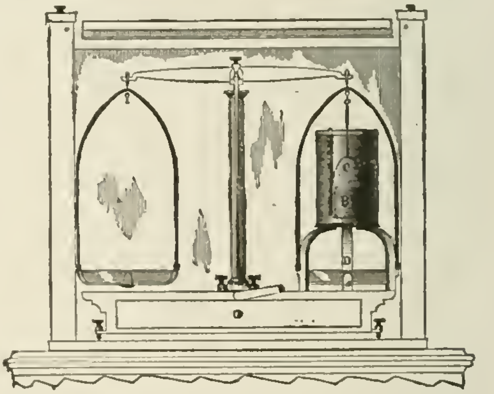
Canals may be temporarily disabled by cutting embankments. The most effectual way, however, is to blow up a lock, which may be done by digging down behind a facing wall and placing against it a charge of two or three hundred pounds of powder or a few pounds of dynamite, tamping well and exploding it. A lock destroyed in this manner requires a long time to repair. The arches of an aqueduct may be broken by drilling holes and blasting. An army depending upon a railroad for its supplies should be provided with an organized Construction Corps, fully equipped with every means for making speedy repairs. Damages done to railroads are easily repaired, in comparison with those done to canals.

DEMOLITION OF ARTILLERY.—The destruction of ordnance by artificial or other means. This is performed, if the gun is an iron one, by half filling the piece with powder, and jamming in one or two shot with stones, bits of iron, etc.; over this a complete tamping with stones and earth till the bore is filled. To break off the trunnions is not always an infallible mode of destroying ordnance, as they can still be fired from the ground. When time admits of only partially crippling guns by removing one of the trunnions, it is best done by laying the end of the trunnion on a block of wood, the blow being given by a sledge-hammer, or (if that be not at hand) by heavy shot. A gun may be destroyed by firing a shot at it behind one of the trunnions, which, if it should not break it, would render it unsafe. The first method, however, particularly if the muzzle is partly buried in the ground, will be found certain to burst the gun. To render bronze guns unserviceable, fire a shot into them from some other piece, behind the trunnions, which will prevent the possibility of their being used again. See *Demolition*.

DEMONSTRATION.—In military operations, an apparent movement or maneuver the chief object of which is to deceive the enemy and induce him to divide his force, as if to meet dangers from various quarters. When thus divided and weakened, he may be attacked with greater chance of success.

DENONCIATEUR.—In a general sense, a person not improperly called a military informer. So rigid indeed were the regulations (even in the most corrupt state of the French Government) against every species of misapplication and embezzlement, that if a private dragoon gave information to the Commissary of Musters of a troop-horse that had passed muster, having been used in the private service of an officer, he was not only entitled to his discharge, but received, moreover, 100 livres in cash, and became master of the horse and equipage, with which he retired unmolested. The officer was summarily dealt with.

DENSIMETER.—This instrument, employed in the determination of the specific gravities of metals for cannon, is simply a form of the hydrostatic balance, and was adopted in place of the hydrometer, formerly in use, in order to substitute a more expeditious process for the slow and tedious operation by the latter. The instrument consists of a delicate beam-scale, A, having suspended from one extremity of the beam a brass bucket, B, the bottom of which is perforated with holes. Underneath the bucket, and resting on a tripod, D—which stands over the scale-pan in such a manner as not to interfere with either the movement of the balance or working with the pan—is a glass jar, C, to contain water for the immersion of the bucket and specimen. A mark is scratched upon the jar near the top, and this mark indicates the height at which the water should, after the immersion of the bucket, always stand previous to an experiment. The immersion of the specimen causes the water to rise above this mark, immersing an additional portion of the stem of the bucket, and the latter loses, in consequence, a slight portion of its weight in reference to the beam. A correction, therefore, becomes necessary to compensate for this apparent loss in weight. To determine this correction, the bucket-stem is graduated in the following manner: The beam having been thrown into action, and the immersed bucket balanced by weights in the pan attached to the opposite arm, a mark is made upon the stem of the bucket where it is intersected by the surface of the water. The height of the water in the jar is then raised till as much more of the stem is immersed as is likely ever to be the case in practice. Another mark is then made where the stem is now intersected by the water, and the loss of weight in the bucket ascertained. The loss in weight, for the maximum immersion of the stem, amounts to only one tenth of a grain, while the corresponding length of stem is nearly one inch; the space between the marks, therefore, may be readily subdivided into tenths, and the necessary corrections can thus be read off the stem in actual weight to the nearest tenth of a grain. By using simply a thread in place of the bucket, the above correction might be neglected; but the greater convenience offered by the latter has led to its final adoption. A thermometer is suspended from the upper edge of the jar, as shown in the drawing.



The process, with this instrument, of taking the specific gravity of a specimen of metal naturally suggests itself. The jar being filled with water to the fixed mark, and the bucket suspended therein, the beam is thrown into action, and the weight of the immersed bucket ascertained by means of weights placed in the opposite scale-pan. This weight being noted for different temperatures can be tabulated, and thus become a known element for all calculations of the specific gravity with this instrument. The specimen of metal is then placed in the pan underneath the jar, and weights added to the other pan till the balance of the beam is restored. The sum of these weights is the weight of the specimen in air plus the weight of the bucket in water. The specimen is now transferred from the pan to the bucket, and replaced by weights in the pan underneath the jar, till the equilibrium is again established. The sum of these latter weights is the weight of the volume of water displaced by the specimen plus the weight lost in the bucket due to the immersion of an additional portion of its stem. The loss in weight is read off the bucket-stem in tenths of a grain, and is to be subtracted from the weights in the pan underneath. Denote the weight

See *Dupont de Nemours Densimeter* and *Mercury Densimeter*.

DENSITY.—When of two bodies of equal bulk or volume the one contains more matter than the other, it is said to have greater density than that other. The quantity of matter is measured by the weight, and thus density and specific gravity come to be proportional to one another. Platina, which is about 21 times the weight of water, long passed for the densest body; but Breithaupt of Freiburg, in 1833, made out *iridium* to be twice as dense. Rare is opposed to dense, and the rarest body known is *hydrogen*, which is about 14½ times rarer than atmospheric air. The density of bodies is diminished by heat and increased by cold. In the manufacture of gunpowder it is very necessary to attend to the density, as so much depends upon this all-important point in regulating the uniformity, time of burning, and strength of the powder. Experience has shown the density most likely, under certain circumstances, to produce a good result in the different natures of powder manufactured, both as regards their action upon the velocity of the shot and the pressure upon the gun. A large-grained dense powder burns slower than a small-grained powder of low density, and tends to preserve the gun better, as it does not throw such a strain upon it; hence the reason that large-grained and dense powder is used with all large ordnance. See *Gunpowder*.

DEPARTMENT COMMANDER.—An officer assimilated to the Commander of a separate army, with the same powers and duties in similar cases over all the troops within the limits of the Department. He derives his authority to command from the highest power of the Government. In the United States, certain duties of the Department Commander are defined by statute. He can convene Courts-Martial, and his action is final on all cases tried by such Courts, except in the case of a General Officer, or where the sentence of the Court extends to the loss of life or the dismissal of a Commissioned Officer. In time of war he is authorized to execute the death-penalty in cases of persons convicted as spies, mutineers, deserters, or murderers, and in cases of guerrilla marauders convicted in time of war of robbery, burglary, arson, rape, assault with intent to commit rape, or violation of the laws of war. See *Geographical Departments and Divisions* and *Military Department*.

DEPARTMENT OF ARTILLERY STUDIES.—A Department at Woolwich, for advanced scientific instruction, and for the instruction of officers generally, in *matériel* and kindred subjects.

DEPARTMENT OF THE DIRECTOR OF ARTILLERY STORES.—In the British service, a Department charged with the regulation of armaments and the introduction of new *matériel;* also the superintendence of the manufacture of warlike stores.

DEPARTMENT OF WAR.—"There shall be an Executive Department, to be denominated the Department of War; and there shall be a principal officer therein, to be called the Secretary for the Department of War. He is to perform and execute such duties as shall, from time to time, be enjoined on or intrusted to him by the President of the United States, agreeably to the Constitution, relative to military commissions, or to the land forces or warlike stores of the United States, or such other matters respecting military affairs as the President of the United States shall assign to said Department. And furthermore, that the said principal officer shall conduct the business of the said Department in such manner as the President of the United States shall, from time to time, order or instruct. That there shall be in said Department an inferior officer, to be appointed by the said principal officer, to be employed therein as he shall deem proper, and to be called the Chief Clerk in the Department of War, and who, whenever the said principal officer shall be removed from office by the President of the United States, or in any other case of vacancy, shall, during such vacancy, have the charge and custody of all records, books, and papers appertaining to said Department. The said principal officer, and every other person to be appointed or employed in said Department, shall, before he enters on the execution of his office or employment, take an oath or affirmation well and faithfully to execute the trust committed to him." (Act Aug. 7, 1789.) It seems impossible to read this Act of Congress, and contend that officers of the army are a portion of the War Department. And the statute-book will be searched in vain to find authority given to the Secretary over any officers other than officers of Staff Departments, or over subjects disconnected with the custody of public records, the support and supply of troops, the manufacture and care of warlike stores, the keeping of exact and regular returns of all the forces of the United States, or other kindred administrative matters, such as receiving the proceedings of Courts-Martial and laying them before the President of the United States for his approval or disapproval, and orders in the case. There is no Act of Congress which authorizes the Secretary of War to command the troops, and he being no part of the army, the President, of course, cannot authorize him to do so. But the Secretary of War is the regular constitutional organ of the President for the administration of the military establishment of the nation; and rules and orders publicly promulgated through him must be received as the acts of the Executive, and as such are binding upon all within the sphere of his legal and constitutional authority.

By an Act of Congress approved March 3, 1813, it is provided: That it shall be the duty of the Secretary of War, and he is hereby authorized, to prepare general regulations, better defining and prescribing the respective duties and powers of the several officers in the Adjutant General, Inspector General, Quartermaster General, and Commissary of Ordnance Departments, of the Topographical Engineers, of the Aids of Generals, and generally of the General and Regimental Staff; which regulation, when approved by the President of the United States, shall be respected and obeyed, until altered or revoked by the same authority. Here was a partial delegation of legislative power; and under this power of legislation so confined to the several Staff Departments, the Secretary of War, with the approval of the President, established Bureaus of the War Department, making the head of each Staff Department Chief of a Bureau, in all fiscal and administrative matters connected with his particular Department under the general direction of the Secretary of War. The War Department thus centralized all army administration, and efforts have since been made to centralize in the same way the command and government and regulation of the army. But as the old 62d Article of War declares that when different corps come together the officer highest in rank shall command the whole and give orders for what is needful to the service, unless otherwise specially directed by the President of the United States, according to the nature of the case, while the 61st Article gives the command to the senior regimental officer within his regiment, when other troops are not present, such centralization, if not a violation of law, would be a violation of all military principles, destructive alike to discipline and military spirit. For commands given immediately by the highest authority cause agitation rather than action. The superior authority becomes weakened in proportion as the eye becomes accustomed to it. Fear of it ceases, and when the highest authority habituates itself to doing everything, as soon as it ceases to be sufficient to do all there is nothing done. All degrees of rank and command have their degree of importance. Authority must regularly ascend and descend. Every inferior grade is the lieutenant of its superior grade, even to the oldest soldier, who replaces the corporal. Obedience is reciprocal to authority. Rules established by Congress, defining the rights, powers, and duties of all officers and soldiers, are much needed. See *Secretary of War* and *War Department*.

DEPENSES.—A term used in a military sense to imply secret-service money.

DEPLOYMENTS.—A general term for tactical maneuvers by which the front is extended. The following points are general: *On first or last company*—all companies except the designated company go to right or left, as the Major may command. If to the *right*, the point of rest is the *left* of the line; if to the *left*, the point of rest is the *right* of the line. *If on an interior company*, and the Major commands, "*Fours right and left*," the *front* companies go to *right*, and *rear* companies go to *left*, and point of rest is the *left* of designated company, if the command be, "*Fours left and right*," the front companies go to *left*, and *rear* companies go to *right*, and point of rest is the *right* of the designated company. In all cases companies are dressed toward the *point of rest*.

DEPORTATION.—The forcible removal of a people from their country; in former times employed as a means of securing the fruits of conquest. In the Scriptures it is recorded that not only the Jews but other peoples were carried away captives. Banishment is still a method of punishing political offenders in France and some other countries.

DEPOSITION—The testimony of a witness set down in writing. Depositions are taken either by a Judge or by a Commissioner specially appointed by him for that purpose. The questions to which the depositions are answers are usually put by the legal representatives of the parties to the suit, under the control of the Court or Commissioner, and the answers are taken down by the Clerk of Court, or by a Clerk specially appointed for the purpose. If the competency of the questions or the admissibility of the witnesses be objected to, the objection must be stated to the Court or Commissioner. The latter may either dispose of the objection at the time, or reserve it for the opinion of the Court by which he was appointed. It is a rule in the laws of evidence of all countries that the deposition cannot be read where the witness might be himself produced, because his oral testimony is the best evidence, and secondary evidence is never admissible. Where he is dead, however, or insane, or beyond the jurisdiction of the Court, his deposition then becomes the best evidence and may be read in Court.

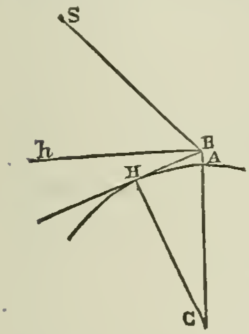
DEPOSITS.—Soldiers may deposit with the Paymaster any portion of their savings, in sums not less than five dollars, the same to remain so deposited until final payment on discharge. The Paymaster furnishes each depositor with a deposit-book, in which each deposit made is entered in the form of a certificate, signed by the Paymaster and the Company Commander, setting forth the date, place, and amount (in words and figures) of deposit, and the name of soldier making same. The attention of enlisted men should be called to the importance of preserving deposit-books as the only certain means of insuring absolutely correct repayment without delay. On the death of a soldier, account should be made of each deposit in the inventory of his effects, and on the accompanying final statements with which his deposit-book will be filed. The separate and accurate statement, by date and amount, of each deposit is absolutely essential to the correct calculation of interest. For any sums not less than fifty dollars deposited for the period of six months or longer, the soldier, on his final discharge, is paid interest at the rate of 4 per cent per annum. Deposits and interest thereon are forfeited by desertion, but are wholly exempt from forfeiture by sentence of Court-Martial and from liability for the soldier's debts.

DÉPOT.—In military matters, a name sometimes given to a place where army stores are deposited during war. In the English Regimental System, however, a depot used to be the town or barrack where certain stores belonging to the regiment were kept, as well as the regimental books and some of the men, when the regiment was ordered on foreign service. It was rarely that a whole regiment was engaged in active service at once; either one or two companies were generally kept at home, under the command of one of the officers, and were called *Depot Companies*. They formed a nucleus where recruits were received and drilled, and where the corporate existence of the regiment might be kept up. By the Military Forces Localization Act of 1872, under which the United Kingdom is divided into seventy sub-districts, every battalion, whether at home or abroad, has a depot of two companies. The depots of two battalions constitute the depot-center, or sub-district brigade, to which the volunteers and militia of the sub-district are affiliated. In time of war the depot would expand into a third battalion.

DEPRESSED GUN.—Any piece of ordnance having its mouth depressed below the horizontal line.

DEPRESSING-CARRIAGES.—These carriages permit the gun to fire over a parapet in the usual manner, and upon recoil allow the piece to descend behind the parapet, where it can be reloaded in safety. Various plans for effecting this have been proposed, but none actually adopted, in the United States service. The King carriage, mounting a 15-inch gun, has, however, been tested and found to work efficiently. This consists in lowering the rear end of the chassis until it nearly touches the ground, thus forming an inclined plane at an angle of about 30° to the horizon. The top-carriage is attached to a counterpoise by a band composed of wire ropes. This counterpoise is a heavy mass of metal descending into a well in front of the pintle. The carriage that has been adopted, and hereafter to be furnished for the barbette service, has an increase of 15 inches in height over those of old pattern. This modification is effected by inserting sections, similar in construction to the chassis-rail, between the rails and feet, props, and fork of the low chassis. The increase of height thus gained admits of a corresponding depression of the terre-plein, and consequently greater protection behind the parapet for the cannoneers. The gun, nevertheless, is exposed as before. Depressing-carriages are intended to protect the piece and carriage as well as the cannoneers. The accuracy of modern artillery-fire increases the danger to the guns with which a work is armed; and the disabling of a piece by the enemy's fire is of greater moment now than formerly, when works were garnished with a greater number, and of such small size as to be readily replaced when injured.

DEPRESSION.—1. The pointing of any piece of ordnance so that its shot may be projected short of the point-blank. 2. The *dip of the horizon*, or the angle through which the horizon appears depressed in consequence of the elevation of the spectator. Let



A be a point on the surface of the earth, and B a point situated in a vertical line from A. Let BH be a tangent to the earth's surface drawn from B. Bh a line in the same vertical plane perpendicular to AB. The angle hBH is the *true* dip of the horizon to a spectator at B. The true dip measured in minutes is equal to the distance in nautical miles of the visible horizon. Let C be the center of curvature of the surface; then, since CHB is a right angle, the angle $h\text{BH} = \text{HCA}$, and the minutes in this angle are the nautical miles in the arc AH. To find this angle in minutes or nautical miles, the rule is: Multiply the square root of the height in feet by 1.063. The true dip of the horizon, however, is not exactly the same as its apparent depression. The apparent sea-horizon is raised above its true place by *refraction* through an angle, which varies according to the state of the atmosphere and the relative temperatures of the air and water, the variation ranging from one third to one twenty-third of the amount of the true dip. The rule commonly employed is to diminish the true dip by about one fourteenth of its amount, to find the apparent dip. If S be a star or the sun in the same vertical plane with ABH, and an observation of the altitude above the sea-horizon be made by means of a sextant from the point B, the apparent dip of the horizon must be subtracted from the observed angle, in order to find the altitude of the sun. Owing to the uncertainty of the amount of refraction, the nearest minute to the dip given in the tables is usually taken. The following table gives a sample of the amount of the apparent dip under ordinary state of the atmosphere and equal temperature of air and water:

Height. Feet.	Dip. m. s.	Height. Feet.	Dip. m. s.
0	0 0	8	2 50
1	1 0	9	3 0
2	1 20	10	3 10
3	1 40	20	4 20
4	2 0	30	5 20
5	2 10	40	6 10
6	2 20	50	7 0
7	2 40	100	9 50

DEPTH.—A technical word peculiarly applicable to bodies of men drawn up in line or column. The depth of a battalion or a squadron is the number of men in rank and file from front to rear.

DEPUTY ADJUTANT GENERAL'S DEPARTMENT.—In the British service, a Department charged (under the Commander-in-Chief) with the discipline, promotion, and distribution of brigades.

DEPUTY ASSISTANT ADJUTANT GENERAL.—In the British service, a subordinate officer of the Adjutant General's Department, who performs similar duties to those of an Assistant Adjutant General. In the field, a Deputy Assistant Adjutant General is attached to each division.

DEPUTY MARSHAL.—In the British service, the senior Sergeant Major of each regiment of Foot-guards, who sees after and makes out the routes of deserters, and receives an allowance for so doing.

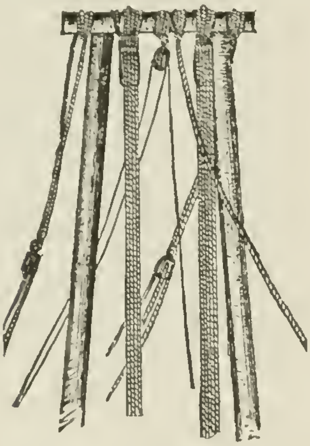
DERASER.—A term meaning to cut off the superfluous clay from a gun-mold previous to its being placed in the pit. See *Casting* and *Mold*.

DERIVATION.—Derivation, or drift, is the deviation peculiar to rifle-projectiles, the divergence being on the side towards which the grooves *twist*. It is a constantly increasing divergence from the plane of fire, and is allowed for, in aiming, by means of a lateral motion given to the rear sight. See *Drift*.

DERRICK.—The derrick is a machine used for hoisting or lowering heavy bodies to or from the top of vertical walls or similar places. It usually consists of one spar or leg; but the one employed for raising 15-inch guns consists of two legs made of round spars of yellow pine, 29 feet long, 11 inches diameter at the foot and 9 inches at the top; one sill, half round, 16 feet long and 11 inches in diameter; one cap, half round, 8 feet long and 9 inches in diameter; two iron straps, with keys and wedges for securing cap to legs. Near each end of the sill, on the square side, is a mortise, into which fits the tenon on the foot of the leg. The cap is similarly mortised to receive the top of the legs, and is held fast in this position by the straps fitting over it and keyed through the legs.

The derrick will be readily understood by noticing its action when raising a 15-inch gun. To perform this work, it is put together on top of the rampart (or other place to which the gun is to be raised); the sill is about five feet from the edge of the wall; the main-tackle upper block is lashed to the cap near one leg, and the muzzle-tackle upper block near the other leg. The ends of the guys are hitched to the ends of the cap; the middle laid across the legs, and a half-hitch taken over each end, thus doubling them; a stout thimble is placed in the bight of each, into which the guy-tackles are hooked. Secure holdfasts must be obtained for the guys; to these the guy-straps are attached, and in the bight of each a stout thimble is placed, into which the guy-tackle is hooked. One end of the fore guy is attached to the middle of the cap by a round turn and two half-hitches, the end being securely stoppered to the guy. A luff-tackle purchase is applied to the fore guy and its holdfast, and by means of this the derrick is raised to a vertical position. The sill is firmly secured, with stakes or by bracing with skids, against some fixed object. The girtline is attached to the cap by a strap, and having been raised with the derrick, a man is sent up by it, who, by the same means, receives the leading blocks, which he secures to the cap by means of straps. The main-tackle fall is next rove through the blocks, and the lower block lashed to the gun 2 feet 6 inches in *rear* of the axis of the trunnions. The muzzle-tackle fall is rove, and the lower block lashed 3 feet in *front* of the axis of the trunnions. These blocks are each lashed to the gun by seven turns with the lower-block lashing, the lashing being frapped on each side of the blocks with its ends. Two snatch-blocks are attached to the sill, one near the foot of each leg, by strong straps. These straps should be laid on the ground under the sill previous to raising the derrick, and if the ground is gravelly they should be protected from chafing by a canvas laid under them. Through these snatch-blocks the main and muzzle tackle falls are severally led, each to one of the capstans. The capstans are manned by sixteen men each. A strain is brought upon the falls, and the guy-tackles hauled upon until the head of the derrick is almost vertically over the edge of the wall. The capstans are worked and the gun is hoisted, care being observed to work the capstans so as to keep the piece in a horizontal position. One or more shifting-planks are let down by ropes against the side of the wall to prevent the gun from chafing against it and to ease it over the coping. When the gun reaches the top of the coping, preventer-tackles are hooked to straps around the breech and muzzle. When the piece is sufficiently high, the guy luff-tackles are hauled upon and the piece landed on cribs or blocks. The preventer-tackles are likewise used to assist in bringing in the piece and landing it in a proper position. If it is desired to place the gun on the cradle, the falls are slacked off and the sill of the derrick moved far enough back to admit the cradle. The gun is again raised and landed in its bed on the cradle. The derrick should not be allowed to assume an inclination of less than four on one.

To lower the gun, the piece is brought to the edge of the wall on the cradle; the derrick is erected over



it; the gun-sling and the tackling are attached, all in the manner explained for hoisting; the capstans are worked; the piece lifted and eased to near the edge of the wall by the preventer-tackles. The cap of the derrick having been placed directly over the piece, the strain will increase its inclination sufficiently to allow the gun to be eased to the edge of the wall. In this position the piece is allowed to rest on blocks or skids, the cradle is removed, and the sill of the derrick moved up close to the gun. The gun is then hoisted, eased over the edge, and lowered to the foot of the wall. The derrick is dismantled in the inverse order in which it was put up. One capstan, if powerful enough, is sufficient for lowering or hoisting the gun, in which case the lower block is lashed to the piece at the center of gravity. The lashing is executed as before explained. The capstan usually issued to artillery posts is, however, not sufficiently powerful, and it will invariably require two of them. Care must be taken to keep the guys hauled upon so that the cap and sill remain always parallel to each other; the derrick is thus prevented from twisting. By omitting the cap and then lashing the heads of the spars together with shear lashing, the derrick may be used as shears. In this case, only the main tackle can be used. When spars can be procured of sufficient length to construct shears high enough, it is best to place the shears at the foot of the wall instead of on the top. The shears should be not less than 20 feet higher than the wall. This method permits the piece to be raised and eased over to the terre-plein with less inclination, and consequently less strain upon the legs of the shears and on the guys. See *Capstan*, *Gin*, and *Mechanical Maneuvers*.

DERRICK-CRANE.—A heavy crane for out-door use. Its construction is substantially identical with that of the jib-crane except that the head of the mast is supported by guy-rods, instead of by attachment to a roof or ceiling. This style of crane is built of capacities from 5 to 20 tons, and of any desired dimensions of mast and jib. The description of the jib-crane will apply to this crane also, all of their several parts being identical, except that in this case the mast is extended somewhat above the jib, and the upper bearing, in which the mast revolves, is supported laterally by guy-ropes, or rods, attached at their lower ends to suitable anchors in the ground, or to adjacent buildings. The motions of hoisting and lowering, and travel of the trolley on the jib, are all effected by means of the mechanism at the foot of the mast. By pushing or pulling the suspended load rotation of the crane is effected as easily as in the case of the ordinary jib-crane. This crane is adapted for use in foundry-yards, quarries, and on wharves, and can be substituted for the pillar-crane, where the guy-rods are not objectionable, or where there is difficulty in obtaining the foundation needed to support a pillar-crane. It can also be arranged for operation by power, or by direct steam. See *Cranes* and *Jib-crane*.

DESCEND.—A term, in a military sense, signifying to make an attack or incursion as if from a vantage-ground.

DESCENTS.—In fortification, the holes, vaults, and hollow places made by undermining the ground. The *descents into the ditch* are cuts and excavations made by means of saps in the counterscarp, beneath the covered-way. They are covered with thick boards and hurdles; and a certain quantity of earth is thrown upon the top in order to obviate the bad effects which might arise from shells, etc.

DESCRIPTIVE BOOK.—A company book in which *descriptive lists* of the soldiers are kept.

DESCRIPTIVE LIST.—A paper giving a brief history of the soldier, a description of his person, and the statement of his account. It accompanies him wherever he goes, being intrusted to his Detachment or Company Commander.

DESCRIPTIVE MEMOIR.—This memoir, which should always accompany a sketch of a topographical reconnoissance, is intended to convey that information relating to the natural features of the ground not expressed upon the sketch; to express that information for which there are no conventional signs; and to present those facts relative to the ground which become important by being considered in connection with the probable military operations to be undertaken.

DESERTER.—A soldier who forsakes his flag. In time of war such an act is punishable with death or otherwise as a Court-Martial may decide. In time of peace the punishment is comparatively light. Deserters from the American army, having entered the service of the enemy, suffer death if they fall again into the hands of the United States, whether by capture or being delivered up to the American army; and if a deserter from the enemy, having taken service in the army of the United States, is captured by the enemy and punished by them with death or otherwise, it is not a breach against the law and usages of war, requiring redress or retaliation.

DESERTION.—The crime of a man absconding, during the period for which he is enlisted, from the service. In England this crime was, by certain old statutes, made punishable with death; but now the punishment for desertion is prescribed by the annual Mutiny Acts. By these any Court-Martial may inflict a sentence of corporal punishment, not exceeding fifty lashes, for desertion, and may in addition award imprisonment for the period prescribed by the Articles of War. By 20 Vict. c. 13, s. 35, and 22 Vict. c. 4, s. 35, it is provided that deserters may be marked on the breast in gunpowder or ink with the letter D. This provision is omitted in the Mutiny Act, 1860. Recruits deserting before they have joined their regiments are to be taken to the regiment nearest to the place where they were found, but to suffer no punishment except loss of bounty. Inducing to desert was formerly punishable by death; the punishment has, by modern statutes, been commuted to penal servitude. If simply "absent without leave," a British soldier, besides undergoing some kind of punishment, forfeits his regular pay for the days of absence; but if his non-appearance involves actual desertion, he loses all claim to additional pay, good-conduct money, and pension. The number of deserters from the British army is very great. In one particular period of eight months it was found that no less than 8822 men deserted from the regular army, and 6614 men from the militia; in 1874, 7939 men deserted from the army; and in 1875, 5629. Many experienced officers attribute the evil to the temptations of bounty, rather than to any other cause; and advise that the same amount of money should be applied to the soldier's benefit in some other form.

In the United States, the President is authorized to drop from the rolls of the army for desertion any officer who is absent from duty three months without leave; and no officer so dropped shall be eligible for reappointment. And no officer in the military or naval service is in time of peace dismissed from service except upon and in pursuance of the sentence of a Court-Martial to that effect, or in commutation thereof. A reward of $30 is paid for the apprehension and delivery of a deserter to an officer of the army at the most convenient post or recruiting station. This reward includes the remuneration for all expenses incurred in apprehending, securing, and delivering the deserter. Rewards and expenses paid for apprehending a deserter are set against his pay on conviction by a Court-Martial of desertion, or upon his restoration to duty without trial on such condition. Where a soldier, for whose apprehension as a supposed deserter the reward of $30 has been paid, is brought to trial under a charge of desertion and acquitted, or convicted of absence without leave only, the amount of the reward is not stopped against his pay. Deserters make good the time lost by desertion, unless discharged by competent authority. They are considered as again in service upon return as deserters to military control. Deserters are brought to trial with the least practicable delay. While awaiting trial they receive only the clothing absolutely necessary, and no pay. Every deserter forfeits all pay and allowances due at the time of desertion. The authorized stoppages and fines due at the time of desertion are deducted from the arrears of pay. If the stoppages and fines are greater than the arrears of pay, the balance is deducted from pay due after apprehension.

Deserters from the enemy, after being examined, are secured for some days, as they may be spies in disguise; as opportunities offer they are sent to the rear; after which, if they are found lurking about the army, or attempting to return to the enemy, they are treated with severity. The arms and accouterments of deserters are turned over to the Ordnance Department, and their horses to the corps in want of them, after being branded with the letters "U. S." The compensation to be accorded to deserters for such objects is according to appraisement made under the direction of the Quartermaster's Department. The enlistment of deserters from the enemy, without express permission from General Headquarters, is prohibited. Soldiers who may be discovered to be deserters from the Navy or Marine Corps are immediately dropped from the rolls of the army. In all such cases reports are forwarded with descriptive rolls to the Adjutant General's Office, and the men held without pay, awaiting instructions. This is not regarded as requiring the discharge of any man who may have been enlisted in the army after having received a discharge from the Navy or Marine Corps, the recruiting officer being in ignorance of the fact that he had deserted from either of those branches of the service; but whenever such fact of desertion becomes known, it will be regarded as a bar to enlistment in the army. In case, however, of such enlistments, no benefit can accrue to the soldier for previous time served in the army. Every person who entices or procures, or attempts or endeavors to entice or procure, any soldier in the military service of the United States, or who has been recruited for such service, to desert therefrom, or who aids any such soldier in deserting or attempting to desert from such service, or who harbors, conceals, protects, or assists any such soldier who may have deserted from such service, knowing him to have deserted therefrom, or who refuses to give up and deliver such soldier on the demand of any officer authorized to receive him, is punished by imprisonment for not less than six months nor more than two years, and by a fine not exceeding $500.

DESICCATION.—The expulsion of moisture from solid substances. This is effected at various temperatures, according to the nature of the substance, and by different means, such as the water-oven, air-bath, etc. The wood of fuses is thus treated.

DESPATCH.—An official document or letter penned by a Commander in the field to other authorities. The term is also applied to letters received from Governors of Colonies. All correspondence from Military Commanders to superior authority in the field, detailing their acts before the enemy, come under the head of despatches.

DETACH.—To separate for a special object or use; as to send out a body of men on some particular service, separate from that of the main body.

DETACHED BASTION.—In fortification, a bastion which is separated from the enceinte by a ditch.

DETACHED WORKS.—In fortification, the works that are situated beyond the range of fire of any other works, and which, for their security, have to rely upon their own strength and resources. The object of such works is to defend and hold isolated points that are of importance, such as railroad or other bridges, mountain-passes, narrow defiles, fords, points upon rivers, to close them against the passage of hostile vessels, etc. The character and extent of a work of this class will depend upon the degree of importance attached to the object for which it is constructed, the amount of force available for its occupancy, and the nature of the locality. In every instance

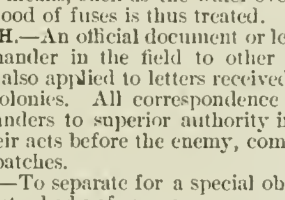


Fig. 1.

artillery would form an important element in its means of defense, and the position of the work should be selected so as to allow free use of it. Works of this kind may be classified under three heads: 1. Those which, being secure on the flanks and in the rear, are assailable only in front. Under this class may be placed open batteries located on the banks of rivers, or at the entrance of harbors, to prevent the passage of an enemy's vessels. 2. Those which are assailable in front and on the flanks, but not in rear. 3. Those which are assailable on all sides.

First Class.—This is applicable to narrow defiles where the flanks are secure against being turned. When the width of the defile is not greater than 1800 yards, the line may be a straight one (A B) for infantry, with short advanced lines on the flanks, as represented in the drawing (Fig. 1), for artillery. Should the conformation of the ground be not suitable for placing artillery precisely as represented in the drawing, then the most commanding position on some other part of the line will be selected for it, bearing in mind always to secure as far as possible cross-fire over the ground in front. When the defile exceeds 1800 yards in width, a *crémaillère* or *serrated* line is adopted, and on it the artillery is disposed as represented in Fig. 2.

Second Class.—The plan of works of the second class admits of great variety, depending on the extent of the position. The most simple is that of a work of only two faces, the salient being towards the assailant's line of approach. This work is termed a *redan.* The faces should receive such direction as to sweep the approaches to the flanks of the position. As

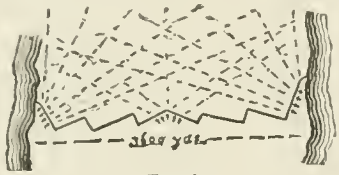

Fig. 2.

many pieces as possible are placed in the salient, and others disposed along the faces in the most commanding positions for sweeping the ground in their front. The angle formed at the salient by the faces should never be less than 60 . When the flank approaches extend somewhat to the rear, a flank is added to each face of the redan; it then becomes a *lunette.* The flanks receive such directions as will sweep by their fire that portion of the flank approaches which cannot be reached from the faces except by a very oblique fire. The artillery is placed in position at the salients, in each of which is a pan-coupée.

Third Class.—The works comprised in this class are termed inclosed works; as, being assailable on all sides, they must, for security, present a complete line throughout to any assault. These works may be divided into three orders: 1. *Polygonal works,* or *redoubts;* 2. *Tenailled works,* or *star-forts;* 3. *Bastioned works.* See *Field-fortification.*

DETACHMENT. — Detachments consist of small bodies of troops, composed of one or several arms, to which are intrusted some mission connected with the operations of the main body, but, for the most part, performed beyond the sphere of its support; such, for example, as the occupation of some post, or defile, which is to be held temporarily, as necessary to the movements of the main body; the surprise of a post held by the enemy; the seizure of a convoy, etc. The composition of a detachment will depend upon the nature of the duty to be performed; the character of the country in which it is to operate; the distance of the point to be reached; and the more or less celerity required in the operation. As a general rule, detachments should be formed only of light troops, well acquainted with their duties; and, in every case where it can be done, they should consist of a proper proportion of each arm of the service, if the duty upon which they are sent is at all of an important character. By this combination each arm is enabled to act with more boldness and vigor, from the support with which it will meet in the others, and can better select its moment for action, according to the character of the ground on which it finds itself. The combats of detachments will be mostly restricted to firing and the skillful employment of skirmishers. The troops must be kept perfectly in hand for mutual support, the artillery keeping near the infantry, and the cavalry, whenever the opportunity is presented, hazarding only short but vigorous charges against the enemy. The officer placed in command of a detachment should be thoroughly conversant with the handling of troops, so as to insure constant reciprocity of support, and to be able to seize upon those opportunities of bringing the proper arm into action, and for passing from the defensive to the offensive, which combats between small bodies of troops so frequently present.

As a detachment must rely mainly on its own resources, the *personnel* and *matériel* of the troops should be rigidly inspected before marching, to see that the men and horses are in a sound state; that nothing is wanting in their equipments; that the gun and other carriages are in good traveling order; and that the necessary amount of ammunition, provisions, and forage have been provided for the expedition. Every source of information should be consulted with respect to the nature of the roads and the country over which the column is to march; and good maps, telescopes, and guides should be provided. If a reconnaissance of the line of march has been directed, it should be placed in charge of a well-informed staff or other officer conversant with the duties required of him, so that the Commander of the detachment may be accurately informed of the state of the roads, as to their practicability for men, horses, and carriages; particularly the number of hours of march from station to station; and the character of the obstacles with which he may be liable to meet, from the state of the bridges, the nature of the water-courses, and the defiles along the route. In order to avoid being anticipated in our object by the enemy, every attention should be paid to preserve strict order among the troops, and to advance with celerity, so that secrecy may be kept until the detachment reaches its destination. The troops for this purpose should be kept as closely together as the character of the ground will permit; and when guides are employed they must be strictly watched, and not be dismissed until the march is completed. The distribution of troops, or the *order of march,* will mainly depend upon the character of the country; the general rule to be followed is so to place each arm in the column that the troops may be formed for action by the most prompt and simple movements. In a very open country the greater part of the cavalry will be at the head of the column; where it is somewhat broken, half of the cavalry may be in front, and the remainder in the rear; and in a very difficult country the infantry will lead. The artillery may be placed in the intervals of the column where the country is not difficult; in the contrary case it will be in the rear, but covered by a small detachment which it precedes.

The column must be secured from a sudden attack of the enemy by an advanced-guard, flankers, and a rear-guard. The advanced-guard will be composed of cavalry or infantry, or of the two combined, according to the character of the country. In some cases it may be well to have two or three light pieces with the advanced guard. The strength of the advanced-guard, for detachments not over two thousand men, need not be greater than one fifth of the whole; for larger bodies it may be between a fourth and a third, according to the degree of resistance it may be required to offer. The advanced-guard of a detachment should seldom leave a wider interval than about a thousand paces between it and the main body. In a broken country, when this force consists of infantry alone the distance should be less, to avoid an ambush. The main body of the advanced-guard should always be preceded a few hundred paces by a strong patrol of cavalry or infantry, to search the ground and secure the advanced-guard from falling into an ambush, or from a sudden attack. The flankers will consist mainly of a few detachments, which march parallel to the column and a few hundred paces from it, according to the character of the ground; these will throw out a few men, from a hundred to a hundred and fifty paces, on their exposed flank, to keep a vigilant lookout, in that direction, for the enemy. Occasional patrols may also be sent out on the flanks when it is deemed necessary to push an examination to some distant point, or to gain a height offering a commanding view of the country. As the object of the flankers is rather to give timely notice to the main body of an enemy's approach than to offer any serious resistance, the detachments of which they are composed need only consist of a few men. The rear-guard, except in a very broken or mountainous country, which would offer facilities to the enemy for slipping to the rear, need only be a small detachment, placed more to prevent stragglers from falling to the rear than for any other object. Night-marches should not be made, except in case of necessity. When their object is to surprise an enemy, if there be an advanced-guard, it should be kept near the head of the column. Patrols should be sent forward, with orders to advance with great caution and not push on too far. Flying patrols may, if requisite, be kept up on the flanks. The most exact order and silence should be maintained, and extreme vigilance be exercised to avoid placing the enemy on the alert.

DETAIL FOR DUTY.—A roster, or table, for the regular performance of duty either in camp or garrison. The general detail is regulated by the Adjutant General, according to the strength of the several corps. The Adjutant of each regiment superintends the detail of the officers and non-commissioned officers for duty, and the Orderly Sergeants detail the privates.

DETONATING-FUSE.—By a detonating-fuse, or detonator, is meant one that causes a detonating explosion. The ordinary method of producing explosion is by the direct application of flame. By the detonating method, explosion of the main charge is caused by the concussion exerted by a small charge of explosive material in the fuse. Fulminating-mercury seems to possess peculiar properties as a detonator, and practically is the only body so used. Detonating-fuses are used when violent shattering explosions are desired. Thus nitro-glycerine, gun-cotton, and their preparations are always fired by means of a fulminate exploder. The ignition of the fulminate may be accomplished in the ordinary manner, or by the use of electricity.

The simplest fulminate exploder is made by attaching a copper case or large cap containing the fulminate to the end of a piece of common running-fuse. If the fuse fits the cap closely it may be retained in place, and the cap protected against moisture by pressing round it wax, hard soap, or other similar substance. If the fuse is too small, it must be passed through a plug of wood or small cork fitting the cap, and the whole fastened on as above. Before it is fastened into the cap the end of the fuse must be spread out so as to insure contact with the fulminate. Fifteen grains is the usual amount of fulminate placed in the cap; it should be put in when wet, with some gummy solution or varnish, so that it will dry to a solid lump which will not shake loose. Even in exploding powder there is often great advantage in using detonating-fuses. It is difficult to prove that actual detonation of the powder is brought about, but experiment has shown that a much more violent action can be obtained by using this mode of firing. See *Detonation* and *Fuse*.

DETONATING POWDER.—One which explodes by a blow. The compound used in the priming of percussion-caps and fuses is the fulminate of mercury or of silver, collected as a precipitate when the metal, dissolved in nitric acid, is poured into warm alcohol. The precipitate is collected, washed, and dried.

DETONATING-PRIMER.—A primer exploded by a fuse, and used in blasting-operations to violently explode gun-cotton, instead of the former plan by which the charge of gun-cotton was simply ignited.

DETONATION.—The instantaneous explosion of the whole mass of a body. Thus, when gunpowder is fired in the usual manner, true combustion takes place, which goes on with comparative slowness from the surfaces of the grains toward their interiors. On the other hand, when nitro-glycerine is fired by means of fulminating-mercury, the whole mass explodes simultaneously, or very nearly so. Doubtless a certain time is always necessary; but with the so-called detonating explosives it can be practically neglected, and the explosion called instantaneous.

Some explosives seem to always detonate, no matter how fired (chloride of nitrogen, the fulminates, etc.), while others are detonated or not according to the method of firing (gun-cotton, gunpowder, etc.). Probably all explosives can be detonated if the right methods of doing so are known. Gun-cotton seems to have a greater range of susceptibility to different modes of firing than any other explosive agent. It can be made to burn slowly without explosion, and the rapidity of its action can be increased up to the detonating point. Nitro-glycerine always explodes powerfully, but its effect is much lessened when fired with gunpowder. Gunpowder, as ordinarily used, is, of course, not detonated, as the violent, sudden effects of detonation would be undesirable. For other purposes (e.g., torpedoes, etc.) it would be a great advantage if it could be made to give more violent explosive effects by a peculiar mode of firing. It has been demonstrated that this can be done, although the best mode of doing it, or whether detonation is actually accomplished, is not known. Probably a mechanical mixture like gunpowder can never be brought by any mode of firing to approach as near to a perfect detonation as the chemical substance nitro-glycerine or gun-cotton; but, even if not detonated, better effects for certain uses may be obtained from it if the proper means are used.

Detonation is produced by the application of the requisite concussive force by means of a detonating-fuse. A detonating-fuse is one which causes explosion by the blow or shock it gives, while the ordinary fuse usually ignites by simple inflammation. Detonating-fuses are generally charged with fulminating-mercury, a substance which seems to be specially adapted for this use. With such fuses are fired nitro-glycerine and its preparations and dry gun cotton. There seems to be for each explosive about a certain amount and kind of force required to effect detonation, which must not be materially departed from. If the fuse is too weak, inflammation or a feeble explosion only will result; if too heavily charged, it is more likely to scatter or disintegrate the material acted upon than to explode it. There is also a relation between the mass of the explosive and the charge of the detonating-fuse which must be observed. This relation is more marked with some explosives than with others. Thus, nitro-glycerine is a body easily detonated, and the same amount of fulminate seems to fire equally well all usual quantities. If a single particle is detonated, the action quickly extends through the whole mass. Other substances, less easily detonated, require that as the mass is increased the force applied shall be increased, so that all the particles shall receive a sufficient blow, otherwise only a part will be detonated.

In a detonation we have the fullest *explosive* effect. The suddenness of the explosion concentrates the blow, making it sharp and violent. For certain purposes this is much more effective than would be the same total amount of force more slowly exerted. For instance, in blasting hard rock the violent explosion will throw out and shatter much more rock proportionally than the slower explosion, which intends to escape in the direction of the least resistance. Therefore, in blasting with nitro-glycerine, for example, hard tamping is unnecessary. The explosion is too sudden to allow the gases to blow out the tamping and so escape. The effect is consequently equal in all directions. The advantages gained in blasting with nitro-glycerine and its preparations are so great that their use is constantly increasing, in spite of their high cost and the prejudice against them on account of the many accidents that have occurred with them. When a scattering, tearing effect is desired, the detonating explosive must be used. See *Detonating-fuse*, *Explosion*, and *Gunpowder*.

DEVASTATION.—In warfare, the act of destroying, laying waste, demolishing, or unpeopling towns, fortified places, etc.

DEVELOPMENT. — That process in photography which immediately follows exposure, and which renders the picture visible in all its details. It consists in the precipitation or deposition of *new material* on that portion of the sensitive surface which has been acted on by light; the same principle therefore prevails in all processes. This may be made clearer by reference to a few examples. In the daguerreotype process, an iodized silver plate, after exposure in the camera, is exposed to the vapor of mercury; the vapor adheres to those portions of the plate which have undergone a peculiar molecular change from the action of light, but not to those parts unacted on. The lights of the picture are therefore "developed," or "brought out," by the acquisition of *new material*, i.e., mercury. A collodion negative is similarly "brought out" by the precipitation, by means of a deoxidizing agent, such as pyrogallic acid, or protosulphate of iron, on the *actinized* portion of the plate, of *new material*, composed of metallic silver and organic matter. A similar change takes place in the chrysotype process, where the metallic salt with which the paper is impregnated is reduced to a state of protosalt, which reacts through the decomposition of water, and causes the precipitation of *new material*, in the form of finely divided metallic gold, on the parts where light has acted. Other processes might be cited, but these are deemed sufficient to illustrate the principle stated above.

DEVIATION OF PROJECTILES.—The term *deviation* must be understood to mean not only the deflections, right or left, of the line of fire, but also the differences between the ranges of similar projectiles fired under like condition from the same guns. Very great irregularities occur in the paths of spherical projectiles. If a number of projectiles be fired from the same gun, with equal charges and elevations, and with gunpowder of the same quality, the gun-carriage resting upon a platform, and the piece being pointed with the greatest care before each round, very few of the projectiles will range to the same distance; and, moreover, the greater part will be found to deflect considerably, unless the range be very short, to the right or left of the line in which the gun is pointed. With elongated projectiles the fire is far more accurate, but still the ranges and deflections are subject to variations of greater or less amount. The causes of the deviations of projectiles, whether fired from smooth-bore or rifled guns, and independent of inaccuracy in pointing, and variable position of the gun-carriage, are *wind*, *variable projectile force*, and *rotation of the earth*.

Should the wind be blowing in gusts and be changeable in direction, it is difficult to allow for it in pointing the gun; but with a steady breeze in a pretty constant direction, a few rounds will generally be sufficient to show the allowance necessary. The velocity of the wind is very low compared with that of the projectiles, but it remains usually nearly the same throughout its flight, whereas the velocity of the projectile decreases rapidly; it therefore frequently happens that the wind appears to have greater effect towards the end of the range, and it may be often noticed in practice that projectiles deviate in a rapidly increasing curved line. The wind, if strong, will greatly affect the ranges of projectiles; decreasing or increasing the range according as it may be blowing with or against the projectile. The lower the velocity of a projectile, the greater will be its deflection caused by the wind, as, for instance, upon mortar-shells, on which, having low velocities and long times of flight, the wind exercises a very disturbing influence. The greater the density of the projectile, the less will its motion, during flight, be affected by the wind; and thus shells are more influenced by wind than shot. The wind exercises a very great deflecting influence upon an elongated projectile during its flight, rendering it difficult to obtain accuracy of fire at long ranges, even from rifled guns, excepting in very calm weather. If the center of gravity be placed very near the center of the long axis, the force of the wind will be pretty evenly distributed over the whole length of the projectile. Should, however, the center of gravity be placed far in advance of or behind the center of figure, the force of the wind will press unequally upon the shot, and uncertain deflections will most probably occur.

It is impossible with our present facilities to manufacture large quantities of powder of a perfectly uniform quality; but supposing it could be accomplished, the force from a given charge would be liable to variation according to the state of the atmosphere, and the condition of the powder as affected by the time it has been in store; it will also be frequently found in practice that the charges have not been weighed out with perfect accuracy, nor the gun loaded so that the projectile is always in the same position with reference to the charge. The consequence is that very few projectiles fired from the same gun with what are called equal charges leave the bore with exactly the same initial velocity.

The deviation of a projectile caused by the rotation of the earth is a complicated problem. The principle that this rotation will impress upon the projectile a tendency, upon leaving the bore, to move with the same velocity in the same direction as the point upon the surface from which the gun is fired is readily comprehended, but not its application to some particular cases. The deviation due to this cause is too slight to be regarded in practice.

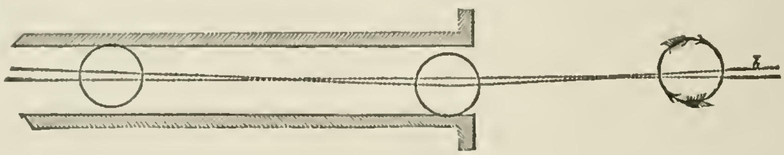

Fig. 1.

The line of sight may be improperly placed and situated out of the vertical plane, either in consequence of the construction of the gun or its carriage, or by the effect of the inclination of the plane upon which it is placed. In these two cases the line of fire maintaining a fixed and determined position, in respect to the axis of the gun and the vertical plane of fire, the deviations are constant for equal distances and equal inclinations, and it becomes easy to correct them after a few trials.

The barometric state of the atmosphere may also produce an effect upon the ranges; for the greater the density and elasticity of the displaced fluid, the greater will be the retardation of the projectile.

Spherical Projectiles.—The principal causes of the deviations of projectiles fired from smooth-bore guns are: 1st. Windage. 2d. The imperfect form and roughness of the surface of the projectile. 3d. Eccentricity of projectiles arising from their not being homogeneous.

Windage causes irregularity in the flight of a projectile, from the fact of the elastic gas acting in the first instance on the upper portion of the projectile and driving it against the bottom of the bore. The projectile reacts at the same time that it is impelled forward by the charge, and strikes the upper surface of the bore some distance in advance, and so on, by a succession of rebounds until it leaves the bore in an accidental direction and with a rotatory motion, depending chiefly upon the position of the last impact against the bore. Thus, should the last impact of a concentric projectile, when fired from a gun, be on the right-hand side of the bore, as represented in Fig. 1, it will have a tendency to deflect to the left in the direction *b*, while at the same time a rotation will be given to it in the direction indicated by the arrows, or to the right; the effect of this rotation being to cause the projectile itself to deviate to the right during its flight, so that the deflection will not be to the left, but to the right, unless the range is very short. If the projectile leave the gun, rotating on a vertical axis, with its forward part moving from left to right —supposing the observer to be behind the piece— there will be a diminished pressure on the right side, and an increased one on the left side, which will therefore cause it to deviate to the right. If a projectile strike the bottom of the bore, the rotation of the fore-part would be from up downwards, and instead of deflecting to the right, the range would be decreased. Suppose the projectile to rotate in an opposite direction, the results would be reversed. Should it, on leaving, strike any intermediate part of the bore, a compound effect would be produced, according to the position of the point of impact. It appears from these explanations that a projectile leaving the gun, rotating on any axis except one parallel to that of the bore, will deviate according to the direction of the rotation.

Should the center of gravity of a projectile not coincide with the center of figure, it is termed *eccentric*, and is found to deviate according to the position of the center of gravity when the ball is placed in the bore of the gun; should the line joining the center of gravity and the center of figure of a projectile be not parallel to the axis of the bore, the charge of powder will act on a larger surface on one side of the center of gravity than on the other, so that there will be a rotation from the lighter towards the heavier side.

It is found in practice that projectiles deviate in a curved line, either to the right or to the left, the curve rapidly increasing towards the end of the range. This probably occurs from the velocity of rotation decreasing but slightly compared to the velocity of translation; or if a very strong wind is blowing steadily across the range during the whole time of its flight, this deflecting cause being constant, while the velocity of the projectile diminishes, the curve will manifestly increase with the range; the trajectory is, therefore, a *curve of double curvature*, its projection on either a horizontal or vertical plane being a curved line.

From the foregoing considerations it follows that the smoother the surface of the projectiles and the less their windage and eccentricity, other things being equal, the greater will be their accuracy. Experiments show that the preponderating side should be put next the charge, and the line joining the center of gravity and the center of figure should be parallel to the axis of the bore. The position of the preponderating side is found by floating the projectile in a bath of mercury, and the degree of promptness with which an eccentric shot, floated as above, assumes the position due to its preponderance is regarded as the measure of that preponderance.

Elongated Projectiles.—If the projectile come out of the gun perfectly centered, that is, rotating round its longest axis, and having that axis coincident with the line of flight, there will be no tendency, either of the axis of rotation or of the projectile itself, to deflect, so long as the motion is in a straight line, because the resistance of the air will act uniformly all around. As soon, however, as the trajectory has begun to curve downwards under the influence of gravity, the resistance of the air acts more on the under side than on the upper, and effects will be produced depending on the resultant direction of the resistance of the air in relation to the center of gravity. Practically, the path of the projectile is found to result in a deviation increasing uniformly with the distance from the gun, and depending, as to its direction, on the direction of the deflecting force at the moment of its first application. If the deflecting force act on the projectile in a vertical direction upwards, the horizontal projection of the line of flight will be a line deviating to the right or left of the plane of fire, according as the twist is right- or left-handed. If the deflecting force act in the opposite direction, the projectile will be deflected to the left or right, according as the twist is right or left; and whatever be the direction of the deflecting force, the deviation will be a uniformly increasing one at right angles to it.

These effects may be illustrated experimentally by means of a gyroscope provided with a small elongated projectile instead of the disk used for ordinary experiments. The projectile must be made with the greatest care, so that its center of gravity coincides exactly with that of the two rings within which it is placed; the rings are so arranged that one can turn round a vertical axis, and the other round a horizontal axis, the projectile being therefore free to turn in any direction. A cylindrical portion of metal extends beyond the base of the projectile, in prolongation of its longer axis, round which the string is wound to give the required rotatory motion. As the projectile in the gyroscope has no motion of translation, a strong current of air must be directed upon it, so as to represent the resistance of the atmosphere to a projectile moving with a high velocity. The diameter of the nozzle of the blower should be equal to, or rather larger than, that of the projectile, and the center of the blast should be directed below the point of the projectile.

The line of flight is not absolutely a straight line, but becomes a curve of double curvature; and if projected on a vertical plane at right angles to the plane of fire, would consist of a series of cycloidal curves, were the time of flight sufficiently great, increasing the distance of the projectile from the plane of fire by the length of one of them at each revolution. The length of these curves depends upon the amount of the deflecting force, and their number is equal to the number of revolutions made by the projectile in its flight.

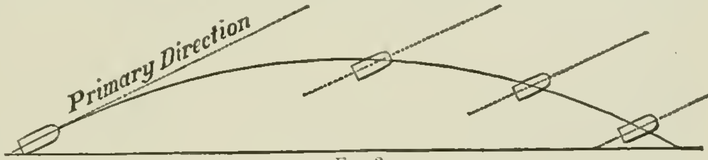

FIG. 2.

When an elongated projectile is fired from a rifled gun, it leaves the bore rotating rapidly round its longer axis; and if the initial velocity were very low, the projectile experiencing but slight resistance from the atmosphere, the larger axis would remain (as in vacuo) during the whole time of flight parallel or nearly so to its primary direction, as shown in Fig. 2. While explaining the effect produced by the resistance of the air upon an elongated projectile moving with a high velocity, the projectile will be supposed to have what is termed a right-handed rotation; that is, the upper part turns from left to right, with reference to an observer placed behind the gun: for the direction of the grooves of rifled pieces is almost invariably so as to give such rotation. After the projectile has left the bore, the resultant of the resistance of the air will, unless the center of gravity be very far forward, act upon a point in front of the center of gravity and below the longer axis, at all angles of elevation given in practical gunnery. The effect produced by this pressure will depend chiefly upon the form of the head of the projectile; therefore let us in the first place consider the effect upon a conoidal head.

Of course the longer axis of an elongated projectile does not remain, during flight, continually a tangent to the trajectory, unless the center of gravity, as in an arrow or rocket, is very near the face-end; yet, practically, on account of the drooping of the point, the longer axis may throughout a considerable portion of the time of flight approximate very nearly to a tangent to the trajectory. The effects on targets furnish most satisfactory evidence of this; it is almost invariably found that the holes made in targets are circular, even when elongated projectiles descend at considerable angles. The most probable explanation of this fact must evidently be that the point of the projectile has drooped during flight, so that, on striking, the longer axis is nearly perpendicular to the plane of the target.

This drooping of the point is of importance; for did the axis remain parallel during flight to its primary direction, the projectile would most probably, when fired at any but a very low angle, on striking an object of hard material and solid structure, turn up against it lengthways, and therefore produce but trifling effect. This has not, however, been found to take place in practice; but on the contrary the penetration of elongated projectiles at considerable ranges is always remarkably great. There is little fear of the projectile turning up against an object unless the velocity of translation and rotation be very low, and the angle of fire very high.

It is found in practice that conoidal-headed projectiles fired from rifled guns giving a right-handed rotation always deviate to the right; and in the few cases tried with guns giving a left-handed rotation the deviation is to the left; with flat-headed projectiles these deviations are reversed. This peculiar deviation is called *drift*, and is generally constant for the same ranges; so that it can be allowed for in pointing the gun, by using a horizontal slide graduated and attached to the tangent scale, or by inclining the tangent scale to the left. See *Projectiles* and *Trajectory*.

DEVICE.—A motto expressed by means of a pictorial emblem. The motto proper originated in the emblem, a written inscription coming to be added to the pictorial design, with the view of rendering the meaning more explicit. Devices thus consist of two parts—a pictorial figure called the "body," and a motto in words called the "soul" of the device. As early as the times of Æschylus, the "Seven Heroes before Thebes" all appear with devices on their shields; and the same is related by Xenophon of the Lacedæmonians and Sicyonians. In the Middle Ages, devices on coat-armor came into regular and formal use, and Chivalry employed them in its courtly expressions of devotion to the fair sex. They were used both as charges on the shield and as crests. The only respect in which the device differs from other heraldic emblems is that it has always some specific reference to the history, or circumstances, or position of the bearer. As an example: Louis XIII. of France had a falcon as a device, with these words: "*Aquila generosior ales*" (A more generous bird than the eagle), by which he meant to denote his own superiority to the Emperor, whose device was an eagle. Devices, moreover, were generally borne only by the individual who assumed them, and not by the other members of his family or his descendants, like the crest or cognizance. They were often contrived to typify a special enterprise, the general character of the wearer, or even to designate his name—as the *mulberry* trees in the embroidered trappings of the horse of Thomas Mowbray, Duke of Norfolk. On all festal occasions they figured on triumphal arches, on banners and hangings. At a later period it became customary to work devices into buildings: friezes and stained windows were often covered with them. This practice has recently much gone out, at least in its original form. See *Heraldry*.

DEXTER RIFLE.—A breech-loading small-arm possessing a fixed chamber closed by a movable breech-block, which rotates about a horizontal axis at 90°. to the axis of the barrel, lying below the axis of the barrel and in front—being moved from above by a thumb-piece.

The arm is opened by half- or full-cocking the hammer, and then swinging down the breech-block by depressing the thumb-piece on the right side of the frame. This pushes back the firing-pin and the locking-brace, by the cam acting on the firing-pin retractor and locking-brace retractor respectively. It is closed by raising the thumb-piece, so as to swing the breech-block up into place. In so doing, the locking-brace is thrown forward by its spring into place under the breech-block, as soon as the latter is closed.

The piece is locked by the position of the locking-brace, the lower end of which abuts upon the guard, and is fired by a center lock of the usual pattern. Both extraction and ejection are accomplished by a revolving extractor, pivoted near the breech-block pin, and struck by the block in its descent. In opening the block the locking-brace is forced against the trigger, and is held there by the block; the hammer, therefore, cannot be made to fall while the piece is opened.

DHALL-BUSH.—The wood used in India in the preparation of charcoal for gunpowder. It grows in most parts of India, and has been found to make the best charcoal of the several woods at present known in that country. Dhall-bush has a growth of a few months: the seed is planted in April, and the grain ripens about the 1st of January the next year, when the bushes are cut down. The stalks are brought in and stacked for use at the powder-works. The wood is white and soft, and contains much saccharine matter. Hence insects breed internally, while externally it is attacked by various moths, which deposit their larvæ. The charcoal is good, its fibrous texture distinct, and it rings with a clear, metallic sound, being at the same time soft and friable. A *beegah of urhur*, another word for the dhall-bush, is calculated to give about 200 maunds of wood in its yearly crop, or the charcoal for 160 barrels; hence 10,000 barrels would require a yearly cultivation of 60 beegahs. As a general rule, the wood should be stripped of its bark previous to charring; this practice was not uniformly pursued in the Indian powder-manufactories in former years, owing, it is supposed, to the expense, and, perhaps, the importance of peeling the wood not having been realized. The peeling process is now strictly carried out. See *Charcoal*.

DHAO.—A Burman tool or weapon (half chopper, half sword) used in clearing jungle and in cutting down trees of all kinds. The Burmese make great use of this cutting instrument.

D'HARSCH SYSTEM OF FORTIFICATION.—In this system the enceinte en tenaille consists of a mere wall, forming a parapet, and covered by counterguards, ravelins, and lunettes. Defensive barracks are constructed on the terre-plein of the ravelins.

DHURREE.—An Indian term for a coarse kind of cotton carpet, called also a *satringee;* it is used for the flooring of tents, and very generally for carpets in most houses in the Northwest Provinces of India. This kind of cloth is made in different parts of the country, and very often by prisoners in jails. A small satringee is issued by the Commissariat Department to every European soldier, which is placed on his sleeping-cot in barracks, and in which his bedding is folded up on the march.

DIABLE.—A truck-carriage on four trucks, used for moving heavy ordnance short distances; it is provided with draught-hooks at each end, so as to be easily drawn to front or rear.

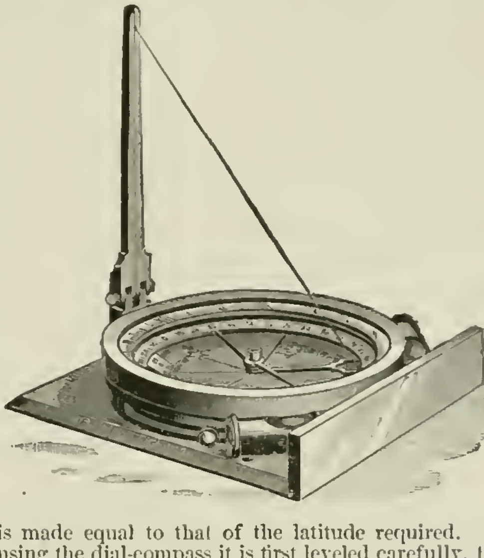
DIADEM.—The name given to the fillet of silk, woolen, or linen which served as the distinguishing ornament of kings. It was generally narrow, being only a little broader on the forehead. The diadem of the Egyptian goddesses and kings bore the symbol of the sacred serpent. The diadem of Bacchus, as it appears in ancient sculptures, was a plaited band going round the forehead and temples, and tied behind, with the ends hanging down. Among the Persians the diadem was bound round the tiara or turban, and was of a blue color, worked with white. The early Roman Emperors refrained from using this ornament, in order not to call up recollections of the hated kingly office. Diocletian was the first to introduce it again, and Constantine the Great added new ornaments to it. After his time it was adorned with a single or double row of pearls and precious stones. Queens are also seen on coins ornamented with the diadem, with the addition of a veil. It was finally superseded by the crown. See *Crown.*

DIAGOMETER.—A kind of electroscope, in which a dry pile is employed to measure the amount of electricity transmitted by different bodies or determine their conducting power. Used to detect foreign mixture in olive-oil.

DIAGONAL. — In plane geometry, a straight line joining any two angles, not adjacent, of a rectilineal figure. A line drawn between two adjacent angles would coincide with the boundary-line. A triangle has no diagonal, because any two of its angles are adjacent; a four sided figure has two diagonals; a five-sided, five; a six-sided, nine; etc. The number of possible diagonals in any figure is found by taking three from the number of sides, multiplying the remainder by the number of sides, and taking half the product. Thus, in the six-sided figure, the process is $\frac{3 \times 6}{2} = 9$. If the diagonals must be so drawn as not to intersect, their number is always three less than the number of sides. It makes no difference whether they all proceed from one angle or not. A diagonal in a solid bounded by planes is a line joining any two solid angles so situated that the line does not coincide with any line on the surface. To find the number of such diagonals in a given solid: Multiply the number of solid angles by the same number diminished by one, and from half this product subtract the number of edges on the figure, and also the sum of the number of diagonals in all the faces. Thus, the cube gives $\frac{8 \times 7}{2} - 12 - 6 \times 2 = 4$ diagonals.

DIAGONAL SCALE.—A system of lines by means of which hundredths of units may be laid down or measured with compasses. When the numbers representing the lengths of the sides of any figure would give lines of an inconvenient size taken from the scale, the numbers may be all multiplied or all divided by such a number as will adapt the lengths of the lines to the required dimensions of the figure. See *Scale*.

DIAL-COMPASS. — This little instrument has a needle three inches long, and with its compass-circle is inclosed in a circular box set upon a brass base four inches square, three edges of which are chamfered and divided; one on the W side of the compass into inches and tenths, the two others into degrees and half-degrees, and figured from a center on the southwest corner of the base. The compass-circle is movable in order to set off the variation of the needle, and has a vernier attached to it on the inside, reading a divided arc on the face of the compass to three minutes of a degree. There is also on the south side of the face an arc of 180°, figured from 0 to 90 on each side of the south or zero line of the face. A little pendulum with index-point hung from the center-pin reads this arc, when the compass is set up, vertical, on the raised south edge, thus making it a clinometer or slope-measurer. The sight is hinged so as to fold in packing, but when erect makes taut a fine silk thread attached at one end to the sight and at the other to a brass hour circle above the compass-glass, at an angle with the plane of the hour-circle equal to that of the latitude of the place where the compass is used. The hour-circle is divided for any required latitude like that of a sun-dial, the hair serving as a gnomon to give apparent time with the sun. When it is desired to use the instrument at a latitude a degree or two either higher or lower than that for which the hour-circle is divided, the end of the thread attached to the sight may be made adjustable, so as to be either raised or lowered on the sight until the angle of the thread with the plane of the hour-circle



is made equal to that of the latitude required. In using the dial-compass it is first leveled carefully, the equation of time for the given day allowed for, and then by observation on the sun at midday the true meridian approximately obtained. The needle may then be set to the meridian by laying off the variation, and any deflection of the needle from the true meridian will indicate the presence of veins of magnetic iron-ore. See *Clinometer* and *Solar Compass*.

DIAMAGNETISM.—The fact that iron is attracted by the magnet has been known from very remote times; that bismuth exhibits a repulsive action towards the magnetic needle has been now known for nearly a hundred years. Dr. Faraday was the first (1845) to show that all bodies are more or less affected by magnetic influence, and his beautiful researches on the subject have opened up a new field in the domain of science. He found that the magnetism of bodies was manifested in two ways—either in being attracted by the magnet, as iron, or in being repelled, like bismuth. When a needle or slender rod of iron is suspended between the poles of a magnet, as in Fig. 1, being

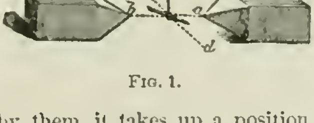


FIG. 1.

attracted by them, it takes up a position of rest on the line, *a b*, joining the two poles. When a substance behaves itself in this manner, it is said by Faraday to be *paramagnetic*, and to place itself *axially*, *a b* being the axis. A rod of bismuth, on the other hand, being repelled by the poles of the magnet, comes to rest in the line, *c d*, at right angles to *a b*. Bismuth, and the like substances, he calls *diamagnetic*, and they are said to place themselves *equatorially*, *c d* being the equator. These terms, being both definite and graphic, have been universally adopted. Magnetic is the term used by Faraday to indicate magnetism of either sort, although in general language it is understood to refer to paramagnetic bodies, such as iron, etc. Paramagnetic bodies, then, are those which manifest the same properties with regard to the magnet that iron does; and diamagnetic bodies are those which, like bismuth, show opposite but corresponding properties; so that in circumstances where paramagnetic bodies place themselves axially, diamagnetic bodies place themselves equatorially; and where the former are attracted, the latter are repelled, and *vice versa*. A paramagnetic, therefore, not in the elongated form, but in a compact shape, such as a ball or cube, is attracted by either pole of the magnet when suspended near it; a ball or cube of a diamagnetic, on the other hand, experiences, when so placed, repulsion. The paramagnetism of iron, nickel, and cobalt becomes manifest in the presence of magnets of ordinary power; but the magnetism of most other substances is so feeble as to be developed only under the influence of the strongest magnets. As electro-magnets far exceed permanent steel magnets in strength, they are selected for investigations on the magnetism of bodies. To observe the effect of the magnet on liquids, Faraday placed them in long tubes of very thin glass, and suspended them as in the case of solid needles. It was found that some arranged themselves axially, and others equatorially. The attraction and repulsion that liquids experience in the presence of the magnet has been prettily shown by Plucker. A large drop of liquid is placed in a watch-glass, Figs. 2 and 3, and laid upon two poles of the magnet. If the liquid be paramagnetic, the surface becomes depressed at the interval between the poles, and heaped up over the extreme edges of them, Fig. 2. A diamagnetic liquid, on the other hand, shows a de-

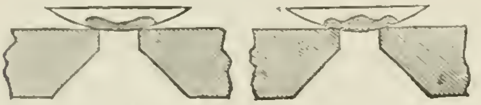

FIG. 2. FIG. 3.

pression at each edge of the poles, and a heaping up at the center, Fig. 3. The magnetic nature of flames and gases has been also studied. When the flame of a candle is brought between the poles of a magnet, it is repelled by them, and thrown out horizontally into an equatorial position. To ascertain the magnetism of gases, Faraday inflated soap-bubbles with them, and their para- or dia-magnetism was exhibited by their being attracted or repelled by the poles. He ascertained the same by causing the gases to flow out from glass tubes in the presence of the poles, when the peculiar magnetism of the gas was shown by its choosing an axial or equatorial means of egress. The following list gives the kind of magnetism displayed by the more common substances: *Paramagnetic*—Iron, nickel, cobalt, manganese, chromium, titanium, palladium, paper, sealing-wax, peroxide of lead, plumbago, red-lead, sulphate of zinc, shellac, vermilion, charcoal, proto and per salts of iron, salts of manganese, oxygen, air. *Diamagnetic*—Bismuth, antimony, zinc, tin, cadmium, sodium, mercury, lead, silver, copper, gold, arsenic, uranium, tungsten, rock-crystal, mineral acids, alum, glass, litharge, niter, phosphorus, sulphur, resin, water, alcohol, ether, sugar, starch, wood, bread, leather, caoutchouc, hydrogen, carbonic acid, coal-gas, nitrogen. The nature of the medium in which the body under examination moves exerts a powerful influence on the nature and amount of the magnetism it exhibits; thus, if a glass tube be filled with a solution of the protosulphate of iron, and suspended between the poles, it will place itself axially. It will do the same if made to move in water, or a solution more dilute of the protosulphate of iron. It will be indifferent in a solution of the same strength; but it will place itself equatorially in a stronger solution. Thus, the same substance may appear paramagnetic, indifferent, or diamagnetic according to the nature of the medium in which it moves. As a general rule, a body shows itself paramagnetic towards one less paramagnetic than itself, indifferent towards one equally magnetic, and diamagnetic towards one more paramagnetic than itself. The same takes place, *mutatis mutandis*, with diamagnetic substances This has given rise to the theory that there is no such thing as diamagnetism *per se*, and that bodies are diamagnetic only in media of greater paramagnetic power than their own. This view of the case is, however, rendered highly improbable from the fact that diamagnetism is exhibited as decidedly in a vacuum as in any medium, and a vacuum cannot be supposed to possess magnetic properties of any kind.

DIAMETER.—A line passing through the center of a circle, bounded at each end by the circumference. When great accuracy is not required, the proportion of the diameter of a circle to the circumference may be taken as 1 to 3.1416. To find the diameter of a spherical shot, its weight being given, multiply the cube root of the shot's weight by 1.923 for the diameter. In taking the diameter or caliber of the bore of a rifled gun, it is measured across the *lands*.

DIAMOND-POINT.—A stylus armed with a diamond, either ground, conical, or made of a selected fragment of the desired shape. Wilson Lowry introduced the diamond-point into engravers' ruling-machines. Etching-tools have been pointed with diamonds. Diamond-points are used in ruling the graduation of the finer kinds of instruments; also by Nobert, it is supposed, in ruling the wonderful series of lines that form the tests of the microscopes of higher powers.

DIAMOND-TOOL.—A metal-turning tool whose cutting edge is formed by facets. Much used in the arsenal.

DIAPHRAGM-SHELL.—A shrapnel shell used in the English service. It is used with smooth-bore ordnance, and is an improvement on the original shrapnel shell; it is the invention of General Boxer, R.A. It has a wrought-iron partition or diaphragm which separates the bursting-charge from the bullets. The channel of communication, termed the loading-hole, from the exterior of the shell to the powder-chamber, into which the bursting-charge is poured, is closed and opened by a small screw. The bursting-charge in this shell is considerably reduced, and the interior of the shell is coated with marine glue, in order to insure complete separation between the powder of the bursting-charge and the coal-dust thrown between the bullets. The bursting of the shell is facilitated by four grooves formed in its interior surface which act as so many lines of "least resistance." See *Shell*.

DIAPRE.—A term applied in Heraldry to fields and charges relieved by arabesque and geometrical patterns. These patterns were generally of a darker shade of the same tincture. This being merely an ornamental device, not affecting the heraldic value of the objects to which it was applied, was generally left to the fancy of the painter. See *Heraldry*.

DICTATOR.—In the earliest times, the name of the highest Magistrate of the Latin Confederation, and in some of the Latin towns the title was continued long after these towns were subjected to the dominion of Rome. In the Roman Republic the Dictator was an extraordinary Magistrate, irresponsible and endowed with absolute authority, whose original name was *Magister Populi*. The frequency of *crises*, or critical periods, in the quick, aggressive growth of the Roman State necessitated such an office. The first Dictator (T. Larcius or M. Valerius) was appointed 501 B.C., nine years after the expulsion of the Tarquins. According to Livy, the immediate cause of this dictatorship was a formidable war with the Latins. In general no one could be appointed Dictator who had not been previously Consul, and this condition was very rarely dispensed with. Niebuhr is of opinion that the Dictator was originally created or elected by the Curiæ, like the Kings, but it is more probable that the Senate passed a decree ordering one of the Consuls to name or proclaim (*dicere*) a Dictator. Originally, of course, the Dictator was a Patrician; the first Plebeian who filled the office being C. Marcius Rutilus, 356 B.C., who was nominated by the Plebeian Consul M. Popillius Lænas. The Dictatorship could not *lawfully* be held longer than six months, nor was it ever so, except in the cases of Sulla and Cæsar, which were altogether peculiar. It must not be supposed that during a Dictatorship the functions of the other Magistrates were positively suspended. The Consuls and other regular authorities continued to discharge their proper duties, but in subordination to the direction and command of the Dictator; being for the time simply his officers. The superiority of his power, when compared with that of the Consuls, appears chiefly in these three points: he was far more independent of the Senate; he had a more extensive power of punishment, without any appeal; and he could not be called to account after his abdication of the Dictatorship for anything he had done during the period of his office. The *limits* of his power were as follows: he could not touch the Treasury; he could not leave Italy; and he could not ride through Rome on horseback without previously obtaining the permission of the people. While the Consuls had only 12 Lictors, the Dictator was preceded by 24, bearing the *secures* and *fasces*. To him also belonged the *sella curulis* and the *toga prætexta*. The last legally elected Dictator was M. Junius Pera, who entered on his office 216 B.C. From this time *nominal* Dictators were frequently appointed for the purpose of holding the elections, but even these finally disappeared, 202 B.C. Henceforth, in critical times, a sort of dictatorial power was conferred on the Consuls by the Senate by the well-known formula, "That the Consuls should see to it that the State should receive no damage." This practice rendered the appointment of *Dictators* no longer necessary.

DIDION'S FORMULAS. — In consequence of the variable nature of the resistance of the air, it has been found impossible to integrate the differential equations of the real trajectory, even under the supposition that this resistance varies in as simple a ratio as the square of the velocity. Several distinguished mathematicians have obtained expressions which approximate to the true results, but the expressions are generally too complicated to be of much practical value.

Captain Didion, Professor of Gunnery in the Artillery School at Metz, however, furnishes an approximate solution to this difficult question, which may be used in practice. To do this, he considers the resistance of the air equal to

$$A\pi R^2\left(1+\frac{v}{r}\right)v^2;$$

and by assuming a mean value for the different inclinations of the elements of the trajectory to their horizontal projections, which makes $\frac{ds}{dx}$ constant, he is able to integrate the differential equations, and place them under the following forms:

$$y = x\tan A - \frac{g}{2}\,\frac{x^2}{V^2\cos^2 A}\,B;$$

$$\tan\theta = \tan A - g\frac{x}{V^2\cos^2 A}I;$$

$$t = \frac{x}{V\cos A}D; \qquad v = \frac{V\cos A}{\cos\theta}\,\frac{1}{U}.$$

The same notation being preserved as in the equations in the article Equations of Motion of Projectiles, it will be perceived that the equations in air differ from those in vacuo by the multipliers B, I, D, and U respectively. The multiplier B relates to the fall of the projectile; I, to the inclination; D, to the duration; and U, to the velocity; they are each functions of $\frac{\alpha x}{c}$ and $\frac{\alpha V}{r}$; in which α is the constant relation of the arc to its projection, $V_1 = V\cos A$, and c and r are coefficients of the formula for the resistance of the air. The general expression for a particular multiplier, B for instance, is $B\left(\frac{\alpha x}{c};\frac{\alpha V}{r}\right)$. The values B, I, D, and U, for such values of c and r as are likely to arise in service, have been computed, and arranged in tabular form.

So long as the inclination of the trajectory is slight, α differs but slightly from unity; for an angle of 15° it does not exceed .01; and as it only enters into the term which relates to the resistance of the air, the error does not exceed a pressure corresponding to .25 inch in the height of the barometer; it may, therefore, be regarded as unity, and $\frac{\alpha x}{c}$ reduces to $\frac{x}{c}$. The same with regard to $\frac{\alpha V}{r}$, or $\frac{\alpha V\cos A}{r}$; as $\alpha \cos A$, when $A = 10°$, differs only about .01 from unity; and this expression may be reduced to $\frac{V}{r}$. When the angle of projection does not exceed 3°, cos A differs only .001 from unity, and we can everywhere replace $V\cos A$ by V. Under this angle, $\frac{\cos A}{\cos\theta}$ differs but slightly from unity, and we have $v = \frac{V}{U}$, which is the same as if motion took place in a horizontal plane.

All cases of the movement of projectiles which occur in practice may be divided into three distinct classes: 1st. When the angle of projection is slight or does not exceed 3°, as in the ordinary fire of guns, howitzers, and small-arms; 2d. When the angle of projection is greater than this, but does not exceed 10° or 15°, as in ricochet-fire, etc.; 3d. When the angle of projection exceeds 15°, as in the fire of mortars.

1st Class. *For small angles of projection, as in guns, howitzers, and small-arms.* — For slight variations of the angle of projection above or below the horizon, the form of the trajectory may be considered constant; and when the object is but slightly raised above or depressed below the horizontal plane, it may be considered as in this plane. In consequence of the windage, and the balloting of the projectile which results from it, the projectile does not always leave the bore in the direction of the axis. The angle formed by the line of departure and the axis of the piece is called the *angle of departure*. For guns in good condition the vertical deviations do not exceed 5′, and for howitzers 10′; the side deviations never exceed 4′ 30″. To obtain exact results, therefore, it is necessary to correct the angle of projection for the angle of departure, when the latter is known. Under the supposition that α, cos A, and $\frac{\cos A}{\cos\theta}$ are each equal to unity, the equations of the trajectory in air may be reduced to

$$y = x\tan A - \frac{gx^2}{2V^2}B; \quad . \quad . \quad . \quad (1)$$

$$\tan\theta = \tan A - g\frac{x}{V^2}I; \quad . \quad . \quad . \quad . \quad (2)$$

$$t = \frac{x}{V}D; \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

$$v = \frac{V}{U}. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

Knowing the weight and diameter of the projectile, c can be calculated by the formula $c = \frac{2\,RD}{3\,gA}$ if it be not found in the table which accompanies it. We know $\frac{x}{c}$ and $\frac{V}{r}$, and by means of the tables can determine the desired values of B, I, D, and U.

Of the three things, the initial velocity, V, the distance of the object, X, and the angle of projection, A, two being known, to determine the third.

1. *To determine the angle of projection, A.*—Make $y = 0$ in equation (1), and solve it with reference to $\tan A$; we have

$$\tan A = \frac{g}{2}\frac{X}{V^2}B.$$

2. *To determine the initial velocity, V.*—Make $y = 0$ in equation (1), solve it with reference to V, and multiply both members by $\frac{1}{r}$; we have

$$\frac{\frac{V}{r}}{\sqrt{B}} = \frac{1}{r}\sqrt{\frac{g}{2}\frac{X}{\tan A}} = q.$$

Having the values of $\frac{X}{c}$ and q, seek in the Tables of Multipliers for the value of $\frac{X}{c}$ the value of $\frac{V}{r}$, which gives that of q; multiply $\frac{V}{r}$ by 1427 and we shall have V.

3. *To determine the range, X.*—Make $y = 0$ in equation (1), obtain the value of X, and divide both members of the equation by c; we have

$$\frac{X}{c}B = \frac{\tan A V^2}{c\frac{1}{2}g} = p.$$

Having the initial velocity, V, and angle of projection, A, we can determine $\frac{V}{r}$ and p; seek in the tables for the value of $\frac{V}{r}$ that of $\frac{X}{c}$, which gives p; having $\frac{X}{c}$, multiply it by c, and we have X.

In firing spherical case-shot it is important not only to know the time of flight, in order to regulate the fuse, but it is important to know that the projectile will have sufficient remaining velocity to render the impact of the contained projectiles effective.

4. The *time of flight* can be obtained from equation (3), or $t = \frac{x}{V}D$. Knowing $\frac{x}{c}$ and $\frac{V}{r}$, we can obtain the corresponding value of D from the tables.

5. The *remaining velocity* can be obtained from equation (4), or $v = \frac{V}{U}$. Knowing $\frac{X}{c}$ and $\frac{V}{r}$, obtain from the tables the corresponding value of U.

2D CLASS. *For angles of projection not exceeding* 10° *or* 15°, *as in the ricochet-fire of guns, howitzers, and mortars.*—The formulas are:

$$y = x\tan A - \frac{g}{2}\frac{x^2}{V^2\cos^2 A}B; \quad . \quad (5)$$

$$\tan\theta = \tan A - g\frac{x}{V^2\cos^2 A}I; \quad . \quad . \quad . \quad (6)$$

$$t = \frac{x}{V\cos A}D; \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

$$v = \frac{V\cos A}{U\cos\theta}. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

If the object be on a level with the piece, the solution of this class of problems is the same as those of class 1st, when the angle is very small; if not, it will be necessary to substitute for V, $V = V\cos A$, and after having obtained V, divide it by $\cos A$, which gives V. The object being situated at the distance a from the piece, and at the distance b above the horizontal plane passing through the center of the muzzle, is seen under an *angle of elevation* ε, for which $\tan\varepsilon = \frac{b}{a}$. One of the two things, the initial velocity or angle of projection, being known, to determine the other.

1. *To determine the initial velocity, V.*—Substitute in equation (5) the co-ordinates a and b, and V_i; solve it with reference to V; substitute $\tan\varepsilon$ for $\frac{b}{a}$, and divide both members by r. We have

$$\frac{\frac{V_i}{r}}{\sqrt{B}} = \frac{1}{r}\sqrt{\frac{\frac{g}{2}a}{\tan A - \tan\varepsilon}} = q.$$

Having the value of q, seek in the tables for the known value of $\frac{a}{c}$ the value of $\frac{V_i}{r}$ corresponding to it, and multiplying by $\frac{r}{\cos a}$, we shall have V.

2. *To determine the angle of projection.*—The result will be sufficiently near the truth if we substitute, in equation (5), V for V_i, or $V\cos A$; and solving it with reference to $\tan A$, we have

$$\tan A = \tan\varepsilon + \frac{ga}{2V^2}B,$$

in which we substitute for B its value corresponding to $\frac{a}{c}$ and $\frac{V}{r}$, obtained from the tables.

3D CLASS. *Properties of trajectories under high angles of projection.*—As a projectile rises in the ascending branch of its trajectory, its *velocity* is diminished by the retarding effect of the air and the force of gravity: in consequence of the resistance of the air alone, the velocity continues to diminish to a point a little beyond the summit of the trajectory, where it is a minimum; and from this point it increases, as it descends, under the influence of the force of gravity, until it becomes uniform, which event depends on the diameter and weight of the projectile and the density of the air, or, in other words, upon the value of c. The *inclination* of the trajectory decreases from the origin to the summit, where it is nothing; it increases in the descending branch from the summit to its termination, and if the ground did not interpose an obstacle, it would become vertical at an infinite distance. An element of the trajectory in the descending branch has a greater inclination than the corresponding element of the ascending branch. Strictly speaking, the trajectory in air is an exponential curve with two asymptotes; the *first* is the axis of the piece, which is tangent to the trajectory when the initial velocity is infinite; the *second* is the vertical line toward which the trajectory approaches as the horizontal component of the velocity diminishes and the effect of the force of gravity increases. The *curvature* of the trajectory increases in the ascending branch to a point a little beyond the summit. The point of greatest curvature is situated nearer the summit than the point of minimum velocity. In the fire of mortar-shells under great angles of projection, and at customary distances, the trajectory may be considered as an arc, in which the angle of fall is slightly greater than the angle of projection. In the ascending branch the arc commences under an angle of A, and terminates under an angle of 0; the ratio of the length of this arc to its projection, or α, is calculated for all arcs from 5° to 75°, and arranged in groups of fives. The value of α is considered the same in the descending as in the ascending branch. The multipliers, B, I, D, and the divisor, U, are calculated for the values $\frac{\alpha x}{c}$ and $\frac{\alpha V}{r}$, and they are employed in equations (5), (6), (7), (8), as in the preceding class of cases.

1. *Find the initial velocity of a mortar-shell, knowing the range and angle of projection.*—We know $\frac{\alpha x}{c}$, and by solving equation (5) as before we have

$$\frac{\frac{\alpha V}{r}}{\sqrt{B}} = \frac{\alpha}{r}\sqrt{\frac{\frac{1}{2}gX}{\tan A}} = q.$$

Having determined the value of q, seek in the tables the value of $\frac{\alpha V}{r}$ corresponding to it for $\frac{\alpha x}{c}$; then multiply it by $\frac{r}{\alpha \cos A}$, and we have V.

2. *To determine the angle and velocity of fall, and the time of flight, knowing the initial velocity and range.*

3. *To determine the range, knowing the initial velocity and angle of projection.*—We have α and $\frac{\alpha V}{r}$; make $y = 0$ in equation (5); solve it with reference to X, and multiply both members by $\frac{\alpha X}{c}$, and we have

$$\frac{\alpha X}{c} B = \frac{\alpha V^2}{gc} \sin 2A = p.$$

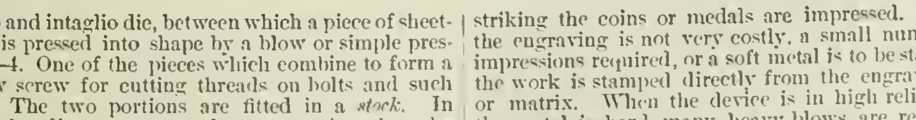
Having found the value of $\frac{\alpha X}{c}$, which for $\frac{\alpha V}{r}$ gives p, multiply it by $\frac{c}{\alpha}$, and we have X.

In consequence of considering the inclination of the trajectory as constant in the preceding equations, the resistance of the air is slightly underestimated in the more inclined portions of the trajectory, or at the beginning and end, and slightly overestimated in the less inclined portions, or about the summit. It follows that the calculated trajectory will at first rise above the true one, then pass below it, and again pass above it; the calculated ranges will therefore be found slightly in excess. From the law of inertia, a rifle-projectile moves through the air with its axis of rotation parallel to the axis of the bore. Hence it follows that an oblong projectile, fired under a low angle of projection, presents a greater surface toward the earth, and less parallel to it, than a round projectile of the same weight; consequently the vertical component of the resistance of the air is greater, and the horizontal component less, in the first case than in the second. The effect of this will be to give an oblong projectile a flatter trajectory and longer range than a round one. See *Equations of Motion of Projectiles, Multipliers, Projectiles,* and *Resistance of the Air.*

DIE.—1. In punching-machines, a bed-piece which has an opening the size of the punch, and through which the piece is driven. This piece may be a planchet or blank, or it may be merely a plug driven out of the object to form a bolt- or rivet-hole. In nut-machines the nut-blanks may be made by one die and punched by another.—2. A device consisting of two parts which coact to give to the piece swaged between them the desired form.—3. A former and punch, or a cameo and intaglio die, between which a piece of sheet-metal is pressed into shape by a blow or simple pressure.—4. One of the pieces which combine to form a hollow screw for cutting threads on bolts and such like. The two portions are fitted in a *stock.* In some the dies are set up by screws, in others by scrolls. The drawing represents the Billings stock and dies. The arrangement for holding in the dies is novel. Two feathers hold the dies in position, as shown in the drawing. Turning the screw from the top die and pressing on the pin at the lower edge of the plate leaves the dies free to fall out. A pair of dies for holding *taps* may be used in the plate in place of the thread-dies, making a very convenient tap-wrench and at the same time saving the necessity of an extra wrench, as it combines the two.

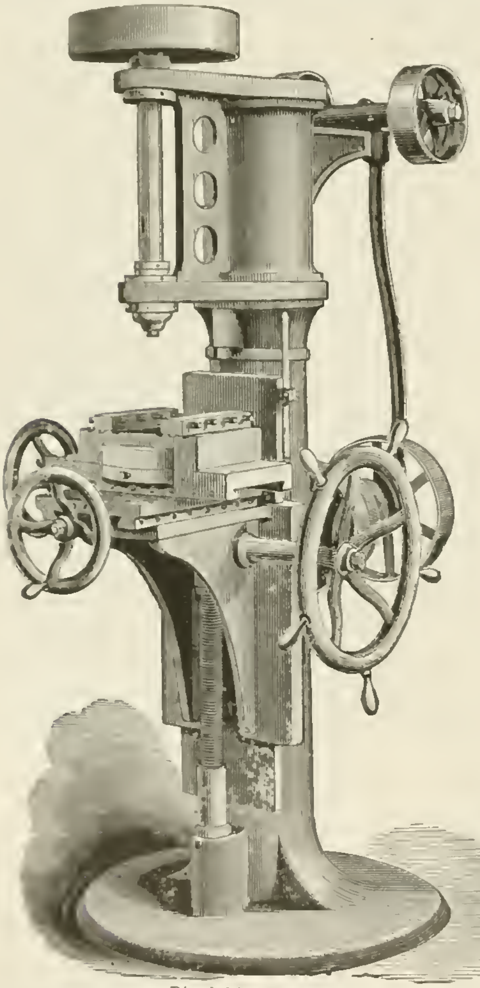
DIEGO.—A very strong and heavy sword commonly used in combat.

DIE-SINKING.—The art of engraving the die or stamp used for striking the impression on coins, etc., and for stamping thin plates of metal into various devices. The importance of die-sinking has much increased of late on account of the great extension of the process of stamping thin metal. Many kinds of work formerly bent into shape by the hammer and punch are now struck by a few blows between suitable dies. As examples of these we may mention the ornamental work of gas-fittings, window-curtain cornices, common jewelry, ornamental trays, dishes, boxes, etc. For such purposes a pair of dies is required, one in relief, the other in intaglio, and the metal is pressed between them. Not only are ornamental articles stamped in this manner, but useful articles, composed of many parts, are made entirely by cutters and dies, each part being cut and stamped by a pair of dies, and then the parts united by another pair, the junction being effected by overlaps, which the uniting dies press into their places. The astonishing cheapness of many of the Birmingham products is mainly due to the use of dies for doing by a single blow the work that formerly required long and tedious manipulation. The most ancient and familiar application of dies is in the striking of coins and medals; the method of sinking the dies used for this purpose will serve to illustrate the general method of die-sinking. Suppose the coin to be of the size of a shilling: a cylindrical piece of steel, about three or four inches in length, and two in diameter, is prepared by slightly rounding one end of the cylinder, then turning and smoothing upon the middle of this a flat face equal to the size of the coin. This blank die, which is carefully softened, is then engraved with the device of the coin in intaglio. This is a very delicate and artistic process, and is effected by a great number of careful touches with small and very hard steel tools. The face of the die is now hardened by placing it face downwards in a crucible upon a layer of bone-dust, or a mixture of charcoal and oil. In this position it is raised to a cherry-red heat, then taken out and plunged in water. When properly tempered, it is in a state to be used for stamping the coin; but dies of superior workmanship, from which many impressions are required, are not thus directly used, as the expense of engraving is very great, and the risk of breakage considerable. This first engraved die, called the matrix, is therefore reserved only for making other dies. An impression in relief is made from this matrix on a small block of steel, which is called the puncheon; this is retouched and hardened, and from it the dies directly used for striking the coins or medals are impressed. When the engraving is not very costly, a small number of impressions required, or a soft metal is to be stamped, the work is stamped directly from the engraved die or matrix. When the device is in high relief, and the metal is hard, many heavy blows are required. Some of the finest large bronze medals require 200 or 300 blows for each impression, and the metal has to be annealed by heating between every two or three blows. It is on this account that the difference between the price of pewter and bronze medals of the same subject is so great, the pewter being so much softer. Copper, although harder than pewter, is much softer than bronze, and hence the reader will easily understand



Billings Stock and Dies.

why the device on the bronze coinage, manufactured at the new mint of Birmingham, is in much lower relief than the old copper coinage, as it would not pay to use repeated blows and annealing in striking common coins. An impression in high relief or in deep intaglio may be obtained by one single blow by the *cliché* method. For this a fusible alloy is used, such as type-metal, or, still better, an alloy of two parts bismuth, one lead, and one tin, which fuses at about 212°, and becomes pasty before solidifying. The metal is poured into a box or tray a little larger than the die, and when in a pasty condition the die is placed over it and struck smartly with a heavy mallet or a coining-press. A steel die is by no means necessary for this; sharp impressions may be obtained from bronze medals themselves, or even from wood and plaster casts. A cliché mold may be made in the first instance from the medal, and then a cliché relief from



Die-sinking Machine.

this mold, if the process is skillfully conducted. The skill required consists mainly in striking the blow with a force proportionate to the depth of the impression and the softness of the metal, and in selecting the right moment for doing so, just as the fused metal is on the point of solidifying; for, if too fluid, it will merely be driven aside; and if at all set, an imperfect impression results. The metal should be of about the consistence of melted sealing-wax, and then the surface is set by contact with the cool die or medal, while the body of the metal still yields to the pressure. Cliché molds are admirably adapted for electro-depositing. The drawing represents the Pratt and Whitney die-sinking machine, which is much used in the arsenal for work on small-arms, recessing dies, and finishing recesses of all varieties of curved or irregular shapes. The work to be operated upon is held in the vise, which may be moved in all directions horizontally by compound slides on the table of the machine, and may be elevated or depressed by the vertical movement of the platen. The cutter, which may be of any suitable size or form, revolves with the spindle which is driven by a belt, giving much smoother action than is possible with gears. The work may be guided either by a pattern or forming-piece, or controlled wholly by the operator. These machines are very strongly built, insuring smooth work, free from chatter-marks, and are adapted particularly to forming and finishing recesses of circular or irregular shape, and for recessing dies for the drop-press. See *Stamping*.

DIETARY.—Rule of diet, or an allowance of food. On the opposite page is the diet-table for hospitals in the United States army.

The following are the recipes for full diet for ten men:

1. Coffee.—Coffee, roasted, 5 oz.; sugar, $6\frac{1}{2}$ oz.; milk, $\frac{4}{5}$ pt.

Directions.—Put the coffee in $4\frac{1}{2}$ quarts of boiling water. Stir well until boiling has recommenced. Cover the boiler and continue the boiling two minutes. Take the boiler off the fire, pour into it one pint of cold water, and replace the cover. In ten minutes the coffee may be carefully poured into coffee-pots, and the sugar and milk added.

2. Tea.—Tea, $\frac{4}{5}$ oz.; sugar, 5 oz.; milk, $\frac{1}{2}$ pt.

Directions.—Put the tea, closely tied up in a bag of netting, into five quarts of boiling water. Let it boil one or two minutes. Take it off the fire and let it stand, covered, on the range fifteen minutes to draw. Add the milk and sugar.

3. Hominy.—Hominy, 15 oz.; salt, $\frac{4}{5}$ oz.

Directions.—Wash the hominy thoroughly in warm water. Put the salt into the boiler with one quart of water. When boiling stir in the hominy. Let it boil, very gently, twelve hours, filling up with boiling water as the water in the boiler wastes, but without stirring. Drain off all the water that remains after it is sufficiently cooked. Add any beans that may be left from Wednesday's dinner to Thursday's breakfast.

4. Rice.—Rice, 1 lb.; salt, $\frac{4}{5}$ oz.; water, 1 gill.

Directions.—Put the salt and water into a boiler, and when boiling add the rice, previously well washed. Boil three quarters of an hour, or until the grains are soft. Drain off the water; let it stand a few minutes beside the fire.

5. Succotash.—Beans, $\frac{1}{2}$ lb.; hominy, $\frac{1}{2}$ lb.; gravy, $\frac{1}{2}$ pt.; salt, $\frac{2}{5}$ oz.; pepper, $\frac{1}{20}$ oz.

Directions.—Wash the beans and hominy thoroughly in three waters to cleanse them. Then put them to soak in a sufficient quantity of water to cover them for five hours, after which pour off the water, being careful to drain them quite dry. Then put them in a boiler or vessel previously prepared with $\frac{1}{2}$ pint of boiling water and boil over a slow fire six hours; then add $\frac{1}{2}$ pint of gravy, $\frac{2}{5}$ ounce of salt, $\frac{1}{20}$ ounce of pepper, and simmer over the fire one hour, after which it is ready for use. Frequent stirring is necessary to keep it from scorching.

6. Gravy.—Beef-drippings, $\frac{4}{5}$ pt.; water, $\frac{2}{5}$ pt.; flour, $2\frac{2}{5}$ oz.

Directions.—Heat the beef-drippings. Mix the flour into a smooth paste with $\frac{8}{5}$ pint of cold water. Stir the paste into $\frac{2}{5}$ pint of boiling water and let it boil 8 minutes. Add to it the hot beef-drippings and let the whole heat together for a few minutes. The gravy will require neither pepper nor salt if the beef from which the drippings are taken has been sufficiently seasoned while roasting.

7. Meat-Hash.—Meat, $2\frac{1}{2}$ lbs.; bread, 10 oz.; potatoes, 15 oz.; pepper, $\frac{1}{10}$ oz.; salt, $\frac{4}{5}$ oz.

Directions.—Chop the meat (previously boiled with the bones) fine; boil and mash the potatoes; mix both together with the bread, crumbled fine, and the pepper and salt, moistening with the broth in which the meat and bones were boiled, without adding water. Simmer for half an hour, stirring constantly.

8. Codfish-hash.—Codfish, 4¾ lbs.; potatoes, 8 lbs.; pork-drippings, ⅝ lb.

Directions.—Put the codfish to soak overnight, fleshy side downward; drain off, and renew the water twice, if possible. In the morning put it into a boiler and simmer it until it is tender. Chop it fine. Have the potatoes boiled and mashed; mix them well with the codfish. Put the whole over the fire; stir in the pork-drippings, and let it heat thoroughly.

9. Codfish, Boiled.—Codfish, 4¾ lbs.

Directions.—Soak the codfish overnight, as for codfish-hash; put it into a boiler with water enough to cover it entirely. Let it simmer gently half an hour, or until tender.

Mackerel, Boiled.—Proceed as with codfish, except that it is to be boiled only a quarter of an hour.

10. Potatoes.—Potatoes, 6¼ lbs.; salt, ⅜ oz.

Directions.—Wash the potatoes thoroughly; put them into boiling water, enough to cover them. Let them boil twenty minutes or half an hour, and drain off the water. Let them remain at the fire a few minutes.

11. Beef-soup.—Beef, 7½ lbs.; flour, ⅛ lb.; turnips, 13 oz.; onions, ½ lb.; cabbage, 10 oz.; pepper, $\frac{1}{16}$ oz.; salt, 2½ oz.; water, 6½ qts.; rice, 2½ oz.

Directions.—Cut the meat in pieces of 3 pounds each; crack the bones, so as to expose the marrow, without splintering them in fine pieces. Put all the ingredients, except the rice and pepper, into a boiler with 6½ quarts of cold water and heat till it boils. Boil very gently for two and a half hours. Take out all the meat; cut it from the large bones, and return the bones to the boiler. When boiling recommences, put in the rice and continue to boil briskly one and a quarter hours. Add the pepper. Have the flour mixed into a smooth paste with cold water; stir it in carefully. Let it boil a quarter of an hour, stirring all the time.

12. Beef (or Mutton) Stew.—Beef or mutton, 3½ lbs.; flour, ¼ lb.; rice, 6½ oz.; potatoes, 1 lb.; pepper, $\frac{1}{16}$ oz.; mixed vegetables, 2 oz.; salt, $\frac{1}{16}$ lb.; water, 1 gal. and 1 pt.

Directions.—Cut the meat in pieces of 6 ounces each. Put it into boiling water with the salt. Let it boil one and a half hours. Add the rice, which must first be thoroughly washed. Boil three quarters of an hour. Cut the potatoes and mixed vegetables into small slices and add them to the meat and rice. Let the whole boil half an hour longer. Put in the pepper. Mix the flour into a smooth paste with cold water and stir it in the stew. Let the whole boil ten minutes, stirring constantly.

13. Roast Beef or Mutton.—Roast beef or mutton, 3½ lbs.; pepper, ⅛ oz.; salt, ⅛ lb.; water, ½ gal.

Directions.—Cut the meat from the bones in as large pieces as practicable; roll and tie them. Bake the meat in pans with the salt and water. Put into the oven and bake three hours, or longer if necessary. Add the pepper ten minutes before it is done. The quantity of meat above named is three quarters of that issued for dinner and the next day's breakfast; the other quarter is to be thrown with the bones, which must be cracked, into a boiler, with water enough to cover them, the whole to simmer until the meat can be easily separated from the bones. The meat with the broth is to be set aside for hash.

14. Pork and Beans.—Pork, 4¾ lbs.; beans, 1 qt.; pepper, $\frac{1}{16}$ oz.

Directions.—Soak the beans overnight in plenty of water. Boil the pork and beans separately for two hours. Put about one seventh of the whole quantity of the pork in pans, surrounded and covered with the beans. Add the pepper. Bake one hour over a moderate fire. Bake the remainder of the pork for the same length of time. Any beans left from dinner will be mixed with hominy for Thursday's breakfast.

15. Cabbage.—Cabbage, 2½ lbs.; salt, ⅜ oz.

Directions.—Put the cabbage and salt in boiling water. Boil half an hour. Drain off the water.

16. TURNIPS.—Turnips, 2½ lbs.; salt, ⅜ oz.

Directions.—Wash the turnips thoroughly and pare them. Put them with the salt into boiling water. Let them boil one hour.

17. COLD-SLAW.—Cabbage, 2½ lbs.; vinegar, $\frac{3}{10}$ pt.

Directions.—Slice the cabbage fine. Pour over the vinegar and mix well.

18. PICKLED BEETS.—Beets, 2½ lbs.; vinegar, $\frac{3}{10}$ pt.

Directions.—Boil the beets two hours. Pare and slice them. Pour the vinegar over them.

19. RICE-PUDDING.—Rice, 10 oz.; sugar, 3¼ oz.; flour, 1$\frac{3}{10}$ oz.; salt, ⅜ oz.; cinnamon, ⅛ oz.; water, 3½ qts.

Directions.—Wash the rice carefully. Put it into the water when boiling, with the sugar and salt. Boil gently three quarters of an hour. Add the flour, previously mixed into a smooth paste with cold water, and the cinnamon. Stir it on the fire carefully for five or ten minutes. Put it into pans and bake for two hours.

20. STEWED FRUIT.—Dried fruit, 15 oz.; sugar, 2 oz.; water, 2½ qts.

Directions.—Soak the dried fruit for three hours in three gallons of water. Drain and add the sugar. Boil gently two hours, or until quite soft.

21. SAVORY BREAD.—Bread, 2½ lbs.; onions, $\frac{1}{10}$ lb.; beef-drippings, ⅛ lb.; pepper, $\frac{1}{10}$ oz.; salt, ⅜ oz.

Directions.—Crumble the bread fine. Chop the onions. Mix together with the beef-drippings, salt, and pepper. Bake until nicely brown. See *Food* and *Ration*.

DIEU ET MON DROIT.—The motto of the Royal Arms of England, first assumed by Richard I., to intimate that he did not hold his empire in vassalage of any mortal. It was afterwards assumed by Edward III., and was continued without interruption to the time of William, who used the motto *Je maintiendray*, though the former was still retained upon the great seal. After him Anne used the motto *Semper eadem;* but ever since her time *Dieu et mon droit* has continued to be the Royal motto.

DIFFERENCES.—Differences, in Heraldry, though often, or indeed generally, confounded with marks of cadency, have, in strict usage, a totally different function—the former being employed to distinguish brothers and their descendants after the death of the father, the latter whilst he is still alive. Differences in this limited sense may consist either of a chief added to or a bordure placed round the plain shield borne by the head of the house; or should the shield exhibit any of the ordinaries, as the bend, fess, pale, etc., the difference may be indicated by an alteration on the lines. The proximity of the bearer to the head of the house is indicated by the character of the line by which the differencing chief or bordure or ordinary is marked off from the field, the following being the order usually observed: the first or eldest brother, on the death of his father, inherits the pure arms of the house; the second brother, if the difference is to consist of a bordure, carries it plain; the third, ingrailed; the fourth, invected; the fifth, embattled; etc. Other modes of differencing have been invented by heralds, and are not unknown to practice; such, for example, as changing the tinctures either of the field or of the principal figures, of which Nisbet gives many famous examples—altering the position or number of the figures on the shield, adding different figures from the mother's coat or from lands, and the like. Where the cadet is far removed from the principal family, if the field be of one tincture, it is sometimes divided into two, the charge or charges being counter-charged, so that metal may not lie on metal, or color on color. The confusion between differences and marks of cadency, above referred to, is by no means peculiar to the heraldic usage of England, though there it is more prevalent than in Scotland. In France the cadets of the House of Bourbon have been in the habit of continuing these marks, and at the present day, as in Mackenzie's time, the label or lambel is to be seen on the arms of all the members of the Orleans family. That no distinction between what we call marks of cadency and differences was there observed is further apparent from the fact that whilst such was the practice of the House of Orleans, the House of Anjou carried a bordure gules, and that of Alençon a bordure gules charged with eight bezants. In Germany, Sir George Mackenzie says that the several branches of great families distinguish themselves only by different crests, and he gives as the reason that all the sons succeed equally to the honors of the family. In Britain and in France some change is always made on the shield as carried by the head of the house; but the practice even of good heralds has been so irregular as to bring the rule very nearly to what Mackenzie holds to be the correct one—viz., that every private person should be allowed, with the sanction of the proper authorities, "to make what marks of distinction can suit best with the coat which his chief bears." See *Cadency* and *Heraldry*.

DIFFERENTIAL PULLEY-BLOCK. — The portable hoisting-device generally known by this name was invented some twenty years ago. It secured immediately great popularity, and its use extended rapidly throughout the civilized world, wherever modern machinery was known and appliances for lifting heavy weights were needed. No previous device had ever embodied the same conveniences, namely, great lifting power and the ability to hold the load suspended at any point, and the accomplishment of these ends by a machine of great simplicity, compactness, and of light weight. The universal adoption, throughout the world, of the Weston differential pulley-block as the standard type of portable hoists is due to the fact that it perfectly meets all of these requirements and in the simplest possible way. Since its introduction other machines have been invented for similar uses, but no one of them combines in itself the important

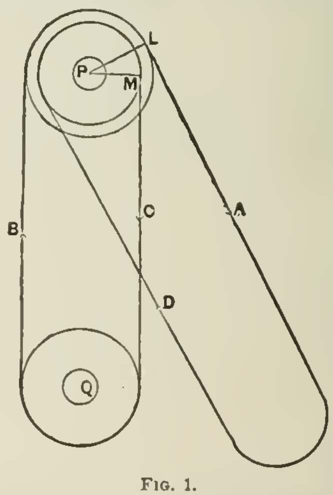

FIG. 1.

characteristics of power, safety, simplicity, and portability to a degree which equals that of the Weston block. The latter is demonstrably a reduction of the problem to its simplest possible form, and therefore can never be superseded. In recent text-books it is given a place among the other mechanical powers or elements, thus recognizing the fundamental character of its design and usefulness.

The principle of the device is very ancient, but it is only recently that it has been embodied in a machine of practical utility. In designing any mechanical power the object to be aimed at is this, that while the power moves over a considerable distance, the load shall only be raised a short distance. When this object is attained we then know by the principle of energy that we have gained an increase of power. The principal points of this machine will be understood from Fig. 1 and Fig. 2. It consists of three parts—an upper pulley-block, a movable pulley, and an endless chain. We shall briefly describe them. The upper block, P, is furnished with a hook for attachment to a support. The sheave it contains resembles two sheaves, one a little smaller than the other, fastened together; they are in fact one piece. The grooves are furnished with ridges which prevent the chain from slipping around them. The lower pulley, Q, consists of one sheave which is also furnished with a groove. It carries a hook to which the load is attached. The endless chain performs a part that will be understood by the arrow-heads attached to it in the figure. The chain passes from the hand at A up to L, over the larger groove in the upper pulley, then downwards at B, under the lower pulley, up again at C, over the smaller groove in the upper pulley at M, and then back again by D to the hand at A. When the hand pulls the chain downwards, the grooves of the upper pulley begin to turn together in the direction shown by the arrows on the chain. The large groove is therefore winding up the chain while the smaller is lowering.

In the pulley which has been employed in the experiments to be described the effective circumference of the large groove is found to be 11.84 inches, while that of the small groove is 10.36 inches. When the upper pulley has made one revolution the large groove must have drawn up 11.84 inches of chain, since the chain cannot slip on account of the ridges; but in the same time the small groove has lowered 10.36 inches of chain; hence, when the upper pulley has revolved once, the chain between the two must have been shortened by the difference between 11.84 and 10.36 inches, that is, by 1.48 inch; but this can only have taken place by raising the movable pulley through half of 1.48 inch, that is, through a space of .74 inch. The power has then acted through 11.84 inches and has raised the resistance .74 inch. The power has therefore gone through a space 16 times greater than that through which the load moves. In fact it is very easy to verify by actual trial that the power must be moved through 16 feet in order that the load may be raised 1 foot. We express this by saying that the velocity ratio is 16. By applying power to the chain, D, proceeding from the smaller groove, the chain is lowered by the large groove faster than it is raised by the small one, and the lower pulley descends. The load is thus raised or lowered with great facility by simply pulling one chain, A, or the other, D.

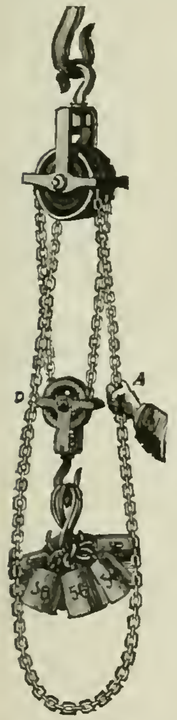

Fig. 2.

We shall next consider the mechanical efficiency of the differential pulley-block. The block which we shall use is intended to be worked by one man and will raise any weight not exceeding a quarter of a ton. We have already learned that for the load to be raised 1 foot the power must act through 16 feet. Hence were it not for friction we should infer that the power need only be the sixteenth part of the load. A few trials will show us that the real efficiency is not so large, and that in fact more than half the power exerted is merely expended upon overcoming friction. This will lead afterwards to a result of considerable practical importance. Placing upon the load-hook a weight of 200 pounds, we find that 38 pounds attached to a hook fastened on the power-chain is sufficient to raise the load; that is to say, the power is about $\frac{1}{5}$ of the load. If we make the load 400 pounds we find the requisite power to be 64 pounds, which is only about 3 pounds less than $\frac{1}{6}$ of 400 pounds. We may safely adopt the practical rule that with a differential pulley-block of this class a man will be able to raise a weight six times greater than he could raise without such assistance.

A series of experiments carefully tried with different loads have given the results shown in the following table:

Circumference of large groove, 11.84 inches; of small groove, 10.36 inches; velocity ratio, 16; mechanical efficiency, 6.07; useful effect, 38 per cent; formula $P = 3.87 + .1508R$.

Number of Experiment.	R. Load in pounds.	Observed power in pounds.	P. Calculated power in pounds.	Difference of the observed and calculated values.
1	56	10	12.3	+ 2.3
2	112	20	20.8	+ .8
3	168	31	29.2	− 1.8
4	224	38	37.7	− .3
5	280	48	46.1	− 1.9
6	336	54	54.6	+ .6
7	392	64	63.1	− .9
8	448	72	71.5	− .5
9	504	80	80.0	.0
10	560	86	88.4	+ 2.4

The first column contains the numbers of the experiments; the second, the weights raised; the third, the values of the corresponding powers. The calculated values of the powers are given in the fourth column, and the differences between the observed and calculated values in the last column. The differences do not in any case amount to 2.5 pounds, and considering the size of the loads raised (up to a quarter of a ton), the formula represents the experiments with satisfactory precision.

Suppose, for example, 280 pounds is to be raised; the product of 280 and .1508 is 42.22, to which when 3.87 is added we find 46.09 to be the requisite power. The mechanical efficiency found by dividing 46.09 into 280 is 6.07. To raise 280 pounds 1 foot, 280 foot-pounds of energy would be necessary; but in the differential pulley-block 46.09 pounds must be exerted for a distance of 16 feet in order to accomplish this object. The product of 46.09 and 16 is 737.4. Hence the differential pulley-block requires 737.4 foot-pounds of energy to be applied to it in order to produce 280 foot-pounds; but 280 is only 38 per cent of 737.4, and therefore with a load of 280 pounds only 38 per cent of the energy applied to a differential pulley-block is utilized. In general we may state that not more than about 40 per cent is profitably used, and that the remainder is employed in overcoming friction.

It is a very remarkable and useful property of the differential pulley that a weight which has been hoisted by it will remain suspended, without any tendency to run down; this is a point of great practical convenience. The reason why the load does not run down in the differential pulley may be thus explained. Let us suppose that a weight of 400 pounds is to be raised 1 foot by the differential pulley-block; 400 units of work are necessary, and therefore 1000 units of work must be applied to the power-chain to produce the 400 units (since only 40 per cent is utilized). The friction will thus have consumed 600 units of work when the load has been raised 1 foot. If the power-weight be removed, the pressure supported by the upper pulley-block is diminished. In fact, since the power-weight is about $\frac{1}{6}$ of the load, the pressure on the axle when the power-weight has been removed is only $\frac{5}{6}$ of its previous value. The friction is produced by the pressure of the pulleys on their axles and is nearly proportional to that pressure; hence when the power has been removed the friction on the upper axle is $\frac{5}{6}$ of its previous value, while the friction on the lower pulley remains unaltered. We may therefore assume that the total friction is at least $\frac{5}{6}$ of what it was before the power-weight was removed. Will friction allow the load to descend?

600 foot-pounds of work were required to overcome the friction in the ascent: at least $\frac{6}{7} \times 600 = 514$ foot-pounds would be necessary to overcome friction in the descent. But where is this energy to come from? The load in its descent could only yield 400 units, and thus descent by the mere weight of the load is impossible. To enable the load to descend, we have actually to aid the movement by pulling the chain D (Figs. 1 and 2), which proceeds through the small groove in the upper pulley.

The principle which we have here established extends to other mechanical powers and may be stated generally. Whenever rather more than half of the applied energy is uselessly consumed by friction, the load will remain suspended without overhauling. See *Cranes*, *Hoisting-machines*, and *Tramrail*.

DIFFERENTIAL WINDLASS.—A windlass whose barrel consists of two portions of varying diameters. The rope winds on to one as it winds off the other, the effect of a revolution being governed by the difference between the circumferences of the two portions. If it wind on to the larger and off of the smaller the load is elevated, and conversely. See *Chinese Windlass*.

DIKES.—Dikes and bridges, used in fortification, in no way differ in principle from similar constructions used elsewhere. The communication across the enceinte-ditch leading from the gateway is usually an ordinary wooden bridge. The bay of this bridge at the gateway is spanned by a drawbridge of timber, which when drawn up closes and secures the gateway. This drawbridge is manuevered by some of the usual mechanisms employed for this purpose; and for convenience of maneuvering should not be longer than 12 feet. Care should be taken that it should fit the recess in the face of the wall so closely that there will not be room enough between it and the jambs of the gateway to insert a crowbar to force back the bridge. See *Bridges* and *Communications*.

DILLICH SYSTEM OF FORTIFICATION.—In this system the ravelins before the bastion are replaced by counterguards and the counterscarp of the main ditch is directed on the shoulder-angles. The low flanks are casemated on the Italian method. In another system Dillich adopts the tenaille-tracing.

DIMACHÆ.—In ancient times a kind of horsemen, answering to the dragoons of the moderns.

DIMIDIATION.—In Heraldry a mode of marshaling arms, adopted chiefly before quartering and impaling according to the modern practice came into use, and subsequently retained to some extent in Continental though not in English Heraldry. It consists in cutting two coats of arms in half by a vertical line, and uniting the dexter half of the one to the sinister half of the other. Coats of husband and wife were often so marshaled in England in the thirteenth and fourteenth centuries. Mr. Planché traces the double-headed eagle of the German Empire to a dimidiated coat, with half an eagle for the Eastern and another half for the Western Empire. See *Heraldry*.

DIMINISH.—In a military sense, to decrease the front of a battalion; to adopt the columns of march, or maneuver according to the obstructions and difficulties which it meets in advancing.

DIMINISHED ANGLE.—In fortification, the angle formed by the exterior side and the line of defense.

DIMINUTIONS.—A word sometimes used in Heraldry for differences, marks of cadency, and brisures, indifferently.

DIOPHANTINE ANALYSIS.—That section of the theory of unlimited or indeterminate problems which attempts to find rational and commensurable values answering to certain equations between squares and cubes. This class of problems was first and chiefly treated of by Diophantus, who has given his name to the theory of their solution. We shall not here attempt to explain the nature of the analysis, which is very subtle and guided by few general rules. The difficulties of the solution of diophantine problems in most cases fail to be overcome by the skill and ingenuity of the analyst. We confine ourselves to stating the following examples of the problems solved by the diophantine analysis: 1. To find two whole numbers the sum of whose squares is a square. 2. To find three square numbers in arithmetical progression. 3. To find a number from which two given squares being severally subtracted, each of the remainders may be a square. Solutions of problems in gunnery are frequently accomplished by this analysis.

DIOPTRICS.—That branch of geometrical optics which treats of the transmission of rays of light from one medium into another, differing in kind. It consists of the results of the application of geometry to ascertain in particular cases the action of what are called the laws of refraction. When a ray of homogeneous light is incident upon a surface, the angle which its direction makes with the normal or perpendicular to the surface at the point of incidence is in dioptrics, as in catoptrics, called the angle of incidence. The angle which the refracted ray makes with the same line is called the angle of refraction. This being premised, we may state the laws of refraction. 1. The incident and refracted ray lie in the same plane with the normal, at the point of incidence, and on opposite sides of it. 2. The sine of the angle of incidence, whatever that angle may be, bears to the sine of the angle of refraction a constant ratio dependent only on the nature of the media between which the refraction takes place, and on the nature of the light. According to the second law, if we call the angle of incidence i, and that of refraction r, we shall have $\sin i = \mu \sin r$, where μ is a quantity depending upon the nature of the media and of the light. It will have, for instance, a certain value for refraction from vacuum into glass, another from glass into water, and so on; also, it will have one value for red light, another for green, and so on. The quantity μ is called the refractive index, and is greater than 1 when refraction takes place from vacuum into a medium, and in general is greater than 1 when the refraction is from a rarer into a denser medium, and less than 1 when the opposite is the case. In dioptrics the laws of refraction may be considered as depending for their truth upon experiment; in physical optics they are deductions from an hypothesis respecting the constitution of light. They are not merely approximately true; they are absolute physical laws.

Before proceeding to consider the simpler leading cases of refraction, one or two interesting propositions in dioptrics require to be explained. 1. If the refractive index for a medium, when light is incident upon it from vacuum, be μ, and the index for another medium, under the same circumstances, be μ', then, when light proceeds from the second medium into the first, the refractive index is $\frac{\mu}{\mu'}$. The proof of this proposition depends upon the two following experimental laws: (1) If a ray of light proceed from a point to a second, suffering any reflections or refractions in its course, then, if it be incident in the reverse direction, i.e., from the second point, it will follow the exactly reverse course to the first point. This is proved by experiment, but may be accepted as axiomatic. (2) If a ray pass from vacuum through any number of media, having their faces plane and parallel, when the ray emerges into vacuum its direction will be parallel to that which it had before incidence. To deduce the proposition from these laws, let i be the angle of incidence from vacuum upon the first medium, r the angle of refraction, which will also be the angle of incidence upon the second medium. Also let r' be the angle of refraction into the second medium, which will also be the angle of incidence upon the second bounding surface. By the second of the preceding experimental laws, the angle of emergence into vacuum will be i. Hence we shall have, by the first of these laws, $\sin i = \mu' \sin r$ at the first surface, and $\sin i = \mu \sin r'$ at the second. From these equations we have sin

$r = \frac{\mu}{\mu'} \sin r'$, which proves the proposition. It follows that if μ be the refractive index from vacuum into a medium, that from the medium into vacuum will be $\frac{1}{\mu}$. 2. Our second proposition relates to what is called the *critical angle*. If i be the angle of incidence of a ray within a medium, the refractive index of which is μ, and r the angle of refraction into vacuum, then we have from the former proposition $\sin i = \frac{1}{\mu} \sin r$. From this formula, if i be given, r may be found, and a real value will be given to r so long as $\sin i$ is $< \frac{1}{\mu}$; but when i has a value greater than that determined by the equation $\sin i = \frac{1}{\mu}$, the formula fails to give us a value of r, for the sine of an angle cannot be greater than 1. And experiment shows that, in fact, there is no refracted ray when the angle of incidence is greater than that above assigned, the ray being wholly reflected within the medium. The angle of which the sine is $\frac{1}{\mu}$ is called the *critical angle*. For glass it is about 41 45; for water, about 48° 30'. This angle is sometimes called the angle of *total reflection*. In internal reflection at the surfaces of media, the reflected light is more nearly equal in intensity to the incident than in any other case of reflection. While it thus appears that refraction from a denser into a rarer medium is not always possible, it may be added that it is always possible from a rarer into a denser.

We shall now investigate some simple cases of refraction. 1. In case of refraction at a plane sursurface. Let DIMN (Fig. 1) be any medium bounded by a plan, DI, and let R be a radiant point and RD and RI two incident rays of a divergent pencil proceeding from R to the surface of the medium; then RD being perpendicular to the surface suffers no refraction, but proceeds along DM within the medium; but RI is refracted in the direction IN, which, produced outwards, meets the normal DF in F.

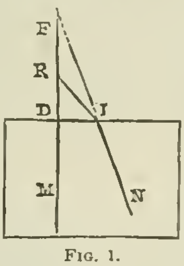

Fig. 1.

Therefore a small pencil of rays proceeding from R, and having RD, perpendicular to the surface, for axis, will be refracted into another pencil diverging from the imaginary focus F; for all the rays intermediate between RD and RI will converge very near F when the pencil is small. An eye within the medium, and between N and M, would thus, the pencil being small, see the luminous point R as if it were at F, or further off than it really is. In the opposite case, in which the luminous point is within the refracting medium, similar reasoning shows that after the rays emerge from the plane surface into the air they will, if the pencil be small, appear to proceed from an imaginary focus nearer to the surface than the luminous point. 2. The case of refraction through a prism, which we are next to consider, is, in fact, but the case of refraction through a medium bounded by plane surfaces which are not parallel. Conceive any two planes at right angles to the plane of the paper, and making on that plane the figure BAC (Fig. 2). The question is as to the laws of transmission of a ray, SPQR, of homogeneous light through the prism. Draw mn' and $n'n$ perpendicular to the sides. Then $n'PQ$ and $n'QP$ are respectively the angles of refraction at the first, and

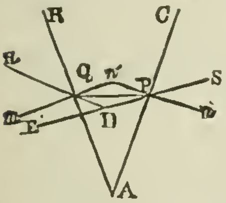

Fig. 2.

of incidence at the second surface. Now, as n QA and n'PA are each of them right angles, and as all the angles in the figure n QAP are equal to four right angles, it follows that the angles at n' and at A together are equal to two right angles. But the angle at n, together with the angles n PQ and n QP, are equal to two right angles; therefore must the angles n PQ and n QP together be equal to the angle at A. In other words, in refraction through a prism: *The sum of the angles of refraction at the first surface, and of incidence at the second, is equal to the angle contained between the plane sides of the prism.* From this it might be shown that the deviation of a ray caused by passing through a prism is always towards the thicker part of the prism, if the medium be denser than the surrounding atmosphere. It is a geometrical proposition which the student may solve for himself, that if i be the angle of incidence at the first surface, and e that of emergence at the second, and if α be the angle of the prism, then σ, or the change of direction of the ray in its passage, is obtained from the formula $\sigma = i + e - \alpha$. 3. We now take up the case of refraction at a single spherical surface of a medium denser than the surrounding air. And first, of parallel rays refracted at a convex spherical surface. Let ABQP (Fig. 3) be the refracting medium, whose terminating convex surface is spherical, C being the center of the surface, while V is its vertex.

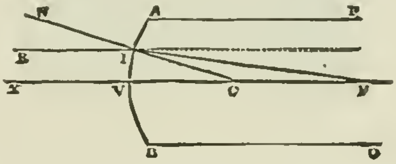

Fig. 3.

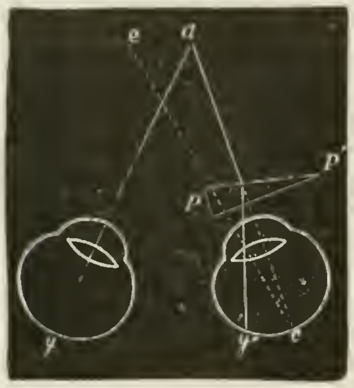
Let XV be the axis of a pencil of parallel rays, of which any ray, RI, is incident at I. Then, if CIN be a normal, the angle of refraction, CIF, will be less than the angle of incidence, RIN, and the refracted ray will thus turn towards the axis, and meet it at some point, F. When the pencil is small, or the aperture, AVB, of only a few degrees, the rays will clearly nearly all converge to the same point, F. To find the position of F, we have, in the triangle ICF, the angle CIF = r, the angle of refraction, and ICF, the supplement of ICV or NIR (by parallel lines), i.e., of i, or the angle of incidence. Therefore IF : CF : : sin i : sin r. And as for a very small pencil IF may be taken = VF, we have FV : FC : : sin i : sin r, or : : μ : 1. And putting FV = F, the principal focal distance, and VC = R, we have $F = \frac{\mu}{\mu - 1} R$. If the medium be crown-glass, for which the value of μ is $\frac{3}{2}$, we have $F = \frac{\frac{3}{2}}{\frac{3}{2} - 1} R$, or F = 3 R; i.e., the principal focal distance is equal to three times the radius of the sphere. The student may, by similar reasoning, ascertain for himself the focus of parallel rays incident on a concave spherical refracting surface, as also the focus in the case of a pencil of parallel rays within the medium and emerging from it. The case of a divergent pencil is incapable of such elementary treatment as to justify its insertion here. For branches of the subject treated under separate heads the reader should refer to the articles Caustic, Lens, and Refraction. Under Refraction he will find a table of the values of μ—the refractive index—for various media and kinds of light. See *Catoptrics* and *Chromatics*.

DIP.—1. A name sometimes given to the superior slope of a parapet. 2. The inclination of the sole of an embrasure. 3. The slight downward inclination of the arms of an axle.

DIPLOPIA.—To insure correct and comfortable vision the two eyes must work in unison; for if the rays of light do not fall on a corresponding spot of the retina of each eye, two objects instead of one will be seen, as represented in the drawing. Diplopia, or double-sight, is caused by weakness of the muscles which move the eye from side to side. They are no longer able to hold the two eyes steadily fixed toward the object, and the eye moving out or in causes the individual to see the object double. This can often be very much relieved by prismatic lenses. Paresis of the ciliary muscle is the inability to maintain the adjustment of the eyes for near objects any length of time without fatigue; for instance, in reading or sewing, especially by insufficient light, the fatigued ciliary muscle relaxes and the accommodative power of the



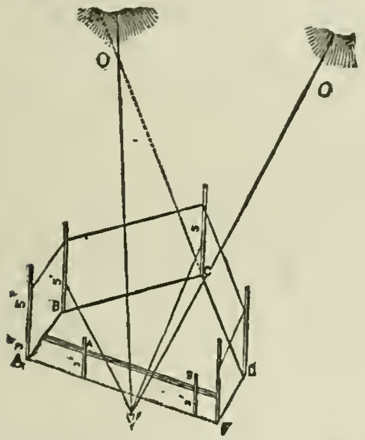
eyes is suddenly lost, causing the print or work to become confused and unintelligible, together with a feeling of fatigue and pain about the eyeballs. In such cases, after a few minutes' rest and closing the eyes, work can be resumed but for a short time only, as the muscle will again lose its strength and relax. This disagreeable trouble arises from a debilitated condition of the whole system, which, though not felt in other parts of the body, is apparent in the muscle of accommodation, on account of its position and the character of the work it is called upon to perform. After a fit of illness, or a great shock causing nervous prostration, this difficulty is often apparent. Persons whose eyesight had been previously perfect should not resort to glasses of any kind when affected with these spasms of the sight, but wait patiently until nature does the work by restoring the tone of the whole system. This advice does not apply to those who have this same trouble that arises from a hypermetropic form of the eye, and not from the cause mentioned above. A skilled oculist, on examination, would at once detect the cause and prescribe the remedy. See *Myopia*.

DIPPING-NEEDLE.—If a magnetic needle be supported so as to be free to move vertically, it does not at most places on the earth's surface rest in a horizontal position, but inclines more or less from it. If the vertical plane in which the needle moves is the magnetic meridian of the place, the angle between the needle and the horizontal line is called the dip or inclination of the needle. The dip of the magnetic needle at any place can be ascertained with very great exactness by means of the dipping-needle. It consists of a graduated circle fixed vertically in a frame, and moving with it and a vernier on a horizontal graduated circle. This last is supported by a stand furnished with leveling-screws. At the center of the vertical circle there are two knife-edges of agate, supported by the frame, and parallel to the plane of the circle. The needle rests on these knife-edges by means of two fine polished cylinders of steel, which are placed accurately at the center of the needle, and project at right angles from it; so adjusted, the needle moves with little or no friction. It is so made, moreover, that before being magnetized it remains indifferently in any position; after magnetization, therefore, the dip which it shows is wholly due to the magnetic influence of the earth. In order to understand how an observation is made with the dipping-needle, we must regard the directing force of the earth's magnetism exerted upon the poles of the needle in any vertical plane in which it may happen to be, as resolved into two forces, one acting at right angles to the plane, and the other acting in the plane. There being a corresponding but opposite force at each pole, we have thus two statical couples acting on the needle—one tending to turn it at right angles to the plane in which it moves, and the other tending to bring it round to a position in the plane such that the needle and the forces of the couple may be in a line. In the dipping-needle the mode of support completely neutralizes the first of the couples ; and the position that the needle takes in any plane is due wholly to the second. When the plane of the needle is at right angles to the magnetic meridian, the forces of this latter couple act vertically, and bring the needle to the same position. This, then, gives us the means of determining the magnetic meridian, for we have only to bring the vertical circle round till the needle stands at 90° to put it in a plane at right angles to that meridian ; and then by moving the vernier on the horizontal circle over 90° we place the upper circle and needle in the plane of the magnetic meridian. The dipping-needle thus serves the purpose of a declination-needle. In bringing the needle round from the plane at right angles to the magnetic meridian, the dip is less and less, till it becomes least in the plane of that meridian. We might thus also find the magnetic meridian, for it is that plane in which the dip of the needle is least. When the needle is in the plane of the magnetic meridian, the couple which acts in other vertical planes at right angles to them disappears, and the whole force of the terrestrial magnetism acts at each pole of the needle, forming a couple which swings the needle round till it stands in a line with itself. The degree on the circle then pointed to by the needle is the dip at the place of observation. Two readings are necessary, for the reason stated under DECLINATION-NEEDLE. One reading is taken,

the needle is then reversed so as to change its supports, and then a second reading is noted, and the mean of the two gives the correct reading. The position of the needle when the dip is read off is manifestly the same that a needle suspended in air, if that were possible, and free to move in any way, would finally assume. In resolving, therefore, the total directive force of the earth as we have done above, we must keep in mind that it always acts parallel to the direction of the dipping-needle. See *Inclination-needle*.

DIPPING OF THE MUZZLE.—When a piece of artillery is fired, the action at the vent brings increased pressure on the elevating-screw or quoin. The reaction from this naturally throws down the muzzle.

DIRECT DEFILEMENT.—The direct defilement of a work may be practically performed on the ground as follows: Let A B C D F be the plan of a work, a lunette for example; and the points O, O, etc., lying within the angle formed by the prolonged direction of the two faces B C, D C, the most elevated points of a commanding position in front of the work. At the points A, B, etc., let straight poles be planted vertically, and on the poles along the gorge-line let a point be marked, at three feet above the ground. Let two pickets be driven in the ground along the gorge-line, and a cord, A B, or a straight-edge of pine, be fastened to them on the same level as the two points marked on the poles at A and B. Let an observer now place himself in the rear of A B, so as to bring the poles at B, C, and D, and the points O, O, etc., within the same field of vision. Let observers be placed at B, C, and D. The first observer now sights along A B until he brings his eye in the position that A B will appear tangent to the most elevated of the points O. Having accurately determined this position, he next directs the other observers to slide their hands along the poles until they are brought into the same plane of vision with the point O and the line A B, and to mark those points on the poles. These points, together with the two first marked, will evi-



Plan of Work, A B C D F, showing the manner of Defiling it from the Heights, O, O, lying in front of its faces.

dently be in the same plane, and this plane, produced, will be tangent to the highest point O. It is denominated the *rampant plane*. Now if a point be marked on each pole at five feet above the points thus determined, these points will be contained in a second ideal plane, parallel to the first, and five feet above it. This plane is denominated the *plane of defilement*, and the interior crests of the work are contained in this plane, being the lines joining the highest points marked on the poles. As the gorge-line is farthest from the heights, and the rampant plane ascends towards them, it will necessarily pass at more than three feet above every other point of the parade of the work; and the plane of defilement, in like manner, will pass at eight feet above the parade at the gorge, and at five feet above the highest point O. A plane of front defilement is therefore defined to be that plane which, containing the interior crests of a work, passes at least eight feet above every point of the parade, and at least five feet above every point that the enemy can occupy within the range of cannon. See *Defilement* and *Plane of Defilement*.

DIRECT EMBRASURE.—When the directrix of an embrasure is perpendicular to the direction of the parapet, the embrasure is termed *direct*. The form, dimensions, and construction of the embrasure in mask-walls present a problem which has offered no little difficulty, in a satisfactory solution, to engineers, by which the best cover could be given to the guns and men by exposing the least surface to embrasure-shots, whilst the guns should receive a suitable traverse to command a wide field of fire. In the embrasures of our works the general form is the same as those usually found in Europe, but they present a very considerably less amount of exterior and throat opening than European embrasures. In some of our earlier works the sole, cheeks, and top of the embrasures are constructed of brick, as being a material that would be less destructive from the splinters driven in by embrasure-shots. This view, however, has been abandoned in our more recent works, the embrasures being constructed, on the contrary, of heavy stone blocks carefully and strongly bonded; a brick arch being thrown above the embrasure within the mass of the mask-wall to secure the upper portion from yielding, should the block forming the ceiling of the embrasure be damaged. See *Embrasure*.

DIRECT FIRE.—*Direct* or *horizontal fire* is where the piece is discharged having but a small angle of elevation, and the projectile strikes the object without touching the intermediate ground. A fire is said to be *direct*, *slant*, or *enfilading* according as its direction is perpendicular to, makes an angle of 30° with, or is on the prolongation of the line at which it is aimed; when the line is taken in the rear the fire is denominated a *reverse fire*; and when a given space is defended by the fire from several points crossing over it, the defense is denominated a *cross fire*.

DIRECTING-CIRCLE.—To form a gabion, a *directing-circle* is made of two hoops, the difference between their radii being such that, when placed concentrically, there shall be about 1$\frac{3}{4}$ inch between them. They are kept in this position by placing small blocks of wood between them, to which they are tied with pack-thread. The directing-circle is placed on the ground, and seven or nine stakes, about 1 inch in diameter and 3 feet long, are driven slightly into the ground between the hoops, at equal distances apart; the directing-circle is then slipped up midway from the bottom, and tied in that position. Twigs about half an inch in diameter, and as long as they can be procured, are wattled between the stakes like ordinary basket-work. When finished to within about 2 inches of the top, the gabion is placed with the other end up, the directing-circle taken off, and the gabion completed to within 2 inches of the other extremities of the stakes. The wicker-work at the two ends is secured by several withes, and the ends of the pickets are sharpened. The gabion is then ready for use. See *Gabion*.

DIRECTING-SERGEANT.—When a company is being drilled in marching, a Sergeant distinguished for precision in marching is selected, who is called a Directing-sergeant, and placed in front of the guide on the line established. This Sergeant is charged with the direction and step, and marches on points selected by himself directly in front of him. The right guide of the company marches straight in the trace of the Directing-sergeant.

DIRECTION.—1. In gunnery, the path or course a projectile takes when fired from a gun. The path pursued may be either a *good* or *bad* direction, with reference to the points aimed at. 2. That element of pointing which relates to the movement of the piece around an imaginary vertical axis. The direction is given when the plane of sight passes through the object. Elevation is a movement about a horizontal axis. See *Pointing*.

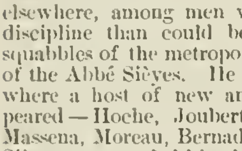
DIRECTOR OF ARTILLERY AND STORES.—An officer in the English service appointed by the Secretary of State for War to assist the Controller-in-Chief. His duties are confined to all questions relating to the manufacture, provision, supply, and maintenance of munitions of war.

DIRECTOR OF SUPPLIES AND TRANSPORT.—An officer in the English service appointed by the Secretary of State for War to assist the Controller-in-Chief. This officer has to deal with all questions relating to the provision and supply of food, forage, fuel and light, lodging and transport.

DIRECTORY.—Upon the death of Robespierre, in

1794, a reaction commenced in the Convention itself, as well as throughout all France, against the sanguinary excesses of the Terrorists. Ultimately a new Constitution—that of the year 3 (1795)—gave birth to a new government, composed of a legislative body divided into two Councils; the Council of Five Hundred, whose function was to propose laws; and the Council of the Ancients, whose function was to pass them. The actual executive power was intrusted to five members chosen from both sections, and who sat at the Luxembourg. Their names were Lépeaux, Letourneur, Rewbel, Barras, and Carnot. These five constituted the famous *Directory*. They assumed authority in a moment of immense peril. France was environed with gigantic adversaries, while distrust, discontent, and the malice of rival factions made her internal administration almost hopeless. The frantic heroism of her soldiers saved her from spoliation by the foreigner; and had all the members of the Directory been patriotic and honest, she might have been saved also from spoliation by her own children. But, on the contrary, the home-policy of the Directory was deplorable. The demoralization which had begun to characterize officials even in Danton's time now seized almost every class. Barras, a representative of all the turpitude of the hour, set the example. The majority of the two Councils were equally corrupt; and although there were some both in the Councils and Directory whose virtues and talents were unimpeachable, yet they were too weak to counteract the knavery of their associates. It soon became clear that France could not be reconsolidated by the fag-ends of the Revolution. The power and skill requisite for such a herculean work must be sought for elsewhere, among men who had received a nobler discipline than could be obtained in the political squabbles of the metropolis. Such was the thought of the Abbé Sièyes. He turned his eyes to the army, where a host of new and brilliant names had appeared — Hoche, Joubert, Brune, Kleber, Desaix, Massena, Moreau, Bernadotte, Augereau, Bonaparte. Sièyes propounded his plan for the overthrow of the Directory, and the establishment of a Consulate, that should be, in reality, a Monarchy under republican forms, first of all to Moreau, who was frightened by its audacity; then to Bernadotte, whose excessive caution hindered him from approving of it; then to Augereau, who could not understand it; and finally to Bonaparte, on his return from Egypt. The last admired the project; a conspiracy was rapidly formed; all those functionaries who had been promised places by the Directory, but had not received them, offered their aid; and by the *coup d'état* of the 18th Brumaire an end was put to a government of weakness, immorality, and intrigue. It was succeeded by the Consulate.

DIRECTRIX.—1. The center line in the plane of fire of an embrasure or platform. See *Embrasure*. 2. A right line perpendicular to the axis of a conic section in reference to which its nature may be defined. Assuming the indefinite line AB in the figure as the directrix, and F a point without it as a focus, then if the line FD revolves about F as a center, while a point D moves in it in such a manner that its distance from F shall always be to CD, its perpendicular distance from the line AB, in a constant ratio, then the curve VD, described by the point D, is a conic section, and is an ellipse, a parabola, or an hyperbola according as FD is less than, equal to, or greater than CD, or FV than VA. The constant ratio referred to is called the determining ratio of the conic.



DIRK.—A variety of dagger or poniard worn by Highland regiments. It is at present worn by officers rather for ornament than for use, though in former days it was a valuable weapon. The *dirk-knife* is a clasp-knife having a large, dirk-like blade.

DISABILITY.—1. State of being disabled; want of competent physical or intellectual power. When a soldier becomes disabled from exposure, accidents, or other causes, he is discharged from the service on a Surgeon's Certificate of Disability, which enables him to draw a pension. 2. Legal disability is either absolute, which wholly disables the person from doing any legal act—e.g., outlawry, excommunication, attainder, alienage—or partial, such as infancy, coverture, lunacy, drunkenness, and the like. It may arise from the act of God, of the law, of the individual himself, or of his ancestor, or the person from whom he inherits.

DISABLING CANNON.—If necessary to abandon *matériel*, it must be disabled or destroyed, so as to be useless to the enemy. Guns are permanently disabled by bursting, bending the chase, breaking off the trunnions, or by scoring the surface of the bore; they are temporarily disabled by spiking, breaking off the sights and the seat for the hausse, or in breech-loaders by carrying off or permanently destroying the breech-blocks, etc.

To burst a cast-iron gun, load with a heavy charge, fill the bore with sand or shot, and fire at a high elevation. To bend the chase of a bronze gun, fire a shotted piece against another, muzzle to muzzle or muzzle to chase; or kindle a fire under the chase and strike on it with a sledge-hammer. To break off a trunnion of a cast-iron cannon, strike on it with a heavy hammer or fire a shotted gun against it. To score the surface of the bore and injure the rifling, cause shells to burst in the gun or fire broken shot from it with high charges.

To spike a gun, drive into the vent a jagged and hardened steel spike with a soft point, break it off flush with the vent-field, and clinch it in the bore with the rammer; a nail without a head, a piece of ram-rod, or even a plug of hard wood may be used in the absence of a spike. To prevent the spike from being blown out, make a projectile fast in the bottom of the bore by wrapping it with cloth or felt, or by means of iron wedges driven in with a rammer or with an iron bar; if the wedges were of wood they could be easily burnt out by a charcoal-fire lighted with a pair of bellows.

When it is expected to retake a gun, use a spring spike with a shoulder to prevent its coming out too readily. Mitrailleurs are permanently disabled by bending the barrels, etc.; they are made temporarily useless by removing the crank-handles, locks, etc. Carriages are destroyed by piling them up and burning them; to prevent them from moving, the spokes and poles may be cut or sawed off. Ammunition-chests are blown up or water is poured over their contents. Implements are carried off or destroyed.

To unspike a gun, try to drive the spike into the bore with a punch; if there be a shot wedged in the bore, expel it by powder inserted through the vent. When it is impossible to drive down the spike, if the bore be unobstructed, insert a charge of one third the weight of the projectile, and ram down junk wads with a handspike, first placing on the bottom of the bore a strip of wood with a groove on the lower side containing a strand of quick-match by which the charge is ignited; this plan will not answer when the spike is screwed or riveted into the vent. In a bronze gun, remove some of the metal at the upper orifice of the vent, and pour sulphuric acid into the cavity before firing. Should the preceding methods fail, after several trials, drill out the spike, or drill a new vent if the gun be iron; if it be bronze, unscrew the vent-piece.

To drive out a shot wedged in the bore, unscrew the vent-piece, if there be one, and drive in wedges so as to start the shot forward, then ram it back again, and with a hook withdraw the wedges that may have held it; or pour in powder and fire it after replacing the vent-piece. As a last resort, bore a hole in the bottom of the breech, drive out the shot, and stop the hole with a screw. See *Spike* and *Unspike*.

DISARM.—The act of depriving a body of troops of arms for some gross misconduct or crime which renders dismissal from the service necessary. The Indian Mutiny in 1857–58 affords instances of whole regiments being disarmed and disbanded. Other regiments, at the same time, apparently loyal, were simply disarmed, to prevent the chance of the men falling upon their officers.

DISARRAY.—Want of array or regular order; likewise to throw into disorder or to break the array of.

DISBANDING.—In military matters, the breaking up of a regiment or corps. When peace is proclaimed after a war, and a reduction of the army becomes necessary, this is effected by disbanding or disembodying; the men are discharged and the officers are mustered out or placed on half-pay.

DISBURSING OFFICERS.—Officers whose special functions are to make disbursements of public moneys. The regulations governing this class of officers are very properly and necessarily rigid. The following are duly enforced in the United States service:

If any Disbursing Officer bets at cards or any game of hazard, his Commanding Officer suspends his functions, requires him to turn over all the public funds in his keeping, and immediately reports the case to the proper Bureau of the War Department. In every case where an officer intrusted with the care or disbursement of public funds violates this regulation, he is brought to trial before a General Court-Martial by the Department Commander, and is not assigned to duty, or again put in possession of public funds subsequent to his trial, without the approval of the Secretary of War.

Every officer charged with the payment of any of the appropriations made by any Act of Congress, who pays to any clerk, or other employé of the United States, a sum less than that provided by law, and requires such employé to receipt or give a voucher for an amount greater than that actually paid to and received by him, is guilty of embezzlement, and is fined in double the amount so withheld from any employé of the Government, and is imprisoned at hard labor for the term of two years.

Every person who, having charge, possession, custody, or control of any money or other public property used or to be used in the military service, who, with intent to defraud the United States or willfully to conceal such money or other property, delivers or causes to be delivered to any other person having authority to receive the same, any amount of such money or other property less than that for which he received a certificate or took a receipt, is imprisoned at hard labor for not less than one nor more than five years, or fined not less than one thousand nor more than five thousand dollars.

If any officer charged with the disbursement of the public moneys accepts, receives, or transmits to the Treasury Department, to be allowed in his favor, any receipt or voucher from a creditor of the United States, without having paid to such creditor in such funds as the officer received for disbursement, or in such funds as he may be authorized by law to take in exchange, the full amount specified in such receipt or voucher, every such act is an act of conversion, by such officer, to his own use, of the amount specified in such receipt or voucher.

Every officer of the United States, and every person acting for or on behalf of the United States, in any official capacity under or by virtue of the authority of any department or office of the Government thereof, who asks, accepts, or receives any money, or any contract, promise, undertaking, obligation, gratuity, or security for the payment of money, or for the delivery or conveyance of anything of value, with intent to have his decision or action on any question, matter, cause, or proceeding which may, at any time, be pending, or which may be by law brought before him in his official capacity, or in his place of trust or profit, influenced thereby, is punished by a fine not more than three times the amount asked, accepted, or received, and by imprisonment not more than three years. And if he hold any place of profit or trust, forfeits his office or place; and is thereafter forever disqualified from holding any office of honor, trust, or profit under the United States.

The sureties to the bonds to be given by Disbursing Officers are bound jointly and severally for the whole amount of the bond, and must satisfy the Secretary of War that they are worth jointly double the amount of the bond, by the affidavit of each surety, stating that he is worth, over and above his debts and liabilities, the amount of the bond or such other sum as he may specify; and each surety states his place of residence. See *Public Moneys*.

DISCHARGE.—1. The action of firing off a charge from a piece of ordnance or small-arm. Guns were formerly discharged by priming-powder poured into the vent, or by quick-match, which was ignited by means of slow-match or port-fire. Friction-tubes have for some years past been introduced into the service, and have been found to be vastly superior in power and certainty of ignition to either of the above modes, and are now universally used. Breech-loading small-arms are discharged by means of a needle or piston coming in contact with detonating composition at the base of the cartridge.

2. A release from military service either under compulsion or authority. There are several classes of discharge. First, on a soldier having completed the term of service for which he engaged, and not wishing to renew his services. This is either completion of limited engagement or service for pension. Second, when permitted to purchase his discharge. Third, when disabled from wounds or sickness to serve any longer. Fourth, when discharged by sentence of Court-Martial to penal servitude. Fifth, when discharged with ignominy for some offense that brings dishonor on the corps. Sixth, when summarily discharged as a worthless and incorrigible character. In England, a discharge from the military service is by right at the expiration of the period for which attested; or earlier, by indulgence. In the latter case the grant may be gratuitous, as on reduction of numbers, or when the man is not worth retaining, or paid for by the man discharged. In the last case the soldier pays a sum of money computed with reference to the unexpired period of service. If a soldier has many years still to serve, the discharge-purchase may amount to as much as £20. In the Sappers and Miners, where the men are all artisans, it may amount to £35; and among this Corps such discharges are very frequent, on account of the value placed on the services of these intelligent men by private employers. Soldiers are, under the Act of 1870, frequently discharged from service in the regular forces, after three or six years therein, on condition of serving the remainder of their original term in the Reserve. Earl Grey, when Colonial Secretary, introduced the plan of enabling discharged soldiers to settle on a piece of land in the Colonies instead of returning home. Soldiers are occasionally "discharged with ignominy," for some offense that brings dishonor on the corps. In such case the regiment is assembled, the crime recapitulated, and the sentence read. The buttons, facings, chevrons, medals, and all decorations are cut from the man's uniform, and he is "drummed out" of the regiment, if a foot-soldier, or by sound of trumpet, if it be a cavalry regiment. Notice of his degradation is afterwards sent in writing from the War Office to his parents or relations.

In the United States service no enlisted man is discharged before the expiration of his term, except—1. By order of the President, or Secretary of War, or the Commanding Officer of a Department. 2. By sentence of a General Court-Martial. 3. On certificate of disability by the Commander of a Geographical Department or an army in the field. 4. By order of one of the United States Courts, or Justices or Judges thereof, on writ of *habeas corpus*. The authority of State Courts to issue writs of *habeas corpus* in this matter is not recognized. 5. General service clerks may be discharged by their Commanders. When an enlisted man is to be discharged, his Company Commander furnishes him certificates of his account or final statements. And to *insure* his being at the post to get these, no leave of absence, terminating with his service, is given to him. The cause of discharge, and the soldier's age *at its date*, are stated in the body of the discharge-certificate. The soldier's character is carefully described according to the facts. Whenever the man is unfit for re-enlistment because of bad conduct, the space in the discharge-certificate left for description of character is cut off. The officer signing the character on the discharge-certificate of an enlisted man states thereon whether or not the soldier is married. Insane soldiers are not discharged at the posts where they may be serving, but are discharged by the Secretary of War after their arrival at the Government Hospital for the Insane. The Company Commanders forward with their descriptive lists, and accounts of pay and clothing, certificates of disability in the usual form, and a medical history of the cases for the information of the Superintendent of the Hospital. An honest and faithful service of twenty years in the army entitles a soldier to admission to the Soldiers' Home; but applications for discharge by reason of twenty years' service are not entertained unless the soldier is a fit subject for discharge on certificate of disability, or upon condition that he shall enter the Soldiers' Home.

DISCIPLINE.—Under a perfect discipline, troops in peace and in war, in garrison or in campaign, would be fitted for all the duties of war. To attain this perfection, it is necessary that discipline should rest entirely upon law; it ought to have its roots in patriotism; to be adapted to the character of the people; to the spirit of the age, and the nature of the government. It is essential to make rights and duties inseparable. This absolute necessity, and the importance of regularity of pay, are truths dwelt upon by the French writers. Discipline may be distinguished as active and passive. The first derives its power from a military hierarchy or range of subordination, skillfully established and regulated; it is secured by calmness, impartiality, promptness, firmness, and the prestige of character in officers. These qualities are manifested by preventing wrongs rather than by punishing faults, and by abstaining from arbitrary corrections when obliged to chastise. Discipline, intrusted to such authorities enlightened by military experience, will partake of the character of paternal government, and will not be enforced with an unsparing harshness suited only to governments essentially despotic.

The dogma that military discipline can only be sustained by the aid of severe and unpitying punishment is far removed from the idea here suggested. That unpitying military discipline seems to have prompted Peter the Great when he sacrificed a young officer who triumphantly fought the Swedes without orders. Thus also thought Frederick the Great when he executed the unfortunate Zietten, who violated an order by keeping a light a little too long in his tent. But such harsh principles are no longer inculcated in the best-governed armies of Europe. Passive discipline is the fusion of individual interest in national interest. The first military virtue is *esprit de corps*, with fidelity to the oath taken upon assuming the military character. These duties exact obedience to the laws, and to the lawful orders of the President of the United States, and officers set over us according to law. These laws should command obedience from all inferiors, and distinctly define the extent of all authority. They ought to bind the President or Commander-in-Chief as well as the simple soldier. Rights and duties must be reciprocal, and be alike established by law, which should, to maintain discipline, "precisely determine the functions, duties, and rights of all military men—Soldiers, Officers, Chiefs of Corps, Generals." Discipline that has attained this perfection supplies the deficiency of numbers, and gives new solidity to valor; since, although surrounded by dangers, the brave man feels that his leaders and comrades are not less devoted, less vigorous, or less experienced than himself.

Discipline is sometimes used as meaning "system of instruction," but its signification is much broader. Its technical military sense includes not only the means provided for exercise and instruction, but subjection to all laws framed for the government and regulation of the army. The good or bad discipline of an army depends primarily upon the laws established for its creation, as well as its government and regulation.

DISCRETION.—This term includes prudence, wisdom, the liberty of acting at pleasure, uncontrolled and with unconditional power; all which qualities, if wisely directed, will contribute much, in military affairs, to the successful termination of all undertakings. The military phrase, *to surrender at discretion*, implies surrendering without stipulation, throwing one's self on the mercy of a victorious enemy.

DISEMBARKATION.—The act of landing troops, arms, and supplies from a boat or ship. When this can be done at a wharf, it is simply the reverse operation of embarking. When wharf-accommodations are not available, arrangements will have to be made for transferring the men, horses, and *matériel* from the vessel to the shore. An army or other considerable body of troops embarked for an expedition, to be landed under such circumstances, will be provided with general means for disembarking, and the artillery, which usually constitutes an important feature of the outfit, shares with the rest in these general arrangements; but, owing to its nature, much of a special character is required for it, demanding the most careful consideration and attention from Artillery Officers. Such expeditions usually embark at seaports where there are accommodations that make the operation comparatively simple and easy, and for this reason the many preparations necessary for landing on an open shore are apt to be overlooked, or to be inadequately provided for. It becomes the especial province of the Artillery Commander to look out for this, and to give his advice and make his wants known to the Army Commander, so that the latter may cause proper provision to be made. The following method for the disembarkation of an army corps proved successful during the War of the Rebellion, and the same, or some modification of it, will apply in every case.

The essential articles for forming a landing-place were, several canal-barges; a number of ponton-boats, with balks, chess, oars, anchors, etc., complete; a number of gang-planks; a plentiful supply of lumber, and the necessary amount of ground-tackle, cordage, and tools. The canal-barges were about 14 feet wide and 70 to 80 feet long (drawing, when loaded, 5 feet of water; when light, 2 feet), and of about 80 tons burden. The gang planks were from 12 to 30 feet long and 10 feet wide, and very strong; ropes were attached to their corners, and the larger ones furnished with rollers. By lashing two of the canal-barges together, placing the boats some 12 feet apart, and throwing a false or additional deck over the whole, a platform was formed about 40 feet wide and 45 feet long, capable of holding all the pieces and caissons of a six-gun field-battery, or from forty to fifty horses. This boat or raft, when thus loaded, drew about 4 feet of water. Several of these rafts were prepared for the purpose of forming a *wharf-head*, alongside of which vessels could lie and discharge. From this wharf-head to the shore a ponton-bridge was constructed. The operation of disembarking consisted in bringing the transports alongside of the wharf-head, placing a gang-plank from the deck to the gunwale, and another from the gunwale to the wharf-head. Over these gang-planks the horses were led and taken ashore. The guns, caissons, and other carriages were run down the gang-plank and over the bridge by hand. In this way but two or three hours were consumed in disembarking an entire battery.

For disembarking artillery by this method or indeed by any method, smooth or comparatively smooth water is a *sine qua non*. Infantry and even artillery *matériel*, may be landed with small boats or lighters through a heavy surf, but a smooth sea is required for horses. When it is not considered expedient to construct a wharf-head and bridge, and the water near shore is of sufficient depth, double canal boats may be used for rafts to disembark both horses and *matériel*. The rafts must have railing around them; this should be strong, the stanchions extending into the boats and secured throughout with bolts and nuts. The horses are loaded from the vessel onto the raft either by means of gang-planks or by slinging them. The raft is towed to the shore by small boats or, better, by a small steam-tug; a gang-plank is run out and the horses led ashore. The guns and caissons are brought ashore in the same manner. When canal-barges are not to be had, small coasting-schooners may, by removing their deck-hampers, be used instead. Large decked-over scows, such as are to be found in seaport towns, make excellent rafts. When the distance from the vessel to the shore does not exceed 1000 yards or thereabouts, a warp-line may be used for bringing back and forth the raft. Every exertion should be made to erect a wharf, rough and temporary though it be, using for the purpose any kind of boats or scows that can be obtained. It may sometimes be advisable to sacrifice a ship for the purpose of forming a wharf-head, by scuttling and sinking her in such depth of water as to leave her spar-deck three or four feet above high water. With a sandy or muddy bottom, a ship might be sunk by loading her down until she rests firmly on the bottom. If the weather is calm she will suffer no great injury, and can be floated off when no longer required. The business of constructing rafts and wharfs as described belongs, as a general rule, to the Engineers; but should the Artillery Commander of an expedition anticipate, even in the remotest degree, a failure to provide the requisite means for disembarking, it becomes his duty to look after it, and he cannot be too zealous in doing so. The best plan under such circumstances is for each transport to carry along with it an outfit capable of discharging its cargo. The most useful boat for lightering that can be carried is the wooden ponton, such as is used for military bridges. It is 31 feet long, 5.5 feet wide at top, 4.5 feet wide at bottom, and 2.5 feet deep. Besides the three men required for managing it, it is capable of carrying 40 infantrymen with their arms and knapsacks, and it will very readily carry six horses.

Each transport should carry four ponton-boats and all the equipment for two rafts. If there is not sufficient room on deck for the boats, they may be carried stowed flat to the sides of the ship, bottom outwards, resting on strong solid chocks bolted to the wales. A strong parbuckle-sling passes around each, with which it is hoisted into place by the yard and stay purchases, and secured by lashings; by the same means it is lowered into the water. With several transports, each carrying the above-described outfit, it is generally practicable, by combining all, to form a bridge. Suitable vessels can nearly always be obtained for forming the wharf-head.

When there are several transports unloading at the same time, conspicuous and well-understood signal-marks must be placed opposite each, on the beach, so that it may be known to what points to direct the boats and rafts without confusion. A strong party for each should be on shore to secure the rafts upon touching, to haul up the guns and caissons, and to take care of the horses. Unless there is some special reason to the contrary, horses will always be landed first. This gives them an opportunity of resting and recovering from the trip while the *matériel* is being landed.

As a last resort, the horses may be swum ashore, and the *matériel* landed in the ship's boats—a very tedious operation. The horse is lowered over the side by slinging; a boat must be in attendance below to unhook the fall and clear the sling. A man in the small boat takes him by the halter and, conducting him a short distance, gives him the proper direction to the shore; without this precaution, horses sometimes become bewildered and swim around the vessel until exhausted. When the deck of the vessel is low, say not over ten feet, and there is a gangway, the horses may be backed off into the water without slinging. This method should not, however, be resorted to if it can possibly be avoided; it is liable to strain and injure the animal, and will ever after make him timid and shy about taking the water when it is necessary to cross streams on the march.

Siege-guns are embarked and disembarked in the same general manner as light field-pieces. When gang-planks are used, they are hauled up or let down by means of tackle. When embarking from a wharf or raft without gang-planks, the piece is run with its carriage under the ship's tackle; the gun is slung and hoisted aboard and lowered onto the deck or into the hold. In disembarking, the carriage is first put upon the wharf or raft, under the ship's tackle, and the piece then lowered onto it.

When it is necessary to land heavy guns by means of lighters, or from small vessels, the latter may be beached at high tide; the pieces are raised by blocking and skids until they can be rolled down two inclined skids from the vessel to the beach, where they are received upon skids or blocks of sufficient size to prevent them from burying themselves in the sand. At low tide they are removed from the beach.

Sieges, and similar operations calling for the use of the heavier classes of ordnance, are usually of such a protracted nature as to allow of substantial wharves being constructed, and cranes, derricks, and shears provided for unloading weighty *matériel*. It is but loss of time and labor, often ending in failure, to proceed with imperfect arrangements of this kind.

The disembarkation of an army must be considered under two heads: 1st. When made without any chance of interruption from any enemy; 2d. When made in presence of an enemy, or where an attack is possible. So far as artillery is concerned, the first of these conditions has been discussed in the foregoing paragraphs, and it will not be necessary to enter into further details here.

With regard to the latter, all questions, political, strategical, or otherwise, entering into the object of the expedition, having been settled by the proper authorities, and the army for carrying it out having been organized, embarked, and the transports arrived within the general limits of the field of operations, the first thing to be decided upon is the exact place or places where the various parts of the command are to be put ashore. Many local circumstances will influence this decision; among the most important of which will be to secure good anchorage and depth of water near the shore, a general configuration of ground in front which will admit of its being swept by the fire of the fleet, a firm and commodious beach, and freedom from prevailing winds or currents which may interrupt the disembarkation. The fire of the fleet must clear the country in front. The infantry is first landed and immediately pushed out sufficiently far to keep the enemy beyond cannon-range of the landing-place; here it intrenches itself, forming a *tête-de-pont* around the landing.

Meanwhile preparations will be made for landing the batteries. All the boat-rafts will be put together, and if a wharf-head and floating bridge is to be constructed it will be commenced at once. Steam-tugs must be in attendance for towing the rafts, carrying orders, and other miscellaneous duties. The Artillery Commander designates the order in which the batteries are to disembark, and will see that the transports take proper positions for effecting this without causing intervals of unnecessary delay.

If the attacks of the enemy are formidable and persistent, demanding the immediate service of artillery, the guns of several or of all the batteries may be landed without their horses, and taken to positions on the line by hand, or by the horses of one of the batteries landed for that special purpose.

When the expedition is large and the number of transports, store-ships, etc., great, the worst of confusion will arise unless some system of marking and distinguishing them is adopted. The best method is for each one to carry, instead, of her own burgee, the distinguishing flag of the corps to which the troops on board belong. This will show at a glance whether they are infantry, artillery, or cavalry, and to what corps, division, and brigade they belong. Besides this, each vessel should have a number painted, as large as possible, on each quarter. When embarking, a memorandum is kept and furnished to Commanding and Staff Officers showing what troops are on board of each transport. The Chief of Transports, who should be a Quartermaster selected for his practical capacity in such business, designates the anchorage-ground for each part of the command, and sees that they move up at the proper time and in the required order to the place of debarkation. It is with him that the Artillery Commander communicates in reference to the movements of the artillery transports. See *Transports.*

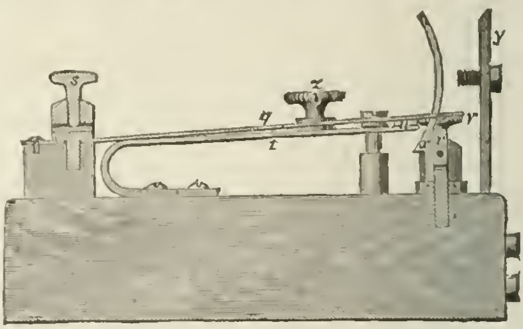
DISEMBODY.—To disarm a military body, and to dispense with its services for any stated period. The disembodying of the militia is an instance in point.

DISENGAGE.—1. To separate the wings of a battalion or regiment, which is necessary when the battalion counter-marches from its center and on its center by files. 2. To clear a column or line which may have lost its proper front by the overlapping of any particular division. 3. To extricate one's self and the troops commanded from a critical situation. 4. To break suddenly from any particular order in line or column, and to repair to some rallying-point. 5. In bayonet-exercise or fencing, to quit that side of an enemy's blade on which one is opposed by his guard, in order to effect a cut or thrust where an opportunity may present. The movement is executed as follows: Being engaged in *tierce*, number two covered, the Instructor commands: 1. *Number one*, 2. DISENGAGE. Number one passes his bayonet quickly under the bayonet of number two, to the left side, and lunges as explained for the *lunge in quarte*. Number two, as soon as he loses the touch of his adversary, executes the *quarte*, *prime*, or *butt-parry*, and then thrusts or lunges at command. Being engaged in *quarte*, number two covered, number one disengages from the left to the right side, and lunges as explained for the *lunge in tierce*. Number two, as soon as he loses the touch of his adversary, parries in *tierce* or *seconde* and then thrusts or lunges at command. See *Bayonet-exercise* and *Engage.*

DISGRACEFUL CONDUCT.—In the army this term implies conduct unbecoming an officer or soldier, and includes the following crimes: fraudulently misapplying public money or stores; malingering and feigning disease; willfully maiming or mutilating; maiming or injuring another soldier; tampering with eyes; stealing or feloniously receiving; offense of a felonious or fraudulent nature upon a civilian; indecent assault; producing false or fraudulent accounts or returns. For each of which crimes an officer or soldier can be tried by a General Court-Martial.

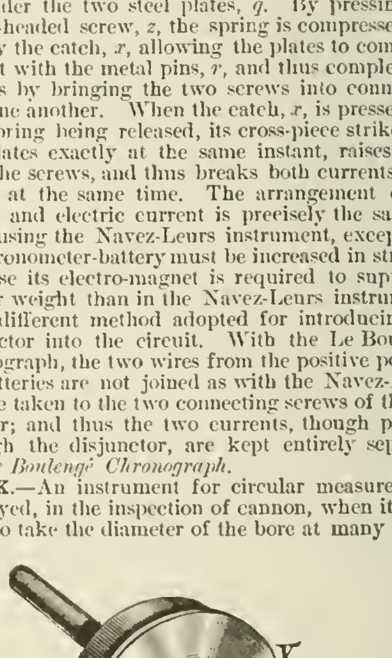
DISH OF A WHEEL.—The inclination or angle with the nave given to the spokes of a gun-wheel. The most severe stress to which spokes are subject is from the lateral thrust brought to bear upon the nave when one wheel becomes lower than the other by slipping into a rut, etc. In order, therefore, to place them in a better position to resist this thrust, the wheel is "dished," or formed into a kind of dome; and just as the dome or arch is strong, from its form, to resist pressure upon the crown tending to crush it in, so is the wheel made strong by the dish to resist the lateral thrust tending to force the nave outwards. In fact, not only do the spokes, sustained by the tire, yield mutual support to each other, but the lateral thrust upon each becomes partly converted into a compressing strain, which the wood has better power to resist. The greater the dish, the stronger the wheel will be to resist the lateral strain; but no more dish should be given than necessary for the safety of the spokes. See *Archibald Wheel* and *Wheel.*

DISJUNCTOR.—This important apparatus, as applied to the chronoscope and shown in the drawing in section, is composed of a mainspring, *t*, carrying a



cross-piece covered with insulating material, and passing under the two steel plates, *q*. By pressing the milled-headed screw, *z*, the spring is compressed and held by the catch, *x*, allowing the plates to come into contact with the metal pins, *r*, and thus complete the circuits by bringing the two screws into connection with one another. When the catch, *x*, is pressed, the mainspring being released, its cross-piece strikes the two plates exactly at the same instant, raises them from the screws, and thus breaks both currents identically at the same time. The arrangement of the screws and electric current is precisely the same as when using the Navez-Leurs instrument, except that the chronometer-battery must be increased in strength (because its electro-magnet is required to support a greater weight than in the Navez-Leurs instrument), and a different method adopted for introducing the disjunctor into the circuit. With the Le Boulengé chronograph, the two wires from the positive poles of the batteries are not joined as with the Navez-Leurs, but are taken to the two connecting screws of the disjunctor; and thus the two currents, though passing through the disjunctor, are kept entirely separate. See *Le Boulengé Chronograph.*

DISK.—An instrument for circular measurements employed, in the inspection of cannon, when it is desired to take the diameter of the bore at many points



of the circle. There is a brass tompion, V, to fit the muzzle of the gun, with a hole through its center to receive the staff of the star-gauge. It is turned to fit snugly the bore of the piece, into which it enters two or three inches, to hold it firmly in place; and has a projecting flange or face to prevent it going in too far.

The face is a plane surface with its circumference divided into as many equal parts as may be thought desirable, and numbered in regular order. On the staff of the star-gauge a brass slide, X, is fitted, having a thumb-screw to hold it in any position: from its inner end an arm, Z, extends at right angles to the staff, of sufficient length to meet the points on the circumference of the disk and having a center-line marked upon it. This slide is secured at any distance on the staff at which a circular measurement is desired, and with the center-line of the arm coinciding with the center-line of the staff; when the arm will indicate the direction of the pair of measuring-points; being in the same plane with them.

The disk is secured in the muzzle, with its zero-mark coinciding with a light punch-mark on the muzzle-face directly below the *line of sight*, so that it is in a plane passing through the axis of the piece and perpendicular to the axis of the trunnions. To take the measurements, press the staff home until the arm of the slide comes in contact with the face of the disk, and turn it to coincide with the various divisions of the disk at which measurements are desired. The disk is divided into halves, and the center-hole is reinforced on the inside by a projection, which is turned to receive a collar that fits closely around it, and holds the two halves together when they are placed on the staff. See *Inspection of Ordnance* and *Star-gauge*.

DISLODGE.—In a military sense, to drive an enemy from the position he has taken up.

DISMANTLE.—To render fortifications incapable of defense by razing them to the ground.

DISMISSION.—No sentence of a Court-Martial in time of peace dismissing a Commissioned Officer, or which, in war or peace, affects a General Officer, can be carried into execution without the approval of the President of the United States. Disbursing Officers may be dismissed by the President alone, without the intervention of a Court-Martial, on failure to account properly for moneys placed in their hands. A General Court-Martial in time of peace may dismiss, with the approval of the President, in all cases in which they are authorized to sentence to "death or such other punishment as may be inflicted by a General Court Martial." Such Court may also sentence a Commissioned Officer to be cashiered or dismissed the service. In the English service, dismissal is the sentence passed upon an officer by a Court Martial for conduct which renders him unfit to remain in the army. From the date of publishing the order the dismissed officer's connection with the army ceases. It is in the power of Her Majesty to dismiss any officer from the service without bringing him to trial.

DISMOUNT.—1. A word of command, in the School of the Soldier mounted, for mounted men to leave the saddle. To execute the command, rise upon the left stirrup; pass the right leg extended over the croup of the horse without touching him; bring the right heel to the side of the left; descend lightly to the ground; remove the left foot from the stirrup, and place it by the side of the right, keeping the body erect; let go the mane; pass the end of the reins over the pommel of the saddle with the right hand, which then seizes the left rein. (Two.) Face to the left, take two short steps, left foot first; slip the right hand along the left rein, and take the position of *stand to horse*. See *Mount*.

2. In artillery, to take a piece of ordnance off its carriage. With light guns it is performed by the gun's crew with the aid of drag-ropes. With heavy guns, gins and jacks have to be resorted to; but guns of moderate weight can be dismounted by means of tackles, rollers, and handspikes.

3. Guards, when relieved, are said to dismount. They are marched with the utmost regularity to the parade-ground where they are paraded, and from thence to their regimental or company parades, previously to being dismissed to their quarters.

DISOBEDIENCE OF ORDERS.—A crime severely punished in all armies. In the United States the Articles of War provide that any officer or soldier who, on any pretense whatsoever, strikes his Superior Officer, or draws or lifts up any weapon, or offers any violence against him, being in the execution of his office, or disobeys any lawful command of his Superior Officer, shall suffer death or such other punishment as a Court-Martial may direct.

DISPART.—In gunnery, the dispart is generally defined as a patch of metal placed on the highest point of the muzzle of a gun or howitzer, and which is half the difference between the diameter of the base-ring and that of the swell of the muzzle. This definition will only strictly apply to cast-iron and bronze ordnance. Most of the *dispart-sights* or *patches* are not placed near the muzzle, but on the top of the gun, a little in advance of the trunnions; or, as with rifled guns, just above the trunnions. A better definition for dispart would then be, half the difference between the diameter of those parts of the gun upon which the sights are placed. The term is derived from the mode of ascertaining the dispart, as shown above, and disparting (dividing in two) the difference between the two diameters, which *half* difference shows the tapering or coning of the metal between the base ring and swell of the muzzle. This patch of metal is intended, in laying the piece, to avoid the inconvenience arising from the line of sights or metal not being parallel to the axis of the gun. Disparts are either fixed or movable. See *Sight*.

DISPART-SIGHT.—A gun-sight, made to allow for the dispart, and bring the line of sight and the axis of the piece into parallelism. See *Dispart*.

DISPATCHES.—Official messages. In war, important dispatches which have to pass through the enemy's country, or in the vicinity of his forces, are only intrusted to officers to whom their contents can be confided. Dispatches are frequently in cipher, especially when telegraphed or signaled with a liability to interception. See *Cryptography*.

DISPERSE.—In a military sense, the power which an armed body, either better handled or in larger numbers, has of scattering a hostile force drawn up to oppose it. Cavalry, under these circumstances, forms a prominent part in pursuing or dispersing the enemy.

DISPLACED.—A term, in the British service, applied to officers who are sometimes removed from a particular regiment in consequence of misconduct, but who are at liberty to serve in any other corps.

DISPLAY.—A military term meaning to extend the front of a column, and thereby bring it into line.

DISPLAYED.—In Heraldry, a term meaning *expanded;* as, an eagle displayed, or what is commonly known as a spread eagle. See *Heraldry*.

DISPLUME.—In a military sense, to deprive of decoration or ornament; to degrade.

DISPOSITION.—In military language, as applied to the strategic position of troops, is of infinite consideration both in war and time of peace. In the former case, a knowledge of the country in which the campaign is to be fought, and the various combinations which should be carried out, formed on the disposition of the troops, is very necessary on the part of the General in command, to bring matters to a successful termination, or to prevent the enemy from taking advantage of a bad disposition of his opponent's forces to harass or break them up. The following maxims from the memoirs of General Montecuculi are worth remembering:

"Deliberate leisurely, execute promptly.

"Let the safety of your army be ever first.

"Leave nothing to chance.

"Take advantage of circumstances.

"Use all the means in your power to secure a good reputation."

DISPOSITION DE GUERRE.—Warlike arrangement or disposition. Under this head may be considered the mode of establishing, combining, conducting, and finally terminating a war, so as to produce success and victory.

DISRESPECT.—In a well-disciplined army disrespect is not tolerated. The Articles of War provide that any officer or soldier in the United States army who uses contemptuous or disrespectful words against the President, the Vice President, the Congress of the United States, or the Chief Magistrate or Legislature of any of the United States in which he is quartered, or who behaves himself with disrespect towards his Commanding Officer, shall be punished as a Court-Martial may direct.

DISTANCE.—1. The space between the observer and any object. In gunnery, *to judge distance* accurately is a high qualification in artillerymen, as well as in soldiers of the line, and is only to be attained by a clear sight, constant observation, and practice in the drill laid down on this subject, termed "judging distance drill," the introduction of which into the army has been attended with such excellent results. Under the most favorable circumstances, however, judging distances by the eye is not to be depended upon, and this is so much felt in the artillery service that to each gun a range-finder will doubtless be attached, giving the distance of objects very accurately, and rendering it unnecessary to depend on the eye.

2. A term in tactics, expressing the relative space left between troops in the ranks, after a formation or movement. *Distance* is estimated perpendicularly to the front, while *interval* is estimated parallel to the front. When mounted, the following distances are approved: distance between companies in column of fours is 9 yards (front of four troopers, plus 5 yards); distance between companies in column of platoons is platoon front, plus 5 yards; distance between companies in column of companies is company front, plus 5 yards; in echelon of companies, distance between companies is company front, plus 5 yards; in echelon formed from line of platoon column, distance between companies is platoon front, plus 5 yards; in echelon of double columns, distance between companies is 9 yards; distance between companies in close column is 12 yards; full distance between companies in double column of fours is ½ company front, plus 9 yards; closed distance between companies in double column of fours is 9 yards; full distance between companies in column, double rank, is front of company in single rank, plus 1 yard; closed distance between companies in column, double rank, is front of company in double rank, plus 1 yard; interval between companies in line, single or double rank, is 8 yards; full interval between companies in line of platoon columns is company front, plus 8 yards, less the front of one platoon; closed interval between companies in line of platoon columns is 12 yards; full interval between companies in line of double columns is front of company in line; closed interval between companies in line of double columns is ½ front of company in line; full interval between companies in line of companies in columns of fours is front of company in line, plus 4 yards; half interval between companies in line of companies in columns of fours is ½ front of company in line, plus 4 yards.

DISTANCE OF THE BASTION.—In fortification, a general term applied to the exterior polygon.

DISTANT DEFENSE.—A defense consisting in being able to interrupt the enemy's movements by circuitous inundations; to inundate, for instance, a bridge when a convoy is passing, or to insulate batteries, the heads of saps, or lodgments which have been made in the covered-way. By this species of defense an enemy's communications may be perpetually intercepted, and his approaches so obstructed as to force him to leave dangerous intervals.

DISTLLATION.—The separation of a body from extraneous substances by its conversion into vapor, its removal in that state, and its subsequent condensation. The operation is termed *distillation* if the vapor assumes the form of liquid upon condensation, even if that liquid should solidify upon further cooling. The vessels used for distilling are few and simple; those for raising the temperature of the water are generally of metal, and termed *stills*. A still consists of a boiler to contain the liquid, to which is adapted a head terminating in a beak, which fits into the condensing apparatus. There are several forms of condensers in general use—among them the *Worm* and the *Liebig*.

DISTORTED SECTION.—The name applied to a method of approximately determining the center of gravity of a gun by experiment. A figure differing from a longitudinal half-section of the gun by the substitution in the place of the ordinates representing semi-diameters of those proportionate to the squares of the diameters is cut from cardboard or other material of uniform weight for a given area. In this a point of suspension from which the axis assumes a horizontal position is readily found by trial, and its position relative to the length of the figure is the same as that of the center of gravity in the gun. In the application of the method a convenient scale for the length of the gun and for abscissas in the line of its axis is one tenth. For the ordinates it will usually be convenient to take one hundredth of the square of semi-diameters. The principles involved will hardly need explanation. *Areas* are made to correspond to volumes, and occupy the same relation to the center of gravity. An extension of the plan gives a means of ascertaining approximately the *weight* of a gun. It will be found that the area of the figure drawn on the scale proposed presents one square inch for every 3141.6 cubic inches of volume of the gun. The area may conveniently be found by comparing the weight of the irregular piece of cardboard with that of a carefully measured rectangular piece cut from the same sheet. The volume of the gun being found in cubic inches, the only remaining step to find its weight is, of course, to multiply by the weight per cubic inch. Cardboard of the better sort is commonly very uniform in weight in parts of the same sheet. See *Center of Gravity*, and *Centrobaric Method*.

DISTORTION.—The rules of perspective impose certain conditions in the delineation of natural objects, and when the image formed by a lens on the focusing-screen of a camera obscura does not fulfill those conditions, it is said to be distorted. The effect of distortion is to render all straight lines which do not pass through the center of the lens curvilinear, and also so to alter the relative proportions of objects in the picture as to be opposed to the principles of true perspective. Distortion, in the camera obscura, is generally produced by the eccentrical incidence of the oblique pencils.

DISTRIBUTION.—In a general military sense, any division or allotment made for the purposes of war; also minor arrangements made for the supply of corps.

DISTRICT.—The term Military District is applied to one of those portions into which a country is divided for the convenience of command and to insure a co-operation between distant bodies of troops. Before Mr. Cardwell's Act of 1872 England was divided into four Districts, and Ireland into five, while Scotland formed one. Now there are nine general Districts in England—namely, the Northern, with Manchester as its headquarters; the Eastern, with Colchester; the Southern, Portsmouth; the Southeastern, Dover; the Home District, London; the Chatham; the Woolwich; the Aldershott. In Ireland there are four—Belfast, Dublin, Cork, and the Curragh. Scotland is still one District, with Edinburgh as headquarters. Jersey is a Military District; and Guernsey and Alderney form another.

DISVELOPED.—A term in Heraldry applied to the colors of a regiment or army, which are said, heraldically, to be disveloped when flying. Also written *Developed*.

DITCH.—The ditch, sometimes called *fosse*, is the excavation made round the works, from which the earth required for the construction of the rampart, parapet, and banquette is obtained. In besieging a fortification, when the ditch is dry, and a descending gallery has been constructed, the passage of the ditch consists of an ordinary sap pushed from the opening in the counterscarp-wall to the slope of the breach, and, when necessary, it is carried on to crown the summit of the breach. If the ditch be full of water, and the locality favors its being drained, every means must be used to break the batardeaux, to cause the water to flow away entirely or in part. If none of the batteries can see the batardeaux, the sluices must be sought and destroyed by shells, or by mining. Should the assailants be unable to breach the batardeaux or to destroy the sluices, a bridge or causeway must be thrown across. This is one of the most difficult operations in a siege. The bridge or causeway, with its epaulement, is constructed with pontons or casks, or, if without them, with fascines, hurdles, gabions, and sand-bags, openings being left in the causeway to allow the free flowing of the water, if it be a running stream, or can be made so by the defenders. A wet ditch may sometimes be crossed by a raft of sufficient length, which should be constructed along the counterscarp, and attached by one end to the bottom of the descent. The raft is then allowed to swing round with the current, if there be one, or is rowed or pulled round, if there is not one, so as to form a connection across the ditch with the breach.

The ditch should be regulated to furnish the earth for the parapet. To determine its dimensions the following points require attention: its depth should not be *less than six feet*, nor its width *less than twelve feet*, to present a respectable obstacle to the enemy. It cannot, with convenience, be made *deeper than twelve feet;* and its greatest width is regulated by the inclination of the superior slope, which, produced, should not pass *below the crest of the counterscarp.* If we assume the height and thickness of the parapet, we can calculate the dimensions of the ditch as follows: Denote by R the volume of the parapet, S the area of the profile of the parapet, and l the right line generated by the center of gravity of the profile of the parapet, supposing this profile moving parallel to itself, and generating the volume of the parapet under consideration. Denote by R', S', and l' similar quantities for the ditch. The volumes for the parapet and the ditch, for any part of the work under consideration, will be expressed as follows:

$$R = S \times l \quad \text{and} \quad R' = S' \times l'. \quad . \quad . \quad (1)$$

Earth when made into an embankment occupies a greater space than it did in the natural state. Denote this increase of volume by $\frac{1}{m}$. Since the volume of the earth in embankment is furnished by the volume excavated from the ditch, there results

$$R = R'\left(\frac{m+1}{m}\right). \quad . \quad . \quad . \quad . \quad . \quad (2)$$

Substituting in equation (2) the values taken from equations (1), there results

$$S' = S\frac{l}{l'}\left(\frac{m}{m+1}\right). \quad . \quad . \quad . \quad . \quad (3)$$

It will be sufficiently exact to take l' equal to the length of the middle line of the ditch; which being substituted gives S' in known terms. Assume the slope of the scarp $\frac{1}{3}$ and the counterscarp $\frac{1}{4}$ greater than the natural slope. Represent the width of the ditch at top by x, and its depth at the middle by y. Denote the angle of the natural slope by φ. Using this notation, the area of the profile of the ditch is given as follows:

$$S' = y\left(x - \frac{7}{12}y \cot \varphi\right). \quad . \quad . \quad . \quad (4)$$

Solving equation (4) with respect to x, there results

$$x = \frac{7}{12}y \cot \varphi + \frac{S}{y}; \quad . \quad . \quad . \quad . \quad (5)$$

and solving with respect to y, and taking the minus sign of the radical, it gives

$$y = \frac{6}{7} \tan \varphi \left(x - \sqrt{x^2 - \tfrac{7}{3}S' \cot \varphi}\right). \quad . \quad (6)$$

From these equations (5 and 6) y can be assumed and x deduced, or x assumed and y deduced. Making $\varphi = 45°$, these last equations reduce to

$$x = \frac{7}{12}y + \frac{S'}{y} \quad \text{and} \quad y = \frac{6}{7}\left(x - \sqrt{x^2 - \tfrac{7}{3}S}\right).$$

It should be remembered, in assuming values for x and y, that x must not be less than twelve feet, and y not less than six nor greater than twelve feet. In practice it will be sufficiently accurate to calculate the area of the assumed profile, assume a depth for the ditch, and, without making an allowance for the increase of volume of the earth in the embankment, divide the area of the profile by the assumed depth of the ditch. The result will give the width of the ditch at the top.

DITCH-DEFENSES.—There are two kinds of arrangements employed on the exterior of a parapet to add to the strength of a work; viz., the arrangements made to defend the ditch, and those made to obstruct an enemy's approach. The term *ditch-defense* is used to designate the arrangement made exterior to the parapet by which a fire is made to sweep the ditch. The term *obstacle* is applied to any construction or arrangement, whatever may be its nature, which, by its passive resistance, obstructs the approach of an enemy advancing to assault the work. Hence anything is an obstacle which diverts the attention of the enemy from the assault to the immediate surroundings of himself. The surest defense for a ditch is a good flanking arrangement of the work itself; but as this is, in many cases, impracticable, owing either to the relief or to the plan, flank-defenses must be procured by a construction made in the ditch. Several methods may be resorted to for this purpose, the structures being termed *caponieres, scarp* and *counterscarp galleries.*

DIVERGENT RETREAT.—In marches in retreat, like those in advance, the same general rule holds of keeping to a single line, so as to have our fractions well in hand to oppose the greatest force possible to the enemy. Those retreats that are termed *divergent,* or *eccentric,* and which are made at the same time on divergent routes to deceive the enemy and render his pursuit uncertain, are extremely dangerous. In separating, to follow these divergent lines, we weaken ourselves on every point; the corps, being isolated, offer no mutual support; they are easily beaten, and, being forced upon any impassable obstacle, or surrounded, must be either annihilated or forced to surrender. The enemy, without allowing his attention to be drawn off from his object, will stick to one of these fractions until he has destroyed it, knowing that the others must fall an easy prey wherever they may be found, as from their dispersed condition they can offer no effectual resistance. Merely to keep them from reuniting will be enough for present purposes. There is but one case in which our forces can be dispersed with safety, and that is when we have just gained a decisive victory and are in the presence of an enemy who, having lost his communications, is entirely disorganized and demoralized. In this position of affairs we have only to throw our force into the midst of these broken-up fractions to determine them to fly. We may here attempt any blow; no movements can fail to turn out well except those which are too slow and methodical. This exception only becomes legitimate under the supposition that the disorganization and demoralization of the defeated army are complete.

DIVERSION.—In connection with marches as strategical movements, those operations performed by detachments, made to favor some design of the main body, and termed *diversions,* find a place. Diversions, and detachments made to aid the operations of the main body, when they have a long circuit to accomplish, are contrary to sound strategical principles.

In war, as in every other art based upon settled principles, there are exceptions to all general rules. It is in discerning these cases that the talent of the General is shown. Diversions belong to this class of exceptions. There are cases where they are not only called for, but are imperative upon the General. As, for example, when there is some position held by the enemy that must be carried before any other step can be taken, a diversion may be made either to threaten his line of communications, or to seize some commanding point near his position which, by forcing him to detach to meet the danger to him, will so weaken him as to allow us to make our main attack with good prospects of success. Cases of this kind are of frequent occurrence in mountainous positions, where, in order to force the enemy from some vantage-ground, a diversion on his flank or rear has to be made by a long circuit. Here the exception becomes the rule. Still, even in such cases care should be taken to call in the detachment as soon as the result is obtained, and fall back upon the rule of concentration and unity of operations. Besides, diversions are less dangerous in countries broken by forests and mountains, as the enemy finds it more difficult to throw himself between the main body and the detachment than in a country which has but few such obstructions and masks. In a mountainous region a small corps may find itself in a narrow valley, where it can neither be turned by its rear nor by its flanks, and where a large body would not find room to fight. In such cases the isolated corps need only be strong enough to defend themselves in front along the valleys they occupy. Here dissemination of our forces is only an apparent violation of the general principle; as, by falling back, each corps has still its line of retreat secure, and all can concentrate on some central point in rear of the mountain-passes. Another exception is found where our force is very superior to that of the enemy, and that we can better subsist our troops by separating them. Here we but follow a rule of Napoleon which he invariably put in practice; which is, *to disperse our force to subsist and to concentrate for battle*. However simple this rule may appear, none but an able General can carry it out successfully in practice; for it supposes a talent for military combinations possessed alone by Generals of this class. When our superiority in strength and *morale* is decidedly superior to that of our adversary, we may then resort to diversions to threaten his communications, to force him to abandon his fortified positions, to make raids into his territory, placing them under contribution, etc. All operations of this character, undertaken even under the most favorable circumstances, must be carried out with promptitude, vigor, and even audacity, to insure success. If made against a timid, irresolute Commander, the chances of their success are still further increased. But unless such favorable circumstances co-operate, it will be safer not to risk them.

DIVIDE.—In order to successfully travel the mountains it is necessary to understand their complete make-up and to know how to skillfully follow the *divides*. When a divide separates the waters of two streams not uniting with each other it is known as a *principal divide*, and always affords the best route of travel. The sides of cañons and ravines are frequently so precipitous that it is neither advisable nor possible to cross them; and although it is sometimes easy traveling along the bottoms (the level land inclosed between the sides), when not too narrow and rocky, the best route will, considering all things, be found along the divides. Such a route is frequently long and crooked, but it is a good one. Suppose it be required to pass from one stream to another parallel to it, but separated from it by very high and broken mountains. To accomplish this most expeditiously, follow up the first stream to a point where we will suppose a tributary of the stream puts in. Now if there be a good route, apparently, over the divide above this tributary, turn and follow it until the principal divide is reached. The route, if practicable, may be taken along the bottom, should water be desirable, as far as necessary. Having reached the principal divide, pass over it and descend by any suitable and practical divide leading from the principal divide to the other stream. It will be found that all the divides lead to the principal divide, and hence there will be no doubt as to finding the principal divide; but it will often require good judgment in selecting the most practicable divide leading to it. It will be still more difficult to select the practicable divide in descending, as all appear more or less practicable from the summit. The innumerable *cul-de-sacs* met with in descending can only be avoided by exercising great caution. In every case the divide selected should separate tributary ravines of two *important* tributaries of the stream. It is easily understood how these ravines frequently overlap each other and render the route very sinuous. It is recommended to follow game-trails, when discovered, in passing from one stream to another. They usually follow the most direct and practicable route over a fair divide. When arriving at the steep edge of a ridge, and where difficulty in finding a good trail is anticipated, it is a safe rule to descend first on foot and seek a trail for the command or train as you climb back again. It is much easier to make this selection while ascending than while descending; for when at the bottom of a hill its bluffs and precipices face you, so that they may be readily avoided, but when at the top of the hill these parts are overlooked and not seen until closely approached. The investigation of ravines is the exact reverse of that of the divides; but localities are much more readily lost when the ravines proceed thence in various directions. On crossing a divide and coming upon a system of ravines leading to a different *principal ravine*, the traveler should make very sure of his course and frequently take the bearings of the most prominent landmarks.

DIVIDING-ENGINE.—A machine for dividing a circle into a number of parts of equal proportions, either for the purpose of graduation, as the circles and arcs of astronomical, surveying, and plotting instruments, or for spacing off and cutting the circumference of a wheel into teeth. The dividing-engine was early applied to a mode of originating screws by Pappus Alexandrinus, a Greek mathematician of the fourth century. The methods of graduating instruments received much attention from Tompion (1660), Sharp (1689), and Bird (1745), the latter receiving 500 pounds from the Board of Longitude for his method of dividing. Numerous inventions and improvements in this line followed. The methods of *original graduation* are not practically adopted except for the largest and most important astronomical or geodetical instruments. Ordinary instruments are graduated by dividing-plates or engines which copy and adapt a set of already existing divisions. The dividing-plate which is used for common purposes, such as dividing compass-rings, etc., is a divided circle with a steel straight-edge made movable on the axis or arbor of the plate in such a manner that its edge during every part of its revolution shall fall in the exact line from center to circumference. The ring, protractor, or other instrument to be divided is clamped upon the plate with its center exactly coinciding with that of the plate, and the straight-edge is moved round and made to halt at the required divisions on the circumference of the dividing-plate, and by using the steel straight-edge as a guide corresponding divisions are marked off upon the concentric arc of the instrument to be divided. The *dividing-engine* is a very complex machine requiring the greatest accuracy and care in its construction; so much so that the possession of a good one affords the means of obtaining a very good income with a moderate amount of labor in using it.

Such was the case with the instrument of Mr. Parsons of London, who for many years divided a large proportion of the best theodolites, sextants, etc., that were made in Great Britain. Among the most celebrated dividing-engines may be mentioned those of Ramsden, Troughton, Simms, and Ross. A detailed account of the construction of these would far exceed our limits. Their principal parts consist of a large circle divided with extreme care by original graduation. This wheel is racked on its edge with teeth as equal and accurate as the divisions; a very carefully constructed endless screw works in these teeth, and is moved through any given number of revolutions, or any measured fraction of a revolution, by means of a treadle or other suitable power, thus making the requisite steps for each division; another part of the machine cutting a fine line at the moment of the halt of each step. These divisions are cut upon an arc of silver, gold, or platinum, which is soldered or inlaid upon the limb of the instrument, the precious metals being used on account of the oxidation to which common metals are liable. In 1843 Mr. Simms applied a self-acting apparatus to Troughton's circular dividing-engine, and an instrument of this manufacture may be seen at the Coast Survey Building, Capitol Hill, Washington. It has been somewhat modified, and is now driven by a small turbine in the stand. See *Graduation*.

DIVINE SERVICE.—In the United States army it is earnestly recommended to all officers and soldiers diligently to attend divine service. The Articles of War provide that any officer who behaves indecently or irreverently at any place of divine worship shall be brought before a General Court Martial, there to be publicly and severely reprimanded by the President thereof. Any soldier who so offends shall, for his first offense, forfeit one sixth of a dollar; for each further offense he shall forfeit a like sum, and shall be confined twenty-four hours. The money so forfeited shall be deducted from his next pay, and shall be applied by the Captain or Senior Officer of his troop, battery, or company to the use of the sick soldiers of the same.

DIVING-BELL.—A vessel inverted in water and let down to any depth by means of a rope, air occupying the upper part of the vessel. By means of the diving-bell men are able to descend to great depths, and to carry on such submarine operations as may be necessary in masonry, laying stones, and the like, and of keeping under water for some hours by the aid of fresh air supplied by pipes or barrels attached to the bell. The workmen accustomed to subaqueous existence do not suffer inconveniences; novices feel pains in the head and ears, but these pass away after a short initiation. It is stated that one man who had suffered from difficulty of breathing was completely cured by "belling," and that deafness is not produced by it, but, on the contrary, is in some cases relieved.

DIVING-DRESS.—In Schott's *Technica Curiosa*, published in 1664, is described a *lorica aquatica*, or aquatic armor, which consisted of a leathern dress, to protect the diver from the water, and a helmet. In 1721, Halley describes a contrivance of his own of nearly the same kind; its object was to enable the diver to go out from the bell and walk about; he was to be provided with a water-proof dress, and a small diving-bell, with glass front, as a helmet over his head, which was to be supplied with air by means of a tube from the diving-bell. The modern diving-dress is made of India-rubber cloth; a strong metal helmet, with round pieces of plate-glass in front, rests upon a pad on the shoulders; the air is supplied to this helmet from above, in the same manner as for the diving bell, but instead of the waste air passing out below, a second tube carries it up. Leaden weights are attached to the side of the diver, and thus he may descend a ladder and walk about below. He carries with him one end of a cord communicating with the assistants above, and by pulling this, as agreed upon, makes a series of signals.

DIVISION.—1. A section of an army, indefinite in point of numbers, but established as a matter of convenience. It often comprises infantry, cavalry, and artillery, and is in effect a small army in itself, commanded by a General Officer. In the Crimean War, for instance, a division comprised two brigades, each of three or four battalions.

The manner in which a division is posted varies with circumstances: it may be deployed in single line, with an interval of 100 yards between brigades for batteries, Fig. 1; two brigades may be deployed in the first line, the third in a second, Fig. 2; the three brigades may be deployed in two lines each, Fig. 3; or two brigades may be deployed in two lines, the third being held in reserve in line of masses, Fig. 4. The batteries are specially assigned by the General of Division to the most advantageous positions, an interval of 100 yards being allowed for each.

Fig. 1.

Fig. 2.

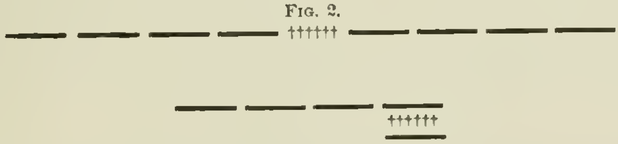


Fig. 3.

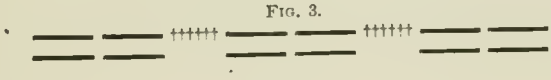

Fig. 4.

The commands of the General of Division are communicated through Staff-officers; they should be explicit, should be couched as far as possible in tactical language, and should be thoroughly comprehended by the officers delivering them. The batteries receive their orders through a Chief of Artillery, and conform in their movements to the tactics of the artillery arm.

The field-exercises of a division should be limited to those movements most practiced in active campaign, such as deploying into line from column of fours; advancing and retiring in line of battle; changes of front; change of front of one brigade; deployment of the reserve brigade on its right or left, and withdrawal of the third brigade into reserve; change of direction to the right or left by echelon from the left or right, and such other movements as occasion may require. Brigades in line are designated *right*, *center*, and *left*; or, if one be in rear, *right*, *left*, and *rear*; in column they are designated *leading*, *center*, and *rear*. In order that no mistakes may occur in transmitting orders, the names of the Brigade Commanders are always to be mentioned. In all successive formations, each brigade after completing the movement stacks arms and breaks ranks. The brigade is called to attention upon the receipt of the next command from the General.

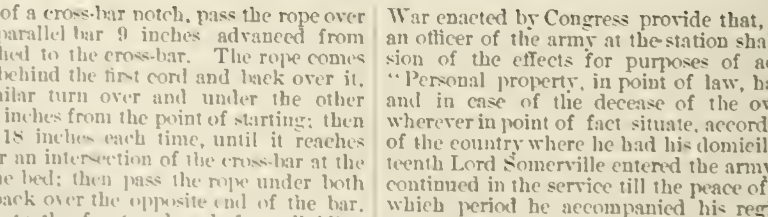
2. A Military Division is one of those larger portions into which a country is divided for convenience and to fix responsibility. The United States are at present divided into the following Military Divisions, viz.: 1. Division of the Missouri, comprehending the Departments of Missouri, Dakota, Texas, and the Platte; headquarters Chicago. 2. Division of the Pacific, including the Departments of California, Columbia, and Arizona; headquarters San Francisco. 3. Division of the Atlantic, including the Departments of the East and the South; headquarters New York.

DIVISIONAL ARTILLERY.—A portion of the field-artillery left to co-operate with the division of infantry or cavalry to which it is attached.

DIVISION COMMANDER.—The Commander of a Division, or of a geographical division of a country. He is assimilated to the Commander of a separate army, with the same powers and duties in similar cases over all the troops within the limits of his Department. See *Geographical Departments* and *Divisions*.

DIVISION-PLATE.—The disk or wheel in the gear-cutting lathe, which is pierced with various circular systems of holes; each circle represents the division of a circumference into a given number of parts.

DOANE LITTER.—A litter of poles and raw-hide, proposed by Lieutenant G. C. Doane, United States Army. The poles are 16 feet long, and the frame is so constructed as to give a bed 7 feet long, 3 feet 2 inches wide at one end and 3½ feet at the other. A lariat or raw-hide thong is used to cord the bed-space in the following manner: Tie one end at a corner over a lashing of a cross-bar notch, pass the rope over the opposite parallel bar 9 inches advanced from where it is lashed to the cross-bar. The rope comes under the bar behind the first cord and back over it, making a similar turn over and under the other parallel bar 18 inches from the point of starting; then back, gaining 18 inches each time, until it reaches and passes over an intersection of the cross-bar at the other end of the bed; then pass the rope under both parallels and back over the opposite end of the bar, and cord back to the front end as before, dividing each space of 18 inches, so that when finished the spaces will be 9 inches between bearings. The object of a second cording is to counterbalance the strain of the first, which would tend to throw one parallel forward and the other to the rear.



Doane Litter.

DOCK-YARD BATTALIONS.—Prior to the establishment of Volunteer Corps, Dock-yard Battalions formed a special element in the British military service, intended chiefly for the defense of the Royal Dock-yards. It was in 1847 that an item first appeared in the estimates of £20,000 for training and exercising about 9000 men in these battalions. Clerks, artisans, and laborers formed the body. The Colonel was a naval officer, and commissions were given to the other officers. The men received remuneration for time lost in drilling. A few hours per week in summer were set apart for drilling under the management of Sergeants and Corporals of Marines. At first the enlistment was voluntary, afterwards compulsory. These battalions were abolished in 1861.

DOG.—A clamp fastened to a piece suspended on the centers of a lathe, and by which the rotation of the chuck or face-plate is imparted to the piece to be turned. The chuck, known as the *dog and driver*, has two parts. The dog slips upon and is fastened by a set-screw to the object to be turned. The driver is attached to the lathe-mandrel, and has a projecting arm which comes in contact with the dog, and causes it and the work to revolve with the mandrel.

DOG-BOLT.—The bolt of the cap-square placed over the trunnion of a gun.

DOLABRA.—A rude ancient hatchet. Dolabras are represented on the columns of Trajan and Antoninus, and abound in all museums. When made of flint, which was their earliest and rudest form, they were usually called *celts*.

DOLPHINS.—Two handles formerly placed upon a piece of ordnance, with their centers over the center of gravity, by which it was mounted or dismounted.

DOMICILE.—By law every man's domicile is in the country where he has his permanent residence, or to which he ordinarily returns for the purpose of residence after occasional absence; and in case of his death, the right of succession to his goods and chattels and personal property of all sorts is regulated by the law of the country of his domicile, although he may happen to die beyond its limits. As regards military men, their employment on duty involving only temporary absence in intention would not, on common principles, cause a change of domicile; and as the laws of different States of the Union vary on the subject of the right of succession to property, the subject is of great interest to military men. An officer who was a native of South Carolina died intestate in the city of New York, and no heirs being forthcoming, his estate was taken possession of by the Public Administrator, although the Rules and Articles of War enacted by Congress provide that, in such cases, an officer of the army at the station shall take possession of the effects for purposes of administration. "Personal property, in point of law, has no locality, and in case of the decease of the owner must go wherever in point of fact situate, according to the law of the country where he had his domicile." The fourteenth Lord Somerville entered the army in 1745, and continued in the service till the peace of 1763, during which period he accompanied his regiment to England, Scotland, and Germany, both in quarters and on active duty. At his death, in 1796, a question arose whether, under the circumstances, his domicile was English or Scotch; and the Master of the Rolls (Sir R. P. Arden), in giving judgment, said: "I am clearly of opinion Lord Somerville was a Scotchman upon his birth, and continued so to the end of his days. He *never ceased* to be so, never having abandoned his Scotch domicile, or established another. The decree, therefore, must be that the succession to his personal estate ought to be regulated according to the law of Scotland." His Honor must consequently have been of opinion that, a Scotchman entering the British army does not thereby lose his original Scotch domicile; and since the union of England and Scotland, the army is certainly as much that of Scotland as of England. Sir Charles Douglas, a Scotchman by birth and original domicile, left his native country at the age of twelve, to enter the navy. From that time to his death he was in Scotland only four times: first, as Captain of a frigate; secondly, to introduce his wife to his friends, on which occasion he staid about a year; thirdly, upon a visit; and fourthly, when, upon his appointment to a command upon the Halifax Station, he went in the mail-coach to Scotland, and died there in 1789. He was not for a day resident there in any house of his own; nor was he ever there except for temporary occasions. He also commanded the Russian navy for about a year, and was afterwards in the Dutch service. He had no fixed residence in England till 1776, in which year he took a house at Gosport, where he lived as his home when on shore. This was his only residence in the British dominions; and when he went on service he left his wife and family at Gosport. At his death it became necessary to decide whether his domicile was Scotch or English, because he had made a will, bequeathing a legacy to his daughter, with certain conditions, which were void by the law of Scotland, but valid by the law of England. The House of Lords decided that his original domicile was Scotch, and that though he did not lose it in this first instance, by becoming an officer in the British navy, he abandoned it by entering a foreign service, and acquired a Russian domicile; that on returning to England, and resuming his position as a British officer, he acquired an English domicile, but did not recover his Scotch domicile; that his subsequent visits to Scotland, not being made *animo manendi*, did not revive his Scotch domicile, and that the succession to his property, as that of an Englishman, was therefore to be governed by the law of England, in which country he last acquired a domicile. In connection with this subject, it may be proper to notice an opinion expressed by the Master of the Rolls during the argument of Lord Somerville's case—that an officer entering the military or naval service of a foreign power, with consent of the British Government, and taking a qualified oath of allegiance to the *foreign* State, does not thereby abandon or lose his native domicile. In Forrest *v.* Funston, the defendant was a Lieutenant in the King's army, and held a situation of Master Gunner at Blackness Castle in Scotland, where he had the charge of considerable military stores, with an apartment for his residence. He was a native of Strabane in Ireland; and it was held by the Court of Session that, though it was his duty to reside at Blackness, he did not by the possession of his office acquire a Scotch domicile. With respect to the East India Company's Service, the question of domicile does not turn upon the simple fact of the party being under an obligation, by his commission, to serve in India; but when an officer accepts a commission or employment the duties of which necessarily require residence in India, and there is no stipulated period of service, and he proceeds to India accordingly, the law from such circumstances presumes an intention consistent with his duty, and holds his residence to be *animo et facto* in India. In the case of General Forbes, in the Court of Chancery, the subject of domicile in its relation to military men was extensively discussed before the Vice-Chancellor Wood. Nathaniel Forbes, afterwards General Forbes, was born in Scotland of Scotch parents; his father being possessed of an ancestral estate called Auchernach, on which there was then no house. In 1786, Nathaniel Forbes, being then a minor, and a Lieutenant on half-pay in the 102d Foot, a disbanded regiment, contracted a marriage with a Scotch lady. He shortly afterwards obtained an appointment in the service of the East India Company; and in December, 1787, he sailed for India, where he continued until 1808. He then obtained a furlough, and returned with his wife to Scotland. On the death of his father in 1794 he had succeeded to the family estate in Scotland; and during his furlough he built a house there, and furnished it, and made some improvements in the grounds. In 1812 he returned with his wife to India, and remained there for several years. The wife left India in 1818; and in 1822 her husband, who had then attained the rank of a General Officer and was Colonel of a regiment, also quitted India, according to the rules of the service, with the intention of never returning to that country; and he never did return thither. During the whole of his service under the East India Company General Forbes retained his commission and rank of a Lieutenant in the King's army. His domicile was without doubt originally Scottish. After his final return from India he had an establishment at a hired house in Sloane Street, London. He also kept his house at Auchernach furnished; and had some servants there also. He likewise became a Justice of the Peace and a Commissioner of Taxes in Scotland; and kept his pedigree and papers (including his will) at Auchernach, where he was in the habit of residing half the year, and where he had constructed a mausoleum in which he wished to be buried. But his health did not permit him to reside constantly at Auchernach, where his establishment was also not suitable for his wife; and his house in Sloane Street was manifestly his chief establishment, and his wife resided there. He died in 1851. His wife thereupon laid claim to a share of his property according to the Scotch law of succession, and contended that, in the events which had happened, he must be considered to have died possessed of his original Scottish domicile. The substantial question in the case was whether his domicile was in England or in Scotland. If he had been a single man, his final domicile would probably have been considered Scottish. But the Court held that Sloane Street, having been his chief establishment, and the abode of his wife, must be taken to have been the seat of his domicile. In pronouncing judgment upon the case, the learned Vice-Chancellor ruled the following points: 1. That the Scottish domicile of General Forbes, notwithstanding his having gone to India during his minority, in the service of the East India Company, continued until he attained the age of twenty-one: on the principle that a minor cannot change his domicile by his own act. 2. That on attaining twenty-one he acquired an Anglo-Indian domicile; and thereupon his Scottish domicile ceased: on the principle that a service in India, under a commission in the Indian army, of a person having no other residence, creates an Indian domicile. 3. That the circumstance of his being a Lieutenant on half-pay in a disbanded King's regiment did not affect the question. 4. That the Anglo-Indian domicile of General Forbes continued unchanged until his departure from India in 1822: the furlough, or limited leave of absence, implying by its nature that it was his duty to return to India on its expiration. 5. That in 1822 the Anglo-Indian domicile of General Forbes was abandoned and lost: the possibility of his being called upon, as Colonel of a regiment, to return at some indefinite time to active service in India being too remote to have any material bearing upon the question. 6. That he had acquired by choice a new domicile in England on his return from India.

DOMMAGE.—In a general acceptation of the term, *dommage* signified, in the old French service, the compensation which every Captain of a troop or company was obliged to make in consequence of any damage that his men might have done in a town or on a march.

DONATO ROSETTI SYSTEM OF FORTIFICATION.—This system has a large ravelin with flanks. Its double flanks are not retired. The shoulder-angle of each ravelin is connected by a fausse-braye. The shoulder-angles of the bastions and the flanks of the ravelin are joined by a wall destined to prevent desertion, and to enable the officers to go the rounds. This wall is destroyed towards the latter part of the siege, to enable the flanks to defend the ditch.

DONJON.—The principal tower or keep of a castle or fortress. It was so called either from being placed on a *dun* or elevation, natural or artificial, or because, from its position, it dominated or commanded the other parts of the fortress. From the circumstance that the lower or underground story of the donjon was used as a prison has come the modern meaning of the word. Also written *Dungeon*.

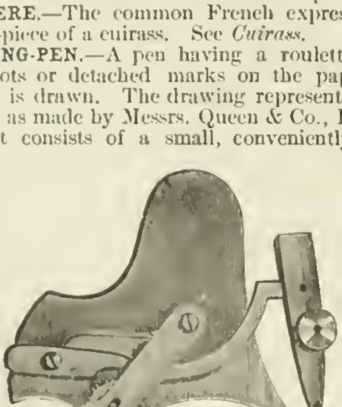
DOOLIE.—An Indian term: a stretcher for carrying the sick and wounded in India. It is composed of a framework of wood, and the seat or flooring of cane or nawar (a coarse cotton tape). At each end of the doolie a triangular piece of wood is fastened to the frame, on the top of which there is an iron ring attached through which the bamboo for lifting the doolie is placed. The top of the doolie has a light framework of wood, over which a coarse red cloth curtain is hung to screen the sun and wind from the patient. Sometimes written *Doolee*.

DORMANT.—In heraldic representation, an animal *dormant* has its head resting on its forepaws, whereas an animal *couchant* has its head erect. See *Heraldry*.

DOSSER.—A sort of basket carried on the shoulders of men, and used in carrying the earth from one part of a fortification to another where it is required.

DOSSIERE.—The common French expression for the back-piece of a cuirass. See *Cuirass*.

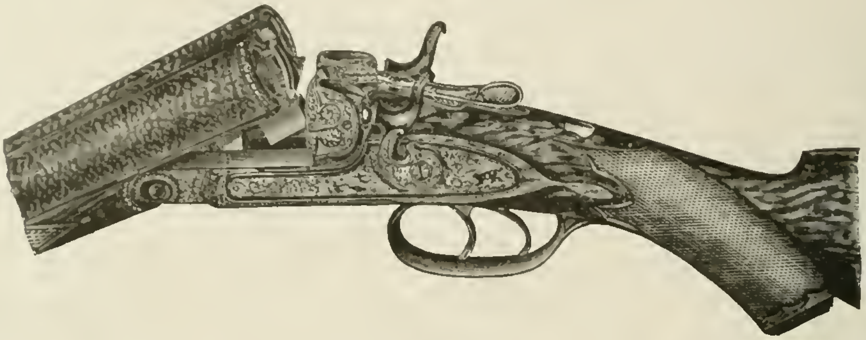
DOTTING-PEN.—A pen having a roulette which makes dots or detached marks on the paper over which it is drawn. The drawing represents the instrument as made by Messrs. Queen & Co., Philadelphia. It consists of a small, conveniently-shaped



German-silver plate, upon which is fastened a pen connected by a small bar and a ratchet movement with a rolling wheel. The bar is kept in its place by a small spring. Extra wheels of different patterns accompany the instrument, which, being readily changed, allow the making of various forms of lines. In using the instrument, care should be taken that the small point behind the pen rests on the paper, as it secures evenness in the stroke of the pen. See *Roulette*.

DOUBLE.—In tactics, to unite, as the ranks or files, so as to form one. *To double upon* is an expression meaning to inclose between two fires.

DOUBLE BARRELED GUN.—A gun having a pair of parallel barrels on the same stock; sometimes one is a rifle-barrel and the other a smooth-bore for shot. This combination breech-loading rifle and shot-gun is excellent for hunting purposes, and a single one judiciously handled will furnish a large command a good daily allowance of game in great variety. A few shot-guns should accompany every command in the field. The hunters should be selected with a view to the particular game sought after, as they seldom have the same success with all game. The barrels are usually placed side by side, as in the drawing; but some sportsmen prefer that one barrel be placed under the other.



Double-barreled Gun.

DOUBLE-BITTED AXE.—An ancient form of battle-axe, having two opposite bits or blades. It was a favorite weapon with the Franks in the time of Clotaire, seventh century, and with the Danes in the time of Alfred the Great, ninth century. It is also shown in the sculptures of Karnak, in Egypt. The battle-axe of the Scythians in the time of Herodotus was double-bitted. It is the Sacan *sagaris*. The double-bitted axe is found in the tumuli and barrows of North America. It is in three forms: 1, with a circumferential groove for the occupation of the withe or split handle to which it is lashed; 2, with an eye traversing the head; 3, with a socket for the handle.

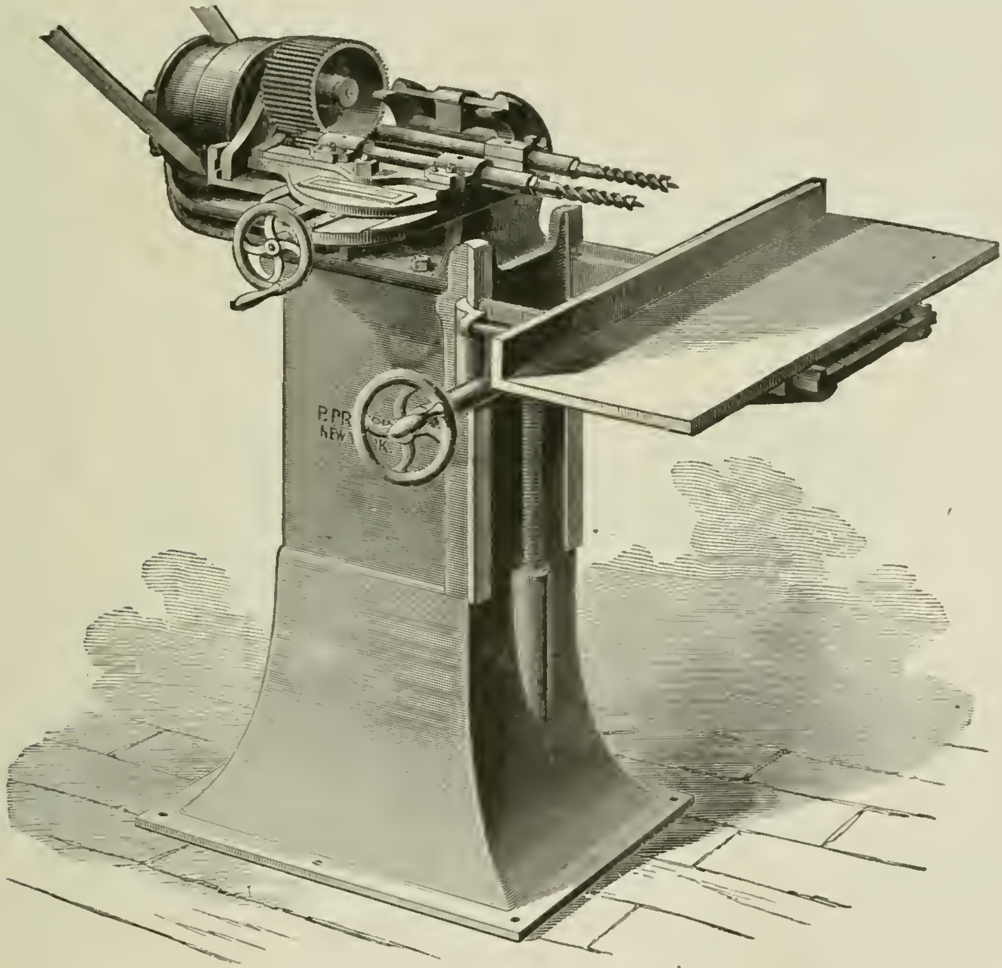
DOUBLE BORING AND MORTISING MACHINE.—A machine designed for that class of work in which two holes are to be bored at a given distance and angle, as in doweling, and in frame, carriage, and cabinet work. The two spindles are mounted on an adjustable head which enables them to be set to an angle from the horizontal, as shown in the drawing, to the vertical, where one would be over the other; and to any distance from one to five inches between centers. The table has a vertical movement of twelve inches from the spindle down, slides forward and back, and when prepared for mortising, sideways also. Adjustable stops determine the extent of these motions. Mortising is done with a revolving cutter cutting on both end and side, producing, when the work is moved sideways, a mortise with half-round ends. When only one spindle is to be used, it may be disconnected from the large gear-wheel by loosening and drawing back the bracket which supports the latter. This should be done whenever the machine is to be used for mortising, for then the belt may be run upon the small pulley and the spindle be driven at the high speed required, without injury to the gears. For boring, the belt should be run upon the large pulley, as so high a speed is not necessary for boring as for mortising. The spindles and their pinions are of steel, and the bearings are adjustable. The weight of the machine as used in the arsenal is about 500 pounds, and the speed of the countershaft, 950 to 1000 revolutions per minute. See *Boring-machine* and *Mortising-machine.*

DOUBLE BRIDGE-HEAD.—When the bridge crosses the river at a point where there is no bend, it is frequently the case that works are constructed at both extremities of the bridge. When this is the case, the works form what is known as a *double bridge-head*, to distinguish it from those usually termed single bridge-heads. See *Bridge-head.*

DOUBLE CAPONIERE.—A structure, in permanent fortification, which serves both as a communication and as a defensive work for the ditch. As the former, the passage should admit of a convenient circulation, without being too wide, which has determined its width at 3.30 yards. The interior crests should cover the troops within the caponiere from the enemy's establishments on the crest of the bastion covered-way; a relief of nine feet has been found sufficient for this purpose. As a defensive work, its fire should sweep the ditch. It is for this purpose that its embankments are arranged on the interior as an ordinary parapet, and on the exterior in the form of a glacis. Its banquette tread is made 2 yards wide, as it should be palisaded. In order that the embankment of the caponiere may not, by its relief, form dead spaces in the ditch, the plane of the first glacis is arranged so as to be swept by the artillery-fire of the opposite flank. The plane of the second glacis, and the return-wall, are so arranged as to be swept by the fire of the curtain, and of a part of the flank. The portion of the first glacis near the extremity is made into a *glacis-coupé*, leaving a sufficient thickness of parapet to cover the passage. See *Noizet System of Fortification.*

DOUBLE HAMMER.—A forging device for operating upon a bloom or puddler's ball, striking it upon opposite sides simultaneously.

DOUBLE HARQUEBUSE.—A firearm with a double catch or match-holder. It was mostly used for defending ramparts; the length being from three to seven feet. The lock is distinguished from that of the simple harquebuse in having two match-holders working in opposite directions. It was often supported by a stand resting on iron spikes or wheels that was called *fourquine.*



Double Boring and Mortising-machine.

DOUBLE-HEADED SHOT.—A projectile formerly in use, consisting of two shot united at their bases.

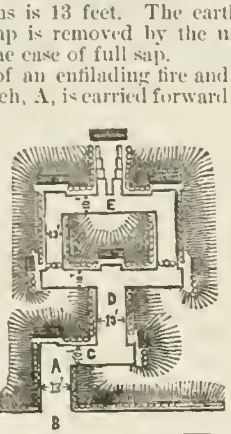
DOUBLE-QUICK.—Performed in the time called *double-quick;* a double-quick step or march as prescribed in Tactics. See *Step.*

DOUBLE RANK.—A line formed of double files. In the United States army, the distance between ranks, from back to breast, is *facing distance:* but on rough ground, and when marching in double time, it is increased to thirty-two inches; upon halting, the rear rank closes to facing distance. When the knapsack is worn, the distance between the ranks is increased by the depth of the knapsack. In alignments in double rank, the rear-rank men cast their eyes to the side of the guide with the front-rank men, and maintain the proper distance between the ranks. The double rank, faced by the flank, is called a *column of files*, the same as a single rank. In marching in column of files, each rear-rank man dresses on his front-rank man, who is the guide of the file. In obliquing in line in double rank, each rear-rank man follows the man next on the right or left, or the second man on the right or left, of his front-rank man, according as the rear-rank is at facing distance, or at thirty-two inches from the front rank. In obliquing in column of files, the guide of each file is the man of the rank toward which the oblique is made, the guide of the column being the guide of the leading file.

DOUBLE REDAN.—Two redans are sometimes placed side by side and joined to each other, making a work known as the *double redan;* sometimes the outer faces of the double redan are made much longer than the faces which are connected, in which case the work receives the name of *priest-cap* or *swallow-tail.*

DOUBLE SAP.—This sap consists of two heads of sap pushed forward by two brigades working abreast. Its object is to form a trench in a position exposed to fire in front and on both sides. The head of the sap is covered by two sap-rollers placed end to end; a bag of wool, or a short sap-roller, being placed at their junction, for a screen. The distance between the two rows of gabions is 13 feet. The earth between the two lines of sap is removed by the usual working-parties, as in the case of full sap.

In the case of an enfilading fire and a fire on both flanks, the trench, A, is carried forward by the double



Plan of a Double Sap exposed to a fire in front and on both flanks. A, D, Double Direct Sap; B, Parallel; C, Full Sap at right angles to gain the direction D; E, Full Sap connecting the two branches of double direct sap on the right and left.

sap, until the point of departure, B, is about being exposed to the fire coming in over the sap-rollers; a change of direction, C, at right angles is then made by the full sap, to the right or left, and pushed forward the length of about fifteen gabions, or so far as to intercept any slant fire on either side of the trench in rear, when the original direction, D, is resumed by the double sap. A change of direction is sometimes made by the full sap both to the right and left at right angles to the original line, and pushed to the length of twelve or fourteen gabions each way. Then, from the extremities of these branches, a direction parallel to the original is taken up by the double sap, and pushed on until the point of departure to the rear is about being exposed, when a change of direction towards each other is made at right angles, by the full sap, and two branches are united on the original direction, E, which is resumed by the double sap. See *Sap.*

DOUBLE SHELL.—This nature of projectile has been introduced into the English service for the use of certain R.M.L. guns, such as the 7-inch and 7-pdr. M.T. gun, but for no other, though very good practice has been made with these shells from the 16-pdr. field-battery gun. The 7-inch double shell is nearly four calibers long, strengthened by three ribs internally, otherwise resembling the common shell. A bag is used to contain the bursting-charge as given for common shell. See *Double-shotting.*

DOUBLE-SHOTTING.—A term applied to the doubling of the shot in the gun, whereby increased effect is expected. This was formerly a practice more often adopted in the navy than in land-artillery. In the latter, double-shotting was only resorted to when, the enemy being close on the guns, a double charge of case-shot was likely to render good service. The introduction of rifled guns has done away with this mode of fire. What is now known as a "double shell" is nothing more than a shell of increased length and capacity.

DOUBLET.—An under-garment of linen, slightly quilted, and having rings of mail under the breast-plate and under the knees and arms, so as to protect the body where the armor was weakest, and wherever an opening might occur for the sword or poniard. It was almost identical with the jerkin. The sleeves were sometimes separate, and tied on at the arm.

DOUBLE TIME.—The fastest time or step in marching, next to the run, requiring 165 steps, each 33 inches in length, to be taken in one minute. The degree of swiftness may vary in urgent cases, and the number of steps be thus increased up to 180 per minute. See *Double-quick.*

DOUBLINGS.—The heraldic term for the linings of robes or mantles, or of the mantlings of achievements. See *Mantling.*

DOVER IRON.—Previous to casting the gun-casing of the 12.25-inch muzzle-loading rifle of the South Boston Foundry, a number of experimental castings were made and tested with a view to determine the proper quality of iron to be employed. This course was necessary in order to provide a substitute for the Richmond pig-iron, which can no longer be procured of suitable quality for gun construction. The most satisfactory results in these experiments were obtained from a mixture of equal quantities of Dover and Muirkirk pig-iron. A trial-cylinder, of the same form and dimensions as those described in Captain Rodman's *Experiments on Metals for Cannon*, was then cast from the mixture. This cylinder was cut up in the same manner as those above referred to, and was subjected to a similar series of tests for the purpose of determining the physical properties of the metal. The results obtained from these tests were satisfactory, and it was decided to use a similar mixture for the gun-casing. The Dover is made at Chatham, Columbia County, New York, being smelted with charcoal from a brown hematite ore found a few miles south of Dover Plains, Dutchess County, New York. This ore is mined in a wide vein, and is of two kinds, there being two lines of deposit in the stratum. One is a rich, solid ore, yielding from 48 to 55 per cent of iron; the other yields from 38 to 42 per cent. In smelting the iron the two kinds of ore are used in nearly equal proportions, it having been found that such a mixture gave the best results. See *Iron* and *Muirkirk Iron.*

DOWLAS.—A coarse kind of linen; it is used in a saltpeter-refinery for filtering the saltpeter liquid as it is drawn off from the boilers.

DRABANTS.—A choice company of 200 picked men, of which Charles IX. of Sweden was Captain.

DRAFT.—A selecting or detaching of soldiers from an army, or any part of it, or from a military post; also from any company or collection of persons, or from the people at large for military service. Also written *Draught.*

DRAG.—A mechanism for slackening the speed of carriages, by operating on one or more of the wheels. The form of drag best known is that of the "shoe," a hollow piece of iron attached by a chain to the carriage, which being put below one of the hind wheels partially reduces the vehicle to the quality of a sledge; by which dragging process the carriage is suitably retarded on going down-hill. As the shoe-drag required to be applied and removed with some inconvenient detention of the vehicle, a step was made in advance when a method of retarding a wheel without detention was discovered. This new process, which is known as the patent drag, consists of a connected piece of mechanism, altogether operated upon by the driver without moving from his seat. A handle affects a series of rods and levers by which a species of shoe is pressed against one of the wheels, so as to slacken its motion. Such is the kind of drag now very generally attached to gentlemen's traveling-carriages, omnibuses, and other vehicles for passengers on the roads much traveled. It is of French origin. Applied in either form, the use of the drag, independently of its safety, is to allow horses to continue running at ordinary speed down-hill without being unduly pressed on by the carriage behind them. A similar contrivance, but of a more powerful kind, called a *break* or *brake*, is applied to arrest the motion of railway-trains. See *Brake.*

DRAGON.—A small kind of blunderbuss; a short hand-gun of great bore to carry several pistol or carbine balls or small slugs, and so called from the fact of its having a dragon's head at the muzzle.

DRAGON ET DRAGON VOLANT.—The ancient title for two old pieces of artillery. The dragon was a 40-pounder; the dragon volant, a 32-pounder. But neither the name nor the size of the caliber of either piece is now in use.

DRAGONNER.—According to the French acceptation of the term, to attack any person in a rude and violent manner; to take anything by force; to adopt prompt and vigorous means; and to bring those people to reason by hard blows who could not be persuaded by fair words.

DRAGON'S-BLOOD.—A deep red resinous substance found in the East Indies, Cochin-China, and the Eastern islands. It occurs in masses of various degrees of purity, and in sticks, enveloped in palm-leaves. Dragon's-blood is employed as a coloring matter, and as an ingredient in varnishes. Formerly it was used in the browning liquid for gun-barrels, but has been discontinued for some years past.

DRAGOON.—From the old fable that the dragon spouts fire, the head of the monster was worked upon the muzzles of a peculiar kind of short muskets which were first carried by the horsemen raised by Marshal Brissac in the year 1600. This circumstance led to their being called dragoons; and from the general adoption of the same weapon, though without the emblem in question, the term gradually extended itself till it became almost synonymous with horse-soldier. Dragoons were at one time a kind of mounted infantry, drilled to perform the services both of horse and foot. At present, *dragoon* is simply one among many designations for cavalry, not very precise in its application. In the British army, the *heavy* dragoons and the *light* dragoons are carefully distinguished in regard to the weight of the men, horses, and appointments. The first dragoons in the army were the Scots Greys, established in 1683. The dragoon, when first instituted to combine the functions both of the foot soldier and cavalier, was found, like most mongrels, to have the qualities of neither in a very serviceable degree. He still retains his musquetoon, and on outpost duty, and skirmishing in broken ground, does a soldier's duty with this weapon. Apt for attacks, whether in close order or dispersed, he should lend himself to the charge kindly; and in cases where thrown on his own resources, display all the intelligence, activity, and circumspection of the best light infantry. See *Cavalry* and *Horse-guards.*

DRAGOON GUARDS.—A title borne by seven regiments of heavy cavalry in the British service.

DRAG-ROPE.—A rope having a small chain and hook attached to one end of it; it is used in the artillery service for pulling or drawing. Drag-ropes are attached to all ordnance-carriages, to assist in extricating them when in difficulty, in sandy soil, steep ascents, or in descents when there is no shoe attached to the carriage, or locking-chain for holding upon the carriage. They are of two sizes in the English service, *heavy* and *light;* the former are issued to the 20-pdr., 40-pdr. B.L.R., and 16-pdr. M.L.R. batteries; the latter to the 9-pdr., 12-pdr. B.L.R., and 9-pdr. M.L.R. batteries. The chain end is intended to prevent the rope being cut by the tire of the wheel.

DRAG-ROPE KNOT.—A knot the same as the *men's harness-hitch;* it is used for fixing handspikes to the ropes attached to heavy carriages which are to be moved by men; three men are attached to each handspike. Sometimes called *lever-hitch.*

DRAG-ROPE MEN.—The men attached to light or heavy ordnance, for the purpose of expediting movements in action. The French *Servans à la prolonge* are of this description.

DRAG-WASHER.—A flat iron ring on the axle-arm of a carriage, having an iron loop attached for the purpose of fastening the drag-rope when necessary; hence the term *drag washer.* It is placed on the axle-arm to prevent the wheel or nave from pressing upon the linch-pin.

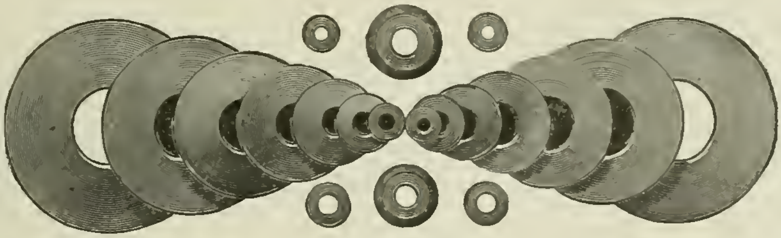


Plate-washers of the pattern represented in the drawing are usually made in large quantities at the arsenals. The following table exhibits their particulars:

Diameter.	Size of Hole.	Thickness Wire Gauge.	Size of Bolt.	Number in 100 Pounds.
1/2	1/4	No. 18	3/16	45,000
5/8	5/16	" 16	1/4	21,000
3/4	5/16	" 16	1/4	13,900
7/8	3/8	" 16	5/16	11,250
1	7/16	" 14	3/8	6,800
1 1/8	1/2	" 14	7/16	5,450
1 1/4	1/2	" 14	7/16	4,300
1 3/8	9/16	" 12	1/2	2,600
1 1/2	9/16	" 12	1/2	2,000
1 1/2	5/8	" 12	9/16	2,250
1 3/4	11/16	" 10	5/8	1,310

3	1 3/8	" 9	1 1/4	400
3 1/2	1 1/2	" 8	1 3/8	280
3 3/4	1 5/8	" 8	1 1/2	240
4	1 7/8	" 8	1 3/4	220
4 1/2	2 1/8	" 8	2	175

DRAIN.—In the military art, a trench provided to draw water out of a ditch, which is afterwards filled with hurdles and earth, or with fascines or bundles of rushes, and planks to facilitate the passage over the mud. Also written *Drein.*

DRAKE.—A small piece of artillery used in ancient times, but now obsolete.

DRAUGHT-ANIMALS.—The subject of draught is of the greatest importance in the artillery arm of the service, in which the greater portion of the transport of artillery *matériel* is dependent on draught-animals. Horses are usually employed for this purpose, though in India the heavy artillery, with the rest of the *matériel* of the army, is drawn or carried by elephants and bullocks.

In a four-footed animal, the hinder feet are the fulcrum of the lever by which its weight acts against the load; and when the animal pulls hard it depresses its chest, and thus increases the lever; hence we see the benefit that may be derived from large horses, for their levers necessarily increase with their sizes. Large horses will draw more than small ones, even though they have less muscular force and are unable to carry such a heavy burden.

The force exerted by a draught-animal may be divided into two parts, viz., that which overcomes the inertia and friction of the carriage and sets it in motion, and that which is necessary to overcome the resistances which recur along its path. The first, being of momentary duration, approximates the utmost strength of the animal; its intensity should be known in order to give the necessary strength to the harness.

If Q represents the mean force (in pounds) exerted by an animal, in a unit of time, in drawing a load over a road, the length of which is l, Ql represents the quantity of work performed. The direction of the force is taken parallel to the plane along which the load moves. If it make an angle, a, with this plane, the work will be decomposed into two components, $Ql \cos a$, which is parallel to the plane, and $Ql \sin a$, which is perpendicular to it: the latter transfers a portion of the load from the ground to the animal's shoulders, thereby increasing his friction, and to a certain extent the power of traction.

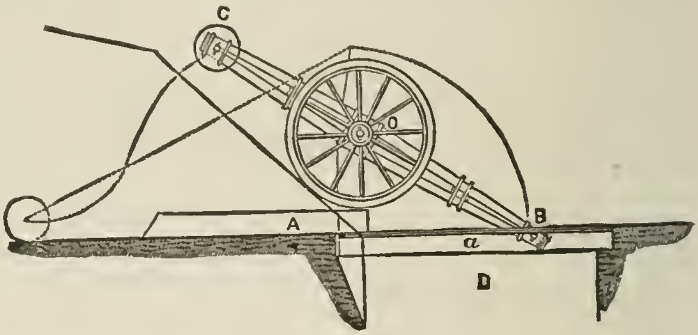
Careful experiments have been made to determine the proportion of those two components most favorable to the exercise of the animal's power. It was found that the most suitable angle for the traces of an unloaded animal, with the ground, was from 10° to 12°; and for one that carried his driver, from 6° to 7°; or, in other words, a draught-animal should *carry* ⅛ of his load on his back.

The relation between the weight of a loaded carriage and the force to be expended by the animal to keep it in motion depends upon so many circumstances that it is impossible to give a general expression for its determination. It can only be determined by direct experiment in each particular case. See *Artillery-horses*, *Bullock*, *Elephant*, and *Mule*.

DRAUGHT-HOOK.—Either of four large hooks of iron fixed on the cheeks of a gun-carriage, two on each side, used in drawing the gun backward and forward.

DRAW-BORING.—The operation of polishing a musket-barrel after it has been rifled.

DRAW-BRIDGE.—For the usually narrow ditches of field-works either a light rolling bridge may be used for a communication, from the outlet, across the ditch, or else an ordinary wooden draw-dridge. A very simple one, and of easy construction, was proposed by Colonel Bergère of the French Engineers. The bridge is a light platform, a, of joists and boards, long enough to span the ditch, D, and so arranged as to turn around an axle at A, the crest of the scarp. At the point B on each side of the platform an iron gudgeon is firmly attached to it, and turns in the eye of a socket at the end of the lever, C B. This lever is formed of two pieces of scantling of some tough flexible wood, each about four inches square. The lever has an eye at the middle point, O, which receives a strong iron bolt that connects two ordinary gun-carriage wheels. The two pieces which form the lever are firmly fastened together, as shown in the figure; a weight, consisting of shells filled with sand or shot, being fastened at the end C and serving as a counterpoise to the bridge. Two rails, A, of heavy scantling are laid for the wheels to run upon in maneuvering the bridge, which is done simply by one or two men taking hold of the spokes of the wheels, and so, by turning them, causing them to run backwards or forwards, and thus raise or lower the bridge. The outlet should be covered by a mask thrown up either on the interior or on the exterior, to prevent the enemy from firing through it into the work. A traverse is thrown across it if placed on the interior. When placed on the exterior a small redan is constructed, just in advance of the counterscarp, of sufficient size to cover the outlet and the bridge over the ditch. The

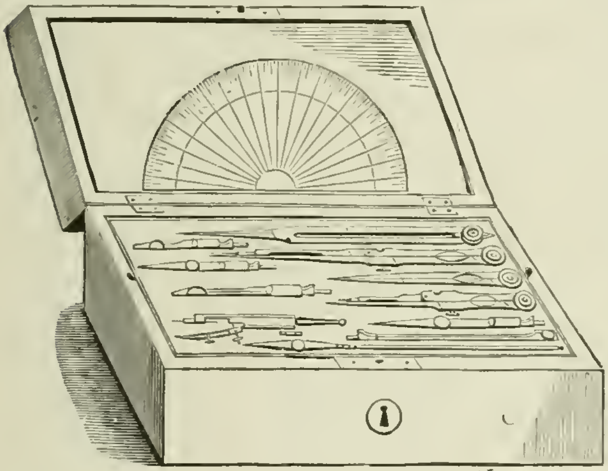


Bergère Draw-bridge.

passage to the exterior may be either through the face of the redan or between one of the faces and the ditch. Sufficient space should be left between the traverse and the parapet for the passage of a gun. The length of the traverse is arranged to prevent the enemy from firing into the work, by an oblique fire through the outlet. The traverse may be of earth or of wood; in either case it should be arranged for defense to enfilade the outlet. In some cases the traverse at one end is broken forward at right angles, and connected with the parapet of the work; the space between the traverse and parapet at the other end being left open for a passage-way. A defensive stockade with a barrier secures this opening from surprise. It should be thrown far enough back to be out of reach of fire.

DRAWING.—1. The operation of hammering, rolling, or drawing through a die, by which a bar or rod of metal or a wire is extended in length to form a rod, tube, or plate. 2. The art of representing the appearances of all kinds of objects by imitation or copying, both with and without the assistance of mathematical rules. The following instruments, necessary for drawing and plotting in the field, should be carefully packed in portable boxes or pocket-cases, and supplied to all Staff and Reconnoitering Officers: one pair of 6-inch needle-point dividers, with pen and pencil points and lengthening-bar; one pair of 4½-inch plain dividers; one pair of 3½-inch needle-point dividers, with pen and pencil points; one spring bow-pen, with needle-point; one drawing-pen; one German-silver protractor; one horn protractor; one irregular curve; two wooden triangles; and one pair of proportional dividers.

The first requisite in all drawings is *minute accuracy*, both in the geometrical constructions and in writing down all letters and numbers which serve either as references or to give dimensions. To attain this, so far as regards the geometrical part, judgment is to be exercised in the selection of the means for establishing on the drawing the positions of the various points which are either given or to be found; as one method, although in theory as correct as some other, may not, in practice, be found to yield as satisfactory results. The following remarks will serve to illustrate this point: 1st. *In setting off from a scale of equal parts* *several distances, along a line*, whether equal or unequal, the most accurate method is to commence by first setting off the entire distance, and then the several parts, taking care to verify, from the scale, the aggregate of the several partial distances. 2d. *When a distance to be set off is so small* that it cannot be laid down with accuracy by the points of the dividers, the following method may be employed: Set back, from the point from which the required distance is to be set off, any arbitrary distance, then set forward, from this last point, a distance equal to the sum of this arbitrary distance and the one required. 3. *To set off a point at a given perpendicular distance from a line*, it will mostly be found more speedy, and more accurate, to take off from the scale the given distance, in the dividers, and, setting one point on the paper, bring the other so that the arc described by it, with the given distance as a radius, shall be tangent to the line, than to employ the usual method of first erecting a perpendicular to the line and then setting off the required point along the perpendicular. This method will be found convenient in drawing a parallel to a line at a given distance from it by setting off another point in the same way, and drawing through the two the required parallel. 4th. In setting off several points for the purpose of *drawing several parallels to a given line*,



Drawing Instruments.

as, for example, the parallel lines which bound the planes of a parapet, it will be found most speedy and accurate to draw first upon a slip of smooth thin paper two lines perpendicular to each other, then marking on one of the lines the respective given distances of the parallels from the other, and cutting the paper close to the line along which the given points are marked off, so that when the strip is laid upon the drawing so as to have one of its lines to coincide with that to which the parallels are to be drawn, their distances from it can be pricked off by a sharp pointed pencil, or in any other way. 5th. *When a point is to be constructed by means of the intersection of two lines arbitrarily chosen*, such a position should be assumed for the arbitrary lines that they shall not form a very acute angle at their point of intersection, as in that case this point might not be so distinct to the eye as to be marked with accuracy. For example, in erecting a perpendicular to a line at a given point, and in like problems, in which points are found by the intersections of arcs of circles, it will be best and most convenient to take for the radii of the arcs the distance between their centers, as the angle between the tangents to the arcs at their point of intersection will then be 60°, which is a sufficient angle to give accurately the point where the lines cross. In all such cases of determining points, and where a point is pricked into the paper, it will be found advisable to *designate the point thus* ⊙, by a small circle drawn around it with the lead-pencil, in order that the eye may see it with more distinctness. 6th. *In determining a portion of a line by the construction of two arbitrary points*, the points should be so chosen that the portion required may fall between them and not beyond them. 7th. No means of verifying the accuracy of the construction of points or lines should be omitted. A general and minute verification of all the parts of the drawing should be made before any portion of it is put in ink. Neatness is a not unimportant element in the attainment of accuracy in drawing. A few minutiæ, when attended to, will subserve this end. That part of the paper on which the draughtsman is not working should be kept covered with clean paper, pasted on the edge of the board, so as to fold over the drawing, and the parts which are finished should be similarly protected. Before commencing the daily work the paper should be carefully dusted, and the scales, rules, and triangles be carefully wiped with a clean dry rag. As few lines of construction as possible should be drawn in pencil, and only that part of each which may be strictly necessary to determine the point sought. As, for example, where a point is to be found by the intersection of two arcs of circles; when the position of the point can be approximately judged of by the eye, only a portion of one arc, which will embrace the point, may be drawn, and the point where the second arc would intersect the first be marked without describing the arc. No more of any line of the drawing should be made in pencil than is to remain permanently in ink. The object of these precautions is to keep the paper from becoming covered with dirt and the lines from being defaced by the wear of the paper. In *inking* the lines the following directions will be found useful: Efface carefully all pencil-lines that are not to be inked, and those parts of the permanent lines which are not to remain, before commencing to ink. When right lines are tangent to curves, put in ink the curve before the right line; draw all arcs of equal radii at once, one after the other; if several arcs are to be described from the same center, it will be well to put a thin bit of quill over the point for the end of the dividers to rest on, to avoid making a large hole in the drawing. If the drawing is not to be colored with the brush, all the lines of one color should be put in before commencing on those of another. If one of the bounding lines of a surface is to be made heavier than the others, its breadth should be taken from the surface they limit and not be added to it; and when the heavy line forms the boundary of two surfaces, its breadth must be taken from the one of greatest declivity. When the drawing is to be *colored*, all lines that are not to be black may be put in first with black, making them very faint, so that they may receive their appropriate colors after the drawing is otherwise completed. No heavy lines should be put in until the work with the brush is completed. When all the lines are in, the drawing should be thoroughly cleaned with stale bread-crumbs, and then have several pitchers of water dashed over it, the board being placed in an inclined position to allow the water, colored by the ink-lines, to escape rapidly and not to discolor the paper. In using the brush, whether for flat tints or graded, the requisite depth of tint should be reached by a number of faint tints laid over each other; this is especially necessary in laying tints of blacks, browns, and reds. To obtain an even flat or graded tint on dry paper requires considerable skill. The best plan for this is first to wet with a large brush or clean rag the surface on which the tint is to be laid, then with a slightly moist rag clear the surface of water, and before the paper has time to dry to lay on the tint. With this precaution, the heaviest tints of Chinese ink, the most difficult of all to manage on dry paper, can be neatly laid down.

The *lettering* and *numbering* of a drawing should be in ordinary printed character; this is particularly requisite in the numbering, to avoid misapprehensions which often arise from individual peculiarities in writing numbers. As has been already remarked, references are written in black, within brackets which, when practicable, embrace the point referred to. When not practicable, a small dotted line may lead from the point to the reference; thus, ⨀...(25.50); but to distinguish references from other numbers the designation of the unit is omitted. All horizontal distances between points are written upon a dotted line drawn between the points, with an arrow-head at each end; where several partial distances in a right line are marked, it will be also well to mark the total distance: the latter may be written above or beneath the former. In writing horizontal distances, the usual designation of the unit is always written thus: *y* for yards, ′ for feet, etc. All the numbers must be expressed in the same unit, the fractional parts being in decimals. References and horizontal distances cannot be too much multiplied, in order to avoid misapprehensions, and the results of errors of construction, as well as to save the time that would be taken in applying dividers to the drawing to find from the scale affixed to it the dimensions of any part. A *scale* very accurately constructed should be affixed to the drawing before it is cut from the board, so that the shrinkage of the paper, which is about $\frac{1}{500}$, may affect all the parts equally, and the scale thus be made to correspond to the real lengths of the lines on the drawing. The scale should be divided according to the decimal system, as being most convenient for counting off. The first division of the scale should furnish the units, and also their decimal parts if the scale bears that proportion to the true dimensions of the object represented which will admit of these divisions. This first division is numbered from right to left, the zero-point being on the right, the 10-point on the left; the succeeding divisions, to 50 inclusive, should each be equal to the first division, containing ten units each. The remaining divisions may contain fifty units each. It will be seen that any number of tens, units, or fractional parts of a unit can thus be readily taken off from the scale by the dividers. The scale should be long enough to give the dimensions of the longest line on the drawing. The proportion which the scale bears to the true dimensions of the object should be written above the scale; thus, *scale one inch to ten yards, or* $\frac{1}{360}$. And the designation of the unit of the drawing should be annexed to the last division on the scale, as *yds.* for yards, *ft.* for feet, etc.

DRAWING AND QUARTERING.—In Great Britain the punishment for treason still is that the offender be *drawn* to the place of execution on a hurdle; that he be hanged by the neck till he be dead; that his head be severed from his body, and that his body be divided into four parts, or *quartered.* The Sovereign may, and now certainly would, by a warrant under the Sign-manual, countersigned by a principal Secretary of State, change the sentence into beheading. In the case of females the quartering is dispensed with.

DRAWING-BOARD.—A board on which drawing-paper is strained for painting on in water-colors. The paper is wetted for the purpose of being strained, and when attached at the edges it is permitted to dry and contract. Formerly the drawing-board was fitted into a frame, the edges of the wet paper being made fast by the pressure of the frame on the board. But the much simpler drawing-board which is now in use is made of a flat piece or pieces of wood, held together and prevented from warping by an edging of other pieces, the grain of which runs in the opposite direction. The wet paper is attached to the edges of the board with paste or thin glue, and when dry becomes perfectly firm and flat. When the work is finished, the paper is cut beyond the drawing with a knife.

DRAWN BATTLE.—A fight from which the combatants withdraw without either side claiming the victory.

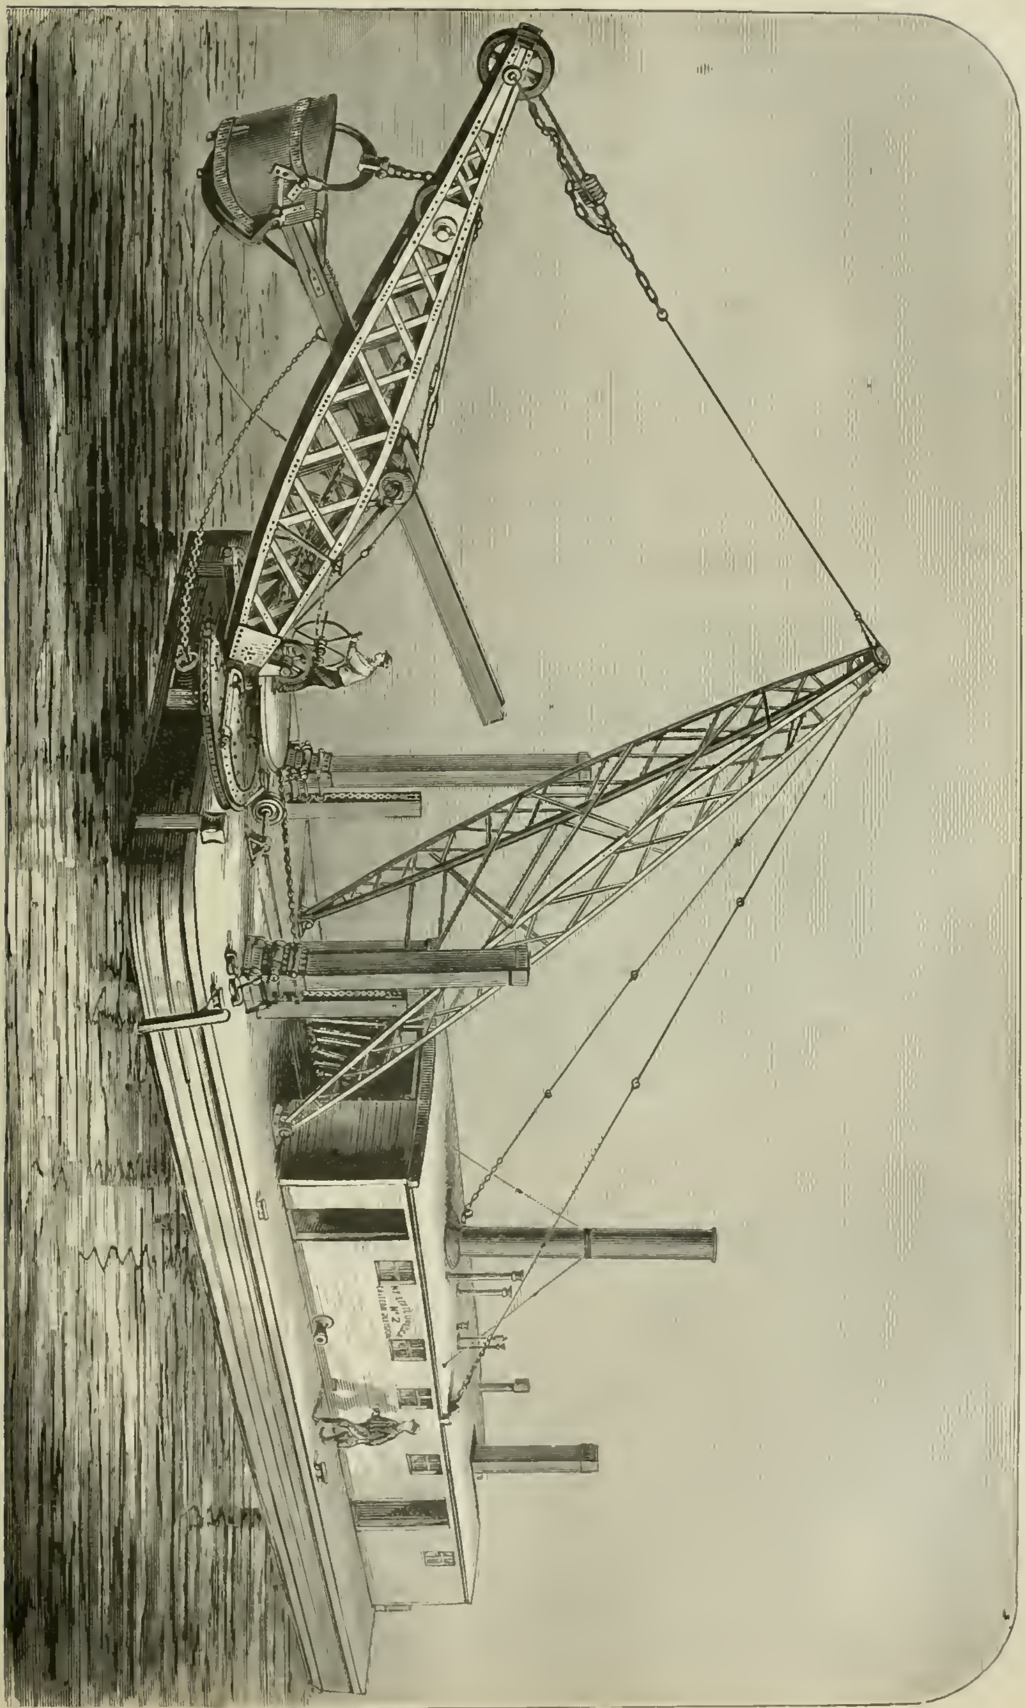
DRAW-PLATE.—A steel plate with a graduated series of holes, through which metals are drawn in making them into wires or bars. Also a name given to a plate of metal placed before a fire or before the lateral opening between the top of the fireplace and the throat of the chimney. Its use is to force the air to pass through the fire on its way into the chimney, instead of allowing it to pass over the fire.

DREDGING-BOX.—To render the fuses of mortar-shells more certain of taking fire, meal-powder is sprinkled over them, after the shell is placed in the mortar, from a *dredging-box.* It is made of sheet-copper. The top fits over the box, and is pierced with holes for the escape of the powder.

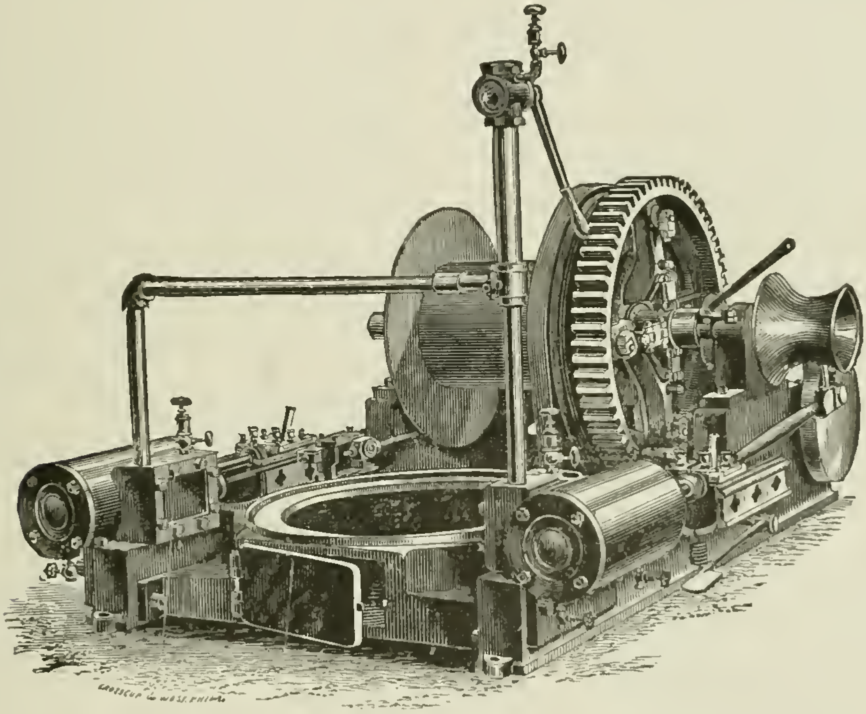
DREDGING-MACHINE.—A machine designed for clearing out or deepening the channels of rivers, harbors, etc. The bucket dredging-machine is very efficient and is much used for the lighter grades of work. It consists of a long stage or framework overhanging the side of the barge. This frame has a wheel at each end, upon which works a powerful endless chain, to which is attached a series of perforated iron buckets, each with a shovel-shaped steel mouth projecting considerably on one side. The overhanging framework forms an inclined plane along which the buckets run, descending on one side and ascending on the other. They are so arranged that they descend empty, and on reaching the bottom the projecting shovel or scoop-mouth digs into the bottom and partially fills the bucket with the silt; it then turns round on the wheel at the lower end of the incline, and runs up it till near the top, when it turns over the upper end, and in doing so its contents are emptied into a second attendant barge. This action is continued by every succeeding bucket of the endless chain. The perforations are for the passage of the water. By varying the inclination of the framework, the working depth may be increased or diminished. Some dredges are fitted with two complete sets of buckets, one on each side of the vessel. A steam-engine and boiler, suitably placed in the dredge, are provided for giving motion to the machinery, and sometimes also to a screw-propeller placed at the stern. The Frisbie engine, shown on page 503, is much used for dredging purposes in the United States. The manner of connecting the spur-gearing to the drums by bolting directly to the rim of the drum does away with all torsion of the shaft and wear upon all keys and feathers, which is a serious defect in most hoisting-engines, causing shafts to split at the key-way. A friction-clutch is set so as to do the work at which the cables are safe, and then slip, and save the engine and gearing from breaking. The motion to operate the clutch is easy and natural; and with a very powerful strap-brake, the engineer can hold or lower carefully any load he can hoist.

Perhaps nowhere has river-dredging been carried such a length as in the case of the Clyde, which by this process of scooping has at and below Glasgow been converted from a river navigable only for small vessels into an estuary capable of bearing the largest ships. The dredges employed for this purpose are moved by steam, the materials scooped out being carried out to sea by lighters. These have a large open tank amidships, while the two ends are decked over, and afford such accommodation for crew or machinery as may be necessary. The sides of the hold are hinged from the top, and open outwards, and thus its contents can easily be emptied into the sea.

The engraving on the opposite page represents a new description of dredging-machine, known as the *boom-dredge*, of which the Osgood Dredge Company, Albany, N. Y., are the patentees and builders. In view of its valuable peculiarities and the marked success which has attended its use, both as to efficiency and economy, we give this illustration and a brief statement of its construction and operation, as matters of interest to readers practically acquainted with this class of machines. The main hull is 80 feet long, 17½ feet wide, and 5½ feet deep. On either side of the hull is attached



a ponton 5 feet in width and with other dimensions the same as those of the hull proper. These pontons can be moved when necessary, to permit the dredge to go through locks. When attached to the hull they give a total width of 27½ feet. The hoisting-engines have two cylinders, each 11 inches bore and 18 inches stroke. The boiler is of locomotive pattern, with a donkey-pump to feed it. The supply- and exhaust-pipes are made with expansion-joints. The sides of the hull have wooden trusses of the Howe pattern to give strength and stiffness. The dipper is made of steel and has a capacity of 46 cubic feet. It is made with a patent double door. The outer door, instead of being hung at the lower edge of the dipper, is hung about the middle, so that in opening it hangs down about half the distance it would if hung in the usual way. This diminishes by so much the height to which it is necessary to raise the dipper in order to dump it. The other and smaller door opens inward and allows the dipper, as it strikes the water, to fill from the bottom, thus taking away much of the shock ordinarily experienced with the old style of dipper when striking the water. The old style of dipper fills from the top. The dipper-handle has neither rack nor pinion, but is worked by friction applied through a hand-wheel on the turn-table. The capacity of this machine is two dippers per minute. The hoisting-chain is a single one and is made of 1¼-inch steel. The "A" frame and the boom are made of angle-iron, riveted together, and are so arranged that they can be raised or lowered by steam-power, so as to permit the dredge to go under bridges without being taken apart. The raising and lowering are performed by chains attached to independent drums, which are operated by the main engines. The spuds are raised by steam-power, by means of chains attached to friction-drums. These drums are also operated by the main engines. The spuds are kept in place after being lowered by patent eccentric binders, which hold the spuds firmly and without any slipping. The spuds go down in wells through the boat, the wells being absolutely water-tight. The after-spud is a "trailing" one. This keeps the machine in line when the forward spuds are raised and the machine is moved ahead. The main hoisting-drums are worked by a novel hydraulic from which satisfactory results have been obtained. The friction can be instantly applied and taken off. The power for this is the combined force of steam and water pressure. This friction is easily applied, and is one of the best features of the machine. By means of it much of the fatigue to the operator incident to the style of "V" and other frictions is avoided. This is no inconsiderable item in the working of a machine during ten consecutive hours. It is an admirable labor-saving appliance. See *Boom-dredge*, *Crane-dredge*, and *Excavator*.



Frisbie Hoisting-engine.

DRESS.—1. A word of command for alignment of troops; also a term expressing the alignment itself. 2. The clothing termed regimentals issued to soldiers. The dress should be light and easy, not encumbering the arms or legs in any way, but leaving the soldier free to shoot and walk. The dress, moreover, should be adapted to the climate of the country in which the soldier serves. The *dress uniform* is the dress prescribed for occasions of ceremony. See *Uniform*.

DRESS-COAT.—A part of the full-dress uniform. In the United States army all officers wear a double-breasted *frock* coat of dark blue cloth, the skirt extending from one half to three fourths the distance from the hip-joint to the bend of the knee. *For a General.*—Two rows of buttons on the breast, twelve in each row; placed by fours; the distance between each row five and one half inches at top and three and one half inches at bottom; stand-up collar, not less than one nor more than two inches in height, to hook in front at the bottom and slope thence up and backward at an angle of thirty degrees on each side, corners rounded; cuffs three inches deep, to go around the sleeves parallel with the lower edge, and with three small buttons at the under seam; pockets in the folds of the skirts, with two buttons at the hip and one at the lower end of each side edge, making four buttons on the back and skirt of the coat; collar and cuffs to be of dark blue velvet; lining of the coat black. *For a Lieutenant General.*—The same as for a General, except that there are ten buttons in each row on the breast, the upper and lower groups by threes, and the middle groups by fours. *For a Major General.*—The same as for a General, except that there are nine buttons in each row on the breast, placed by threes. *For a Brigadier General.*—The same as for a General, except that there are eight buttons in each row on the breast, placed by pairs. *For a Colonel, Lieutenant Colonel, and Major.*—The same as for a General, except that there are nine buttons in each row on the breast, placed at equal distances; collar and cuffs of the same color and material as the coat. *For a Captain, First Lieutenant, Second Lieutenant, and Additional Second Lieutenant.*—The same as for a Colonel, except that there are seven buttons in each row on the breast. *For all Storekeepers.*—The same as prescribed for officers of the same rank in the Quartermaster's, Medical, and Ordnance Departments. This coat is worn on all dress occasions, such as reviews, inspections, dress-parades, guards, and courts-martial. It is habitually worn at battalion drills, except in hot weather, or when otherwise directed by the Commanding Officer. It may also be worn with shoulder-straps when not on armed duty.

For Enlisted Men of Infantry.—The dress-coat is single-breasted, dark blue basque, according to pattern deposited in the Quartermaster General's Office, piped with sky-blue; collar same height as for officers' coat, faced with sky-blue cloth four inches back on each side, cut square to hook up close in front; number of regiment or badge of corps in yellow metal in middle of sky-blue facing of collar on each side; skirt of coat on each side of opening behind to be faced with sky-blue cloth, ornamented with four buttons, as per pattern. Two straps of dark blue cloth, piped with the same color as the facings, let into the waist-seam on each side the coat and buttoning above the hip to sustain the waist-belt; shoulder-straps of cloth the color of the facings let into the shoulder-seam and to button over the shoulder-belts at the collar-seam with one button; shoulder-straps for Engineer soldiers to be scarlet, piped with white. *For Enlisted Men of Artillery, Engineers, and Ordnance.*—Same as for Infantry, except that the facings shall be scarlet for Artillery, scarlet and white for Engineers, and crimson for Ordnance. *For Enlisted Men of Cavalry and Light Artillery.*—Same as for Infantry, excepting that it is shorter in the skirt, and the facing upon the skirt put on differently, according to pattern in the Quartermaster General's Office; facings for Cavalry yellow, and for Light Artillery red. *For Musicians.*—Ornamented on the breast with braid same color as the facings, running from the button as now worn, the outer extremities terminating in "herring-bones" and the braid returning back to the buttons. *For Hospital Stewards.*—Same as for Infantry, except the facings to be of emerald green. *For Ordnance Sergeants.*—Same as for enlisted men of Ordnance. *For Commissary Sergeants.*—The same as for Infantry, except that the facings will be cadet gray. *For Enlisted Men of the Signal Service.*—Same as for Cavalry, except that the trimmings and facings will be orange. Whenever the dress-coat is worn by enlisted men, it is invariably buttoned up and hooked at the collar. See *Blouse* and *Uniform.*

DRESS-PARADE.—A daily parade of troops in the United States army at *troop* or *retreat*, as the Commanding Officer may direct, and which is never dispensed with except on urgent occasions. All Field Officers and men are present, unless specially excused, or on duty incompatible with such attendance. The ceremonies of dress-parade are conducted as prescribed in the authorized Tactics, and are as follows for a regiment:

At the second signal for dress-parade, the companies assemble under arms on their respective parade-grounds, and are inspected by their Captains; the inspection being completed, *adjutants' call* is sounded, at which the line is formed on the battalion parade-ground, bayonets fixed. The Commanding Officer takes his post at a convenient distance in front of the center, facing the line. The Adjutant, having commanded *guides posts*, directs the first Captain to bring his company to *parade rest*. The Captains, commencing on the right, successively face about and command: 1. (Such) *company*, 2. *Carry*, 3. ARMS, 4. *Order*, 5. ARMS, 6. *Parade*, 7. REST, resume their front, and take position of parade rest; the Adjutant then takes his post, commands, SOUND OFF, and takes the position of parade rest. The band, commencing on the right, plays in quick time, passing in front of the Field Officers, or Company Officers if there be no Field Officers, to the left of the line, and back to its post on the right; at evening parade, after the strain is finished, retreat is sounded by the trumpeters or field music. The Adjutant then steps two yards to the front, faces to the left, and commands: 1. *Battalion*, 2. ATTENTION, 3. *Carry*, 4. ARMS, 5. *Rear open order.* Having aligned the guides for the rear rank, the Adjutant steps three yards to the front of the front rank, faces to the left, and commands: 6. MARCH. At which the ranks are opened. The Adjutant, having verified the alignment of the officers, the ranks, and the file-closers, returns to the right of the front rank, faces to the left, commands, FRONT, and then passes in rear of the line of Company Officers to the center of the battalion, turns to the right, and marches to a point midway between the line of Field Officers and the Commanding Officer, when he halts, faces about, and commands: 1. *Present*, 2. ARMS. At the second command, the officers and men present arms. The Adjutant then faces about, salutes the Commanding Officer, and reports: "*Sir! the parade is formed.*" The Commanding Officer returns the salute with the right hand, and directs the Adjutant: "*Take your post, Sir.*" The Adjutant takes his post three yards to the left and one to the rear of the Commanding Officer, passing by his right and rear. The Commanding Officer, while the band is playing, stands at parade rest, with his arms folded, in which position he continues till arms are about to be presented, when he comes to attention. The Adjutant having taken his post, the Commanding Officer draws his sword, commands: 1. *Carry*, 2. ARMS; and adds such exercises in the Manual of Arms as he may desire, concluding with *order arms.* He then directs the Adjutant to receive the reports, and returns his sword. The Adjutant passes by the right of the Commanding Officer, advances toward the line, halts midway between him and the line of Field Officers, and commands: 1. *First Sergeants*, 2. *To the front and center*, 3. MARCH (or, *double time*, MARCH). At the first command, the First Sergeants carry arms; at the second command, they step two yards to the front and face toward the center; the Drum Major at the same time faces to the left; at the third command, the First Sergeants and the Drum Major march to the center, and successively face to the front; the Adjutant then commands, *Report.* At this command, the Drum Major and the First Sergeants, commencing on the right, successively salute and report: the Drum Major, *Band and trumpeters*, or *field-music, present, or accounted for*, or (so many) *musicians*, or *trumpeters, absent;* the Sergeants, *Company* (A, etc.) *present, or accounted for*, or (so many) *sergeants, corporals*, or *privates absent.* The reports being made, the Adjutant commands: 1. *First Sergeants*, 2. *To your posts*, 3. MARCH (or, *double time*, MARCH). At the command *march*, the First Sergeants and Drum Major face outward, and resume their places; the First Sergeants pass through their intervals a yard to the rear, face about, step into the front rank, and then order arms. The Adjutant now faces about, salutes the Commanding Officer, and reports: *Sir! All are present or accounted for;* or *Sir!* (so many) *officers* or *enlisted men are absent.* The Commanding Officer acknowledges his salute, and directs: *Publish the orders, Sir*, when the Adjutant faces about and commands: *Attention to orders.* He then reads the orders, after which he faces about, salutes the Commanding Officer, and reports: *Sir! The orders are published.* The Commander acknowledges the salute, and then directs: *Dismiss the parade, Sir!* at which the Adjutant faces about and commands: *Parade is dismissed.* At this command, all the officers return their swords, and face toward the center; the officers then step off at the same time with the Adjutant, close upon the center, and successively face to the front, the Field Officers on the flanks; the two officers nearest the center preserve an interval for the Adjutant, who passes through the interval a yard to the rear, when he halts, and faces about; all the officers having faced to the front, the Adjutant steps into his place and commands: 1. *Forward*, 2. *Guide center*, 3. MARCH. At the third command, they march to the front, dressing on the center, the band playing; on approaching the Commanding Officer, the Adjutant commands: 1. *Officers*, 2. HALT. At the command *halt*, given at six yards from the Commanding Officer, the music ceases, and the officers halt, and salute with the right hand. The hands remain at the visor till the salute is acknowledged, and drop at the same time with the hand of the Commanding Officer. The Commanding Officer then gives such instructions as he may deem necessary, which concludes the ceremony. As the officers disperse, the music is resumed; the First Sergeants step to the front and close the ranks of their respective companies; the Third Sergeant of each company places himself on the right of the front rank, the First Sergeants then march their companies to the company parade-grounds, where they are dismissed, the band continuing to play till the companies clear the battalion parade-ground. When the line at parade is very short, the band may play in common time; or it may play to the left in common time, ceasing during the countermarch, upon the completion of which, without halting, it strikes up in quick time. See *Evening Parade, Morning Parade*, and *Undress Parade*.

DREYSE NEEDLE-GUN.—A breech-loading small-arm having a fixed chamber closed by a movable breech-block which slides in the line of the barrel by direct action. It is opened by raising the handle of the breech-bolt to a vertical position, and then withdrawing it to the extent permitted by the form of a slot in the receiver in which it slides. In turning up the handle, the needle-bolt is forced back against the pressure of the mainspring which surrounds its stem, by means of a spiral shoulder near its head, which rides over a corresponding helical surface on the stem of the recoil-block. The needle-bolt is compelled to turn with the breech-bolt by means of a projection on its head which slides to and fro in a longitudinal groove in the bore of the breech-bolt; and the recoil-block is prevented from turning with the breech-bolt by a similar projection sliding in a corresponding groove in the receiver. When fully forced back and the pressure of the hand removed, the needle-bolt is kept from being thrown forward by the main spring by means of a square portion of its face coming against a corresponding part of the back surface of the recoil-block. Supported in this way, the needle-bolt moves back with the other parts during the opening of the piece. When the breech is closed by the usual means the needle-bolt catches against the nose of the sear, and is retained by it.

By the act of turning down the handle into place, the square end of the needle-bolt is rotated off its bearing on the stem of the recoil-block, leaving the needle-bolt and the needle free to be driven forward by the mainspring, when the sear is pulled out of its way by the trigger, as in the *Prussian* needle-gun. It is also locked in the same manner as this gun. The arm may be cocked without opening it, if so desired, by drawing back the needle-bolt by means of a thumb-piece, until the nose of the sear catches against a fillet on the needle-bolt as before described. By then pressing forward the thumb-piece till a stud on its upper surface engages in the transverse arm of an L-shaped slot in the breech-bolt, the mainspring is compressed, and may be released as above described. The thumb-piece and needle-bolt are connected together by the needle, which passes through a small hole in the base of the thumb-piece, and is screwed into the rear end of the needle-bolt.

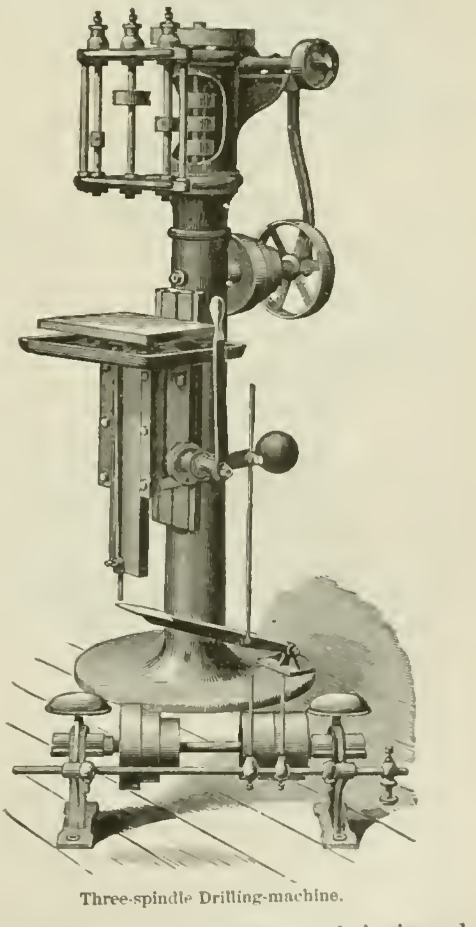
DRIFT.—1. A round piece of steel, made slightly tapering, and used for enlarging a hole in a metallic plate by being driven through it. The drift may have a cutting edge merely upon its advance-face, or it may have spirally-cut grooves which give the sides of the drift a capacity for cutting.

2. A passage in a mine, horizontal or very nearly so, forming a drain for carrying off the water. The name is derived from its being *driven in*. *Driving* is horizontal work; *sinking* and *rising* refer to the direction of work either in shafts or in following the course of a vein.

3. A gun-implement made of steel; it is used for clearing the vent when choked. In using it, a hammer must be applied to the head of the drift to drive it through the vent. There are also wooden drifts, which are used in inserting the *papier-maché* wad in common shells for rifled guns.

4. A deviation peculiar to all oblong rifle-projectiles. See *Projectiles*.

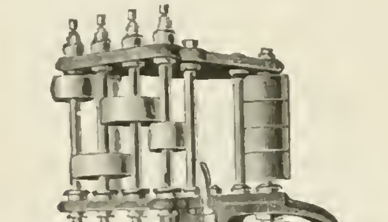
DRILLING-MACHINE.—A machine carrying a rotating tool and a means for chucking the object to



Three-spindle Drilling-machine.

be bored. These machines differ greatly in size and appearance, in the mode of presenting the tool and chucking the work. The larger machines are known as boring-machines. The drawing represents a three-spindle drill, handy for work on a variety of small parts of fire-arms. The spindles of all the gang-drills run in gun-metal boxes, split, and furnished with a nut to compensate for wear. They may be run at the highest speed of which the machine is capable, without danger of binding in the boxes, the longitudinal expansion not being checked by a fixed collet, but being allowed freedom without impairing the accuracy of the machine. The machine has an adjustable hand-lever, a foot-lever, a counterbalanced table, adjustable stop, and gauge for determining the depth of the hole to be drilled. The spindles are of steel—in the smaller machine 13/16 inch diameter, and in the larger machine $1\frac{1}{16}$ inch diameter. The first drills holes up to $\frac{5}{16}$ inch diameter, and the latter up to ½ inch diameter. For heavier work the spindles may be geared. Both sizes are made with two, four, and six spindles. Distance between table and end of spindle in the machines, 5 to 18 inches and 6 to 20 inches respectively. Weight, with countershaft, 625 pounds and 975 pounds. Speed of countershaft, with 8 by 4 inch tight and loose pulleys, 310 revolutions per minute. See *Boring-machine, Chucking-machine, Flexible Shaft, Multiple Drill, Portable Drill, Radial Drill,* and *Vertical Drill.*

DRILL-PRESSES.—Under this head are classed all machines used for boring in which the cutters revolve



and the work remains stationary. Some of the machines classed under the head of drill-presses are known as boring-machines, the word "bore" being commonly applied to holes of a size requiring the use of independent cutters inserted in a "boring-bar." A power-feed is essential to all machines for cutting metal. The drill-press is no exception to this; yet it is almost the only machine-tool which has commonly been built with a hand-feed only. The conditions of cut and variations in the size and strength of the cutting tool make the application of an automatic feed to a drill-press a more difficult matter than to a lathe or a planing-machine, in which a given-sized cutting tool of sufficient strength to do the work is possible. In a drill-press, the smaller and more delicate the drill the finer and more exact or uniform must be the feed. The requirements of a good feed-motion for a drill-press are, that it may be quickly adjusted to the required amount; that it shall be positive in its action when at work; that its range shall be so great, and so fine a feed possible, as not to endanger the smallest drill, while at the same time it shall be capable of giving the utmost amount of feed a large drill or a boring-bar will stand; that it shall be so quickly and readily applied as to make its use more convenient than the hand-feed; and that it shall not in any way interfere with the quick operation of the machine by hand. William Sellers & Co. have recently introduced an improved feed-motion, which fully satisfies all the requirements of a feed for drilling-machines. In their drill-presses, disks of metal are employed to transmit motion by friction, which, being adjustable as to diameter of driving and driven wheels, admits of an infinite variation of feeds between its extreme limits of greatest and least motion. This peculiar feed-motion is applied to those drill-presses in which range is desirable; but in machines for special work, such as for drilling steel plates, the feed is constant at what has been found to work the best, as the size of the drill used in such machines is in a measure constant also. In vertical drill-presses the spindle should be counterbalanced. This is of great value, as the drill held up by the balance-weight will not drop into holes or cavities in the metal, and is much less liable to break.

The drawing shows a four-spindle drill-press, as made by Garvin & Co., for use in government armories. The machine is very heavy, and designed for drilling holes ranging from ¼ to ⅞ inch diameter, also for counterboring, reaming, face-milling, or any work that is convenient to be done on an upright drilling-machine. The spindles are made of steel, $1\frac{5}{16}$ inch diameter and 20 inches long, and are held down by adjustable hardened steel steps at top of frame. The lower end has a taper hole to receive the shanks of tools, ⅞ inch diameter and 4 inches deep, with mortise for drift-key to remove the tools from the spindle. The spindles run in composition-metal boxes fitted up in a very substantial manner, with ample means of adjustment for wear. The head which holds the spindles, drum, and cone-pulley is located centrally over the upright column, giving a well-balanced appearance and sufficient distance between the drum and spindles to insure long belts of great power and durability. The table on which the work is placed has hand and foot levers connected by a milled rack and gear to elevate and lower the table, in connection with adjustable stops to limit the exact motion required. The hand lever can be placed in any position required by loosening the nut outside the friction binder on the pinion-shaft, and should be screwed up firmly again when adjusted. The table guide-frame is planed to fit the front of the column by tongue-and-groove guides, so that the whole table and frame, with all the attachments, can be raised or lowered up or down the column by means of a wire cable with a worm and gear, and can be held in a true position at all points. The advantage of this arrangement is that we may have a press with a very long distance from the spindle to the table, or a very short one, simply by loosening four nuts and locating the table-frame where it is most convenient, and tightening the nuts again. The countershaft has adjustable self-oiling hangers. The weight of the press, with countershaft, is about 1200 pounds. See *Drilling-machine* and *Vertical Drill.*

DRILLS.—A general name for the exercises through which soldiers are passed, to qualify them for their duties. It is subject to numerous varieties, according to the number and organization of the men drilled at one time, and the kind of weapon to which the exercises relate. The infantry, the cavalry, and the artillery, all have different kinds of drill. The militia and the volunteers differ from the regulars, if not in the kind of drill, at least in the circumstances under which it is carried on; the squad-drill, company-drill, and battalion-drill vary both in the numbers concerned and in the routine of exercises. And so likewise in the navy, the drilling of seamen varies in kind, according to the duties likely to be required. It is generally considered that four months' drill is required to fit an infantry recruit for service. The progress depends greatly on the intelligence of the men. It is on this ground that the Rifle Volunteers, enrolled in England in such large numbers in 1860, have been so advantageously placed; composed almost entirely of young men, whose intelligence has been developed by a moderately good education, the Corps have advanced to a degree of proficiency which has attracted the marked attention of military officers.

DRILL-SERGEANT.—A non-commissioned officer whose office is to instruct soldiers as to their duties, and to train them to military evolutions. In the English service the name is given to a non-commissioned officer whose duty it is, under the orders of the Adjutant, to attend to the drill-instruction of young officers and soldiers

DRIVER CORPS.—A Corps formerly consisting of a few subaltern officers, with non-commissioned officers, artificers, drivers, and horses. It was divided into troops, and provided the means of converting a company of foot-artillery into a field-brigade, besides affording small detachments to troops of horse-artillery.

DRIVERS.—Men attached to a battery of artillery to drive the horses. They do not work the guns, but, when they can be spared, are taught the gun-drill. The men enlisted as drivers are of shorter stature than gunners, as height and weight are not required. When men are enlisted as gunners, if they do not fulfill the conditions as to age and standard, they may be entertained as drivers, if likely to become good drivers, but special application must be made to the Adjutant General. In the early days of artillery, both in the English and Continental armies, regularly enlisted drivers were unknown. The horses attached to guns were driven by civilian drivers, who were in the habit of running away on the first available opportunity, and in doing so at the battle of Falkirk, lost the guns. But notwithstanding this catastrophe, it took half a century and upwards before matters in any way righted themselves, and even then, though a vast improvement had taken place upon the old system of dismounted civilians, great confusion in the organization existed. The drivers were enlisted in a corps totally distinct from the regiment, and commanded by their own officers; the drivers were thus separated by a wide gulf from the gunners; this want of connection between the field-artillery and its means of draught led to discord, confusion, and waste of time. In 1817 the drivers were first placed under the command of the artillery officers, and in 1822 men were enlisted into the regiment as gunners and drivers.

DRIVING.—In its usual sense, driving is the act of impelling or directing draught-cattle; it is seen in the act of a driver urging or impelling his horses on. The term is also commonly used in the management of an engine attached to a railway train. In the laboratory the word is applied to the mode formerly, and to some extent at the present day, of filling fuses, port-fires, and rockets with composition. The term is also used in mining, when constructing a gallery. And, frequently, the word is used to express the *driving-side* of the grooves of a rifled gun, in contradistinction to the *loading-side*.

DROMEDARY.—A name sometimes given, probably at first through mistake, to the Arabian or one-humped camel (*Camelus dromedarius*), but properly belonging to a variety of that species, distinguished by slenderness of limbs and symmetry of form, and by extraordinary fleetness. It has been well described as "bearing much the same relation to the ordinary camel as a race-horse or hunter does to a cart-horse." The pace of the dromedary is a trot, which it can maintain without intermission for a prodigious length of time, often at the rate of nine miles an hour for many hours together; whilst a journey of upwards of six hundred miles is performed at a somewhat slower rate in five days. Even its more rapid pace can be maintained for twenty-four hours at a stretch, without sign of weariness and without stopping to bait; and if then it is allowed a little refreshment, of a ball of paste made of barley and powdered dates and a little water or camel's milk, it will resume its journey, and go on with undiminished speed for twenty-four hours more. The jolting to the rider is terrible. The gallop is a pace very unsuitable to the dromedary, and at which it very soon fails. Dromedaries are sometimes trained to run races. White dromedaries are particularly prized in some portions of the East. See *Camel* and *Draught-animals*.

DROOPING.—In artillery, a term applied to the wearing away of the muzzle of smooth-bore guns, especially bronze guns, after long firing. Drooping occurs from the gun having much windage, and not alone from the cause hitherto given, viz., quick firing and consequent heating of the piece. This defect is not likely to happen to rifled guns, as they have little or no windage; moreover, the barrel of rifled guns, being of steel, is not so liable to wear away as gun-metal. There is a method now of condensing the bores of bronze ordnance.

Drop of a Gun.

DROP.—1. The distance of the butt of a gun below the prolongation of the rib. It varies from two to three inches. To measure the drop, get a straight-edge narrow enough to lay along the rib of the gun, and long enough to reach from the sight of the gun over and beyond the butt. After being particular that the straight-edge lies along the rib and touches it at the muzzle and breech, take the measurements from 1 to 2 and 3 to 4, which will give the drop. 2. In fortification, that part of the ditch sunk deeper than the rest, at the sides of a caponiere or in front of an embrasure.

DROP-CHRONOGRAPH.—In the course of the trials made on the working of the apparatus for measuring pressures, called accelerographs, the construction of a tarage apparatus was suggested, founded on the law of the falling of bodies and presenting arrangements borrowed from the two drop-chronographs which Mr. Le Roux has described in his studies on the measurement of the velocity of the transmission of sound through pipes. The addition to this apparatus of electric organs, and especially of Marcel-Deprez registers, has converted it into a very convenient chronograph, adapted with advantage to measurements in which as great precision is sought as that which may be reasonably required with the tuning-fork chronograph. This drop-chronograph has, therefore, been frequently used in the trials made at the Sevran powder-mill for the study of the different phenomena connected with the firing of guns and the working of carriages. It affords, for example, a means of studying the retardation of inflammation of the charge, of determining the precise moment of the first displacement of the projectile or of the beginning of the recoil, and the moment when the carriage attains its maximum of velocity; it also affords means of measuring the velocity of projectiles with a precision little inferior to that of the Le Boulengé chronograph, and gives besides the means of noting their passage through a series of successive frame-targets; finally, it affords a means also of noting the instants of the passage of a projectile in different points of the bore by means of special interrupter organs. We will therefore describe this apparatus here, which, for the simplicity of its construction and management, and the multiplicity of applications to which it is adapted, deserves a place in all practice-grounds, and could, with equal advantage, be introduced in many scientific laboratories. We will notice incidentally some of the experimental adaptabilities realized with this apparatus, in order the better to apprehend the various applications of which it is susceptible.

The drop-chronograph, which was constructed by the works of Mr. Bianchi, of Paris, is represented in Figs. 1 and 2. It is composed essentially of a weight which falls freely between two vertical guide-posts, and which sometimes receives on its own surface the traces left by the apparatus whose movement is the object of study, and sometimes draws with it the electric registers, which leave on the guide-posts traces of the signals which it is desired to obtain. The apparatus is arranged for receiving on one of its faces the organs designed for the first mode of working, and on its other face the organs of electric registration; there is then on one side a mechanical registering chronograph, and on the other an electric chronograph. The mechanical registering chronograph has been especially used, in the researches in which we are engaged, for tarage operations of the accessory organs of the ballistic apparatus, accelerograph-slides, forks, and vibrating plates. The two vertical guide-posts of the apparatus are formed of double T-iron, about 2 meters (6.562 feet) high, and connected at their upper and lower end by cross-pieces, to which they are fastened with screws in such a manner that the distance between them can be slightly varied. In the inside there are two copper rods, perfectly upright, with a V-shaped groove; they serve as guides for the projecting ears of the movable weight. The mounting ought to be adjusted so that the space between these guides is a little less above than at the bottom, so that the weight may have very little play at the upper part, while it is left absolutely free in its fall if the system is placed exactly perpendicular. The whole apparatus rests on a circular base provided with three adjusting-screws, by which the verticalness can be established, and a thread, with a cylindrical plummet fixed on the side, passes through an eye of the same form a little larger in diameter, by which this condition is verified every instant. The weight, of parallelopipedic form and weighing about 10 kilograms (22.046 pounds), is suspended by a hook from a movable cross-piece; this is secured by a clamp-screw at any height on the guide-posts.

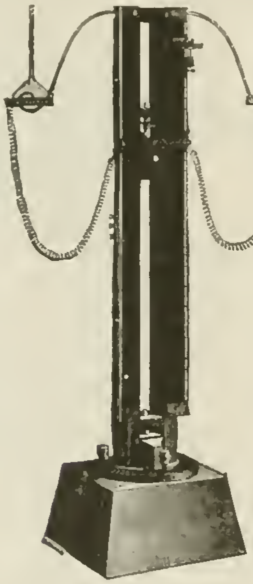


Fig. 1.

The suspension-hook forms part of the lever, the other arm of which bends round horizontally; bearing down on this arm suffices to liberate the weight, and the form of the hook is contrived in such a manner that this operation is effected without producing an oblique action, and without modifying the initial height of the weight until the moment when it is set free. This result is obtained by shaping the inner face of the hook according to an arc of a circle whose center coincides with the center of rotation of the lever, and by placing the edge of the counter-hook, which holds the weight, on the same axis. The weight has, on its front vertical face, two checks, which serve as supports for a horizontal shaft, set with strong friction. This shaft extends, on each side, beyond these checks, so as to form two cylindrical supports on the opposite posts of the apparatus, and on which Marcel-Deprez registers can be mounted side by side. These registers may be five in number on each side, but generally only the number strictly necessary, according to the nature of the experiment in view, is used. The electric wires connecting with each register are of very fine copper covered with silk; they are collected, on each side, into a cluster spirally arranged and sustained by a support attached to the upper part of the apparatus; the whole is arranged in such a manner as to permit the movement of the weight, through the whole extent of its course, without encountering any sensible resistance. On each support the wires connect with small terminals mounted on wood, and which permits each register to be easily secured to the ordinary conductors. On the front faces of the guide-posts are fixed two nickel rules, which may be covered with lamp-black, and on the surface of which the pens of the registers rest, which, during the fall of the weight, trace each a very fine vertical path which is clearly defined on the lamp-black. The pens are so fine and flexible that the pressure exerted by their points cannot sensibly affect the movement of the weight in its fall. In order to facilitate the regulation of this support, and, in case of need, to release all the pens at the same time, the shaft is furnished with a handle by which it is turned in its bearings, and a screw which regulates its movement by bearing against the outer face of the weight. The registers also possess each an individual movement of rotation on the shaft which sustains them, because each of them is mounted on a divided ring-brace forming a clasp at the lower part; this brace is clasped on the shaft, and can be tightened or loosened at will by means of a mill-headed screw which unites the two branches of the clasp. It remains to show how it happens, in the application of this apparatus to ballistic experiments, that the phenomenon to be observed, which results from the inflammation of a charge of powder, is produced during the fall of the weight. It is easy to produce ignition of the charge by electricity, and to close the current which produces ignition by a single passage of the weight in front of a special arrangement which can be placed at any desired height upon one of the guide-posts. Fig. 1 shows this organ. It is composed of an insulating plate mounted on a metallic guide, which can be

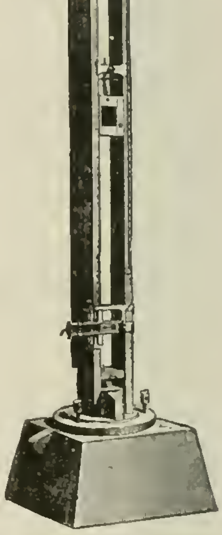

Fig. 2.

moved along a guide on the left guide-post of the apparatus, and can be firmly secured at any height by means of two clamp-screws. The insulating plate has a brass spring-plate, bent round vertically, which rests firmly, when it is left free, against the extremity of a contact-screw. It is the contact of this plate and screw which establishes the current of the firing-battery; the two contact-pieces are for this purpose put in communication with two terminals which receive the extremities of the wire for communicating fire. In order to interrupt this current a light steel lever is used, pivoting in a vertical plane, and forming a hook which catches under a notch made on one of the edges of the conductor-spring, and thus keeps it at a distance from the contact-screw. This lever is extended in front so as to meet the extremity of the axis which supports the registers when the weight falls. It is then carried down and sets free the spring which abuts against its stop, and thus establishes the ignition-current. It is evident that if we know approximately the retardation of ignition, that is to say, the time that elapses between the precise instant when the current is closed and that when the charge takes fire, and if the time also is known approximately that elapses between this latter moment and that when the phenomenon to be observed is produced, we can, by moving the organ for communicating fire along the guide-post, obtain the inscription of the signals in that part of the course of the movable weight which seems most proper, and, consequently, when this weight shall have taken a velocity sufficient to assure the precision of the readings. This same organ for communicating fire has been completed by a simple arrangement which gives the means of measuring, in the course of each experiment, the retardation of disconnection of the registers mounted on the chronograph. This arrangement consists in the addition of a mass of brass fixed at the extremity of a light spring, and which rests against the front face of the spring for communicating fire. This mass, impelled by the movement of this latter spring, when it is set free remains in contact with it during its movement; but as soon as it is arrested by the screw it separates from it, continuing its force by virtue of its inertia, while the spring which urged it so far suddenly becomes stationary. Thus a rupture of contact is obtained at the very moment when, on the other hand, the contact of the detent-spring is established with the stop-screw. At the end of a little time the inert mass resumes its place under the influence of a very weak spring, of which it forms a part. This spring ends at a special terminal, to which a conductor-wire is fixed.

When it is desired to obtain more precision with the drop-chronograph, a vibrating fork can be mounted on the shaft designed to support the registers; one of its branches is furnished with a pen which traces on the lamp-black and produces a sinusoidal tracing whose successive undulations each represent the course of the weight during a unit of time equal to the vibration of the fork. It may be admitted that the movement is approximately uniform during the continuance of each of these vibrations, and supposed that in passing from one to the other it suddenly takes the increase of velocity which the force of gravity communicates and which measures precisely the augmentation in length of the undulatory tracings; by simply counting the vibrations which separate the signals, the corresponding durations can be directly estimated by the entire number of vibrations, and determined, with the aid of a microscope, by a simple proportional calculation like the supplementary durations which correspond to fractions of vibration with the fork-chronograph with revolving cylinder. The fork, mounted thus on the movable weight, may be sustained electrically. But considering the short total duration of the fall of the weight whose movement is to be registered, and if it is proposed to estimate, as is usually the case, only the durations comprehended between the successive signals, it is more simple to employ an ordinary fork mounted by means of a split band forming a vise on the support of the registers and whose vibratory movement is provoked simply by the sudden removal of a small metallic wedge, of suitable dimensions, introduced by force beforehand between its branches. This wedge can be fixed simply to the extremity of a wire fastened at the other end to the upper part of the edge of the apparatus, and whose length must be calculated so as not to withdraw the wedge till the weight has acquired sufficient velocity to produce a sudden impetus. Thus it can only be set in motion a few instants before the

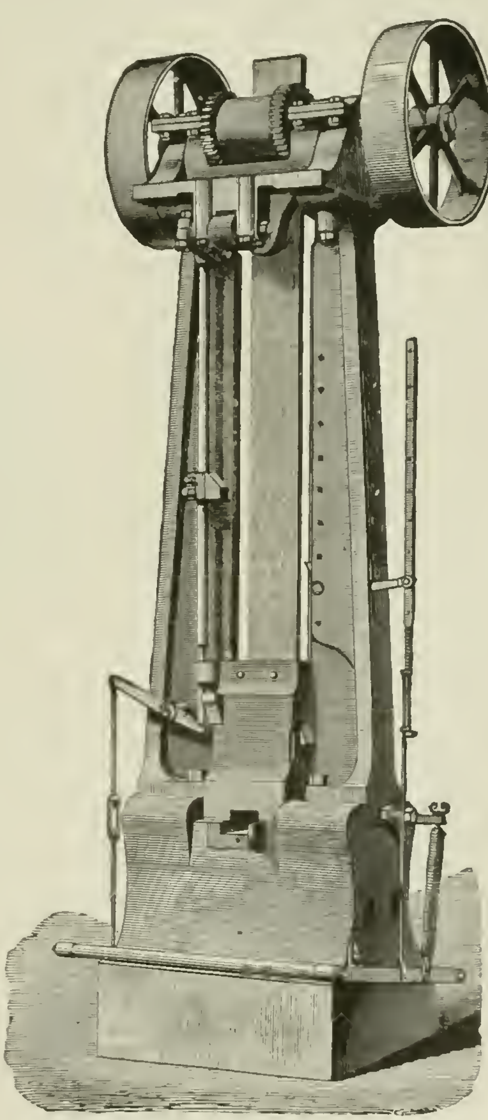

Fig. 1.

moment when the registers are required to work, so that the vibrations have a greater amplitude in the part where the readings are to be made; but sometimes it is expedient to cause this disconnection a certain time in advance (the tenth of a second, for example) in order to leave unemployed the first vibrations, which are subject to some irregularities owing to the position of forced equilibrium which the introduction of the wedge between the extremities of the branches gives to the apparatus. It is well understood, besides, that the wedge must be entered a very little distance and shaped also in such a manner as to require but a very feeble effort to withdraw it, so as to affect the movement of the weight as little as possible; but it is to be remarked that the very principle of the employment of the fork does away with all error that might proceed from this fact, as the tracing left by the pen has the advantage of making known the velocity acquired by the weight at each instant, whatever may be its value. In making use of a vibrating fork, supported electrically and set in operation in place before the fall of the weight, the movement of this weight may be studied along the whole extent of its fall when it has been unobstructed, and it may be ascertained if this movement is according to the law of gravitation, or, in the contrary case, it may be determined how much it deviates from it. In combining the employment of a fork of this kind and an ordinary fork disconnected mechanically by withdrawing the wedge, as was said before, the perturbation that the withdrawing of this wedge gives to the movement may be studied. If, on the contrary, it is admitted that the drop movement of the weight is known, by preserving only this latter arrangement this experiment may be used for determining the number of vibrations given by a fork. The drop-chronograph has been frequently utilized for measurements of this kind. See *Accelerographs*, *Chronograph*, and *Marcel-Deprez Register*.

DROP HAMMER.—A hammer in which the weight is raised by some device and then released, so as to drop upon the object below, which rests upon the anvil. It is used in all Government armories, in swaging, die-work, striking up sheet-metal, etc. In early times the machine was so constructed that the hammer could be raised by means of a hammer-strap, which was drawn upwards by two pulleys, brought together so as to compress the strap between them. One of these, the driving-pulley, was fast upon its axle and turned in fixed bearings, while the other turned loosely upon an eccentrically journaled axis, arranged also in fixed bearings, but so as to be incapable of turning therein except as force was applied to it to effect that object. To one end of the latter shaft there was attached a horizontal arm, the outer end of which was connected to a hand-lever or a treadle by a connecting-rod. By means of these appliances the eccentrically journaled shaft could be turned at will, so as to remove its roller from contact with the strap, and allow the hammer to fall through any length of space desired, within the limits of the machine. The drawing, Fig. 1, on the preceding page shows an efficient drop-hammer, made by the Pratt and Whitney Company, U. S. A. The drop is raised by means of a flat-surfaced strip of tough wood, which engages with the faces of finished cast-iron rolls, driven by gears at the ends. One of these rolls runs in fixed bearings, and the other has its bearings in a yoke suspended on journals which allow it to be moved towards its fellow, to engage with the surface of the lifting-board. This yoke has a central portion projecting downward and engaging by a connecting-bar with a cam operated by a vertical starting-bar through the medium of a crank-lever. By this combination a much greater force is exerted, instantaneously, in placing and retaining the roll in contact with the lifting-board, than is possible when the starting-bar is connected directly with the roll-bearings. The two rolls, with their gears, and the cam movement, are all parts of the head-piece, which may be removed as a whole, or the rolls may be removed separately. The gears are made very strong, and have a peculiar form of tooth, specially adapted to the work they perform. There are two to each roll. An automatic and adjustable stop holds the drop suspended at any height desired. An automatic trip may be attached, which will secure a series of blows of uniform force, at the will of the operator, who can, however, instantly change it from the full impact of the drop falling from the extreme height of the lift to the simple pressure of the weight of the mass without motion. This absolute control and instant adjustment of the force of the blow is appreciated by all practical forgers. The workman has the free use of his hands in operating the machine, as its action is governed entirely by his foot. Experts in the use of the hammer do not attach much value to the automatic trip as having any advantage over the foot-motion, while the latter has many over the former. With each machine is a wrought-iron die-bed secured by a key. This die-bed saves the trouble and expense of dressing the main bed by chisel and file, or by planer, in case of damage, and also adds to the strength of the machine by increasing its resistance to the shock of the blow. The weight of beds may be increased at will.

For all heavy work the steam drop-hammer is now employed. The following drawings show two varieties of double-frame steam drop-hammers, manufactured by the celebrated machine-tool works of Frederick B. Miles, Philadelphia. Fig. 2 is designed for stamping the work in formers. The frames are keyed and bolted to a solid anvil-base, in which is planed the seat for the lower die. The ram carrying the upper die plays between guide-plates, fitted with taper shoes by which they can be accurately adjusted, for the purpose of taking up wear and for matching the dies, which are thus held in the relation to each other necessary for stamping work in molds or formers with accuracy, also for swedging journals or other round work. In this hammer the weight of drop is 100, 400, or 800 pounds; the diameter of cy-

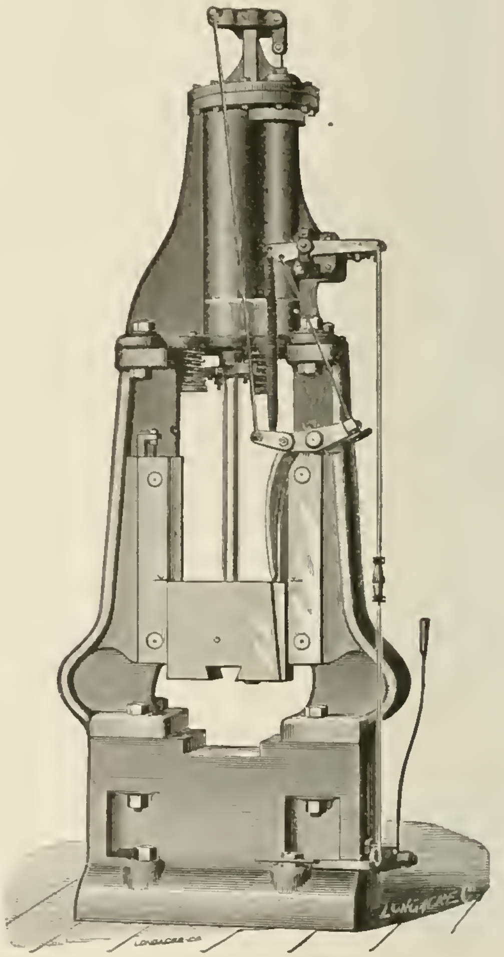

Fig. 2.

linder is 4¾, 6, or 6½ inches; and the length of stroke 10, 14, or 29 inches respectively. Fig. 3 is designed for axles, truck-bars, and heavy drop-forgings, and is both hand-acting and self-acting. Single blows or a succession of automatic blows can be produced at will, and of any required degree of force. The weight of drop is 1500 or 3000 pounds; the diameter

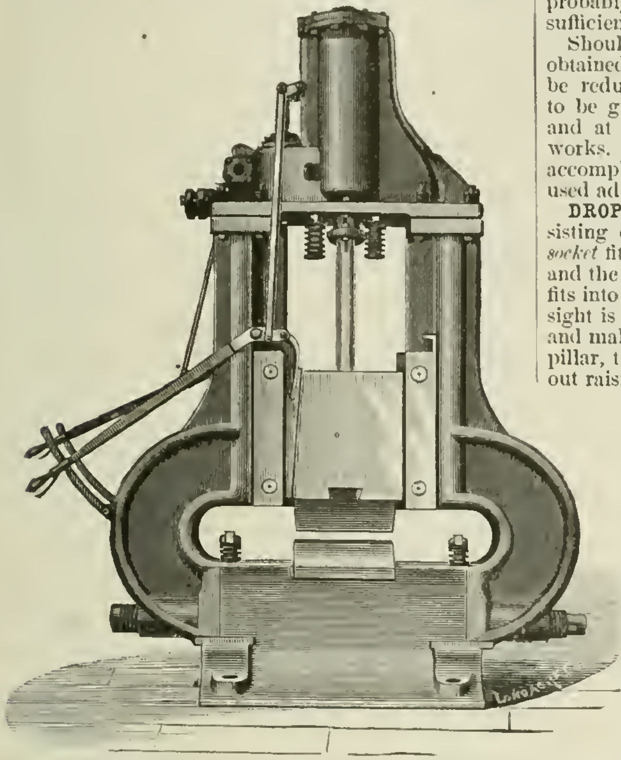

Fig. 3.

of cylinder is 10¾ or 15 inches; and the length of stroke is 30 or 36 inches respectively. These hammers are noted for their adjustable guides and the bumpers made of steel spiral springs. The glands are made in halves for facility of repairs, and brass bushings are introduced in all the principal bearings. See *Steam-hammer*.

DROP OF PROJECTILE.—When seeking protection from the fire of an enemy, either by natural or artificial cover, the *drop* of the projectile must be taken into account. This depends upon the range, kind of piece used, and nature of fire employed.

The following table, showing the *drop* of projectiles at various ranges, indicates the importance of this factor in actual warfare.

Range.	Rifle-musket.		Velocity.	8-inch Rifle.	100-pdr. Parrott.
Yards.	Drop.	Sec'ds.	Feet.	Drop.	Drop.

The numbers in the columns "Drop" denote the number of units of horizontal distance to one unit of vertical.

When the distance to the object can be determined and the range is such as to require considerable elevation, it is by no means necessary that the object should be seen from the gun, provided range-points can be accurately established, as in mortar-firing. In many cases it will be a great advantage to locate guns in this manner, for the reason that the enemy will probably not be able to ascertain their position with sufficient accuracy to do them much damage.

Should the distance behind which cover can be obtained be quite short, the charges for guns may be reduced so as to allow the necessary elevation to be given to carry the projectile over the cover, and at the same time drop them into the enemy's works. A few trial-shots will enable the artillerist to accomplish this with certainty. Siege-howitzers are used advantageously in this way. See *Projectiles*.

DROP-SIGHT.—A variety of trunnion-sight, consisting of a socket, collar, pillar, and leaf. The *socket* fits into the gun, the *collar* locks into the socket, and the *pillar*, at the top of which the *leaf* is screwed, fits into the collar. The arrangement for securing the sight is a kind of bayonet-joint: by lifting the collar, and making a quarter-turn from left to right with the pillar, the collar and pillar are drawn out; but without raising the collar, the pillar is immovable in any direction, and must be exactly in its place. The pillar cannot be separated from the collar while the leaf is fixed. See *Sight*.

DROSS.—The *scum, scoria*, slag, or recrement resulting from the melting of metals combined with extraneous matters.

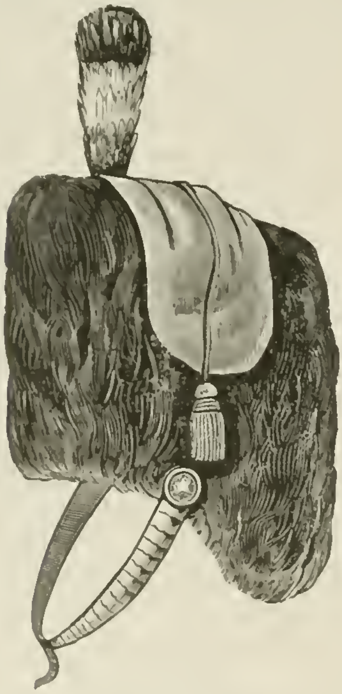
DRUG-CARRIAGE.—The truck-carriage used for moving heavy guns in positions where the size of the platform would be inconvenient. There are several sizes of drugs. The largest is constructed to carry heavy guns of the present day, and is fitted with two pairs of frame-shafts and outriggers for the swingle-trees for four horses abreast. The small and medium drugs are fitted for man-draught.

DRUM.—A hollow cylinder of wood or metal having skin (parchment) stretched across one or both ends, upon which the drummer beats with an instrument of wood or metal called a *drumstick*. The drum is used as an instrument of music along with other instruments in bands, and particularly for military purposes. The military drum serves for giving various signals as well as for music. There are three kinds of drum—the *snare* drum, the *double* or *base* drum, and the *kettle*-drum. Since 1858 the British infantry are supplied with brass snare-drums, 3 lbs. lighter than those formerly in use, and tuned with screws instead of straps and ropes. The cavalry-drum is a copper or brass hemisphere, thus resembling a *kettle*, with a parchment lid. The base-drum has both ends covered with parchment. The ancient Romans used small *hand*-drums—some resembling tambourines, others *kettle*-drums—in their religious dances; and the Parthians are said to have used them in war to give signals. They are believed to have been first brought into western Europe by the Crusaders. See *Base-drum, Kettle-drum*, and *Snare-drum*.

DRUM-HEAD COURT-MARTIAL.—A Court-Martial called suddenly by the Commanding Officer to try offenses committed on the line of march, and which demand an immediate example. This method is not resorted to in time of peace.

DRUM MAJOR.—The introduction of the Drum Major at the head of a band is comparatively of recent date—that is to say, with the ordinary band. Outside of the larger and more pretentious military and professional organizations, his duties and importance have been but little known until within the last few years. It is safe to say that when bands once understand the great improvement in appearance and deportment a few weeks' drill under an officer of this kind will give them, they will consider him a necessary appendage to their organization. Any person having ordinary ability, with practice and a little study, can master the more important points in a very short time, and take his position at the head of the band with credit to himself and associates. We append the directions for the giving, and how to execute, the most important signals. We cannot, of course, within the limits of this work, go into the details for elaborate drill; but what is given is sufficient for an ordinary street-parade, and, when thoroughly mastered, there can be easily added such fancy movements as the star, the cross, the triangle, the hollow square, etc., as may be desired.

The person selected for Drum Major should be of good military form, and, where possible, one who has had experience in military drill. He should have good time, though he need not necessarily be a musician. From the time the band leaves the band-room until return and dismissal, he is the ranking officer, and has full charge of the movements of the band. The leader selects the pieces he desires played, but awaits the proper signal from the Drum Major



Bear-skin of Drum Major.

"to play" and "to cease playing." As soon as one piece is finished the leader should immediately decide upon the next, and so inform the band, though it may not be required that it should be played for an hour; then, without confusion or unnecessary delay, all are in readiness when the signal "play" is given. Conversation in the ranks should be especially avoided, as it detracts attention from the Major, and soon leads to carelessness, which means crooked files, bad "wheels," and general deterioration.

The Drum Major's uniform should, if expedient, contrast somewhat with that of the band. The bear-skin hat of white or black, shown in the drawing, is the conventional emblem, after which the dress can be plain or elaborate, as the wearer may determine.

The position of the Drum Major is three yards in front of the band, opposite the center. The staff is held in the right hand below the chin, the back of the hand to the front, the head of the staff near the hand, the ferrule pointing upward and to the right. After each signal, unless keeping time for the band, the staff should be restored to its original position.

The following signals of the Drum Major must be promptly observed and obeyed:—*To play:* Face toward the music, and extend the right arm to its full length in the direction of the staff. *To cease playing:* Extend the right arm to its full length in the direction of the staff. *To march:* Turn the wrist and bring the staff to the front, the ferrule pointing upward and to the front; extend the arm to its full length in the direction of the staff. *To halt:* Reverse the staff and hold it horizontally above the head with both hands, the arms extended; lower the staff with both hands to a horizontal position at the height of the hips. *To countermarch:* Face to the band and give the signal to march. The countermarch is executed by the file-leaders to the right of the Drum Major wheeling individually about to the right; those to the left, to the left; the other men of each file follow their file-leaders. The Drum Major passes through the center. *To oblique:* Bring the staff to a horizontal position, the head opposite the neck, the ferrule pointing in the direction the oblique is to be made; extend the arm to its full length in the direction of the staff. *To march by the right flank:* Extend the arm to the right, the staff vertical, the ferrule upward, the back of the hand to the rear. *To march by the left flank:* Extend the arm to the left, the staff vertical, the ferrule upward, the back of the hand to the front. *To diminish front:* Let the ferrule fall into the left hand at the height of the eyes, the right hand at the height of the hip. *To increase front:* Let the ferrule fall into the left hand at the height of the hip, the right hand at the height of the neck. *The general:* Bring the staff to a vertical position, the hand opposite the neck, the back of the hand to the front, the ferrule pointing upward. *The assembly:* Bring the staff to a horizontal position, the hand opposite the neck, the back of the hand down, the ferrule pointing to the front. *To the color:* Bring the staff to a horizontal position at the height of the neck, the back of the hand to the rear, the ferrule pointing to the left.

In marching, the Drum Major beats the time with his staff and supports the left hand at the hip, fingers in front, thumb to the rear. The Drum Major, before making his report at parade, salutes by bringing his staff to a vertical position, the head of the staff up and opposite the left shoulder. The Drum Major marching in review passes the staff between the right arm and the body, the head to the front, and then salutes with the left hand. In executing *rear open order*, each rank of the band takes the distance of three yards from the rank next in front. When the field-music is by itself, the fifers are placed in front; in the field-music of a company, the fifer is on the right of the drummer.

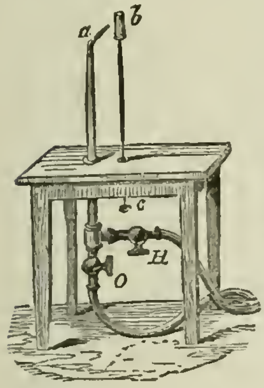
The Drum Major, when saluting, passes the staff between the right arm and the body, the head of the staff to the front; then bringing the left hand up smartly, pointing in the same direction as the left foot, the palm of the hand down, the thumb close to the forefinger, the arm horizontal; bringing the hand round till the side of the forefinger touches the lower edge of the cap over the left eye, at the same time turning the head a little to the right, looking toward the person to be saluted, and retaining the position till the salute is acknowledged; then bringing the hand back to the horizontal position, at the same time casting the eyes to the front; then dropping the hand quickly to the hip. See *Band.*

DRUM MAJOR GENERAL.—The Drum Major, as a component member of a regiment, was not much known in the English army till the time of Charles I. There was in earlier times an officer in the Royal Household called the *Drum Major General*, without whose license no one except Royal troops might use a drum; but this office fell into disuse. The Drum Major, when regularly established, received orders from the Major of the battalion concerning the necessary beats or signals, and communicated them to the drummers. The management of the big drum, and the teaching and control of the drummers generally, still devolve upon the Drum Major. The "beats" at present adopted by the British infantry were composed by Drum Major Potter of the Coldstream Guards. See *Drum Major*.

DRUMMER.—The soldier who plays a drum. The majority of drummers are boys, generally the sons of soldiers. The drummer is a component member of every British regiment. His position is slightly superior to that of the private soldier, but still he is reckoned as one of the rank and file. Besides his ordinary duties, the drummer performs the *drumming out* when a soldier is discharged with ignominy. To the drummers is also intrusted the repulsive duty of flogging, when that sentence is passed upon soldiers. A *Drum-head Court-Martial* (not now much adopted) has no particular connection with the drummers, but is a hasty Council or Court-Martial held in the field around the big drum.

DRUMMING OUT.—The ceremony of ignominiously discharging a soldier from the service. The culprit is marched out of the garrison at the point of the bayonet, the drummers or musicians playing the "Rogue's March."

DRUMMOND LIGHT.—The heat given out during the combustion of a mixture of hydrogen and oxygen gases, or of coal-gas and oxygen, is very intense; and when the mixture is directed on an infusible substance, such as lime, a most brilliant light is evolved. Captain Drummond, R.E., originally proposed the employment of this light in the trigonometrical survey of Great Britain, and constructed apparatus for its production. The most convenient form of the apparatus is represented in the figure, where the mixed gases escaping by the jet *a*, being set fire to and made to impinge upon the cylinder, *b*, of lime, raise the surface of the latter nearest the jet to a white heat, accompanied by a very dazzling light. As minute portions of lime become detached and are volatilized from the spot on the lime on which the jet of burning gases strikes, it is necessary to expose a new surface of lime to the gases, and for this purpose the screw, C, may be turned by the hand or by clockwork. The hydrogen and oxygen ought to be confined in separate gasholders or bags, and to be brought by different tubes, H and O, provided with separate stop-cocks, to within a short distance of the exit-jet. The common tube through which the mingled gases pass to the jet is to prevent the return of the flame, which might lead to a disastrous explosion. When the rays from this light are concentrated by a parabolic reflector, it can be seen at immense distances. Thus on the 31st December, 1845, at half past 3 P.M. (daylight), the light was exhibited on the top of Slieve Donard, in County Down, and was seen from the top of Snowdon, a distance of 108 miles; and in other instances the Drummond light has been seen at distances up to 112 miles. The employment of coal-gas instead of hydrogen has greatly increased the applications of the Drummond light, and it is now often used in magic-lanterns and other apparatus where great brilliancy and penetration of light are required. It has been used lately on the Continent with great effect in illuminations. Great caution should at all times be exercised in the preparation, storing, and employment of the gases, as many dangerous explosions have occurred. Little heat is evolved from the Drummond light, nor does it vitiate the surrounding air or consume its oxygen. See *Electric Light*.

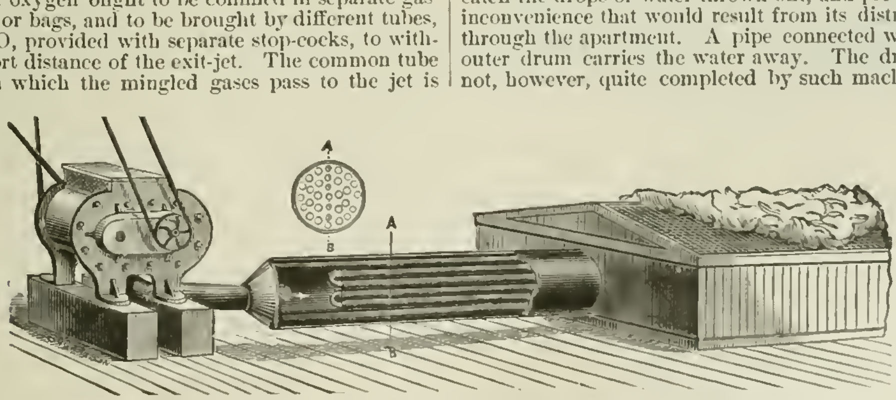


DRUMSTICK.—A stick with which a drum is beaten, or one shaped for the purpose of beating a drum.

DRUNK ON DUTY.—A crime severely and summarily punished in all services. In the United States, the Articles of War provide that any officer who is found drunk on his guard, party, or other duty shall be dismissed from the service. Any soldier who so offends shall suffer such (*corporal*) punishment as a Court-Martial may direct. No Court-Martial shall sentence any soldier to be branded, marked, or tattooed.

DRY CAMP.—Troops on the march are said *to make a dry camp* when they are compelled by exhaustion or other causes to camp at a place where there is no water. For such camps water is usually transported with the troops.

DRYING-MACHINES.—The ordinary processes of drying by exposure in the open air have been found too tedious for large establishments, and hot-air chambers have been extensively used; but a great improvement has been lately made by using the principle of centrifugal force to throw off the greater part of the moisture. The drying-machine commonly used in arsenals and laundries consists of two drums or cylinders open at the top; the inner one, into which the goods are packed, is perforated at its sides, and made to revolve with great velocity either by steam, water, or hand power. The action of the drying-machine is precisely the same in principle as that witnessed when the housemaid is *trundling* a mop, or of the dog when he shakes himself on coming out of the water. The use of the outer cylinder is merely to catch the drops of water thrown out, and prevent the inconvenience that would result from its distribution through the apartment. A pipe connected with this outer drum carries the water away. The drying is not, however, quite completed by such machines: a

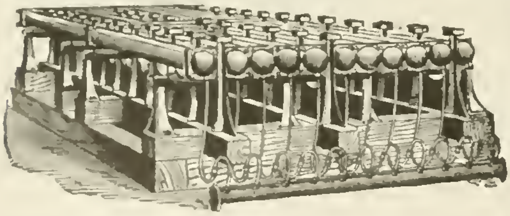


Drying-machine.

about six inches long by two thirds of an inch in diameter; and in Mr. Hemming's construction the tube is very closely packed full of very fine brass wire, which is afterwards wedged in by a stout wire being driven down the center. The object of the fine wires very slight degree of moisture, just perceptible to the touch if the goods are pressed against the cheek, still remains. This is expelled by open-air or hot-chamber drying. These drying-machines are commonly called "extractors." A simpler and cheaper drying-machine has been lately introduced for domestic use. It consists of two rollers mounted parallel, and one above the other, with an adjustment to vary the distances between them. One end of the article to be dried is inserted between the rollers, which are then brought as close as possible together, and one roller is turned by a handle; the other, being free to revolve, turns also as the clothes pass between them—the moisture in this case being extracted by pressure, as in the common process of "wringing."

For articles in bulk, such as wool, cotton, etc., the arrangement for drying shown in the drawing, has a number of advantages over others in use. The method for supplying and heating the air is simple and inexpensive, as compared with some others in which the heater is arranged on the plan of a tubular boiler with inside flues. The steam for heating is let into this boiler, and the air to be heated passes through the inside of the tubes. The heater must have the strength of a boiler, and the tubes secured in the same way, to bear the pressure of the steam. This is necessarily expensive; and the air passing through the inside of the tubes is brought in contact with only a small heating-surface. In the plan illustrated, a Roots' Positive Blower furnishes the blast, and the outside case or air-conductor needs only to be made of No. 18 galvanized iron. The air passes through this conductor, and is heated by steam passing through return-coils of ordinary gas-piping. This arrangement can be made at a small cost, as compared with the plan spoken of above, and is much better, as the air is brought in contact with from twenty-five to fifty per cent more heating surface by passing on the outside of the pipes instead of the inside. When, as in the former case, the air is forced through the inside of the pipes, considerable force or pressure is required to overcome the friction, which is only effected at the expense of considerable power; while, in the plan shown above, a large and ample space is given for the passage of the air.

DRYING-STOVE.—An apparatus employed in the manufacture of gunpowder. It is simply a close chamber heated to a high temperature by steam; the doors and windows of the building are double, so as to prevent the loss of heat, and the interior is fitted up with an open framework of wood, supporting trays upon which the powder is spread out to dry. A series of cast-iron steam-pipes consisting of twenty-two lengths, each about 11 feet long, with an ex-



Drying-stove.

ternal diameter of 7½ inches, are laid a few inches above the floor; these pipes are arranged horizontally, with an inclination or fall of 1 inch in 11 feet from the end where they are connected to the main steam supply-pipe, which pipe is in direct communication with the steam boiler, the quantity and supply of steam being regulated by means of a stop-valve on the boiler. As the steam condenses—which it will do to some extent in the large pipes—the water runs off through a small wrought-iron pipe attached to the ends of the large ones; these drain-pipes are bent in such a form as to allow for the expansion and contraction of the large pipes, each length of which is supported on four rollers fitted into cast-iron brackets, for allowing a freedom of motion laterally. The small wrought-iron pipes conduct the distilled water formed by the condensed steam into a main cast-iron pipe which conveys it into a close tank, whence it is pumped into casks and taken to the incorporating-mills, where it is of much value for damping the charges. The drying-stove is about 32 feet in length by 30 feet in width, and from 10 feet to 11 feet in height, and affords about 10 cubic feet of space to every square foot of heating surface. A wooden staging is erected immediately over the pipes, for supporting the trays; these trays consist of wooden frames with canvas bottoms, each being 3 feet in length by 2 feet 6 inches in width, and about 1¼ inch deep, and upon each of these from 6 pounds to 8 pounds of gunpowder are spread out evenly upon the canvas bottom. The stove contains 256 trays, consequently from 30 to 40 barrels of powder can be dried at one time. It requires about four hours to heat the drying-stove up to a temperature of 130° F., to which heat the powder is subjected. The temperature can always be ascertained by the attendant without opening or entering the drying-stove, as a large thermometer is placed inside the building, at the window, with its face outwards. After the powder has been subjected to the full heat for a period of from sixteen to eighteen hours, the steam stop-valve on the boiler is closed, and the chamber allowed to cool down. In from two to three hours the temperature is sufficiently reduced to admit of the attendant entering for the purpose of removing the trays. It will therefore be seen that by this means one stove is capable of drying a full charge every twenty-four hours; but where the factory is large the better plan is to have two such stoves, with the steam-boiler placed between them, and to work each one alternately. It is of the utmost importance that the heat be applied slowly, otherwise the texture or shape of the grain is apt to change by being cracked or burst into pieces, and consequently spoiled. If the moisture is not carried away as it arises it will settle on the powder, and thereby injure the surface of the grain; to obviate this the roof and also the bottom of the drying-stove are provided with ventilators, and through these all the moist air escapes. These ventilators can, if necessary, be opened from the outside. When no more vapor arises the ventilators are closed, and the powder subjected to the full effect of the hot dry air for some few hours before the doors of the stove are opened. The action of the heat in drying the powder produces a small quantity of dust, consequently the powder has to be taken back to the dusting house, and there passed through a dusting-reel. The large-grain powder is put into a horizontal reel, covered with canvas having twenty-four meshes to the inch, and reeled for half an hour, which effectually cleans it, removing all the dust and giving to the powder a fine finished gloss. The fine-grain powder is run through a slope-reel, covered with canvas having twenty-eight meshes to the inch, and reeled for about two hours, after which it—as well as the large-grain powder—is put into casks provided with copper or ash hoops, and when closed the heads of the casks are branded according to the size and nature of the powder contained in them. This completes the manufacture, and the gunpowder is now ready for use or storage as may be required. In a given quantity of "mill-cake" the proportions obtained are as follows: about seven tenths large-grain, two tenths fine-grain, and one tenth dust; in damp weather, however, these proportions are somewhat altered, the dust during such weather being considerably increased. See *Gunpowder*.

DRY PROCESS.—The collodionized glass plate, on being withdrawn from the bath, previous to and during exposure in the camera, has mechanically adhering to its surface a quantity of solution of free nitrate of silver, and it is partly upon the presence of this salt that the extreme sensitiveness of wet collodion plates depends. This, however, is not the sole cause of sensibility to actinic rays; carefully conducted experiments fairly lead to the assumption that the molecular arrangement of the ultimate particles of iodide of silver, and of the pyroxyline, forming, as it were, the network of the film while wet, materially affect this necessary condition; and it is the object of what is termed a *dry process* to preserve this molecular arrangement as far as possible unaltered, notwithstanding the disturbing influences which would necessarily be exerted by the desiccation of the film. This desirable end for military photography is accomplished with more or less certainty by the employment of solutions of various substances, which are poured over the film after the adhering nitrate of silver has been removed by copious washing with water. The heterogeneous character of the substances so used goes far to prove that their action is principally *mechanical*, they being selected from the animal, vegetable, and mineral kingdoms. Among the first may be mentioned honey, gelatine, glycerine, milk, and albumen; among the second, syrups, gum, wine, beer, balsams, and resins added to the collodion, and linseed tea; and among the third, chloride of calcium, nitrate of zinc, and nitrate of magnesia. The plate, on its removal from the sensitizing bath, being well washed with water, any one of these substances is dissolved in water in suitable proportion, and applied to the surface of the plate by pouring on and off several times. It is then set up to drain and dry on folds of bibulous paper in a dark closet or box. The plate is then ready for use. The pictures obtained on plates so prepared do not suffer by comparison with those taken by the wet collodion process; the only drawback to their use being a slight diminution in the degree of sensibility to light. See *Photography*.

DUALINE.—An explosive composition of nitro-glycerine, fine sawdust, and nitrate of potassa (in proportion of 50, 30, and 20 parts), intended to diminish the danger in the transportation and storage of nitro-glycerine. Compared with dynamite, it is—1. More sensitive to heat, and also to mechanical disturbances, especially when frozen, when it may even be exploded by friction; 2. The sawdust in it has little affinity for the nitro-glycerine, and at best will hold but 40 to 50 per cent of nitro-glycerine, and on this account very strong wrappers are needed for the cartridges; 3. Its specific gravity is 1.02, which is 50 per cent less than that of dynamite, and as nitro-glycerine has the same explosive power in each, its explosive power is 50 per cent less than that of dynamite; 4. The gases from explosions, in consequence of the dualine containing an excess of carbon, contain carbonic oxide and other noxious gases. Lithofracteur and dualine, however, can be exploded, when frozen, by means of an ordinary fulminating-cap, which is not the case with dynamite. Dualine was invented soon after dynamite. The patent describes it as consisting of "cellulose, nitro-cellulose, nitro-starch, nitro-mannite, and nitro-glycerine, mixed in different combinations, depending on the degree of strength desired in adapting its use to various purposes." A sample supplied by the inventor, Carl Dittmar, for trial at the Hoosac Tunnel, was found by analysis to consist of 60 per cent of nitro-glycerine and 40 per cent of washed sawdust, not treated with nitric and sulphuric acids. The best variety now manufactured is believed to be cellulose derived from poplar pulp, treated with nitric and sulphuric acids, and saturated with nitro-glycerine. When soaked in water it can be exploded only by a violent detonation, exceeding that of the ordinary fuse, and even then it loses more than half its power. It congeals at about 45 Fahrenheit, and in this state readily explodes, becoming so sensitive to friction as to make it dangerous to use in cold weather. In other respects its properties resemble those of dynamite. See *Dynamite, Explosive Agents*, and *Nitro-glycerine*.

DUCENARIUS.—The title of an officer in the Roman armies who commanded two Centuries.

DUCTILIMETER.—An instrument invented by M. Regnier for ascertaining the relative ductility of metals. The metal to be tested is subjected to the action of blows from a mass of iron of given weight attached to a lever, and the effect produced is shown upon a graduated arc.

DUEL.—A combat between two persons, at a time and place indicated in the challenge, cartel, or defiance borne by one party to the other. A duel generally takes place in the presence of witnesses, called seconds, who regulate the mode of fighting, place the weapons in the hands of the combatants, and enforce compliance with the rules which they have laid down.

No trace of the duel, as an institution, is to be found in the history of the classical nations of antiquity, the Latin word from which ours is derived having been used to signify a war between two nations. So long as men continued to be barbarians their personal quarrels were no doubt decided in the ancient, as national quarrels still are in the modern world, by an appeal to physical force. But though war has been in all times the practical solution of strife, it was not till the Middle Ages that it came to be regarded as a means, in any sense judicial, of settling disputes. Hitherto it had determined who was able to prevail, justice being set aside, but it was a new view that it would determine who ought to prevail on the principles of justice. The rationale of the *judicial combat* or wager of battle was probably twofold. On the one hand, and generally amongst the people, it depended on a belief that God would interfere directly and miraculously in the conflict to protect the innocent and to punish the guilty, and that thus the weakest combatant who had God on his side would prove more than a match for the strongest when destitute of his aid. But there was a view of the matter which was not so directly superstitious, and which rested rather on a confusion between the principle of the original constitution and the principle of the transmission of rights. All human rights originate in the powers and faculties which God has given to man, and it was supposed that as the right originated in power, its continued existence in the individual could be ascertained by ascertaining whether the power still existed in him. The error consisted, as we have said, in confounding the principle of the constitution with the principle of the transmission of rights. If a field which was claimed by two competitors had as yet been appropriated to nobody, or had been abandoned, and was, as lawyers say, *res nullius*, the fact which of the two claimants ought to become the possessor might be ascertained by judicial combat. But if it was already the property of one of them on a title which was to be held sacred, and the question was which of the two had this sacred title, that fact could never be determined by ascertaining which would have been in a condition to constitute it for the first time, had it been non-existent. The principle of the private duel, in so far as it had any principle at all, and was not merely a piece of barbarous and irrational foppery, was precisely the same as that of the judicial combat. But the latter had been applied to a class of cases which admitted of legal investigation and decision, and it was consequently abandoned in the days of Queen Elizabeth; whereas the former was supposed to be a means of redressing wrongs which hardly can come within the cognizance of a human tribunal, and the consequence was that it continued in green observance in England until recently, and is still in vigor in many Continental countries.

Like the other peculiarities of mediæval life, the duel probably originated with the Germanic nations. It is said to have been introduced into legal proceedings in lieu of an oath by Gundebald, King of the Burgundians, in 501. Louis le Débonnaire was the first of the French kings who permitted litigants to appeal to arms. The practice was prohibited by Henry II., in consequence of a noted duel which took place in his presence between his friend Francis de la Chastaigneric and Guy Chabot de Jarnac, in which the latter was slain. The royal edict, however, was totally ineffectual, and the practice of private dueling has generally prevailed more extensively in France than in any other country. Francis I patronized it by declaring that a lie could be borne without satisfaction only by a base-born churl, and still more by the example which he set in challenging his own great rival Charles V. In 1599 the Parliament of Paris declared all persons who were either principals or seconds in duels to be rebels to the King. But its efforts were unavailing; and it is said that during the first 18 years of Henry IV. no fewer than 4000 gentlemen perished in this foolish manner. In 1609 Henry added to the existing penalties, introducing even punishment by death in extreme cases. But these regulations were forced upon him by popular feeling; he had himself no aversion to the practice, and when he gave permission to Crequi to fight Don Philip of Savoy, he added: "If I were not the king, I would be your second." The consequence of this feeling was that he readily granted pardons to those who had violated the laws which he had been forced to enact, and these laws not unnaturally produced an effect the very reverse of their ostensible object. Duelling acquired the charm of what the French call "forbidden fruit," and thus became a fashionable and favorite vice. In the reign of Louis XIII. the custom was so prevalent that Lord Herbert, the English Ambassador, wrote home to his Court that there was scarcely a Frenchman worth looking on who had not killed his man. It would not seem, however, that it was from negligence in enforcing the royal edicts that duelling then reached to so alarming a height; for it was during this reign that two noblemen, the greatest duelists of the day, the Count de Boutteville and the Marquis de Beuron, were tried and beheaded for persisting to fight. In the commencement of the reign of Louis XIV., duels with four or five a side began to be fought; and two very sanguinary affairs of this description having taken place, in which several persons of the highest rank were slain, the King determined to put an end to the practice. He published an edict in 1679 forbidding it under the highest penalties, which, unlike most of his predecessors, he had the firmness to inflict; and this measure, together with a solemn agreement which was entered into amongst the nobility themselves, led at that time to its almost total abolition.

The duel does not seem to have existed in England in Anglo-Saxon times, and was probably introduced at the Conquest. In its judicial form it was not totally obsolete in the reign of Queen Elizabeth; and Sir Henry Spelman gives an account of a Trial by Battle, which terminated, however, without actual combat, in the year 1571. Private dueling was common, however, both in Elizabeth's reign and in that of her successor, by whom a severe statute against it was enacted in Scotland. During the civil wars men's minds were too much occupied with questions of grave importance to leave time for questions of etiquette, and the duel consequently declined; but it became exceedingly prevalent during the dissolute reign of Charles II. Some attempts were made to suppress it in the reign of William III., both in England and Scotland, and in 1712 the subject was recommended to the attention of Parliament in the Queen's speech. But the bill which was brought in by the Government was thrown out, and the practice continued to prevail. When the custom of wearing the sword was abandoned, the number of duels diminished, though it was then that their irrational character may be said to have attained its maximum. The pistol was substituted for the sword, and the doctrine of chance—which was reduced to an absurdity by the medical duel of a couple of pills, one composed of bread and the other of poison—was inaugurated. Since this period the practice has fallen into disrepute, by the gradual operation of public opinion, and in Great Britain it may probably be now regarded as finally abolished. The duels of the students at the German universities, of which so much has been said and written in this country, are nothing more than fencing-matches with sharp weapons. They are foolish but not deadly affairs, as the seconds, who are also armed, always interfere to prevent serious bloodshed.

In the southern portion of the United States the custom of dueling, though of late years falling into disuse, is a recognized institution of society. Half a century ago the pistol and the bowie-knife were as much a part of a man's equipage as his hat or his boots. A gentleman of good social position who had not fought at least one duel was often looked upon as deficient in the qualities proper to his station. Sudden affrays in the streets, stealthy assassinations, and bitter family feuds, were the consequences. These feuds rivaled in duration and ferocity the Venetian vendetta. The land was full of swaggering bullies who had, metaphorically, in one hand a pack of cards and in the other a pistol. Modern civilization, and more especially the War of the Rebellion, in which the Southern States suffered so terribly, have greatly modified this fire-eating spirit. Other influences have assisted. Not only is the general voice against the practice, but in a large number of the States laws have been enacted which pronounce the killing of a fellow-being in a duel to be murder, and in still more States the mere sending of a challenge is a felony. A person in the military or naval service implicated in a duel, either as principal or second, may be summarily cashiered. In some of the States the killing of a man in a duel is punishable with death; in others by imprisonment and forfeiture of political rights. In some States certain officers are required to swear that they have not been, within a certain period, and will not be, engaged in a duel. See *Articles of War*, 26, 27, and 28; *Challenge*, 2; and *Wager of Battle.*

DUFFADAR.—In the native East Indian cavalry, a non-commissioned officer corresponding with the rank of Sergeant.

DUFFADAR MAJOR.—A rank in the Indian cavalry corresponding with the Sergeant Major of a European regiment of cavalry. See *Kot Duffadar.*

DUFOUR BASTION SYSTEM.—The enceinte is traced as in the modern system; the ditch is 30 yards wide at the salient of the bastion, and the counterscarp is directed on the shoulder-angle. A *cavalier*, or bonnet, 24 feet high, is erected at the salient of the ravelin. The parapet of the cavalier is only 4 yards thick, and is supposed to be sufficiently strong to resist ricochet; there is no rampart; the banquette is destined for musketry, and its slopes descend to the terre-plein of the ravelin. The ravelin is 22 yards wide, with ramps 3 yards wide and slope $\frac{1}{10}$. The *reduit of ravelin* is separated from the ravelin by a ditch 10 yards wide and 6 yards deep, its bottom being 6 feet above that of ravelin and 12 feet above the main ditch. The reduit has a command of 6 feet over the ravelin at the salient and 1½ feet at the rear, so that its plane of defilade passes above the lodgment of the cavalier. The covered-way is 10 yards wide, and has four traverses. This system possesses many advantages, with but few serious faults. The cavalier prevents the defenders from placing artillery at the salient of the ravelin, where its presence is so important, and the reduit of the ravelin has no room for guns. See *Fortification.*

DUKE.—A term applied originally to any military leader. Gibbon informs us that the title came first into use when Constantine separated the civil and the military commands in the Provinces, which had been exercised in common by such men as Agricola. From that time forth, the Military Governors of Provinces were either Counts or Dukes. But these titles originally stood to each other in an opposite relation to that which they afterwards assumed. "It should be recollected," says Gibbon, "that the second of these appellations—that of Duke—is only a corruption of the Latin word which was indiscriminately applied to any Military Chief. All Provincial Generals were therefore *Dukes*, but no more than ten among them were dignified with the rank of *Counts*, or Companions, a title of honor, or rather of favor, which had been recently invented in the Court of Constantine." "A gold belt," continues Gibbon, "was the ensign which distinguished the office of the Counts and Dukes; and, besides their pay, they received a liberal allowance, sufficient to maintain 190 servants and 158 horses. They were strictly prohibited from interfering in any matter which related to the administration of justice or the revenue; and the command which they exercised over the troops of their department was independent of the authority of the Magistrates." When the Goths, and Franks, and other barbarians successfully invaded the Provinces of the Empire, they preserved the titles of Count and Duke, if they had not already borrowed them from the Romans. But amongst races who owed their supremacy to the sword no dignity could prevail over that of the Commander of an Army; and the Dukes, as Military Chiefs, acquired a marked pre-eminence over the Counts, whose lofty functions under the Empire had been partly of a civil and partly of a military nature. The only exception under the first Merovingians was in the case of the Count of the Palace. In the hierarchy observed by the Franks and other Teutonic races, the ordinary Count became the Lieutenant of the Duke, and the government of the latter extended to several Provinces; whereas that of the former was confined to one Province, or even to a single locality. The power of the Dukes grew so rapidly, in consequence of the dissensions of the Merovingians, that, towards the end of the sixth century (582), they arrogated to themselves the right to dispose of the Crown. Amongst the causes which tended to raise the power of the Dukes was the immense wealth which had been acquired by the great provincial families. The Chiefs who had attached themselves to the fortunes of Clovis had been richly endowed with conquered lands. After the close of the seventh century they overshadowed the Crown, and the title of Prince and Chief (*Chef*) began to be attributed to them. It has been said that the *Ducs-maires* of the Palace sometimes assumed the title of Archduke. Under the Second Dynasty the title of Duke retained all its dignity and importance, and it was to the successive invasions of local upon central power that feudality owed its origin.

DUKE OF YORK'S SCHOOL.—The popular designation for the *Royal Military Asylum* at Chelsea. In the French army there have long been *Enfans de Troupe* borne on the books of each company or battalion of soldiers; that is, children of deceased soldiers, unprovided with other homes. In England no such system prevails. The late Duke of York, in the year 1801, used his influence to obtain the formation of a Soldiers' Orphan Asylum. Accommodation was obtained at Chelsea; and in 1803 schools were opened for 700 boys and 300 girls, children of deceased soldiers. The Institution has been kept up ever since for the boys, of whom 500 are now maintained, but was a failure as to the girls. The boys are wholly supported as well as educated. They are not bound to serve the State after they leave the Asylum; but most of them nevertheless enter the army. A soldier's son has not a *right* of admission; a selection is made according as vacancies may occur. When the boys leave the School, those who do not enter the army are apprenticed to trades. The Asylum is under a Board of Commissioners, who make the necessary rules and regulations. The chief officers are the Commandant, Secretary, Quartermaster, Head-master, Chaplain, Surgeon, and Dispenser. The expenses are defrayed by an annual Parliamentary grant, included in the army estimates. No provision is now made by the State for the *daughters* of deceased soldiers. The girls admitted into the Asylum in the early years of its history brought discredit to it by their after-life; and this part of the system was abandoned. There is only a Royal Patriotic Fund Asylum on Wandsworth Common, unaided by the State, for soldiers' orphan daughters; it originated during the Crimean War.

DUKIGI-BACHI.—The Second Officer in the Turkish artillery, who commands the Topelas, or gunners and founders.

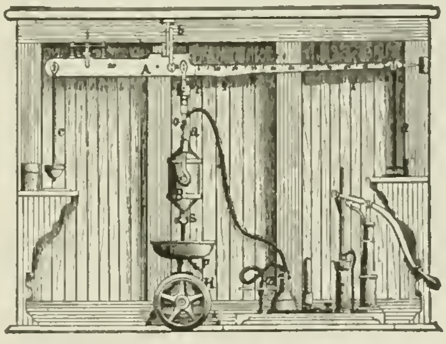
DULEDGE.—A peg of wood which joins the ends of the felloes forming the circle of the wheel of a gun-carriage; the joint is strengthened on the outside of the wheel by a strong plate of iron, called the *duledge-plate*.

DUMMY FRICTION-TUBE.—A non-ignitible tube which is used for drill purposes. It consists of a steel prong, fork, and lanyard; the prong is entered in the fork, which is inserted in the vent and pulled through by the same motion which fires the service friction-tube. Since the original pattern was approved of it has been found that the prongs are liable to fracture the "eye." In the present pattern the prong is made stronger, and the split of the spring is carried through its neck, instead of the latter being solid.

DUMPY LEVEL.—A leveling instrument for short distances. It has a short telescope with a very large field, and the compass is fixed underneath.

DUNDAS GUNS.—Smooth-bore guns of somewhat similar form to those of Mr. Monk's, and introduced into the English service some years ago by Colonel Dundas, R.A. They are not so conical, having a greater thickness of metal in the first and second reinforces. His 68-pdr. (95 cwt.) is used both as a land- and sea-service gun, and his 32-pdr. of 58 cwt. has been largely used in the Navy. There are other guns still in the service bearing his name, which are used for land or sea purposes.

DUPONT DE NEMOURS DENSIMETER.—A mercury densimeter, adapted, by its construction, to the reception of large grains, and having capacity for five pounds of powder, which, for convenience, is the weight of sample always employed. It differs, however, from the small densimeter in ordinary use by a combination of the different parts, such that the reservoir for containing the powder and mercury to be weighed, and the balance by means of which the weighings are made, are assembled together in one instrument. The balance also is so adapted to its special purpose as to simplify considerably the subsequent process of calculation. A great saving of labor and time is gained by this form of the instrument, and the occurrence of breaks and leaks, so frequent in the smaller ones, is in great measure avoided. Again, from the much larger sample of powder employed, a fair representative result of the specific gravity of the entire lot is more likely to be secured.



Dupont De Nemours Instrument.

To describe more particularly, the instrument consists of three principal parts, to wit: A beam-scale, A, a reservoir, B, to contain the powder and mercury to be weighed, and a bowl, C, to contain mercury alone. In connection therewith, an air-pump is employed, the cylinder of which has communication with the interior of the reservoir through a rubber tube leading from the nozzle of the pump to the glass tube, *a*, at the top of the reservoir. The balance is suspended from a hook, *b*, firmly secured to the roof of the housing, and its axis of suspension is a knife-edge lying in the same plane with the axes of suspension of the rods *c* and *d* and of the reservoir B. Platforms are attached to the suspension-rods *c* and *d*, on which to place the weights. The latter consist of pounds, tenths of a pound, and five-hundredths of a pound, marked in reference to the weights they will balance in the reservoir, and of a large unmarked weight, W, termed the "counterpoise." This counterpoise has a cavity bored in it lengthwise; its weight is about eight pounds. The long arm of the beam is also graduated, and by means of "riders," or sliding weights, the weighings can be made to hundredths and thousandths of a pound; the graduated edge of the beam is in the same plane with the knife-edges. There are two counterpoises admitting of movement on screw-spindles passing through them, in directions that are respectively parallel and perpendicular to the beam. The former is used to adjust the arms to the same weight, the latter to regulate the sensibility of the beam. In connection with one counterpoise a light wire is sometimes used along the beam to facilitate the adjustment of the arms. The beam and its appurtenances proper are of brass. The reservoir B is of cast-iron and swings on trunnions in a yoke. It also admits of a horizontal angular movement about a vertical pivot connecting the yoke with a suspension-stirrup. A screw-cap, fitted with a leather washer, covers the mouth of the reservoir, and when removed, for the purpose of introducing powder, is attached to a hook on the outside of the yoke, so as to be included in the weighing. The mercury is admitted or withdrawn through the stop-cock *s*. The conical ends of the reservoir are cast in separate pieces and are afterwards screwed on to the cylinder, the joints being well leaded. Careful workmanship is requisite to prevent the formation of a ledge or recess at these joints, which might serve to retain sufficient portions of the mercury to affect the accuracy of the subsequent weighings. The diaphragms of wire and of leather usually employed to cover respectively the upper and lower apertures of the reservoir are not required in this instrument. The capacity of the reservoir is about seventy-eight pounds of mercury, or forty pounds of mercury and five pounds of powder. The mouth is 2¼ inches in diameter, and the sample of powder fills the reservoir to about the top of the cylindrical portion. The weight of the reservoir is twenty and a half pounds. The bowl C is of cast-iron, and by means of the crank H can be raised or lowered vertically. An outlet-pipe, *p*, at the bottom of the bowl, and furnished with a stop-cock, permits of the discharge of the mercury when desired. The air-pump is one in which, the cylinder remaining stationary, the oscillation takes place in the connecting-rod, which communicates the motion of the handle to the piston-rod.

To use the instrument, the beam is first accurately balanced by means of a counterpoise, when the bowl filled with mercury is run up till the nozzle of the reservoir is well immersed below the surface. The large counterpoise W is then placed on the platform suspended from the shorter arm, the rubber hose slipped over the top of the glass tube of the reservoir, the air exhausted by means of the pump, and the stop-cock *s* opened to admit the mercury. The pumping is continued during the ingress of the mercury, and when the latter has risen to a fixed mark, indicated on the glass tube, the stop-cock is closed and the rubber hose removed. Usually it is necessary to run off a little of the mercury and lower its upper surface to the fixed mark. The balance of the beam is now restored by dropping fine shot into the cavity of the counterpoise W, the weight of the latter being slightly less than the weight of the filled reservoir; this done, the stop-cock *s* is opened and the reservoir emptied. The counterpoise W is then replaced by the 5-pound weight, the screw-cap removed and hooked to the yoke, and a sufficient quantity of the powder to be tested introduced into the reservoir to balance the 5-pound weight. The screw-cap is then replaced, the counterpoise W added to the 5-pound weight, and the reservoir filled with mercury by means of the air-pump to the same height as before. The equipoise is now restored (the rubber tube having been removed) by placing weights on the platform suspended from the longer arm of the beam, and in addition by the "riders" on the beam if necessary. The sum of these weights is the weight of the mercury displaced by the powder, or of a volume of mercury equal to the volume of the powder, and the specific gravity of the latter results from the well-established principle that the specific gravities of two substances are proportional to the weights of equal volumes of those substances. Denote the sum of the weights on the longer arm by W′, the weight of the powder by *w*, and the specific gravity of the mercury at the temperature of the time of observation by D, and we shall have for the specific gravity of the powder, denoted by *d*;

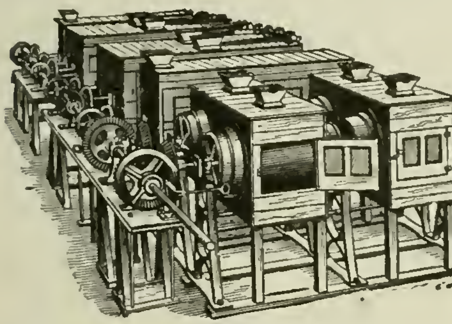
$$d = D\frac{w}{W'}.$$

In the use of this form of the densimeter the weighings not only are rapidly and accurately made, but, it is to be observed, the actual weights required for the computation are obtained directly by a discriminative process peculiar to the balance. To simplify further, the weights for the longer arm are marked double their actual value in reference to the reservoir, so that in the computation the specific gravity is obtained by setting the decimal-point in the value of D one place further to the right, and dividing by the value of W′, as indicated on the weights, the effect being the same as multiplying by 2 both terms of the fraction $\frac{w}{W'}$. See *Densimeter, Inspection of Powder*, and *Mercury Densimeter*.

DURER SYSTEM OF FORTIFICATION.—This fortification consists of a wall, flanked by circular towers or bastions, and a ditch 200 feet wide. The towers are of very different tracings, usually 70 feet high and command the enceinte. The wall of the enceinte is double; the top is provided with loop-holes and is covered with a roof. The great dimensions, together with the immense cost of masonry, render this plan practicably useless. See *Fortification*.

DUSACK.—A Bohemian saber of a peculiar shape, without a handle or a hilt. It was wielded with a gauntlet protecting the hand.

DUSTING-REELS.—The large-grain powder, removed from the granulating-house, is called "foul grain," owing to its containing a large percentage of dust that has been produced under the granulating process, for, although a great deal of it is removed from the powder by means of the lower long sixteen-mesh screen attached to the granulating-machine, still the powder contains a considerable quantity, and the object of passing it through the dusting-reels is to entirely remove what remains, and at the same time to rub down the rough, uneven surfaces of the grain, and thus prevent its becoming dusty again through moving it about in course of transport, for dust in gunpowder is very injurious, as it absorbs moisture from the atmosphere very readily, and this soon affects the whole mass. The dust is removed from large-grain powder by means of horizontal reels: these are cylindrical wooden skeletons, supported upon a central shaft by radial arms, the periphery of the cylinder being covered with canvas having twenty-four meshes per inch. The reel is about 8 feet long by 2 feet 6 inches in diameter; the wooden skeleton is made in halves, so that it may be easily removed for recovering. The ends are closed by disks, secured upon the main central shaft, and one end is so constructed that it can be opened or drawn back for the purpose of unloading the reel. When about to be filled, the reel is turned round until the charging-door is directly under the feeding-hopper; into this latter three barrels of foul grain are emptied, and when it has all passed through the hopper, the door of the reel is closed and fastened, the reel set to work at from 40 to 42 revolutions per minute, and kept in motion for about half an hour; at the end of this time it will be found that the whole of the dust will have passed through the meshes of the canvas covering, and will be lying at the bottom of the outer woodwork casing in which the reel is inclosed, in order to prevent the dust spreading over the house. When a number of reels are used, they are all driven from one main shaft which receives its motion from the water-wheel or steam-engine, and each reel is provided with a separate clutch, so that any one may be stopped or set in motion without affecting the others. When the reel has run the requisite time, it is stopped and the one end lowered about 10 inches, the disk at the lower end is slackened back sufficiently to allow the powder to run out into barrels, which it will do when the reel is again set in motion; when quite empty, the disk is again screwed tightly up to the end, and the reel raised to its horizontal position ready for refilling. By this operation the dust is not only taken from the powder, but the grain—from being rolled over for such a time—has its rough surfaces rubbed off, and in the case of large-grain powder a sufficient gloss is imparted without its



Dusting-reels.

having to be passed through the glazing-barrels. The powder is now ready for the drying-stove. The fine-grain powder used for rifles or small-arms has a much larger proportion of dust in it than the large-grain powder, and is therefore dusted in what is termed a "slope-reel," which consists—as in other reels—of a skeleton frame of wood fixed by radial arms on a central shaft, and lies at an incline of 1¼ inch per foot; the covering of this frame is of very fine canvas having forty-four meshes per inch, and the reel in this case has no ends; it is also much smaller than the horizontal reel, being only 20 inches in diameter by 8 feet in length, and is driven at 38 revolutions per minute. The fine-grain powder, as it leaves the granulating-machine, is brought from the magazine and placed in the feeding-hopper, to which is fixed a loose spout for guiding the powder into the reel. Attached to the central shaft are three ribs or cams which—as the reel revolves—come in contact with and shake the loose guiding-spout, imparting to it 135 vibrations per minute, thereby effectually keeping it clear, the fine-grain powder at this stage being very apt to choke up the hopper and spout. As the powder passes through the reel when in motion it is collected in a tub placed for its reception at the lower end; from this it is emptied back again into the hopper, in order that it may be passed through the reel a second time, and this operation is sometimes performed a third time. The fine grain thus treated, being only about one minute in the reel, has had no gloss imparted to it; the glazing has, therefore, to be effected by passing it through a glazing-barrel before it is carried to the drying-stove. See *Gunpowder*.

DUST-SHOT.—The name usually applied to small shot when used for military purposes; strictly speaking, the term implies the smallest size of shot made.

DUTCH OVEN.—A *camp-oven* used for cooking by hot coals on the hearth. A mode yet common in the field, and unsurpassed in its results with skillful cooks. The oven stands in hot embers, and more of the same are piled on the dish shaped lid.

DUTY.—There is no word oftener used in military parlance than this. In the technical sense it refers to the various services necessary for the maintenance, discipline, and regulation of armies,—as *signal duty*, *staff duty*, *guard duty*, etc. Military duties are variously classed as *duties of detail*, which are those recurring and governed by a roster, such as guard, fatigue, etc.; *special duties*, which are determined by appointment, selection, or order; *extra duty*, continuous special duty of enlisted men, entitling them to pay; *daily duty*, short terms of special service for enlisted men. In a higher and broader sense duty is that which is due one's Country. It covers all the soldier's obligations, and forms his simplest and sublimest rule of action. What is termed the "tour of duty" is invariably from the senior downwards. An officer on one duty cannot be ordered for any other until he has completed the duty on which he is engaged. If an officer's turn for Picket, General Court-Martial, or Fatigue happens when he is upon any other duty, he is not obliged to make good these services when he is relieved, but his tour passes him; however, if an officer is on the Inlying Picket, he is liable to be relieved and placed on other duties. Officers cannot exchange their duties without permission of the Commanding Officer. A guard, detachment, or picket having once marched off the place of parade is reckoned to have performed a duty, though it may have been dismissed immediately afterwards. Officers, on all duties under arms, are to have their swords drawn, without waiting for any word of command for that purpose.

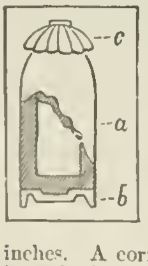
DUUMVIRS.—The officers among the Romans appointed for special services, such as Magistrates of Colonies and Towns, Constructors and Commanders of Fleets and Trains, and Municipal Censors. In the Eastern Empire the people elected for one year *duumviri ludorum*, who were to provide exhibitions of games at their own expense.

DWARF-PLATFORM.—A frame of wrought-iron from which heavy guns are fired when in open batteries. The original pattern is similar in general construction to the "common traversing" platform, and guns mounted upon this nature of platform can fire through ordinary embrasures. By lengthening the legs of a platform of this kind the gun could be fired over a parapet, if required. The ordinary garrison-carriage is used with it, but has blocks instead of axletrees upon which it rests, the part of the block between the cheeks being deeper, and passing between them, so as to keep the carriage in its place. In front of each bracket there is a pair of check-plates, in which a gun-metal truck works, which comes into play when the rear of the carriage is hoisted up by the truck-levers. The carriage is run up by means of tackles. Dwarf-platforms were made to traverse on a pivot, but "raised racers" have been substituted, the platform resting on hollow solid trucks which run upon the racer. Since the introduction of heavy rifled artillery a change of pattern has taken place not only in this nature of platform, but in the carriage adapted to it, which is of the ordinary *single* or *double plate pattern*, both of which are made of wrought-iron. Casemate carriages and platforms are similarly constructed, and the platforms of each only differ in the height they are raised from the ground; the casemate-platform being low for use in casemates, and the dwarf-platform high for open batteries.

DYER POINTING-APPARATUS.—This method of pointing, devised by Lieutenant A. B. Dyer, United States Army, is especially adapted for use with mortars mounted on center-pintle carriages; it is also readily adapted for use with mortars mounted on ordinary and temporary platforms. Practically it is independent of the distance from the crest of the parapet to the platform. The method is as follows: Find the point where the vertical plane containing the directrix of the platform cuts the interior crest of the parapet. At this point establish a level plate containing an arc graduated both ways from the point where the vertical plane cuts it, the center being the point first established on the interior crest. An arm with two vertical sights revolves about this point as a center, and determines, by means of an indicator attached to the front of the arm, the angle made by any object with the vertical plane through the center, called the plane of the zeros. The mortar being given the same angle with the plane of the zeros, the plane of fire will practically intersect the object. To apply this method to a mortar mounted on a center-pintle carriage: On the rear of the platform, with the center of the pintle as a center, describe an arc. Find the point where the plane of the zeros cuts this arc, and mark the point *zero*. Divide the arc both ways from the point into degrees and parts of degrees. An indicator attached to the center of the rear transom (in the vertical plane containing the axis of the piece) will always mark the degrees to the right or left of the plane of the zeros.

A horizontal iron plate is permanently established on the parapet, the rear edge being on the crest and the center in the plane of the zeros. In order that the same instrument may be used at different places in a work, or be removed when not in use, a detachable plate containing the graduation and sights is adjusted to the permanent plate. By the use of this plate the index-arm will always be made to move in a horizontal plane. In the application of the method, place the plate containing the graduated arc on its bed, and level it by means of the tangent-screws; then place the arm to which the sights are attached on the plate. Traverse the chassis until the index on the rear transom indicates the required number of degrees as indicated by the instrument. If the arm of the instrument be to the right of the zero, traverse the chassis to the left; and *vice versa*. For the successful operation of this method with the center-pintle mortar-carriage, it is essential that the guides of the top-carriage should fit true and snug to the chassis-rails. See *Paddock Interpolator*.

DYER PROJECTILE.—A well-known form of projectile which is composed of a cast-iron body, *a*, shown in the cut, and a soft-metal expanding cup, *b*, attached to its base. The adhesion of the cup is effected by tinning the bottom of the projectile, and then casting the cup on to it. The cup is composed of an alloy of lead, tin, and copper in certain proportions. This projectile, as improved by Mr. Taylor at the Washington Arsenal, gives good results for even as large a caliber as 12 inches. A corrugated cap of tinned sheet-iron, *c*, is used with 3-inch projectiles to catch and direct that portion of the flame of the charge which escapes over the projectile on to the fuse to ignite it. See *Expanding Projectiles*.



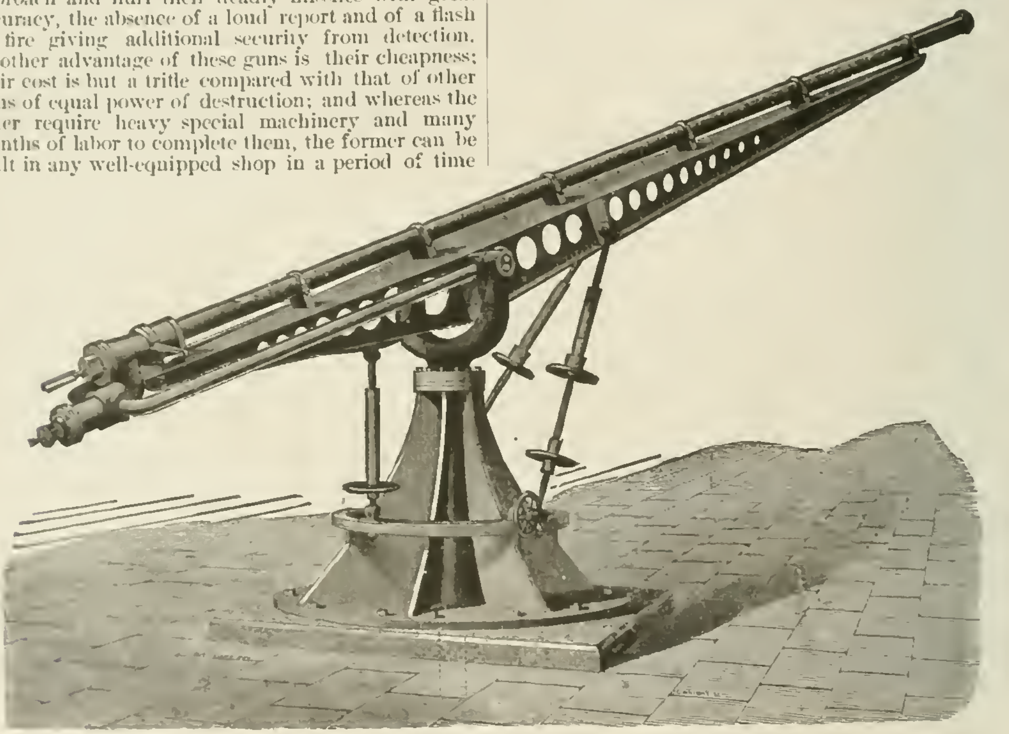
DYNAMICS.—That division of mechanics which contains the doctrine of the motion of bodies produced by forces. It is essentially a science of deduction from the laws of motion. The branches of dynamics capable of being treated in the present work will be found discussed under separate heads. We shall here confine ourselves to giving a view of the main branches and their correlation. I. The first branch of dynamics deals with the fundamental conceptions of the science, their names and definitions, such as velocity and the different kinds of motion, and accelerated motion; force, accelerating force, and moving force. Under this branch also falls the composition of motions. II. The second main branch of dynamics treats of the motion, free or constrained, of points. Here two problems are solved in each case—i.e., whether the motion be free or constrained—viz., a direct and an inverse problem; as, for example: 1. To determine the path of a point when the forces are given which act upon it; 2. To determine the forces or force acting on a point when its path is given. This division of dynamical problems into direct and inverse obtains in all the branches. It may be mentioned that it was by solving the inverse problem that Newton and Huygens effected their greatest glories in connection with dynamics. The method of treating the case of a free point now generally employed is due to Euler. See, under this head, CENTRAL FORCES, FALLING BODIES, and PROJECTILES. III. The third main branch of dynamics is concerned with the motion of a rigid system of points, or of a solid body. Few of the sub-branches of this part of dynamics are capable of exposition in this work, but see CENTER OF GYRATION, CENTER OF OSCILLATION, CENTER OF PERCUSSION, and PENDULUM. The honor belongs to D'Alembert of establishing a general method of treating problems in rigid dynamics. Previous to his time, each set of such problems was treated on some principle peculiarly applicable to itself. D'Alembert invented one (which goes by his name) applicable to all such problems. IV. The fourth main branch of dynamics is concerned with motions of rotation. A system of rigid points may be subject to two independent kinds of motion. It may suffer a motion of *translation* in space, or a motion of *rotation* about some point or axis within itself, or it may suffer at once a motion of translation and a rotatory motion. These may clearly be treated conjointly or independently; they are now uniformly treated independently, by investigating (1) the velocity and direction of the center of gravity of the system, and (2) the direction at each instant of the spontaneous axis of rotation passing through the center of gravity, and the velocity of the rotation of the system round that axis. To effect the second task, Poinsot proposed his theory of couples. For the conservation of living forces (*virium vivarum*), and the principle of least action, see FORCES. See also MOMENT. Dynamics is used by some recent writers with a wider signification, as denoting the science which investigates the action of force (1) in compelling rest or preventing change of motion, and (2) in producing or changing motion; the former branch being called *statics*, and the latter *kinetics*.

DYNAMIC UNITS.—Units for measuring forces and their effects. It is an axiom of mechanics that if a body at rest be impressed by a force and meet no resistance other than its own inertia, it will move in a straight line with a velocity which varies as the force; e.g., twice the force will develop twice the velocity. Also, if the mass of the body be increased, the force must be increased in like ratio to maintain the same velocity; e.g., double the mass will require double the force; or, if the force remain unchanged, double the mass will move with half the velocity. Combining the two statements, we find that the velocity varies directly as the force and inversely as the mass; velocity equals force divided by mass, or $v = \frac{F}{M}$. From this we have $F = Mv$. The unit of force is that force which will impart a unit of velocity to a unit of mass; that is, which will cause a unit of mass to move through a unit of space in a unit of time. If the force considered be that of gravitation, whose action in the same place is practically uniform, and if we remember that the measure of the force of gravitation in a body is the weight of the body, we have $W = Mv$. But if the mass be submitted to the force of gravitation, that is, if it be permitted to fall freely in a vacuum, it traverses a space of 32.16 feet in one second, at New York, approximately. We have then, by experiment, a value for v which makes our equation $W = M \times 32.16$, whence $M = W \div 32.16$. The English or American unit of force is one pound avoirdupois; and the corresponding unit of mass is 1 lb. divided by 32.16. The *unit of work* is the force which will raise a unit of weight through a unit of space. The two items are indicated in the name foot-pound, which by analogy might be exchanged in proper ratio for inch-ounce, ton-mile, etc. The corresponding French unit of work is the kilogram-meter. More generally the foot-pound is the work of a unit of force acting through a unit of space. The horse-power is an arbitrary unit, being the force required to perform 33,000 units of work in one minute. It may be called the *unit of the rate of working*. The French *cheval à vapeur* is 75 kilogram-meters per second, and is equal to 32,550 foot-pounds per minute, or a little less than our horse-power. The theoretical horse-power is merely a conventional quantity, the actual work of horses averaging about 17,000 and rarely exceeding 22,000 foot-pounds per minute.

DYNAMITE.—Nitro-glycerine is the most powerful explosive agent now known, but, uncombined with absorbents, is dangerous in manipulation, and unfit for long storage, from liability to spontaneous decomposition. This led to experiments being made with absorbents, and to the invention and introduction in 1866 of "dynamite" or "giant powder." Dynamite consists of 75 per cent of nitro-glycerine and 25 per cent of a light silicious earth. The best variety of the latter is known as "kieselguhr," an infusorial earth found in Hanover and in other countries; it is a fine white powder, capable of absorbing from two to three times its weight of nitro-glycerine without becoming pasty. The explosive properties of dynamite are those of the nitro-glycerine it contains. It is less liable to accidental detonation from shocks, and to spontaneous combustion, than nitro-glycerine; freezes at the same temperature, and if then in the state of loose powder does not lose the property of exploding from the action of the usual fuse, though it will act with less violence; frozen solid it cannot be fired. If saturated with water it retains very nearly its full explosive power, but requires a much more powerful primer to develop it; ignited in small quantities by a flame and unconfined, it burns quietly. It is not sensitive to friction or moderate percussion. Its explosive force is not quite so instantaneous as that of pure nitro-glycerine. The process of manufacture is simply to mix the nitro-glycerine with the dry, fine powder in a leaden vessel with wooden spatulas; when completed it has a brown color, resembling moist brown sugar. Dynamite is generally put up in paper cartridges, which are ignited by a fulminating-fuse. It is extensively employed in blasting, and has been adopted in the Torpedo Service of the United States army. By combining the ingredients of dynamite in judicious percentages a certain control can be exerted over the quickness of its action, and a classification similar to that of the different grades of gunpowder, but much more restricted in range, may be made. Various attempts to improve upon dynamite, by replacing its inert base with different materials, have produced such compounds as *glyoxiline, lithofracteur*, and *dualine;* none of these are improvements, as the bulk is increased in them in a higher ratio than the power. Glyoxiline is a mixture of gun-cotton pulp and potassium nitrate, saturated with nitro-glycerine; lithofracteur is composed of nitro-glycerine, silica, and mineral bodies; and dualine is a compound of nitro-glycerine with clean sawdust and potassium nitrate. The detonating force of the preparations containing nitro-glycerine in varying amounts is generally admitted to be due alone to the nitro-glycerine contained in them; yet it is far from true that their economic value as explosives can be thus compared. The element of time which determines whether a blow or a push is delivered is of primary importance, and upon it should be based the selection of the compound to be used. In flint-rock nothing exceeds the action of liquid nitro-glycerine; but for common earth gunpowder is far more effective. See *Dualine, Explosive Agents*, and *Nitro-glycerine*.

DYNAMITE-GUN.—Ever since the introduction of what are known as high explosives, some means have been sought by which they could be thrown from guns with accuracy, and a sufficient distance to render their use practicable for purposes of war. The nature of dynamite and nitro-glycerine precludes their being loaded in cannon and fired in the ordinary manner by gunpowder, which has been proved conclusively in many ways, and has almost invariably led to the destruction of the gun in which the attempt was made. Thus far the application of high explosives has been principally confined to torpedoes. These latter in their various forms have attracted a great deal of attention, the different Governments spending large sums in maintaining and perfecting them. The various systems, while undoubtedly advantageous in a great many cases, are nevertheless restricted in their very nature, and this has stimulated investigators to devise means by which high explosives, such as dynamite, could be projected "overland" with safety. It is now claimed that this knotty problem has been fairly solved, and, strange to say, by a medium long since applied to the propulsion of projectiles, but the use of which has never yet been attended with sufficient success to warrant its permanent introduction. We refer to the use of air and steam under high tension, and in the new dynamite-gun compressed air of very high tension is used as the propelling power. This new gun is the joint invention of a number of gentlemen under the leadership of Mr. H. D. Winsor, of New York, and one form of it is now undergoing a series of tests ordered by the United States Government, which are being made under the special direction of Lieutenant E. L. Zalinski. A description of the apparatus will be interesting as illustrating a new departure in appliances of war in a direction which has heretofore proved unsuccessful. The 4-inch gun now building at the Delamater Iron Works, and embodying the latest improvements, is represented on page 522. It will be seen to consist of a tube 40 feet in length and ¼ inch thick, mounted upon a light steel girder. The latter is trunnioned and is pivoted on a cast-iron base, thus enabling it to be swung into any desired position and range. To assist in the latter operation guys are placed on either side of the base, and their length can be altered and fixed by turning the hand-wheels shown. Compressed air is introduced to the gun from below and passes up through the center of the base, the pipe connecting with one of the trunnions (which are hollow); it is thence introduced into the pipe shown at the side of the gun leading into the valve. This valve is a continuation of the breech of the gun, to which it is connected by the short passage shown. An important feature of the system is the projectile, or dart, and upon which the success of the undertaking greatly depends. It consists essentially of two parts; and while several different modifications have been tried, the principal features are alike in all of them. The forward part of the dart consists of a thin brass tube into which the charge of dynamite is inserted. At the rear the tube is closed by a wooden plug, which flares out toward the rear until its diameter equals that of the bore of the gun. The forward end of the brass tube shows a mass of some soft material, into which is inserted a pin firmly held in place, the end being closed by a conical metal cap. Provision has also been made to allow a certain amount of air to act as a cushion for the dynamite cartridge, thus lessening the shock due to a sudden discharge. It is therefore claimed that, under ordinary circumstances, there is little danger of the charge exploding, since the pin cannot reach it and ignite the fulminate at its end; but when thrown from the gun, the impact against a body will displace the soft material and drive the pin home, causing an explosion. Another feature of the projectile is the power which it possesses to correct, to a certain extent, the deflection due to a side wind. It will be noted that with the present construction the center of gravity of the dart is some distance forward of its center of figure. A side wind would, therefore, acting upon the lighter rear part, have the tendency to deflect it so as to turn the head of the dart into the wind, which action would, in a measure, tend to keep it in the line of its trajectory. The firing of the gun, if the expression may be used, is accomplished in the following manner: The dart is inserted in the breech, and a gas-check placed in position; a lever then being moved, the valve is opened, and the air-pressure admitted. This method of discharge will, it is thought, obviate the danger of shock, which had heretofore proved a stumbling-block to success, and in addition the valve-controlling mechanism is automatically arranged to admit the air gently at first, to overcome the inertia of the projectile, following with full pressure, and finally closing at the proper time, as the dart leaves the gun.

In this gun we note a great step in advance, and are forced to believe that the day is not far distant when it will work great changes in warfare, both naval and military. As an auxiliary to coast and harbor defenses such a gun would be of great value; and placed on board small launches the latter might approach and hurl their deadly missiles with great accuracy, the absence of a loud report and of a flash of fire giving additional security from detection. Another advantage of these guns is their cheapness; their cost is but a trifle compared with that of other guns of equal power of destruction; and whereas the latter require heavy special machinery and many months of labor to complete them, the former can be built in any well-equipped shop in a period of time not exceeding a month, if need be. Nor does it seem unlikely that the system may be applicable to the use of armies in the field when engaged in siege-operations. Experiments made thus far have shown that the apparatus can be depended upon for a fair degree of accuracy and rapidity in firing. As regards the range attainable, the 2-inch gun now being tested has attained 1¼ miles with a pressure of 420 pounds to the square inch. In the 4- and 6-inch guns which are now in course of construction it is intended to use pressures of 2000 pounds and over, by the use of which a range of three miles is hoped to be attained. While this new application of compressed air to the propulsion of dynamite is no doubt valuable, it is hardly to be expected that it will, with its limited range, ever take the place of heavy ordnance—a point which its inventors wisely do not claim; but if it shall transpire that the gun is, in itself, a practical success for much shorter distances, it will be of the greatest importance and a valuable accession to our present appliances of war. Especially will this be so in the United States, where the coast-line is so extended, where good harbors are numerous, and appropriations for harbor defense so meager and so often *nil*, and where in fancied security the defenseless shores are exposed to hostile invasion; under these circumstances does it become necessary to substitute cunning for might, and rely upon some such means as torpedoes and dynamite-guns for protection from unexpected and uninvited approach.

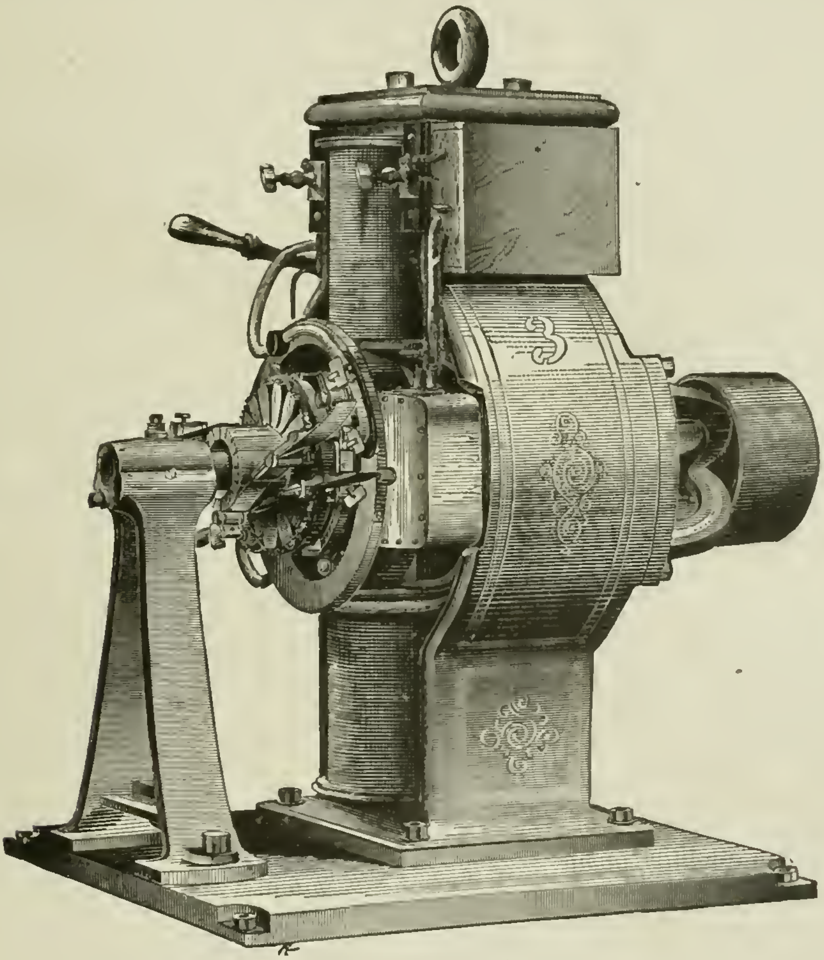


Dynamite-gun.

DYNAMO-ELECTRIC IGNITER.—This igniter, as at present employed, consists of a hard wooden plug, half an inch in length and about $\frac{3}{16}$ of an inch in diameter, having a score cut about its center, and a longitudinal groove on either side (the bottoms of which are $\frac{3}{16}$ of an inch apart) for the reception of the copper wires. There are also two cotton-covered (braided) copper wires, which are twisted together for about an inch, and are stripped of their insulation almost to the twist. These uncovered parts are pressed firmly into the grooves in the sides of the plug, and cut off so that they project about ¼ of an inch above the plug; the ends of the wires are now split with a very fine saw, and the distance between the ends carefully adjusted to $\frac{3}{16}$ of an inch, after which platinum wire No. 40 is stretched between them to form the bridge, and securely soldered to the ends of the split wires. A wisp of gun-cotton, is next wrapped around the platinum wire, and the ends of the copper wire pinched together sufficiently to take all strain off the platinum wire. The plug is now inserted in a hollow wooden case, two inches long, countersinking it about an eighth of an inch. The resistance of the wire is next found, and marked upon the case; it should fall between .40 and .45 ohm. The upper part of the case is filled with rifle-powder, the top being closed with a disk of cork, over which is poured some water-proof composition, and the whole is properly coated with shellac to render it water-proof.

The dynamo-electric fuse is made by inclosing one of the dynamo-electric igniters in a stout paper case about six inches in length, which is filled with rifle-powder to give more flame and consequently a more perfect ignition of the charge than can be obtained by the igniter alone. The ends of the case are properly closed, a wooden plug, with grooves cut in the sides for the wires, being used for the bottom, and a disk of cork for the top, which is coated with collodion, and seals the cork firmly into the case. The fuse is given two coats of brown shellac. The ends of the wires below the plug are stripped of their covering and brightened. See *Fuse*.

DYNAMO-ELECTRIC MACHINE. — All known methods of generating electricity can produce light of greater or less steadiness and brilliancy. Cavallo, in his treatise published a century ago, refers to a wires entering at binding-screws. The rods slide in the heads of glass pillars. The wires from the battery being connected, the points are made to touch, and are then withdrawn a line or two, when a dazzling light appears, approaching the light of the sun in purity and splendor. Its intensity prevents the naked eye from examining its form, but this may be ascertained by projecting the images of the points on a screen, when it is no longer painful to the eyes. The light is partly due to the incandescence of the tips of the carbon, and partly to an arch of incandescent particles extending from the one to the other. The positive pole is brightest and hottest, as may be proved by intercepting the current, when the positive



Dynamo-electric Machine.

light, different from the electric spark, produced by frictional electricity. A needle or wire presented to an insulated person, at the distance of about one inch from his body, while he is actually rubbing the tube, will, he says, exhibit a lucid pencil of rays, seemingly issuing from the point and diverging towards the person; and other like experiments are described by Watson and other early writers. Light from battery electricity was first discovered by Sir Humphry Davy at the Royal Institution, London, in 1810, when, on the continuity of a current from 2000 cells being broken, a brilliant light was seen. To this the name of the "voltaic arc" was given, and the points where the current was broken were termed "electrodes." An early and simple arrangement for producing this light consisted of two carbon points fixed into hollow brass rods, which are connected with the battery by

pole continues red for some time after the negative pole has become dark. During the maintenance of the light a visible change takes place in the condition of the poles, and the positive pole becomes blunt by the loss of particles of carbon. The wasting away of the poles renders the distance between them too wide to allow of the passage of the current, and the light is thus suddenly extinguished, until again renewed by contact and removal. The heat of the *voltaic arc* is very intense. Quartz, the sapphire, magnesia, lime, and other substances equally refractory are forced by it into a state of fusion. The diamond when placed in it becomes white hot, swells up, fuses, and is reduced to a black mass resembling coke. The electric light can be produced in a vacuum, and below the surface of water, oils, and other non-conducting liquids, and is thus quite independent of the action of the air. In 1820 Oersted proved the identity of electricity and magnetism; but it remained for Faraday, in 1831, by his great discovery of induced currents, to render practicable the application of electricity to the production of a good artificial light. It was not, however, until 1853 that the magneto-electric machine was actually applied to the purpose; and in 1857 the first great practical trial took place, when Faraday had the satisfaction of seeing his conception carried into effect. This trial of Holmes's machine resulted in the electric light being then introduced into the South Foreland light-house, December 8, 1858, and later the light was adopted at Dungeness. The French Government adopted the light for two light-houses near Havre in 1863.

The problems to be solved in the production of electric light are to supply a constant and equal current (which the battery-electricity does not yield), and to provide a form of electrode which will not cause the light to blink or go out by wasting away. The first generating-machines were "magneto-electric," revolving coils in front of permanent steel magnets (or contrariwise, revolving magnets in front of the coils), but some later machines are "dynamo-electric," based on a discovery simultaneously made by Werner Siemens, Varley, and Wheatstone, that by revolving coils in front of soft iron electro-magnets the residual magnetism in the iron would gradually be augmented, dynamic force being thus converted into electricity. The currents created by machines of either sort are alternate; but where, as in the case of some forms of lamp, the current must proceed in one direction, the alternate currents are made continuous by the use of a commutator. There are a large number of machines in use for generating currents for producing the electric light. The dynamo-electric machines of the Excelsior Electric Company of New York, represented on page 523, are believed to be superior to all others for the illumination of large areas by the electric arc-light. As the dynamo requires less power than others, the machines can be run where it would be found impracticable to use others, and a special point in their favor is that they require no more attention than any ordinary piece of machinery. Owing to the peculiar construction of these machines, a very powerful magnetic field is obtained with a comparatively small number of convolutions of copper wire around the inducing magnet. The inductor is sectional, making it possible to equip it with wire helices after they have been completely finished on a mandrel and their insulation thoroughly tested. The commutator-bars are fastened to a stone plate and are separated from each other by air spaces. If kept clean, an accidental short-circuiting is impossible. The current from the machine is sent through the lamps or withdrawn from them by means of a switch, which does not break the circuit suddenly and thereby give rise to a dangerous extra current; but it merely deprives the magnetic helices of the exciting current, lowering the power of the magnetic field down to zero and short-circuiting the inductor-helices.

The regulation of the lamp is effected in the following manner: The movement of the upper carbon-holder is controlled by a train of wheels, carried on a lever which swings on a fulcrum. The escapement is arrested when the lever is swung so as to lift the carbons apart, and set free when they are caused to approach each other. The end of the lever carries a U-shaped iron core, whose straight parts are surrounded by fine wire helices fastened to the floor of the lamp-case, and has attached to it a retractile spring capable of adjustment. The iron core of a coarse wire helix is resting on the same lever, and depresses it, owing to its weight overcoming the pull of the spring. This helix forms part of the light-circuit, and raises its core as soon as the current is sent through the lamp, thereby allowing the spring to lift the carbons apart by means of the lever and gear-train. The fine wire helix is connected with the positive and negative terminals, and forms a shunt to the light-circuit. When the carbons burn with a small separation the resistance in the light-circuit is low, and but a small portion of the current traverses the shunt-helix; but as the carbon ends are consumed by the current, the separation increases, and the current has more resistance to overcome in the arc. The shunt will receive a constantly increasing amount of current, and will draw its core and the lever attached to it down till the escapement is released from its detent, and the wheel-train allowed to move sufficiently to let the carbons approach. As soon as the proper length of arc has been re-established, the shunt-helix—the current passing through it being diminished—allows its core to be lifted a little by the retractile spring, and the escapement engages again its detent. The core of the main helix remains firmly drawn up by the strong suction of the helix in the light-circuit, aided by the attraction of an iron armature upon the helix, until the current is cut off and the light thereby extinguished. If a number of lamps are burning in series, the failure of one to feed its carbon down would soon lead to the extinction of all. To prevent such an occurrence, each lamp is provided with an automatic cut-out, which furnishes another path for the current when the distance between the carbons becomes abnormally great. This device consists of a light iron plate hung in pivots near the shunt-helices, and which is forced towards them by the combined attraction of the helix itself and its core when an undue amount of current flows through the shunt. In swinging over it makes contact between the two ends of the helix in the light-circuit, depriving it of the current, and thereby causing its core to drop. But it has also put a lever attached to it in such a position that the falling core can force it against a contact, completing a short circuit between the terminals of the lamp. The hand-switch allows the attendant to re-carbon any lamp of a series while the others are burning. See *Electric Light.*

DYNAMOMETER.—A device for measuring the force which does work in overcoming resistance and producing motion. The foot-pound, as a unit of work, has for its factors the force acting and the distance through which it acts. The larger unit, the horse-power, besides these factors has a third, the time during which the force is exerted. Hence, in getting the data from which the work of a machine is to be calculated, we are to observe the force, the distance, and the time required to accomplish a certain result. Strictly speaking, the dynamometer indicates the first of these items, but it may be so arranged as to show both the others. Dynamometers are designed to indicate the force of *traction*, of *thrust*, or of *rotation*. A traction-dynamometer may be interposed, for example, between a team of horses and a reaper or a plow, to measure the force exerted by the horses in drawing the machine. It is usually some sort of spring balance, fitted with an index and a scale; the figures on the scale show the number of pounds required to bring the index to the corresponding points, if the instrument were hung up and weights suspended by it. A dynamometer for thrust is often connected with the screw-shaft of a steamship, to measure the force with which the screw is driving the vessel through the water. Rotary dynamometers measure the force of a mill-shaft, either by showing what force is required to hold the shaft in check, by absorbing the motion, or what force the shaft transmits to other machinery. Nearly all forms of dynamometers are too complex to be described without the help of elaborate drawings and technical descriptions, for which the reader is referred to special works on mechanism. The use of the dynamometer in skillful hands has acquired great value in exchanging the rough and usually overestimated guesses of the efficiency of machines for the exact determination of their performance.

DYNASTY.—A line, race, series, or succession of princes of the same blood who have reigned in any particular country; as, the Dynasty of the Plantagenets, or Bourbons.

DYSODILE.—A yellow or grayish laminated bituminous mineral, often found with lignite. It burns vividly, and diffuses an odor of asafœtida.

E

EAGLE.—1. The eagle, as a military standard, was adopted by the Romans, and even by nations preceding them in history. The Persians in the time of Cyrus the Younger bore an eagle on a spear as a standard. The Romans for some time used the eagle, the wolf, the boar, the horse, and the minotaur for standards, but afterwards abandoned the last four and confined themselves to the first. The Roman eagle, sometimes of gold, but more frequently of silver, was about as large as a pigeon with extended wings, and was borne on the top of a spear, with a cross-bar or a shield to support it. Some of the eagles were represented as holding thunderbolts in their talons, and usually bore the name of the legion to which each respectively belonged. The eagle was sometimes made of steel, but rarely. In modern times France, Russia, Prussia, Austria, and the United States of America have all adopted the eagle as a national military symbol. The Austrian eagle is represented double-headed.—2. The eagle is used heraldically as an emblem of magnanimity and fortitude. It is variously represented, the best-known mode being displayed or spread out, either with two heads—as in the arms of the Austrian Empire, in which case it is popularly known as a spread eagle—or with one head, as in the arms of the German Empire.—3. The Order of the Black Eagle was founded by the Elector of Brandenburg on 17th January, 1701, the day of his coronation as King of Prussia. The number of knights, in addition to the princes of the royal family, was originally 30, but it is now unlimited. They must at their nomination be at least 30 years of age. They must prove their noble descent for four generations through both parents. A chapter is held twice a year. The insignia of the Order consist of an octagonal cross of blue enamel, and a black eagle displayed between each of the arms of the cross. The cross is suspended by a broad ribbon of orange-color across the left shoulder, and it is accompanied by an embroidered silver star, fastened on the left breast. The center of the star represents a black flying eagle, holding in one claw a laurel wreath, and in the other a thunderbolt, with the legend *Suum cuique*. Fifty ducats must be paid by every new member for the support of the orphan asylum at Königsberg, and he then receives gratis the costume and insignia of the Order. As the Black Eagle is the highest Order in Prussia, no member of it, with the exception of foreign princes and Knights of St. John, is permitted to wear any other order along with it; and as it is generally granted only to those who are expected to be about the person of the king, no one who holds it is permitted to travel from the Court more than 20 German miles without giving notice. Knights of the Black Eagle are likewise Knights of the Red Eagle, first class.—4. The Order of the Red Eagle was founded in 1734 by the Markgraf George Frederick Charles, as a reorganization of the "Ordre de la Sincérité," which had been instituted in the beginning of the century by the hereditary Prince of Anspach and Baireuth. After passing through various modifications, the Order of the Red Eagle was raised in 1791 by Frederick William II. to the rank of the second order in the Monarchy, and it was then that the decoration of a white enameled Maltese cross, surmounted by a royal crown, with the Brandenburg eagle in the corner, was adopted. All the Knights of the Black Eagle were received into this new Order; and it was latterly decreed that only those who had been decorated with the Red Eagle, in the first instance could be received into the Black. In 1810 the Order of the Red Eagle was reorganized, and two more classes were added to it. In 1830 the second class was subdivided into two, one of which only was allowed to wear a square star.

Star of the Order of the Black Eagle.

EAR.—The name given to the lug or loop formerly cast on mortar-shells. The term was also usually applied to the "dolphin" on light guns. The object originally of casting mortar-shells with *ears* was to assist in placing the shell in the mortar, but lewis-holes are now adopted for that purpose.

EAR-BED.—In gun-carriages, the front and hind *ear-beds* connect the corresponding ends of the frame sides, between which latter and parallel to them lie the summers.

EARL.—The early relation which subsisted between the Duke and the Count has been explained under the former title. In Europe, generally, it was not till the Count came to be recognized as a subordinate officer to the Duke, governing a district of the province committed to the latter, that the Earl assumed the position of the Governor of a County, by the name of which he was commonly known. The title of Duke, if it had ever existed, early disappeared in England, and was not revived till the time of Edward III. After the Norman Conquest the French term Count was substituted for Earl; but it held its place only for a very short time as the title of the officer, though it has continued ever since to give a name to the district over which he presided, and a title to his wife. William the Conqueror, after the Battle of Hastings, recompensed his chief Captains by granting to them the lands and offices of the Saxon nobles; but by making the title of Earl hereditary he took, unintentionally perhaps, the first step towards changing it from a title of office to a title of dignity, and thus depriving it of substantial power. The form of creation of an Earl formerly was by the king girding on his sword, and placing his coronet on his head and his mantle on his shoulders; but Earls are now created by letters-patent; and it is not unusual for them to depart so far from the old notion of their being Territorial Officers, as to take as their titles their own names, with the prefix Earl—e.g., Earl Grey, Earl Russell, Earl Spencer, etc. At present the number of Earls, including the peerages of Scotland and Ireland, exceeds 200.

The Earl's coronet is a circle of gold, rising at intervals into eight pyramidal points, or spikes, on the tops of which are placed as many pearls, alternated with strawberry-leaves. See *Crown* and *Duke*.

EARL MARSHAL.—An office of great antiquity, and formerly of importance. There seems reason to believe that the Marshal of England, afterwards the Earl Marshal, was a distinct officer from the Marshal of the King's House, but the point is not altogether clear, and there is, consequently, some difficulty in determining which of the offices was held by the Mareschals, Earls of Pembroke. For many generations the office has been hereditary in the family of the Dukes of Norfolk, though the Earls Marshal having, to an unusual extent, had the fate to die either childless or without heirs-male, the line of descent has been by no means a direct one. The last grant is by King Charles II., and bears date 19th October, 1672. The Earl Marshal presided jointly with the Constable over the Court of Chivalry, the last proceedings of which are said to have taken place in 1631. He is the head of the College of Arms, which has jurisdiction in descents and pedigrees; determines all rival claims to arms; and he grants armorial bearings, through the medium of the Kings-of-Arms, to parties not possessed of hereditary arms. The office of the Lyon in Scotland is generally supposed to correspond to that of the Earl Marshal in England, but not quite correctly. The Lyon having been subordinate to the Marshal and Constable of Scotland, his office was more nearly that of the Kings-of-Arms in England; with this difference, that it extended to the whole kingdom.

EARNEST GUN.—A breech-loading rifle having a fixed chamber closed by a movable breech-block, which rotates about an axis parallel to the axis of the barrel, and on the left side. The block is in two sections, the foremost of which revolves with a screw motion on that in rear, which alone is fastened to the hinge. They are both perforated for the firing-pin and striker. The forward section is provided with a handle by which the breech is opened and closed, receding from and approaching the barrel alternately. The lock is peculiar, involving a device for causing the striker to rebound after delivering its blow upon the firing-pin. The arm is especially designed to prevent the escape of gas from defective cartridges.

EARTH-HOUSE.—*Earth-houses, eird-houses*, or *yird-houses*, were the names which seem to have been given throughout Scotland to the underground buildings which in some places are called also "Picts' houses," and in others, it would appear, "weems," or caves. Martin, in his *Description of the Western Islands*, printed in 1703, when their use would appear to have been still remembered, speaks of them as "little stone houses built under ground, called earth-houses, which served to hide a few people and their goods in time of war." The earth-house, in its simplest form, is a single, irregularly-shaped chamber, from 4 to 10 feet in width, from 20 to 60 feet in length, and from 4 to 7 feet in height, built of unhewn and uncemented stones, roofed by unhewn flags, and entered from near the top by a rude doorway, so low and narrow that only one man can slide down through it at a time. When the chamber is unusually wide, the side-walls converge, one stone overlapping another, until the space at the top can be spanned by stones of 4 or 5 feet in length. In its more advanced form, the earth-house shows two or more chambers, communicating with one another by a narrow passage. There are instances in which one of the chambers has the circular shape and dome-roof to which archæologists have given the name of the "beehive-house." Quite frequently as many as forty or fifty earth-houses are found in the same spot, as in the Moor of Clova, not far from Kildrummy, in Aberdeenshire. They appear to have been almost invariably built in dry places, such as gravelly knolls, steep banks of rivers, and hillsides. They are generally so near the surface of the ground that the plow strikes upon the flagstones of the roof, and thus leads to their discovery. The object most frequently found in them is a stone quern, or hand mill, not differing from that which continued to be used in remote corners of Scotland within the memory of living men. Along with the quern are generally found ashes, bones, and deer's horns; and more rarely small round plates of stone or slate, earthen vessels, cups, and implements of bone, stone celts, bronze swords, gold rings, and the like. Occasionally the surface of the ground beside the earth house shows vestiges of what are supposed to have been rude dwelling-houses, and folds or inclosures for cattle. This, with other things, would indicate that the earth-houses of Scotland and Ireland (for they are found also in that Island) were put to the same purpose as the caves which, as Tacitus tells us, the Germans of his day dug in the earth, as storehouses for their corn, and as places of retreat for themselves during winter or in time of war.

EARTHWORKS.—In fortification, a general name for all military constructions, whether for attack or defense, in which the material employed is chiefly earth. The word *earthwork*, however, has lately received a new importance, in reference to a discussion among Military Engineers whether earthwork defenses generally are better or worse than those of masonry. The subject cannot be discussed here, but its general character may be indicated. The fracture of the Russian granite fortifications at Bomarsund, and the obstinate defense made within the earthen defenses at Sebastopol, led many writers, about the year 1855, to express a preference for earthworks instead of stoneworks. Mr. J. Fergusson has especially distinguished himself by his advocacy of this view. The reasons urged are, that masses of earth can be more quickly and cheaply put up than masses of masonry; that in most places earth is more readily obtained than stone; that if an earthwork be knocked to ruin by balls and shells, it can be repaired in a very short time; and that the defenders are not exposed to so much injury as in masonry-works, where splinters of stone fly about in a perilous way. The late Sir John Burgoyne, the leading Military Engineer in England of his day, combated these views. He contended, among other things, that as a given amount of cannonading will make a much larger breach in earthwork than in stonework, the latter is best fitted to prevent capture by assault. He insisted that earthworks should be regarded rather as temporary expedients than as purposed and permanent constructions; and he claimed the authority of Continental Engineers in support of this opinion. See *Field-fortification*.

EAST INDIA ARMY.—When the East India Company first sent factors or agents to India, an army was not thought of. Military forces arose out of the exigencies of the times. Some of the first troops in the Company's pay were mere adventurers; some were liberated convicts; some deserters from European armies. Gradually organization was introduced, and improved arms furnished. As the power of the Company increased, natives entered the battalions; until at length most of the troops were Hindoos or Mohammedans drilled by non-commissioned officers sent out from England. A few regiments were raised in England; a much larger number were raised in India; but all alike were officered by the Company's favored English officers, largely paid, and having many opportunities for making rapid fortunes. The ranks were filled by enlistment; the Company never compelled the natives to become soldiers; the pay offered was always such as to induce a sufficient number of men to enter. Their periods of leave of absence were liberal; and after a certain number of years' service they retired on a pension sufficient to support them for the remainder of their days.

At the period immediately preceding the outbreak of the revolt in 1857, the army in the pay of the Company comprised about 24,000 Royal troops (lent to, and paid for by, the Company); 18,000 European troops, raised and drilled by the Company in England; 180,000 native regulars; and 60,000 native irregular horse—making about 280,000 in all. This large force was irrespective of 40,000 contingents furnished by dependent native princes, and of the native armies belonging to the independent and semi-independent princes. The Company's troops formed three distinct armies, each under its own Commander-in-Chief, and each stationed in one particular Presidency. In these three armies three kinds of troops—Europeans, native regulars, and native irregulars—had their own special organization. In order to secure unity of action when necessary, it was customary to give the Commander-in-Chief of the Bengal army precedence over those of Madras and Bombay; he was, in effect, Commander-in-Chief of the whole of the Company's forces. There were too few English officers with the native regiments, and these, in most cases, knew too little of the men under their command. This was not the *cause* of the revolt in 1857, but it was one of the circumstances that led to the rapid spread of the revolt when once begun. Speaking generally, it may be said that the armies of the Madras and Bombay Presidencies remained faithful, especially the infantry. It was in the Bengal army that the disruption chiefly occurred. The irregulars, both cavalry and infantry, raised amongst the Sikhs and Punjabees, were in almost every case faithful.

In August, 1858, the Act which transferred the Government of India from the Company to the Crown received the Royal assent. The army was transferred as well as the political power. As the Sikhs had behaved well, most of the regiments from the Punjab were retained, as well as most of the native regiments in the Bombay and Madras Presidencies; but it was not deemed expedient to restore the native regiments of Bengal proper, which had proved so treacherous. In that year, at the suggestion of Earl Canning, a Commission was appointed to inquire into the whole circumstances relating to the reorganization of the army. The Company originated the inquiry, but the Commissioners did not make their report till after the transfer of the Company's powers to the Crown. Although the Commissioners' report was presented in the summer of 1859, very little was effected during the remainder of that year, or in 1860, to reorganize the Indian army; matters were kept together in a provisional way. Meanwhile, when the European troops of the Company's army were turned over to the Crown, a disturbance, amounting almost to a mutiny, occurred. The men claimed that, as they had enlisted in the Company's service, they ought not to be transferred without their own consent being asked, or without receiving a bonus on re-enlisting. To prevent a dangerous excitement, the Government allowed such as chose to retire. In 1861 an Act was passed reorganizing the Indian army. The *British* portion of it now forms part of the Queen's army generally, with certain honorary distinctions, and takes its turn at home and in the Colonies like the rest; but the expenses are paid out of Indian, not Imperial, revenues. The *native* portion is managed wholly in India; but during the Eastern crisis, connected with the war between Russia and Turkey, a considerable force of native Indian troops were sent to Malta, for service in Europe—in case of England being involved in war. On the reorganization of the Indian army in 1861 the 21st Hussars, with the 105th, 106th, 107th, 108th, and 109th Foot, were formed from the European troops previously in the service of the East India Company. See *Army* and *British Army*.

EASTMAN BREECH-APPARATUS.—An efficient apparatus for opening and closing the breech of certain guns when firing rapidly. The breech-screw is divided into six parts, in the direction of its axis, the threads being removed from every other one, both from the plug and from the breech of the gun. When the breech is to be closed, the threaded portions of the plug are presented so that they come opposite the smooth parts of the breech-hole. The plug is then pushed in, when a sixth of a turn with a handle brings the screw of both parts together. A strong cranked lever serves to manipulate the breech-plug, by turning which the threads of the screw enter the corresponding grooves. The movement in the contrary direction disengages them. The breech being closed, the lever-handle is prevented from moving back, and thus allows the plug to be unscrewed by a short metal catch, working freely on a stud placed in the upper part of the right sight of the breech. This catch lifts as the lever-handle reaches it, and allows it to pass, but drops by the action of a spring when the handle has passed, and thus prevents the lever from moving to the left; a stud on the breech prevents it from moving to the right. The weight of the breech-plug for a 9½-inch gun is about 500 pounds; therefore a support, or collar, is used to hold it when withdrawn. This is a metallic frame carrying a bracket, hinged to the side of the breech near the opening. It has a kind of gutter in which slides the screw portion of the plug. This support being placed in a line with the bore, the hand-gripe at the middle of the breech-plug is seized, and the screw being disengaged, a strong pull will bring the whole to the rear. The impulse given swings it open, the breech-screw remaining fixed in its support, or collar. A safety-catch held by a spring secures the collar fair in a line with the bore. To obviate the danger resulting from a neglect to screw up the plug when the breech is closed, the lock-lanyard, which has a bob on it, is made to pass through the eye of a piece of iron fixed to the breech. When the handle is not in its place, that is, when the plug is not properly screwed in, a spring closes the eye and does not allow the bob to pass. When the handle is in position with the plug screwed up, it opens the eye and allows the bob to pass, when the gun can be fired.

EBONY.—This wood, remarkable for its hardness, heaviness, and deep black color, is the heart-wood of different species of *Diospyros*, of the natural order *Ebenaceæ*, the same genus which produces the date-plum, kaki, and other fruits. The best ebony, excelling in uniformity and intensity of color, is the produce of *Diospyros ebenum*, which grows in great abundance in some of the flat parts of Ceylon, and is a tree of such magnitude that logs of its heart-wood 2 feet in diameter, and varying from 10 to 15 feet in length, are easily procured. Ebony is used in the arsenals for handles, press-screws, etc.

EBOULEMENT.—A term applied to the crumbling or falling of the walls of a fortification.

ECCENTRIC.—1. A device applied to the truck-wheels of top-carriages and beds of mortars in sea-coast artillery to give either rolling or sliding friction at will. A similar device is attached to the chassis near the pintle to enable it to be readily traversed when *in gear*, and give it stability when *out of gear*. —2. In machinery, a contrivance for taking an alternating rectilinear motion from a revolving shaft. It consists of a circular disk or pulley, fixed on a shaft or axis which does *not* pass through the center of the disk. The disk has a groove upon its circumference in which the hoop—by means of which the rod is attached to the disk—slides. As the eccentric revolves with the axis, the hoop is alternately raised and lowered, and with it the rod which is keyed into it. The extent of the rise and fall of the rod is equal to twice the distance between the centers. The eccentric is chiefly used where a subsidiary motion of small power is required, as for working the force-pump that supplies the boiler of a steam-engine.

ECCENTRIC CHUCK.—A chuck attached to the mandrel of a lathe, and having a sliding piece which carries the *center*. This piece is adjustable in a plane at right angles to the axis of motion by means of a set-screw, and carries the center to one side of the axis of motion. By its means circular lines of varying size and eccentricity may be produced. No oval or ellipse is produced thereby, but circles on the face of the work, with their centers at such distance from the axis of the mandrel as may be desired.

ECCENTRIC CUTTER.—A cutting tool placed upon the slide-rest, and having a rotation by means of a wheel and shaft, the cutter being attached to the end of the latter. The rotation is obtained by an *overhead motion*, and the eccentricity by fixing the cutter at different distances from the center by means of the groove and screw. The action of the eccentric cutter differs from that of the eccentric chuck in this: in the latter the work is rotated and the tool is stationary; in the former the work is stationary and the tool revolves. When the motions are used in conjunction, the patterns are capable of unlimited variation.

ECCENTRIC PROJECTILE.—A spherical projectile, in which the center of inertia does not coincide with the center of figure. Such projectiles are subject to great deviations, which can be predicted as to direction by knowing the position of the center of inertia of the shot in the bore of the gun. See *Projectiles.*

ECCENTROMETER.—An instrument for determining the position of the center of gravity of a projectile. See *Center of Gravity.*

ECHARGE.—A term employed to signify that a column of troops is struck at a very oblique angle. Also written *Feu d'écharge.*

ECHAUGETTE.—In military history, a word signifying a watch-tower, or kind of sentry-box.

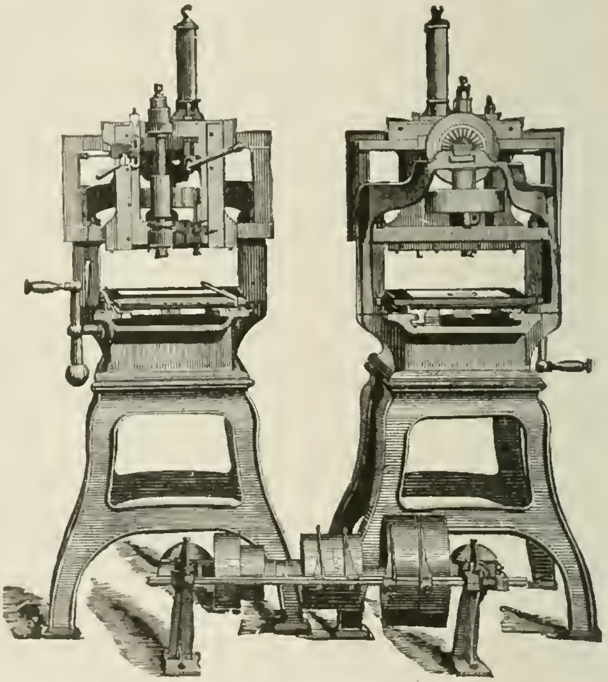
ECHELON.—A military term applied to such a formation or arrangement of troops that, if viewed from a height, they would present some analogy to the successive steps of a ladder or staircase. The several divisions of the force, although parallel, are no two on the same alignment. Each has its front clear of that in advance, so that, by marching directly forward, it can form line with it. There are two kinds of echelon, *direct* and *oblique. Direct echelon* is adapted for attack and retreat; while *oblique echelon* (oblique in reference to the original front of the line) is adapted for changing position, or for getting on the enemy's flank.

ECLAIREURS.—Literally, the feelers of an army. They are bodies, generally of light cavalry, sent to the front or the flank of an army to obtain intelligence as to the movements of the enemy. They are not used as exceptional or distinct bodies, but all the light cavalry is called upon to perform that duty. When the first Napoleon was Chief Consul of France, he raised a regiment of Eclaireurs for the protection of Paris. In the Continental War of 1870, Eclaireurs were employed both by the Germans and French.

ECLOPES.—A military term to express those soldiers who, though invalids, are well enough to follow the army. Among these may be classed dragoons or horsemen whose horses become lame and cannot keep up with the troop or squadron. They always march in rear of the column.

ECOLE POLYTECHNIQUE.—One of the most celebrated Military Academies in France. In 1793 all the public establishments in Paris were in a convulsed state, owing to the Revolution. In 1794 M. Lamblardie, Director of the *Ponts et Chaussées*, proposed the establishment of an *Ecole Centrale des Travaux Publics*, to thoroughly educate young men for military, naval, and civil engineering. Monge and Carnot favoring his plan, it was carried out, and a School established at the Palais Bourbon. The first list of Professors comprised names which afterwards acquired European celebrity—including those of Legrange, Prony, Monge, Hachette, Hassenfratz, Fourcroy, Vauquelin, Berthollet, Chaptal, Pelletier, Guyton-Morveau, and Merimée. In 1795 the name was changed to Ecole Polytechnique; many alterations were made in the organization; artillery studies were included in the course; and the pupils were ordered to wear a uniform. When Napoleon went to Egypt, 40 pupils from the Ecole Polytechnique accompanied him, many of whom greatly distinguished themselves. Napoleon made the organization of the School more strictly military in 1804, to identify it more fully with the army. The School was dissolved in 1816, again in 1830, and again in 1832, on account of the impetuous way in which the pupils mixed themselves up with the political disturbances of those years; but as the School suited the military genius of the French Nation, it was re-established on each occasion, after the restoration of tranquillity. Candidates can be admitted only by competitive examinations, which take place yearly. A Proclamation from the War Office, made public before the 1st of April, informs intending competitors of the subjects on which they are to be examined, and the time when the examinations begin. To be eligible as a candidate, the youth must be French, and must be more than sixteen and less than twenty years of age before the 1st of January following; but soldiers are admissible up to the age of twenty-five, provided they can give proof of two years of service in the regular army. The cost of board alone is 1000 francs ($200) a year. A complete course of instruction lasts for two years; when the pupils who have satisfactorily passed the final examinations have the privilege of choosing, from among the various public services supplied from the School, the particular branch they wish to enter, as the Artillery, the Engineers, the Staff, the Department of Telegraphs, or some of the other government monopolies. The School was reorganized by a decree of the 15th April, 1873. See *United States Military Academy.*

ECONOMY.—In a military sense, this term implies the minutiæ or the interior regulations of a regiment, troop, or company. Hence "regimental economy."



Edging-machine.

ECORCHEURS.—A name given to bands of armed adventurers who desolated France and Belgium during the fifteenth century, beginning about 1435, and who at one time numbered 100,000. They are said to have stripped their victims to their shirts, and to have flayed the cattle. They were favored by the English Invasion and the Civil Wars.

ECOUTES.—Listening-galleries. Such are known to engineers and others in connection with siege-works. These galleries are run out under and beyond the glacis at regular distances in the direction of the besiegers' works, and enable the besieged to hear and estimate how near the besiegers have carried their mining operations.

ECRETER.—To batter or fire at the top of a wall, redoubt, epaulement, etc., so as to dislodge or drive away the men that may be stationed behind it, in order to render the approach more easy. *Ecreter les pointes des palissades* is to blunt the sharp ends of the palisades. This ought always to be done before attacking the covered-way, which is generally fenced by them.

ECREVISSES.—Armor entirely composed of imbricated plates, and commonly called a *suit of splints* in England.

ECU.—A large shield which was used by the ancients, and carried on the left arm to ward off the blows of sword or saber. This instrument of defense was originally invented by the Samnites. The Moors had *ecus*, or shields, sufficiently large to cover the whole of their bodies. The *clipei* of the Romans differed from the *ecu* in shape only; the former being entirely round, and the latter oval.

EDGE.—The thin or cutting part of a sword, saber, or other cutting weapon or implement.

EDGING-MACHINE.—A machine much used in the manufacture of small-arms, for milling inside and out of metal forgings and castings of irregular shapes to an exact shape and size of pattern required. The machine is shown in detail on the opposite page. Power is supplied by a cone-pulley having two speeds (and two friction-pulleys on countershaft, which allow four changes of speed) driving bevel gears which have a direct belt-connection with the cutter-spindle. This arrangement makes the working of the slide very easy. The pattern, or former, is secured to the sliding table, which has a forward-and-back motion, operated and controlled by the hand-crank at the side of the machine. An automatic feed can be substituted when desired. The top or cross slide which holds the cutter-spindle, and moves at right angles with the bed, is operated by the hand-lever in front and has a counterbalance-spring and a notch adjustment. This cross-slide also has a pin which is brought to bear against the pattern, and the four motions to the two slides will allow the pin to follow any pattern secured to the lower table or sliding bed. The work to be cut into shape is also secured by suitable fastenings to the lower table, and as the pin passes around the pattern, so the cutter-spindle will pass around the piece of work and describe the same outline and dimensions as the pattern used. By using a cutter with teeth on the lower end, good surface-milling is nicely and quickly done. The machine as commonly employed in Government arsenals and represented in the drawing has the following general dimensions:

Friction-clutch pulleys on countershaft, 8 and 12 inches by 3 inches face.

Countershaft runs for slow speed	150 revolutions.
" " " fast "	220 "
Working surface of table	14 by 10 inches.
Movement of table	16 "
" " cross slide	9 "
Distance from bed to cross-slide	4⅜ "
Up-and-down movement of spindle	3½ "
Weight of machine	1100 pounds.

These dimensions are frequently varied for special classes of work. See *Profile-machine.*

EDUCATION.—A civil branch of the English army, presided over by a Director General of Military Education, under whose orders are the Military Inspectors of Schools. All officers who are candidates for the Staff College are examined under the orders of the Director General. The studies carried on at the College are regulated by him in concert with the Commandant of that Institution. The final examination of officers who have passed the prescribed time at the College takes place under his cognizance, and a report is submitted by him to the Horse-guards of the qualifications of the officers examined. His Department supervises all Regimental Schools, Garrison Libraries, etc. In fact, on all subjects of education in the army he is the Director and Referee. The following is a list of the Government Educational and Scientific Establishments in England: the Department of Artillery Studies; the School of Engineering at Chatham; the School of Gunnery at Shoeburyness; the School of Instruction at Aldershott; the School of Musketry at Hythe; the Army Medical School, Netley; the Military School for Music at Hounslow; the Royal Military Asylum at Chelsea; the Royal Hibernian Military School, Dublin. See *Artillery School.*

EFFARE.—In Heraldry, a term which signifies that the animal to which it refers is to be represented as rearing on its hind-legs, as if it were frightened or enraged. Also written *Effrayé.* See *Heraldry.*

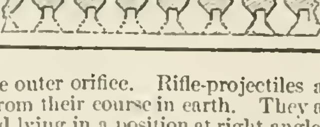
EFFECTIVE.—A term used, in a military sense, to denote the number of men actually borne and doing duty on the strength of a company or regiment, in the field or on parade.

EFFECTS.—The property of a deceased officer or soldier. On the death of either, a Committee of Adjustment is formed to take charge of the property, and to adjust the affairs of the deceased, as directed by law. See *Deceased Officers and Soldiers.*

EFFECTS OF PROJECTILES.—A knowledge of the destructive effects of projectiles on iron, wood, earth, and masonry, the materials of which covering masses are made, is of very great importance in a military point of view. In general, these effects, and particularly that of penetration, depend on the nature of the projectile, its initial velocity, and the distance of the object. The following deductions have been made from trials with armor-plates, extending over several years: 1st. The best material to resist projectiles is soft, tough wrought-iron; and to attain these qualities it should be pure—free from sulphur, phosphorus, and carbon. Steely iron, commonly known as homogeneous iron, puddled steel, etc., when in large masses, is easily cracked by shot, and is not, therefore, suitable for armor-plates. Thin plates afford a greater comparative resistance. Soft steel may be used for armor-plates; but when cost is taken into consideration it is doubtful if it possesses any advantages over wrought-iron. 2d. Rolled iron does not offer quite so much resistance as hammered iron, yet if the size of the plate admit of it, it is to be preferred on the score of economy. Plates should be as large as possible to reduce the number of joints, which are lines of weakness. 3d. A solid plate offers, for the same thickness, a greater resistance to a projectile than a laminated one, or one made up of several thinner plates; but when the surface is rounded in shape and of small extent, as in the Monitor turrets, the latter may be used to great advantage, as great thickness of metal may thereby be easily obtained. 4th. The resistance of a plate to perforation is very much increased by a suitable backing. Cast-iron, granite, and brick in masses, while they enable a plate to offer a very great resistance, are soon broken up by the blows of heavy projectiles, and their fragments thrown off with great force. Oak and teak are the most suitable timbers for backing plates, and are used as such on vessels. A yielding backing is found to occasion less strain on the fastenings than a very hard one. 5th. Where projectiles are made of the same material and are similar in shape, their penetration into unbacked plates is nearly in proportion to their *living force*, or *their weight multiplied by the square of the velocity of impact.* The resistance which an unbacked plate offers to penetration is nearly in proportion to the *square of its thickness*, provided this thickness be confined within ordinary limits. In the case of oblique plates the penetration diminishes nearly with the *sine of the angle of incidence.* 6th. The most suitable material for shells to be used against iron plates is tempered steel. These projectiles should be made of cylindrical shape, with thick sides and bottom, to direct the explosive effect of the charge forward after penetration is effected. The most suitable material for solid shot is hard and tough cast-iron. Round shells made of cast-iron will be broken in passing through an inch plate, and an ordinary cast-iron shot will be broken in passing through a two-inch plate. Late experience shows that the pointed, or ogival, is better than the flat form of head for penetration of iron plates. 7th. It follows from the preceding that the most suitable covering or shield for cannon is a conical-shaped turret made of wrought-iron plates, as large as it is practicable to make them, backed with oak or teak. To protect the gunners from the fragments of projectiles which may penetrate completely through this covering, there should be an "inner skin" of thick boiler-plate placed behind the wood.

Effect on Wood.—The effect of a projectile fired against wood varies with the nature of the wood and the direction of the penetration. If the projectile strike perpendicular to the fibers, and the fibers be tough and elastic, as in the case of oak, a portion of them are crushed, and others are bent under the pressure of the projectile, but regain their form as soon as it has passed by them. It is found that a hole make in oak by a ball 4 inches in diameter closes up again, so as to leave an opening scarcely large enough to measure the depth of penetration. The size of the hole and the shattering effect increases rapidly for the larger calibers. A 9-inch projectile has been found to leave a hole that does not close up, and to tear away large fragments from the back portion of an oak target representing the side of a ship of war, the effect of which on a vessel would have been to injure the crew stationed around, or, if the hole had been situated at or below the water-line, to have endangered the vessel. If penetration take place in the direction of the fibers, the piece is almost always split, even by the smallest shot, and splinters are thrown to a considerable distance. In consequence of the softness of white pine nearly all the fibers struck are broken, and the orifice is nearly the size of the projectile; for the same reason the effects of the projectile do not extend much beyond the orifice; pine is therefore to be preferred to oak for structures that are not intended to resist cannon-projectiles, as block-houses, etc.

Effect on Earth.—Earth possesses advantages over all other materials as a covering against projectiles; it is cheap and easily obtained, it offers considerable resistance to penetration, and to a certain extent regains its position after displacement. It is found by experience that a projectile has very little effect on an earthen parapet unless it passes completely through it, and that injury done by day can be promptly repaired at night. Wherever masonry is liable to be breached, it should be masked by earthworks with natural slopes. The size of the openings formed by the passage of a projectile into earth is about one third larger than the projectile, increasing, however,



towards the outer orifice. Rifle-projectiles are easily deflected from their course in earth. They are sometimes found lying in a position at right angles to their course, and sometimes with the base to the front; hence their penetration is variable. Unless a shell be very large in proportion to the mass of earth penetrated, its explosion will produce but little displacement; generally a small opening is formed around an exploded shell by the action of the gas in pressing back the earth. Experience at Fort Wagner showed that it took one pound of metal to permanently displace 3.27 lbs. of the sand of which the fort was made. Time-fuses, being liable to be extinguished by the pressure of the earth, are inferior to percussion-fuses, which produce explosion when the projectile has made about three fourths of its proper penetration. The penetration in earth of the oblong compared to round projectiles, when fired with the service-charges, and at a distance of about 400 yards, is at least *one fourth greater.* This difference, however, is less at short and greater at long distances. The penetration of the smallest: or 3-inch, cannon-projectile, at a disstance of 400 yards, in a newly made parapet of loam mixed with gravel, is about 6 feet. The 100-pdr. projectile, under similar circumstances, penetrates about 16 feet. A penetration as great as 31½ feet has been obtained at the Washington Navy Yard by firing a 12-inch rifle-projectile into a natural clay-bank at a short distance. The greatest penetration of a 15-inch solid shot, fired with 50 lbs. of powder, in well-rammed sand, at a distance of 400 yards, is 20 feet.

Effect on Masonry.—The effect of a projectile against masonry is to form a truncated conical hole, terminated by another of a cylindrical form, as shown in the drawing. The material in front of and around the projectile is broken and shattered, and the end of the cylindrical hole even reduced to powder. Pieces of the masonry are sometimes thrown 50 or 60 yards from the wall. The elasticity developed by the shock reacts upon the projectile, sometimes throwing it back 150 yards, so as to be dangerous to persons in a breaching-battery. The exterior opening varies from 4 to 5 times the diameter of the projectile, and the depth, as we have seen, varies with the size and density of the projectile and its velocity. With charges of ½, ⅓, ¼, and ⅙, a projectile ceases to rebound from a wall of masonry when the angles formed by the line of fire and the surface of the wall exceed 20°, 24°, 33°, 43°, respectively. With these angles, the angle of reflection is much greater than the angle of incidence, and the velocity after impact is very slight. When a projectile strikes against a surface of oak, as the side of a ship, it will not stick if the angle of incidence be less than 15°, and if it do not penetrate to a depth nearly equal to its diameter. Solid cast-iron shot break against granite, but not against freestone or brick. Shells are broken into small fragments against each of these materials.

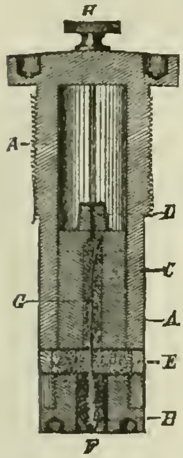
Effect of Bullets.—The penetration of the new breech-loading rifle-musket bullet in a target made of pine boards one inch thick is as follows: at 100 yards, 13 inches; at 500 yards, 9 inches. If bullets are hardened by the addition of a little tin or antimony to the lead, their penetration is very much increased. From experiments made in Denmark, the following relations were found between the penetration of a bullet in pine and its effects on the body of a living horse, viz.: 1st. When the force of the bullet is sufficient to penetrate .31 inch into pine, it is only sufficient to produce a slight contusion of the skin; 2d. When the force of penetration is equal to .63 inch, the wound begins to be dangerous, but does not disable; 3d. When the force of penetration is equal to 1.2 inch, the wound is very dangerous. A plate of wrought-iron three sixteenths of an inch thick is sufficient to resist a rifle-musket bullet at distances varying from 20 to 200 yards. That a rope mantlet may give full protection against rifle-musket bullets, it should be composed of five layers (three vertical and two horizontal) of 4½-inch rope. See *Breaching, Projectiles, Punching,* and *Racking.*

EFFENDI.—A title of honor among the Turks, bestowed upon civil dignitaries and persons of various ranks, in contradistinction to the title of Aga, borne by courtiers and military men. The word is equivalent to the English Sir or the French Monsieur, and is frequently added to the name of an office. Thus, the Sultan's first Physician is termed *Hakim-Effendi;* the Priest in the Seraglio, *Imam-Effendi;* and the Minister of Foreign Affairs was formerly called *Reis-Effendi.*

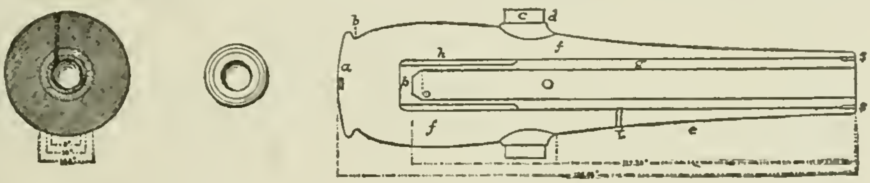
EFFICIENT.—A thoroughly disciplined and capable soldier. It is also a term used in connection with the volunteers. A volunteer is said to be efficient when he has performed the appointed number of drills and fired the regular number of rounds at the target in the course of the year.

EGARD.—An ancient tribunal of Malta which decided, by commission, suits among the Knights.

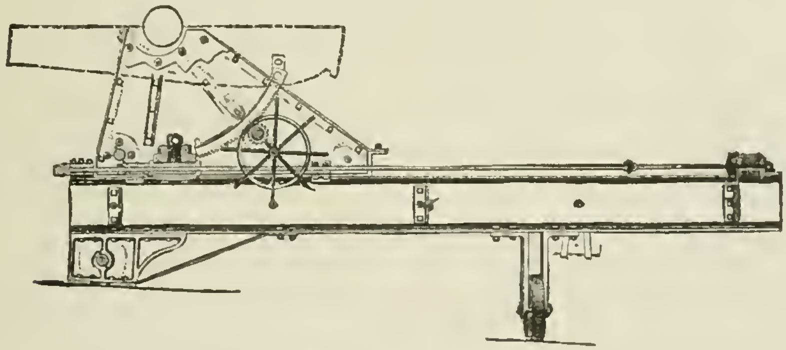
EGGO PERCUSSION-FUSE.—This fuse consists of the stock A, upon the outer surface of the outer part of which is formed a screw-thread, to enable it to be screwed into the shell in the ordinary manner. The outer end of the stock A is made close, with a flange to overlap the seam or joint, and with notches or holes to receive the wrench for screwing it in and out of the shell. The inner end of the stock A is made open and is closed with a screw-plug, B, which is formed with holes or notches to receive the wrench for screwing it in and out. C is the plunger, which is made hollow, and is provided with a nipple, D, at its outer end to receive a cap to cause the shell to be exploded when it strikes, by the forward movement of the plunger C, causing the cap to strike against the closed, outer end of the stock A. The inner end of the stock A is notched or slotted transversely, to receive the ends of the hollow or tubular bar E, with the center of which is connected the inner end of the short tube F. The ends of the bar E may be closed by a paper patch, a slight wooden plug, or other suitable means, to confine the powder until ignited. The outer end of the tube F is flattened, and contains a fulminate to be ignited by friction. The device E F is connected with the plunger C by a wire, G, one end of which is securely attached to the said plunger C, and its other end passes through the tube F. The outer end of the wire G is flattened and roughed or barbed, so that when drawn through the tube F by the forward movement of the plunger C



parts: the *case*, *f*, which is the 10-inch smooth-bore, bored up to a diameter of 13.5 inches, and a *lining-tube* of coiled wrought-iron. The tube consists of two parts, called respectively the A and B tubes. The former extends the entire length of the bore, and contains the rifling; the latter, or B tube, is shrunk upon the inner, or A tube, which has its exterior portion cut away for that purpose. A double tube is thus formed, extending 32.75 inches from the rear end. The two tubes, united in this manner, have the same exterior diameter throughout the entire length, and are made to fit accurately the bore of the cast-iron casing. The bottom of the tube is closed with a wrought-iron cup shaped plug, *p*, screwed into the A tube. The tube is inserted into the casing from the muzzle, and is secured from working out by a muzzle-collar, *s*, screwed in at the face of the piece, and from turning in the casing by a steel pin, *t*, tapped through the casing and into the tube. A shallow and narrow gas-channel is cut spirally around the exterior of the reduced portion of the A tube, communicating with star-grooves cut in the end of the barrel, and with the gas-escape, or *indicator*, bored obliquely through the breech of the casing opposite the vent. Should the inner tube split, under the action of firing, the fact would be indicated by the escape of gas through this hole, and timely warning thus be given of the injury sustained by the gun. The rifling consists of fifteen lands and grooves, each of equal width, viz., .8377 inch. Depth of the grooves, .075 inch.



Eight-inch Rifle.



Carriage for 8-inch Rifle.

it may ignite the fulminate in the said tube F by friction, and thus explode the shell. The screw-plug B has a hole through it to receive the tube F and protect it. H is the safety-pin, which passes in through a screw-hole in the outer, closed end of the stock A in such a position that its forward end may rest against the end of the plunger C at the side of the cap-nipple, and thus holds the said plunger securely in place during transportation and handling, and absolutely secures the shell from being exploded by an accidental blow, shock, or fall. The screw-pin H is removed when the shell is put into the gun and ready to be fired. See *Fuse*.

EIGHT-FOIL.—A term used in Heraldry to signify a grass having eight leaves, as the trefoil has three. According to Sylvanus Morgan, it may be used as the difference of the ninth branch of a family.

EIGHT INCH RIFLE.—This piece, employed in the United States service, is composed, essentially, of two

Twist uniform, one turn in 40 feet. There is no chamber proper to the gun. The rifling stops at a point 10 inches from the bottom of the bore, the diameter of the unrifled portion being equal to that of the rifled portion across lands. The old vent of the case is closed by a wrought-iron screw-plug, and 2.75 inches nearer the muzzle a new one is bored parallel to the vertical plane through the axis of the bore, and distant therefrom 2.5 inches. The axis of the vent enters the bore at 3.5 inches from the bottom.

Length of bore	117.25 inches.
Weight of piece	16,160 pounds.
Counter-preponderance	630 pounds.
Weight of projectile (average)	180 pounds.
Weight of charge (hexagonal powder)	35 pounds.
Initial velocity	1,430 feet.
Pressure upon square inch of bore	33,000 pounds.
Penetration against armor at 1000 yards	7.42 inches.
Penetration against armor at 1800 yards	6.75 inches.

The counter-preponderance is corrected by an eccentric ring of bronze attached to each trunnion.

The following table shows the ranges of this piece, with a charge of 35 pounds hexagonal powder:

Range.	Elevation.	Time of flight.	Angle of fall.	Remain'g velocity.	Drift.
Yards.	° ′	*Seconds.*	° ′	*Ft. sec.*	*Yards.*

It has been found that the 10-inch carriage, upon which this piece is mounted, is not sufficiently stout to stand many discharges with a charge of 35 pounds. Charges of 25 pounds will penetrate any wooden ship at ordinary ranges, but are of no effect against ironclads. The carriages will stand this charge without serious damage.

The four varieties of carriages upon which these pieces are mounted are those altered from the 10-inch barbette-gun carriage, and thus far are only experimental. Carriages Nos. 1 and 2 have friction-bars for checking recoil. Nos. 3 and 4 have hydraulic cylinders for the same object. Nos. 3 and 4 have a geared windlass, with cranks and handles, attached to the rear part of the chassis. Nos. 1 and 2 are without windlass. No. 1 is distinguished from No. 2 by the absence of the ratchet-post, and by having, instead, for elevating, a circular toothed arc operated by a hand wheel and pinions upon the left cheek of the carriage. No. 2 has the ratchet-post, but not a toothed arc. Carriage No. 3 is distinguished from No. 4 by having a wedge-shaped incline bolted to the top of each rail of the chassis, near the rear end, and by having a hand-lever on the outside of each chassis-rail, for the purpose of uncoupling the top-carriage from the chassis. See *Converted Guns.*

EIGHT-INCH SIEGE-MORTAR.—This mortar, used in the United States service, is made of cast-iron, has a smooth bore, and is without chamber. The following tables show the weights, dimensions, and ranges pertaining to the piece:

Designation.	No.	Lbs.	Inch.
Caliber	......	......	8
Weight	......	1010	......
Preponderance	......	00	......
Length of piece	......	......	22
Length of bore (calibers)	2	.....	......
Windage	......	......	.12
Charge (maximum), mortar-powder	... ..	2.25	......
Weight of shell (empty)	......	46	......
Charge to fill shell, musket-powder	......	2.5	......
Charge to blow out fuse-plug	......	.25	......
Weight of carriage	......	900	......
Weight of carriage, mortar, and implements	......	1965	......
(One mortar-wagon will carry three mortars, with their carriages.)			

RANGES.

Charge.	Elevation.	Range, yards.		Time of flight, Seconds.	
Ounces.	Degrees.	Shell,52 lbs	Shell,46 lbs	Shell,52 lbs	Shell,46 lbs
8	45	399	433	9.50	9.65
12	45	717	727	12.45	12.50
10	45	955	1029	14.85	15
14	45	1265	1275	16.50	16.80

EIGHTY-TON GUN.—A large Woolwich gun designed as an armament for the "Inflexible." When first made it weighed 81 tons, having a caliber of 14½ inches. It was bored during the progress of the experiments to 16 inches, and was given an enlarged chamber. The experiments were conducted by the well-known and celebrated "Committee on Explosion." See *Ordnance.*

EISENHUT.—An iron hat or helmet, without vizor or neck-guard, but supplied with a rim. It was first worn in the twelfth century, and remained in use until the seventeenth century.

EJECTOR.—The device commonly used in breech-loading small-arms to throw out the metallic cartridge-case after it is fired. The ejector-spring operates the ejector. See *Springfield Rifle.*

ELASTICITY.—When an external force acts upon a solid body, it produces at first slight alterations in the relative positions of the particles; and if before these alterations exceed a certain limit the force ceases to act, the particles return to their former position and the disfigurement disappears. This power or property of recovering their previous form after alteration is called *elasticity;* and we are justified in ascribing it to all bodies, though in very different degrees. It was once believed that there were definite limits within which changes of form produced by pressure or other forces disappeared completely. It was thought, for instance, that when a weight of no great magnitude is suspended from a metallic wire, the slight increase of length which the wire is observed to undergo is completely lost when the weight is removed; and the limit to which the wire might thus be stretched and still suffer no permanent increase of length was called the limit of its elasticity. But recent more accurate experiments have shown that no such limits exist, at least in the case of metals; or, which is the same thing, that permanent lengthening results, however slightly the wire be loaded—it never contracts again quite so far as it was stretched. It is necessary, therefore, to fix the limit arbitrarily; and this is done by agreeing that it shall be held to begin when the metal in question suffers a permanent elongation of .00005 of its length. To get the elastic extensibility of a wire, then, we must compare its length suspended with its length when the weight is removed. In this way it is found that the extensions produced are proportional to the extending forces or weights. From this law, then, we can calculate what weight it would require to stretch a wire or rod of a square inch in section to double its own length; supposing it possible to proceed so far without breaking it, and that the law of elasticity continued up to this point unaltered. This weight, which is different for every metal or kind of wood, is called the *coefficient* or *modulus of elasticity* of the particular substance; and is used in mechanics in calculating how far a given weight will extend a wire or rod of given diameter. This coefficient is not constant for the same metal; for all circumstances that increase the density of the metal increase the modulus of elasticity. Bodies manifest elasticity not only when extended in length, but also when compressed, when bent, or when twisted. If an ivory ball be dropped from a height upon a marble slab smeared with fat and lamp-black, when caught after the rebound, it is seen to have touched the marble, not in a point, but in a circle of several lines in diameter, and must therefore have lost for a time its spherical shape over that extent. In the same way the mark of a well-hit golf-ball is pretty broadly shown upon the face of a club after the stroke. The elasticity shown by wires and threads of glass when twisted has been turned to account in the torsion-balance used for measuring other weak forces. Steel, ivory, caoutchouc, etc., are well known for their elastic properties, to which they owe much of their utility.

ELASTIC PRESSURE.—Cannon are subjected by the pressure of powder to the following strains: *tangential*, *longitudinal*, *transverse*, and *strains of compression*. If p be the pressure on a unit of surface of the bore, and s the tensile strength of the metal, it can be shown by analysis that the tendency to rupture, or the pressure on a unit of length of the bore, divided by the resistance which the sides are capable of offering to rupture, for a piece of one caliber thickness of metal, will be as follows, viz.:

$$\text{Tangential, } \frac{3p}{2s};$$

or, rupture will take place when three times the pressure is greater than twice the tensile strength.

$$\text{Longitudinal, } \frac{p}{2s};$$

or, rupture will take place in the direction of the length when the pressure is greater than twice the tensile strength.

$$\text{Transverse, } \frac{2p}{3s};$$

or, rupture will take place when twice the pressure is greater than three times the tensile strength. From the above it appears that the tendency to rupture is greater from the action of the tangential force than for any other; and for lengths above two or perhaps three calibers the tangential resistance may be said to act alone, as the aid derived from the transverse resistance will be but trifling for greater lengths of bore or stave; but for lengths of bore less than two calibers this resistance will be aided by both the transverse and the longitudinal resistance. Every piece should, therefore, have sufficient thickness of breech to cause rupture to take place *laterally*, if at all, instead of splitting through the breech.

The most obvious means of enabling any vessel to sustain a greater elastic pressure is to simply thicken its sides, thus increasing the area of substance to be torn asunder. But to obtain much greater strength by casting guns heavier is impossible, because in cast guns the outside helps but very little in restraining the explosive force of the powder tending to burst the gun, the strain not being communicated to it by the intervening metal. The consequence is that, in large guns, the inside is split, while the outside is scarcely strained. This split rapidly increases, and the gun ultimately bursts. If we make equidistant circular marks on the end of an India-rubber cylinder and stretch it, we can see plainly how much more the inside is strained than the outside, or even the intermediate parts. The spaces between the marks will become thinner, each space becoming less thin than that inside of it, but the inner space much thinner than the others, showing that when the inside is strained almost to breaking, the intermediate parts are doing much less work, and those far removed almost none. It is well known that *in cylinders of metal the power exerted by different parts varies inversely as the squares of the distances of the parts from the axis.* Thus, in a 10-inch gun, when the inside, which is 5 inches from the axis, is fully strained, the metal 2 inches from the inside, or 7 inches from the axis, can only exert a force $\frac{25}{49}$, or little more than half, as much. We cannot, therefore, be astonished that it has been found in practice that cylinders for hydraulic presses, with a thickness equal to about one half the diameter of the piston, are almost as strong as if ten times as thick. Hence there is a certain limit beyond which it seems useless to increase the thickness of the metal, and this is when the force exerted on the surface of the bore would be sufficient to rupture the interior portions of the metal before the strain acted to any extent upon the exterior parts. Any arrangement of the parts by which the explosive strain is distributed equally over the entire thickness of the piece necessarily brings a greater amount of resistance into play. In order to obtain the requisite resistance, and with a moderate thickness of metal, it is desirable to equalize as far as possible the strain upon every portion of the metal. There are two methods of accomplishing this, depending upon the principles of *initial tension* and *varying elasticity*. Some gun-makers use the one, some the other, and some a combination of the two. See *Initial Tension* and *Varying Elasticity*.

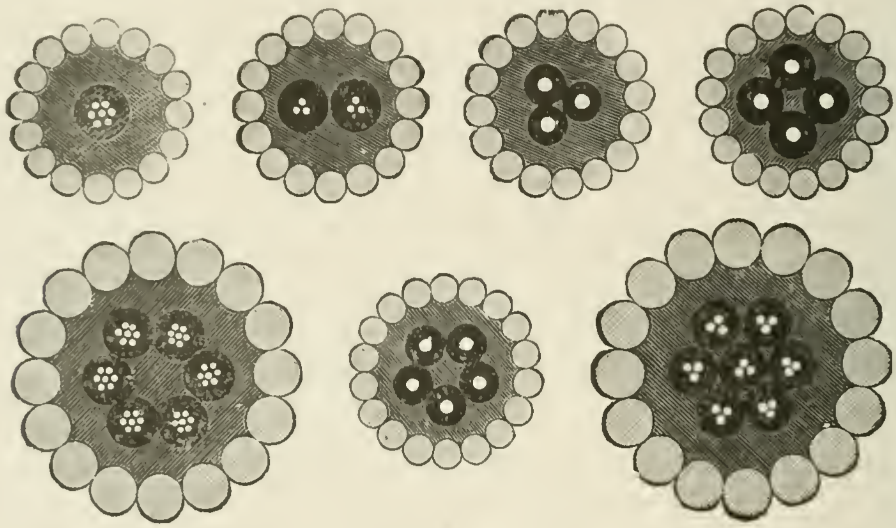
ELBOW-GAUNTLET.—An ancient piece of armor, a gauntlet of plate reaching to the elbow, adopted from the Asiatics in the sixteenth century.

ELBOW-PIECES.—The metal plates used to cover the junction of the rere-brace and vant-brace, by which the upper and lower half of the arm were covered. They increased to an enormous size, as in the effigy of Sir Thomas Peyton, in Isleham Church, but again decreased to their normal size. Also written *Condières*. See *Armor*.

ELECTRIC BOMB-LANCE.—An application of the electric force to the explosion of a bursting-charge in a harpoon or bomb lance. A copper wire is carried through the line, and, when a circuit is established by the gunner, a resistance-section in the fuse of the bomb-lance ignites the charge.

ELECTRIC CABLES.—Electric cables for military use must possess the following qualifications: 1. Capacity to sustain a certain amount of strain without breaking. 2. Good insulation, composed of such a substance that it may be readily stored and kept for a considerable time without being injured. This is essential, as the lines will only be submerged while actually in use in time of war, for which purpose they must consequently be kept in store, and always ready in sufficient quantities. 3. For situations where there is a rocky or shingly bottom, they must be provided with an external covering capable of protecting the insulation from destruction. Special precautions must, of course, be taken to secure the cables at points where they may be necessarily exposed to a considerable wash of the sea, such as the places where they may be led into a fort, etc.; but as there are others where no such special precautions can be applied, an external protecting covering over the insulation must be provided. 4. Pliability, so that it may be wound or paid out from a moderately sized drum without injury. The conducting wire is either soft iron or copper. The best substance for covering it to effect insulation is vulcanized India-rubber, as it can stand any degree of heat likely to occur to a cable, and does not harden and crack as does gutta-percha. The conductor should, however, be galvanized and covered with a thin coating of raw India-rubber, to protect it from the action of the sulphur of the vulcanized rubber. India-rubber insulation possesses one defect as compared with gutta-percha; viz., that it does not adhere to the metallic conductor, and that, consequently, if the India-rubber is once cut through, any strain on the cable has a tendency to pull the conductor away and increase the fault. This does not occur with gutta-percha, which seems to cling to it and prevent such a result. Gutta-percha cracks and perishes unless considerable care is exercised in preserving it, which is best done by keeping it under water. India-rubber possesses higher dielectric properties than gutta-percha.

The Bishop gutta-percha cables and insulated wires, manufactured under the Simpson patent by Messrs. L. G. Tillotson & Co., United States, are in most cases used for submarine mines. The drawings show sections of one, two, three, four, five, six, and seven conductors. These multiple cables are in many cases found convenient where it is required to carry a large number of wires in a compact form into a fort. They may be composed of any suitable number of distinct cores, each of which consists of a strand of copper or iron wire insulated with rubber or gutta-percha. Where there is any strain, or any chance for abrasion against rocks or gravelly bottom, an exterior covering is necessary for protection. Frictional electricity must not be used with the cables, as it would be nearly certain that every mine attached to the cable would explode by induction. See *Galvanometer* and *Submarine Mines*.

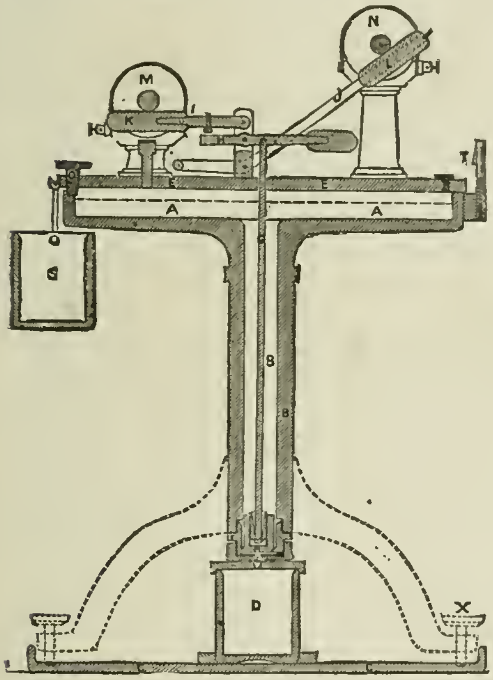


Gutta-percha Multiple Cables.

ELECTRIC CLEPSYDRA.—Generally, with chronometric instruments, the time is deduced from the space passed over during the interval to be measured by a body which moves according to a determined law. This moving body, which we call "chronometer," is the important part of the apparatus; the other fittings are but accessories serving to put the chronometer in operation; that is to say, to render it capable of marking the commencement and the end of the time to be measured. The choice of chronometer, then, is of first importance. A weight falling freely constitutes, incontestably, the most simple and most exact chronometer; regulated by an immutable law of nature, its motion is accomplished without the aid of any intermediary force; neither use nor time can alter its rate; it is absolutely invariable. Unfortunately this chronometer is only applicable to the measure of times relatively short, for the extent of fall increases with the time in very rapid proportions. One can, it is true, transform the vertical fall into a movement of rotation, whether continuous, such as that of revolving cylinders, or alternate, such as that of pendulums; but in both cases the great advantage of a constant chronometric movement is lost; account must then be taken of friction, and this may be varied by causes which escape the observation, and certainty and reliability in the result no longer exist. In order to avoid this inherent inconvenience in the employment of such a mechanical instrument, we may employ as a chronometer the flow of a liquid, and determine the time by means of the weight run out during the interval to be measured. For this purpose mercury presents itself naturally to the mind; this metal, very fluid and homogeneous, has great specific weight, its evaporation is insensible, and, not moistening the inclosing surfaces, its use is extremely clean and convenient. This has been done by Major Le Boulengé of the Belgian Artillery in an instrument to which he has given the name of *electric clepsydra*.

The instrument, represented in section in the drawing, is composed of a circular reservoir, A, of $0^m.20$ diameter by $0^m.03$ high, containing mercury, and supported by a hollow central column, B, of $0^m.20$ height, terminating in a tripod fitted with leveling-screws, X. This vessel, of cast-iron, rests on a circular plate, C, of the same metal, which is fitted with a rim to catch the mercury which may through inadvertence flow out of the receiver, D. A disk of cast-iron, E, covers the reservoir and bears the electrical fittings of the apparatus. The hollow column, which makes a part of the receiver, terminates at the lower end in a fine orifice, above which is fitted a conical valve which prevents the mercury from running out. The face of the orifice, the body of the valve, R, and its seat, F, are of steel. A rigid stem, G, connected by a swivel-joint to the body of the valve, rises, following the axis of the receiver, traverses a central opening in the upper disk, and then connects above this latter to a horizontal lever, H, which is called the valve-lever. If the arm of this lever opposite to the connection of the stem be pressed down, the valve is opened and flow is produced. If the effort be discontinued, the valve falls back upon its seat and the flow is arrested instantaneously. The opening and closing of the valve are performed by the action of two levers, I and J, which fall successively, and of which the heavier extremities, fitted with armatures of soft iron, K and L, are held in the state of "ready" (shown in the figure) by electro-magnets, M and N.

The lever for closing is formed of two parallel arms, united at one end by the armature, at the other by a cross-piece used to raise the lever, K; this disposition permits it to move without touching the valve-lever. If the current which actuates the electro-magnet, M, be broken, the opening lever falls upon the end of the valve-lever, opens the valve permanently, and the mercury flows into the receiver, D, placed immediately under the orifice. We call the lever K, opening-lever; its magnet current and circuit will be called by the name of electro-magnet current and circuit of opening, to distinguish them from similar fittings which operate the closing. If the second current be broken, the closing-lever falls in turn, raises the opening-lever to its original position; then the lever of the valve being freed, this latter falls back into its seat and the flow is arrested. A catch, T, prevents vibration of the closing-lever after its fall. This simple combination of three levers fulfills perfectly the mechanical conditions imposed, for the valve opens suddenly by a shock, while it closes freely by its own action. In actual practice the two currents are bro-



ken successively by the projectile; a weight, P', of mercury flows into the receiver, and it is required to deduce from it the period which has separated the two ruptures.

Let us suppose for a moment that the apparatus furnishes a constant flow, and let P be the flow of the orifice, that is, the weight of mercury which flows per second; by dividing P' by P the time is obtained which has elapsed between the instant of opening and that of closing the value.

The relation $\frac{P'}{P}$ will also give the time which has elapsed between the rupture of two currents, if the valve has opened and closed at the precise instant of the rupture of the corresponding current. But this is not the case; when the first current is broken, a certain time is necessary in order that the magnet may arrive at such a state of demagnetization as to release the armature, then a certain time for the fall of the lever, and finally an additional time for the complete raising of the valve. Analogous periods transpire between the rupture of the closing current and the arrest of the flow. The determination of these short periods is obviated by applying to the instrument the method of simultaneous disjunction, the important feature of which has been devised by Major Navez. To this end the fall of the levers is regulated in such a way that the opening-lever occupies less time than the other from the commencement of its fall to its action on the valve. Thus, when by means of a disjunctor both currents are cut at the same time, the first lever opens the valve a certain time before the second closes it; the weight, P, of mercury run out in this way is the precise quantity to be deducted from P' in order to ascertain from the expression $\frac{P'-p}{P}$ the time which has elapsed between the rupture of the two currents.

This method of procedure takes into account both the time lost in the working of the mechanism and that of demagnetization, which varies with the respective force of the two currents. See *Chronoscope*.

ELECTRIC CLOCK.—A dial with hands and going-train impelled by recurrent impulses from an electro-magnet. The regularity of any clock depends, as is well known, on the action of the pendulum, which is isochronous—that is, has the property, within certain limits, of describing long and short arcs in the same time. The pendulum, however, left to itself, would, in consequence of the resistance of the air, and of the spring on which it hangs, soon come to rest. An impulse must therefore be given it occasionally to keep it going. This impulse need not necessarily be exactly the same, for though it might cause the pendulum to make a longer swing at one time than at another, the time of oscillation would not differ. In ordinary clocks these impulses are given by a heavy weight, and are transmitted to the pendulum through the wheel-work of the clock. No moving power can be more steady than gravity, or less likely to tax the isochronism of the pendulum, but its action on the clock is limited by the distance through which the weight descends, so that the weight must be periodically wound up to preserve gravity in play. The trouble of winding, though small, still leaves room for the wish that a clock might be constructed going for long periods without external help. Such an instrument the electric clock professes to be; but an independent electric clock is not trustworthy as a timekeeper, and all that electric clocks are used for is to copy the time of a good gravity clock. This work the electric clock does to perfection. The electric clock was invented by Bain, an Edinburgh clockmaker, in 1840, and his ideas, though improved and modified, still form the basis of electric-clock-making. In the ordinary clock it is the clock that moves the pendulum; in Bain's clock it is the pendulum that moves the clock. As the construction of the pendulum is the only part of it connected with electricity, we shall confine our notice to a general description of the pendulum action. To the lower part of the pendulum a bob is attached, consisting of a hollow bobbin of insulated copper wire. Wires from both ends ascend the pendulum-rod, and are in metallic connection respectively with the two springs from which the pendulum hangs. Two magnets, or bundles of magnetic rods, are fixed at either side of the bob, and are of such dimensions that the hollow bob in its oscillation can pass a certain way over each without touching. The magnets have their like poles turned towards each other. The two springs of the pendulum-rod are in connection with the two poles of a galvanic battery. The wire connecting one of them is made to pass round by a break, worked by the pendulum-rod. When the pendulum is made to move, say towards the right, it shifts a slider, so as to complete the connection between the poles of the battery. The current thereupon descends one of the wires of the pendulum, passes through the coil of wire forming the bob, and ascends by the other. So doing it converts the bob into a temporary magnet, the S. pole towards the right and the N. pole towards the left. In this way the S. pole of the bob is repelled by the S. pole of the right-hand magnet, and its N.

pole is attracted by the S. pole of the left-hand magnet, so that from this double repulsion and attraction, both acting in the same direction, the bob receives an impulse towards the left. Partly, therefore, from this impulse, and partly from its own weight, the pendulum describes its left oscillation; and when it reaches the end of it, it moves the slider so as to cut off the battery current, and then returns towards the right, under the action simply of its own weight. On reaching the extreme right, as before, it receives a fresh impulse, and thus, under the electric force exerted during its left oscillation, the motion of the pendulum is maintained. So long as the electricity is supplied will the pendulum continue to move. The current required is exceedingly weak, and Bain considered that it could be sufficiently excited by a plate of copper and a plate of zinc sunk into the ground and acted upon by the moisture usually found there. This earth-battery, as he called it, was expected to act steadily for years; but the result proved far otherwise, for the soil not unfrequently dried up, leaving no trace of electrical action. The imperfection of the battery has led to a strong prejudice against these clocks—stronger, certainly, than they merit. Practice has, however, established that a clock driven by an electric pendulum, under no control, is not to be trusted, and clocks of this kind, so far at least as this country is concerned, are entirely abandoned. The next important step in perfecting the electric clock was made by Lewis Jones (patented 1857). All his clocks are ordinary gravity clocks. The standard clock is not an electric clock at all, but its pendulum makes and breaks contact in the battery-circuit which controls the copying clocks. These last, though driven by weights, have Bain's pendulums, and the currents transmitted by the standard clock keep them oscillating in exact accordance with it, so that the standard clock and copying clocks have their pendulums always at exactly the same point in their oscillations. The copying clocks are adjusted to keep nearly the time of the primary, and the margin of error is wholly removed by electric control.

ELECTRIC FUSES.—In most blasting or mining operations the use of galvanic batteries or electrical machines, together with proper exploders, has almost entirely superseded that of the various forms of running fuse. Among the advantages offered by the application of electricity to this purpose may be mentioned: greater ease of application, more complete control, and greater safety; the power to obtain a practically simultaneous explosion of a number of charges, and the ability to work at greater distances, as in torpedo operations. Electric fuses may conveniently be divided into two classes: 1st. Those in which explosion is obtained by disruptive discharge between two points in the circuit. 2d. Those in which the explosion is determined by the heating of a conductor of comparatively high resistance introduced into the circuit.

The first class can be used with the Leyden-jar induction-coil, or any frictional electrical machine, such as Smith's or Von Ebner's, and are known as *frictional fuses*. Fuses of this kind are made in a variety of forms, but in all essential features are alike. All that is necessary is that there shall be a break in a circuit not greater than a spark can easily be made to pass over (generally from $\frac{1}{8}$ to $\frac{1}{16}$ inch), and that between the points of this break shall be placed some composition that will be ignited by the passage of the spark. Gunpowder can be used, but does not ignite readily, and for this reason some more sensitive composition is generally employed. The objections to this class of fuse are: 1st. The highly sensitive compositions used render them dangerous. 2d. Perfect insulation of all leading wires used in connection with them is necessary, particularly when working under water or in damp places. 3d. The frictional machines used with these fuses require great care to keep them in working order, and are much affected by atmospheric causes.

The second class of electric fuses may be further divided into two sub-classes: 1st. *Magneto-electric fuses*, or those in which the introduced or secondary conductor is a substance of high specific resistance, such as plumbago, copper sulphide, or Abel's composition. 2d. *Dynamo-electric fuses*, or those in which the secondary conductor has a comparatively low resistance, such as fine platinum, iron, or German-silver wire.

The magneto-electric fuses are used with Wheatstone's, Beardslee's, and similar machines. The fuse consists essentially of a break in a circuit which is bridged by a layer of plumbago or composition, which, when heated by the passage of the current, burns and ignites the charge of the fuse. These fuses are always of high resistance, but are, however, safe, owing to the fact that no very sensitive composition is used in their construction; but those of the same manufacture vary greatly, both in resistance and the strength of current required to fire them. The principal objections to this class of fuse are: 1st. The great resistance of the fuse makes perfect insulation of all leading wires used in connection with them necessary, for any defect of insulation, particularly when working under water, would probably offer less resistance to the passage of the current than the fuse itself, and the greater part of the current would thus be diverted from the fuse. 2d. Their unavoidable lack of uniformity in resistance and strength of current required to fire them. 3d. Their liability to be rendered worthless by the displacement of the plumbago, from handling or other causes.

The essential feature in the construction of all fuses of this class is the introduction in a circuit of a fine metallic wire, which, when heated by the passage of a current, fires the priming material, or in some instances the charge of the fuse itself, placed in contact with it. These fuses are generally of low resistance and require a moderately strong current to fire them; and by care in construction great uniformity in resistance can be obtained, and much greater regularity in the strength of current required to fire them than with the other classes. The principal advantages of this class of fuse are: 1st. Uniformity. 2d. Safety. 3d. Owing to their low resistance, moderate defects of insulation will not prevent the firing of the fuse. 4th. The condition of the fuse (even after it has been placed in the charge) can always be safely tested by the passage of a weak current, and the certainty of firing be thus demonstrated. 5th. The fuse is not likely to be damaged by handling, storage, or transportation. 6th. The machines used in connection with them require but little care and are not likely to get out of order.

Platinum may be dispensed with by bringing the ends of the conducting wires so close together as barely to be apart, thus forming a break or interval in the conductor. The ends of the wire are held in exact position, usually by being passed through a short plug of wood. Around this plug is wrapped paper, which, projecting at the end where the conductor is broken, forms an envelope for the priming. This wrapping or cap is afterwards covered with a strong shellac varnish. When regularly manufactured fuses cannot be obtained, it may become necessary to improvise them. This may be done in several ways, one of which is to take a small cylinder of hard wood about an inch in diameter and half an inch long; this is provided with a groove around its circumference, in which is tied the paper envelope before mentioned. Two holes about a quarter of an inch apart and of suitable size to receive two moderately fine pieces of copper wire are made lengthwise through the cylinder. One extremity of both of these wires is sharpened with a file, and about a quarter of an inch of the wire bent over at right angles, and slightly flattened with a hammer, the extreme point being bent over in the form of a hook. The straight ends of the wire are then passed through the holes in the cylinder, and the flattened heads are fixed in the wood

by driving the pointed extremities into the latter. In this way the broad, thin metal surfaces which form the poles of the fuse are fixed in a parallel position on the surface of the wood, and should be as close together as possible without actually touching. Before, however, the wires are thus placed in position, the surface of the cylinder, upon which the poles are to be fixed, is brushed over lightly with a solution of ordinary photographic collodion. When the poles have been fixed into the cylinder thus prepared, the small surface of wood which intervenes between them is coated with graphite by drawing a pointed black lead pencil across it two or three times. A cap of paper is then tied round the cylinder so as to inclose the poles of the fuse; this cylinder is filled compactly with fine gunpowder, and the open end is then choked. The protruding wires of the fuse, which serve to connect it with the conducting wires, are coated to within a short distance of their extremities by molding ordinary beeswax around them with the fingers, and then tightly wrapping the wax with thin strips of tape or rag, which is secured to the ends with thread. The entire fuse, except the bare ends of the wires, is then coated with shellac or lacquer. This fuse may be fired by means of a constant battery of sufficient power, or by a magnetic exploder, the former of which generates a continuous current, and the latter a rapid succession of short currents. Currents of this character are required to produce the heating power over the plumbago bridge necessary to ignite the priming. See *Dynamo-electric Igniter*, *Fuse*, and *Galvanism*.

ELECTRICITY.—The name used with reference to an extensive and important class of phenomena, and usually denoting either the unknown cause of the phenomena or the science that treats of them. Most of the phenomena in question fall under the three chief heads of frictional electricity, galvanism, and magneto-electricity. The present article is confined to the first. Thales, about 600 B.C., refers in his writings to the fact that amber, when rubbed, attracts light and dry bodies. This was the only electric fact known to the ancients. The science of electricity dates properly from the year 1600 A.D., when Gilbert of Colchester published a book, entitled *De Arte Magnetica*, in which he gives a list of substances which he found to possess the same property as amber, and speculates on magnetic and electric forces. He is the inventor of the word electricity, which he derived from the Greek word *electron*, amber. Otto von Guericke, Burgomaster of Magdeburg, in his work *Experimenta Nova Magdeburgica* (1672), describes, among his other inventions, the first electric machine ever made, which consisted of a globe of sulphur turned by a handle, and rubbed by a cloth pressed against it by the hand. Hawksbee (1709) constructed a machine in which a glass cylinder, rubbed by the dry hand, replaced Guericke's sulphur globe. Grey and Wehler (1729) were the first to transmit electricity from one point to another, and to distinguish bodies into conductors and non-conductors. Dufay (1733–45) showed the identity of electrics and non-conductors, and of non-electrics and conductors, and was the first to discover the two kinds of electricity, and the fundamental principle which regulates their action. Between the years 1733 and 1744 much attention was given in Germany to the construction of electric machines. Up to this time, notwithstanding the inventions of Guericke and Hawksbee, the glass tube rubbed by a piece of cloth which Gilbert first introduced was used in all experiments. Boze, a Professor at Wittenberg, taking the hint from Hawksbee's machine, employed a globe of glass for his machine, and furnished it with a prime conductor. Winkler, a Professor at Leipsic, was the first to use a fixed cushion in the machine. The Leyden jar was (1746) discovered accidentally at Leyden by Muschenbroek; but the honor of the discovery has been contested also in favor of Cuneus, a rich burgess of that town, and Kleist, Canon of the Cathedral of Camin, in Pomerania. Franklin (1747) showed the electric conditions of the Leyden jar, and (1752) proved the identity of lightning and electricity by his famous kite experiment. The last was performed with the same object about the same time, and quite independently, by Romas of the town of Nerac, in France. In 1760 Franklin made the first lightning-conductor. Canton, Wilke, and Æpinus (1753–59) examined the nature of induction. Ramsden (1768) was the first to construct a plate-machine, and Nairn (1780) a two-fluid cylinder-machine. The electrophorus was invented by Volta in 1775, and the condenser by the same electrician in 1782. In 1786 Galvani made the discovery which led to the addition of the new branch to the science which bears his name, and which now far exceeds the older branch in extent and practical value. In 1787 Coulomb, by means of his torsion-balance, investigated the laws of electric attraction and repulsion. In 1837 Faraday published the first of his researches on induction. Armstrong, in 1840, designed his hydro-electric machine.

Under the head CONDUCTORS it is stated that bodies which do not conduct electricity, or non-conductors, are capable of electrical excitation from friction, and are in consequence termed electrics, and that conductors not so affected are called non-electrics. The *fundamental principles* of electricity are illustrated by the *electric pendulum*. A glass tube bent at right angles, so as to project horizontally, is placed on a convenient stand. On the hook in which its upper end terminates, a cocoon thread is hung, to the end of which a pith-ball is attached. The ball is thus doubly insulated by the glass and the silk thread. If a tube of glass be rubbed by a dry silk handkerchief, and brought near the ball, the ball is at first briskly attracted, and then as briskly repelled; and if the tube be then moved towards it, it moves off, keeping at the same distance from it. The ball being so affected, or charged, as it is called, a rod of shellac or of sealing-wax, after being rubbed with flannel, attracts it, if possible, more briskly than before, and again sends it off exactly as the glass had done. If the glass tube be now again taken up and rubbed a second time, if necessary, the ball will act towards it as it did towards the sealing-wax. The same series of attractions and repulsions would have taken place if we had begun with the sealing-wax instead of the glass tube. We interpret this experiment in the following way: When glass is rubbed with silk, and the silk removed, it is charged with what is called positive electricity. The ball is attracted by it, and becomes on contact also charged with positive electricity, and is then repelled. When sealing wax is rubbed with flannel, and the flannel removed, it becomes charged with negative electricity, which is the counterpart of positive electricity, for it attracts the positively charged ball, and, communicating its own electricity to it, finally repels it. From such an experiment as this we conclude *that bodies electrified either positively or negatively attract neutral bodies and bodies affected with electricity of an opposite name to their own, but repel those affected with electricity of the same name; and that electricity can be communicated from one body to another by contact.* For positive and negative (written also + and −), the terms vitreous and resinous are also employed, as glass and resin are the typical substances from which they may be obtained. Contact is not the only way in which electricity is communicated. We find, when we deal with larger bodies than the pith-ball of the experiment, and sometimes even with it, that the passage of a *spark* between two bodies without contact communicates the electricity of the one to the other. The part played by the rubbers in the above experiment must not be overlooked. The silk handkerchief employed to rub the glass assumes the resinous or − electrical state, and the flannel rubber of the sealing-wax the vitreous or +. This cannot, however, be clearly shown as the experiment is performed, for the rubbers are in each case tightly embraced by the hand, which neutralizes their peculiar electricity. We can perform our fundamental experiment in a way clearly to show this. Let us take for our rubbing and rubbed surfaces two India-rubber balloons inflated with air (such as children play with), and hold them tightly one in each hand. They may be in all respects perfectly alike. Let us then rub them briskly on each other, and then hold the rubbed sides closely together. On bringing the two in contact near the pith-ball, it remains indifferent to them; but if we pull them apart, and put one on each side of the pith-ball, the ball plays actively between them, being attracted and repelled by each in turn. The fact of no attraction occurring when the balloons are together shows that in the rubbing both electricities are generated in equal quantities, for they neutralize each other when brought near; and the fact that the balloons must be separated proves that all electric phenomena take place in an electric field, with positive electricity at its one termination, and negative electricity at its other. The non-conducting nature of the India-rubber prevents the electricities finally neutralizing in contact, and disappearing by the hands when apart. It is also instructive that as force is exerted and work is done in pulling them apart, we have the equivalent of that work in the form of an electric field capable of doing work. The motion of the pith-ball, and the heating caused by the tiny sparks which charge it, are evidences of the truth of the statement. It is again worthy of note that both balloons appear exactly alike, and yet they assume opposite electricities. That there must be some difference may be readily seen from what follows. In most cases of friction, the nature of the rubbing and rubbed surfaces determines the kind of electricity which each assumes. Thus, if glass be rubbed by a cat's fur instead of silk, its electricity is — instead of +. In the following list, each body, when rubbed by any one preceding it, is negatively electrified; by any one succeeding it, positively: cat's fur, smooth glass, linen, feathers, wood, paper, silk, shellac, ground glass. When two pieces of the same material are rubbed together, the colder or smoother becomes positively excited. Metal filings rubbing against a plate of the same metal determine — electricity in themselves, and + electricity in the plate. When a white silk ribbon is rubbed by a black one of the same texture, the white one becomes +. A plate of glass becomes + when a stream of air is directed against it from a pair of bellows. The friction caused by steam of high tension issuing from a narrow pipe develops electricities in the steam and pipe which depend on the material of the latter. This fact has been turned to advantage by Armstrong in the construction of a boiler electrical machine of immense power.

Free electricity has the power of inducing the bodies in its neighborhood to assume a peculiar electrical condition; this is exhibited in the following simple way: A brass cylinder, rounded at both ends, is insulated on a glass pillar. Two pith-balls, hung by cotton threads, are attached at either extremity. When a glass tube is briskly rubbed, and placed within a few inches of the end of the cylinder, the balls at each end diverge, showing that each pair is charged with similar electricities. When the glass tube is withdrawn, the balls hang down as before, so that the electrical excitement of the cylinder is merely temporary, and dependent on the proximity of the excited tube. If, while the balls are apart, a *proof plane*, consisting of a small disk of gilt paper insulated at the end of a glass rod, be made to touch the end next the tube, and then transferred to an electrometer, the electricity is found to be —; if the same be done at the other end, it is +. The nearer end of the cylinder is thus induced by the + electricity of the glass to assume the negative electric state; and as no — electricity can be excited without as much + electricity, we find the other end positively electrified to the same extent. It appears, besides, from the positions taken up by them, that *both electricities observe the same attractions and repulsions as the bodies affected by them*. This action of the electricity of the tube inducing in the cylinder this peculiar electrical condition is called induction; and the cylinder in this state is said to be *polarized*—that is, to have its poles or ends like a magnet, each having its similar, but relatively opposite, force. If the hand touch the cylinder, the balls next the tube diverge further than before, and the other two cease to be affected. In this case, electrically speaking, the cylinder is a portion of the ground, for the hand and body are conductors; the ground is thus brought nearer, more — electricity appears, and the + electricity is lost in the spark with the hand. The — electricity is kept fixed in the part of the cylinder opposite the tube by the + electricity of the latter; and when the hand is first removed, and then the tube, it causes the balls at both ends to diverge permanently. We thus see that electricity can be produced and insulated in conductors by the action of free electricity on them. The + electricity of the further half of the cylinder is as free and insulated as if no — electricity existed within it. This is shown by placing a cylinder near the first, forming a continuation of it, as it were, without touching, when the second cylinder, under the induction of the + electricity of the first, is thrown into the same state as the first. This second can induce the same state in a third, and so on. As the excited tube is withdrawn, the whole series return to their natural condition without being in any way permanently affected. The moment, however, it is again brought near, there is manifested at the further termination of the last a + electricity, which exerts the same influence there as if a portion of the electricity of the tube had been actually communicated or transferred to it. The air intervening between the tube and the cylinder is termed the *dielectric*, for it is through it that the electric action is propagated. In proof of this, we have only to place a cake of shellac between the tube and cylinder, when the polarity of the cylinder will rise higher than before, as would be shown by the further divergence of the balls; and if this or a similar experiment be conducted with sufficient care, we find that the inductive action varies in amount for each non-conductor. Induction, therefore, we have reason to conclude, is not the direct action of one body on another, but an action transmitted through, or possibly residing in, the medium between them. In further proof of this, Faraday, who was the first to examine the function of the dielectric in induction, has shown that the action takes place through air in curved as well as in straight lines, which implies the action of an intervening medium. The relative powers of different substances in facilitating induction are termed by this philosopher *their specific inductive capacities*. The following table by Sir W. S. Harris gives the specific inductive capacities of the more important non-conducting substances, taking that of air as unity: Air, 1.00; resin, 1.77; pitch, 1.80; beeswax, 1.86; glass, 1.90; sulphur, 1.93; shellac, 1.95; India-rubber, 2.8. All gases, whether simple or compound, have the same inductive capacity, and this is not affected by temperature or density. If a large plate of metal be placed between the glass tube and the cylinder, the polarization of the cylinder instantly vanishes, for the induction is diverted by it into the ground.

Some idea of the meaning of the word *potential* may be got from the following comparison. Suppose we have a supply of water with a certain head, to fill an elastic bag: when the water is admitted, the bag will swell till the elasticity of the bag is equal to the head of water, and then the flow will cease. The potential is the head of water or elasticity of the bag, so many feet high, or so many pounds per square inch. The capacity of the bag is usually the amount it holds, but capacity in an elastic bag is a shifting quantity, and we must use the term in this way if we wish to compare the capacity of two elastic bags—

viz., the ratio of the water it holds to the head that filled it. Thus, a bag holding 10 gallons with a head 1 foot would have a ten times greater capacity than a bag holding 10 gallons with a head 10 feet; for if the first were pressed by a head of 10 feet, it would hold 100 gallons, the resistance of the bag being supposed to increase with its contents. Now, let us take a somewhat similar electric problem. An insulated ball is connected with a magazine of energy, ready to make electricity flow when occasion offers, such as a galvanic battery. Let the + pole of a gigantic battery be connected with the ball, and the other pole with the ground: electricity will flow to the ball till the air between the ball and the ground presents an electric reaction equal to the potential of the battery. The charge of the ball taken with reference to this potential gives the capacity of the ball. So much, then, for a popular view of these two words. The potential of a body, or any point in the field, is defined thus, viz.: *the amount of work that would be expended in bringing a small quantity, a unit of + electricity, from an infinite distance to the body or point.* If the body is positive, the work would be expended; if negative, the work would be done on the body and the potential –. The said unit of + electricity will always move from a point where the potential is high to one where it is lower; in other words, electricity will always flow between two points where there is a difference of potential, and will cease to flow when that difference ceases. If E be the charge, V the potential, C the capacity, then $C = E \div V$. From the definition of potential just given, what we have called the potential of the battery in the preceding illustration is in reality its *electro-motive force*, or the difference of potentials of its poles. As these are alike in power but different in sign, and as the difference of two quantities of unlike sign is their sum, the electro-motive force is twice the potential of one pole. If the charging-line be withdrawn, the ball will be in all respects as if charged by an electric machine. The battery having, so long as it acts, an unlimited supply of electricity, its electro-motive force remains the same; but when balls charge one another, the potential falls just as when a limited supply of water has its head reduced when made to run into another vessel. Potential, then, must be estimated by the resistance of the field, or the work value of the unit of charge. The charge being the same, the potential rises with the smallness of the body or the thickness of the dielectric. Density is the quantity of electricity on a unit of surface, and *tension* is the strain which Faraday supposes to exist in the molecules of a dielectric when charged. Tension is commonly used in this country and abroad for potential, though our best writers never use it now in this sense.

We might take it almost as a self-evident truth, that the greater the surface over which electricity is diffused, the less is its electric potential at any particular point, and so we are taught by experiment. When two equal balls are insulated, and a charge is given to one of them, and then communicated to the other by contact with the first, it is found that both equally divide the charge, but that the potential of the electricity of each is one half of that of the originally charged ball. When a watch guard-chain is charged and laid on the plate of an electroscope by means of a glass rod, the gold leaves diverge most when the chain lies in a heap on the plate; and as it is lifted up, the leaves approach each other, showing that as the exposed surface of the chain increases, the electric potential of each part diminishes. The reason of this is obvious. Let us begin with one ball with a certain charge, then take another equal ball and impart half the charge to it by making the two touch. A spark will be seen at the charge of the second ball. The quantity in both is still the same, but energy has been lost by the spark, and the heat generated by the spark is the measure of the loss. If we continue to add ball after ball until we have a very large surface, the quantity is the same as at first, but energy has been squandered in the sparks of each additional ball, and so the potential is lowered. Experiment teaches us that electricity is exhibited only on the surfaces of conductors. A brass ball is suspended by a silk thread, and covered with two hemispheres, which can be held by insulating handles, and which exactly fit it. A charge is then communicated to the ball so compounded. When the hemispheres are withdrawn, they are found to take away all the electricity with them, not the slightest charge being left in the ball. The same fact is exhibited by a hollow ball placed on a glass pillar, with a hole in the top large enough to admit a proof-plane to the inside. When charged, not the faintest evidence of electricity is found on the inner surface, however thin the material of the ball may be. The thinnest metal plate, when under induction, shows opposite electricities on its two faces. We learn from these and numerous other experiments that *electricity is only found on the outer surfaces of conductors in an envelope of inappreciable thickness.* This fact is quite in keeping with Faraday's theory of the action of dielectrics. Within a conducting body we cannot expect electricity, for the moment it appears in it the particles communicate their electricities to each other, and the electric state ceases. In a dielectric they cannot communicate, and the charge remains. Hence the charge at the conductor only appears at the junction of a conductor and dielectric. We are also taught by experiment that the distribution of electricity on the surface of insulated conductors is influenced materially by their form. An electrified ball, for example, exhibits the same density all round, for the resistance is sensibly the same on all sides of it. When, however, a conducting body is made to approach near enough to it, the density of the electricity is found to be greater on the side on which the approach is made. This is proved by the aid of a proof-plane and an electrometer. When work is done in drawing away the proof-planes from the charged body, its potential, as tested by the electrometer, is proportional to the density of the charge at the point where it touched. The reason of this unequal distribution is obvious from the fact that the potential of the ball must be the same at every point. If, therefore, the resistance at one side be less than at another, the density there must be greater to maintain equality of potential. The disturbance of equal distribution here spoken of holds true only for short distances; the disturbing body, for instance, in the case under consideration, has to be brought very near before any inequality in the distribution of electricity on the ball becomes manifest. It is to this concentration of electricity on the side of the approaching conductor that we owe the electric spark; and it is as we near the striking or sparking distance that this disturbance is revealed. The concentration or fixing of electricity on the side of the thinnest and best dielectric is particularly illustrated in the condenser and Leyden jar, whose action depends upon it; but in these the dielectric must be very thin to secure decided effect. When a conductor somewhat in the form of a prolate spheroid is charged, and the electric density of the several parts tested by the proof-plane, it is found to be least at the thickest part, and to increase towards either end; and the difference is found to be all the greater as each end becomes more and more pointed. It is found likewise that the electric density on a point is so great with a considerable charge as to destroy the dielectric condition of the air, the particles of which become electrified, and carry by convection the charge of the point to surrounding conductors. We therefore learn that *electricity concentrates on points and projections.* A similar reasoning with regard to the relations of potential resistance and consequent density bears here as in the previous case. It may be here remarked that the density of charge at any point regulates the amount of tension at that point on the molecules of the dielectric. The constraint which they experience in being charged, and which Faraday calls tension, can only be carried to a certain limit. When that is reached, the molecules are forced to be conducting, and the tension ceases.

The words electrometers and electroscopes are generally taken as synonymous; electroscopes, however, should be applied to the instruments which give evidence of electrical potential without giving the exact measure of it; and electrometers to such as show both. Of late years immense progress has been made in the construction of delicate electrometers, chiefly to meet the demands for such in the working or testing of submarine cables. Sir William Thomson's quadrant electrometer and his absolute electrometer in point of exactness and delicacy are a hundred-fold in advance of previous instruments. The *gold-leaf electroscope* is a handy instrument for estimating roughly medium potentials. In one of the best of its forms a glass ball, about 4 inches in diameter, rests on a brass tripod, and its neck, about 1 inch in diameter, is inclosed by a brass collar fixed with shellac. A brass plate, with a hole of ¼ of an inch in diameter in the middle of it, can be screwed airtight into the collar. Before it is so fitted, a brass rod, ⅛ of an inch in diameter, is fixed by shellac or sealing-wax into the hole in the middle, so as to be perfectly insulated from it. The upper end of the rod terminates in a brass ball, and the lower end is filled on each side, to allow of two strips of gold-leaf, 1 inch long, being attached to it. Before the plate and leaves are finally fixed, the interior of the ball is thoroughly dried by passing hot dry air into it, so that the ball contains no moisture to carry away the charge of the leaves. When the plate is screwed to the collar, there is no communication between the included and external air. The insulation of the leaves is complete; and they keep their charge in dry weather for hours together. When the instrument is used, it may be charged directly, by contact being established with the ball and the body whose electricity we would examine, or a charge may be carried to it by the proof-plane, when the leaves diverge according to the charge communicated.

Coulomb's Torsion-balance has played an important part in examining the laws of electric forces. A glass canister (Fig. 1) is placed on a wooden frame, and is covered above by a plate of glass or wood; in the middle of this plate a round hole is cut, over which is fixed, by wooden fittings, a long glass tube having the graduated rim of a circle attached at its upper end. A circular plate, resting on this rim, closes the upper end of the tube; and when it is turned round, a mark upon it tells the number of degrees through which it has been moved. A cocoon thread or very fine wire is tied to a hook in the center of the lower side of this plate, and thence descends to the body of the canister. It carries below a collar of paper or other light material, in which a needle of shellac is adjusted having a disk of gilt paper placed vertically, or a gilt pith-ball at its one end and a counterpoise at its other. When the plate above is moved through any number of degrees, the needle below, impelled by the torsion of the thread, comes to rest at the same number on the scale below. This last consists of a strip of paper divided into degrees, pasted round the cylinder at the same height as the needle. In the cover of the canister there is another opening, for the admision of a ball insulated at the end of a rod of shellac, and which, when supported by the cover, is on a level with the paper disk of the needle. When adjusted for observation, the mark on the upper plate and the paper disk stand each at the zero-points of their respective scales, there being of course no torsion in the thread. The ball is removed to receive a charge from the body under investigation, and is then placed in the cylinder, when the disk is first attracted, then repelled. Suppose that the disk be driven 40°, as shown by the lower scale, from the ball, and that the upper plate has to be moved in the opposite direction, through 160° of the upper scale, to bring it back to 10°; the total degree of torsion is 160 + 40° = 200°. If the ball and disk be now discharged, and another charge be given to the ball, which requires 250° of torsion to place the disk at 10°, we have the relation 200 to 250 as that of the repulsive forces of the two charges, for the amount of torsion in degrees is proportional to the twisting force. Without entering further into detail, we may state the two laws that Coulomb established by this instrument: *The intensities of the mutual repulsion or attraction of two invariable quantities of electricity of the same or different names are in the inverse ratio of the squares of the distances at which these act. The intensities of the total repulsive or attractive action of two electrified bodies placed at an invariable distance are proportional to the products of their electric charges.*

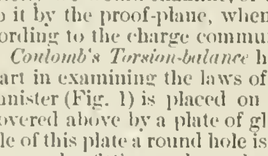

Fig. 1.

In the tube of glass and silk rubber of which we have made frequent mention we have the embryo of the electric machine, viz., a body which when rubbed is positively electrified, and its rubber negatively. The first requisite we should expect in a *machine* of this nature is a large surface, to give a great amount of electricity. But there is another already casually referred to: glass being a non-conductor, the electricity formed on its surface has not a combined action, so that some arrangement is necessary to collect it and render it available—to act, in fact, as its conducting reservoir. This portion of the machine is denominated the *prime conductor*. The rubbed surface of the electric machines is either a cylinder or plate of glass; hence we distinguish them into cylinder-machines and plate machines. The former, from their more compact form, are the more manageable; and the latter, from both sides of the glass plate being rubbed, are the more powerful forms of the instrument. In frictional machines there are two ways in which energy is expended—in friction, and in drawing away the two excited and attracting surfaces. Much of the force expended in friction results in heat, and only a fraction (sometimes a small one) in electricity. Of that spent in drawing away, which is the less considerable, the whole results in increased potential. Machines are therefore very desirable where, with a small initial charge, a constant supply of electricity may be got by the latter method. The electrophorus is a machine of this kind, and has been known since 1776, and Nicholson's doubler, another, since 1788. But the action of these has only been on a small scale. Lately, however, induction-machines of great power have been made, the powers of which quite eclipse the older frictional machines. The best known of these is Holtz's machine (invented 1865), which will suffice to show the general construction of such. Fig. 2 shows Queen's Toepler-Holtz electrical machine, which is destined to be the machine of the future. Omitting a description of the machine, the details of which are clearly set forth in the drawing, we will notice the manner of its operation. Suppose we wish to work the machine, whose plate is two feet in diameter, the usual size. We first put the two poles in contact and see that the revolving plate passes an opening before coming to the row of teeth. We next take a sheet of vulcanite about the breadth of an armature, and rub it with cat's skin (making it −), hold it close to the armature, and then make the plate revolve. We at once know if the machine is working by a rushing sound. We now gradually withdraw the two balls at the poles, and a rush of straight, bright, but not very dense sparks leap across between the two for the first 2 inches or so. When the distance becomes greater than that, brushes proceed from each end, and there is a fine purple glow in the central space. If we withdraw the poles to 5 or 6 inches, two well-defined brushes are seen, one at each pole. If now the hand be placed on one pole and the other hand presented to the other, sparks of 2 inches are got which produce a most painful stinging sensation on the hand, but cause no twitching at the joints of the arm. When the poles are at a distance of half an inch, paper and other combustible substances may be kindled by the spark. On examination it is found that the armature first touched by the excited vulcanite is —, and that the other is +. The plate is + below; that is, after passing the negative armature; and — above, after passing the + armature. If the motion of the plate be reversed, the electricity of the poles changes sign or ceases altogether, when the machine must be excited anew. If kept moving in the same direction, and allowed to rest only for short intervals, it may be kept in action for hours together without renewed excitement. In order to get long dense sparks, a small Leyden jar is hung on the rods with their outer coatings in metallic contact. With these condensers a splendid series of long, intensely brilliant sparks of six inches in length are got, each accompanied with a snap painfully loud, quite eclipsing anything shown by friction-machines. The condensed spark does not kindle paper, but gives a very powerful shock. We have not space to enter into the theory of Holtz's machine. Indeed it may be questioned if, in all points, its action has been fully accounted for. We would only say that reciprocal action of the armatures on each other is common to all induction-machines, and is quite similar to Siemens and Wheatstone's principle for magneto-electricity.

By discharging the Leyden jar or electric battery through particular channels, we obtain some beautiful illustrations of the power of electricity. When the discharge is effected through thin wires of gold or platinum, the heat accompanying its passage is so great as to dissipate them in vapor. The expansion of the air caused by the spark is shown by the *electric mortar*. This is a wooden mortar with two wires entering air-tight at the opposite sides of the breach, with a small wooden ball fitting closely in the muzzle. The spark passing between these wires in discharge causes a sufficient expansion of the air within the mortar to drive the ball to some distance off. When the discharge is made through gunpowder, it tosses the grains violently about, but causes no ignition; when, however, it is retarded by introducing an imperfect conductor, such as a wet string, into the circuit, the gunpowder is fired. When the discharge is made through glass by two points pressing against its opposite surfaces, a small hole is drilled into the glass.

The velocity of electricity is found to vary with the nature of the circuit to the extent, indeed, of its inductive embarrassment. Thus, in air-lines of telegraph it is greater than in sea-cables. Wheatstone was the first to determine the velocity of electricity in an insulated copper wire stretched in air. He did this by the device of a revolving mirror. Any one who takes a mirror in his hand and makes it revolve sees that objects are apparently displaced by it, and that the reflected image describes an angle the double of that of the mirror. If, while the small mirror rotates at 50 turns a second, the image of a spark should show a displacement of 90°, we know that the mirror has moved through 45°, and the time during which this takes place is $\frac{45}{360}$ of $\frac{1}{50} = \frac{1}{400}$ of a second. If the duration of the spark, then, had been $\frac{1}{400}$ of a second, we should have seen its image move through 90°. The eye, however, during this time would not have been able to discern any difference between the beginning and the end of the spark, so that the 90° would have appeared as one arc of light. Examined in this way, however, the spark of a machine and of a Leyden jar were seen as if the mirror had been at rest. He arranged a Leyden-jar circuit of half a mile with three breaks in it, two near the coatings and one in the middle of the half-mile, and had these breaks placed nearly side by side, so that the sparks at them, when discharge took place, could be seen together in the revolving mirror. He found that all three sparks had a duration of $\frac{1}{24000}$ of a second, and that the middle spark occurred so far behind the other two as to indicate a velocity of 194,000 miles per second in the wire.

There are two theories which have played an important part in the history of the science—the two-fluid theory of Dufay, and the one-fluid theory of Franklin. According to the former, matter is pervaded with two highly elastic imponderable electric fluids—one, the vitreous; the other, the resinous. These are supposed to repel themselves but attract each other. Neutral bodies give no evidence of their presence, for they are there neutralized the one by the other; but when by friction or other operation

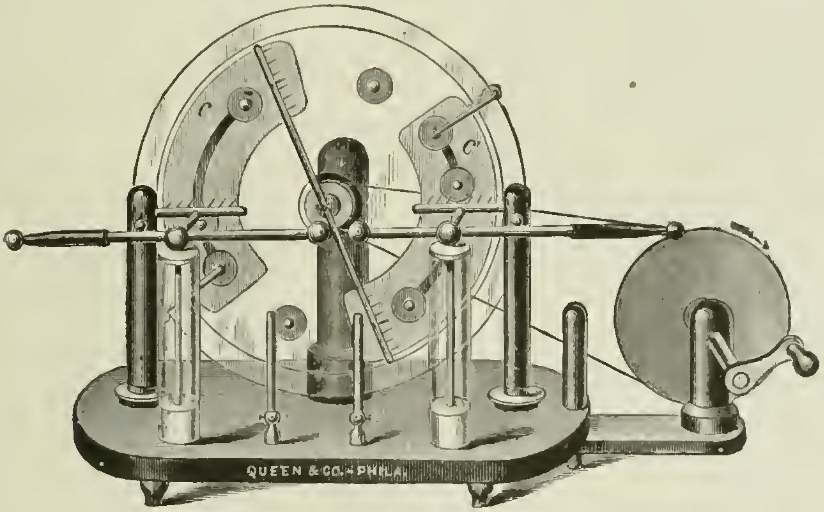

FIG. 2.

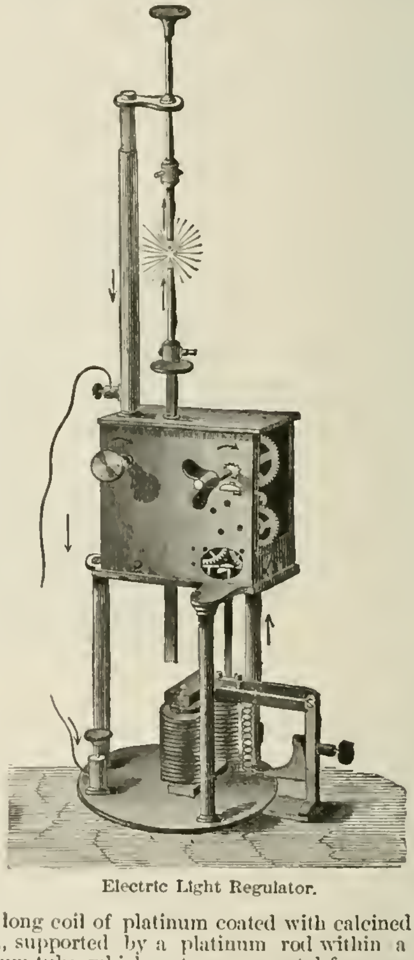
the fluids are separated, each body observes the attractions and repulsions of the fluid it happens to have. According to the latter, there is only one electric fluid which repels itself but attracts matter. Friction determines a gain of the fluid to the positive, and a loss to the negative, body. Faraday's theory of electric induction by contiguous molecules appears to be gaining ground. It explains satisfactorily how conductors and non-conductors are alike in kind; how the charge on the conductor can only reside at the boundary of the conductor and non-conductor, or—which is the same thing—the surface of the conductor; how the charge resides *in* the dielectric; how the polarity of the galvanic circuit is effected; how a battery-current originates in and effects chemical decomposition; and how the velocity of discharge is dependent on the conformation of the circuit. Prof. Clerk Maxwell's classical work, *Electricity and Magnetism* (1873) gives to Faraday's views a mathematical significance and comprehensiveness hardly contemplated by the great philosopher himself. See *Galvanism* and *Magnetism*.

ELECTRIC LAMPS.—The more recent inventions of electrodes producing light are those of Jablochkoff, Lodyguine, Kohn, Sawyer, and Edison. The first of these produces the light by the electric arc; the others by the incandescence of some refractory substance, as carbon or platinum. The principal difference between the Jablochkoff light and the ordinary arrangement with carbon points is in a provision by which the current is reversed from time to time so that the more rapid consumption of the positive electrode is made to take place with one and the other point alternately. When the apparatus is started, there is also a slight bridge of carbon between the two points through which the current passes before the arc is established. The carbon rods are placed parallel and near together, so that a uniform distance may be maintained during their consumption. A pair of carbon points constitutes a "candle," and four candles are usually placed in a globe of opalescent glass. Each candle burns about one hour and a half, so that the set of four will give light about six hours, the change of electric action from one candle to another being accomplished by an automatic switch. The motive power required in the Jablochkoff lamp is about one horse-power applied to a magneto-electric machine for each candle, and each such candle is said to have a light-value of 700 standard candles; but this, from the absorption of light by the opalescent glass, is reduced to that of 300 candles. In 1873, M. Lodyguine, a Russian as well as Jablochkoff, invented a lamp which gave light by rendering carbon incandescent by the electric current. A portion of the conducting-rod of carbon was made much thinner than the rest, so that the increased electrical resistance in that part would cause it to become intensely incandescent. The carbon rod was inclosed in a glass vacuum-chamber, but the apparatus was not practically successful, as the carbon wasted too rapidly, and required too frequent replacement within the vacuum-chamber. In 1875 M. Kohn of St. Petersburg patented an arrangement intended to obviate this difficulty by a device having the same object as that in the Jablochkoff lamp, viz., to supply the place of the consumed carbon with a new piece. This lamp has been used with considerable success. The Sawyer lamp has the following characteristics: It employs the resistance of a small piece of carbon, placed in an air-tight glass cylinder filled with pure nitrogen, which, being a non-supporter of combustion, protects the carbon in a manner like that of a vacuum, the advantage claimed being that it is easier to keep a vessel full of pure nitrogen than to maintain a vacuum, because of the equality of the inward and outward pressure. The heat produced is prevented from reaching the mechanism at the base of the apparatus by having the copper standards present a great radiating surface. Diaphragms are also placed so as to cut off much of the downward heat-rays, and a switch device is employed to prevent the too sudden turning on of the current, and thereby prevent crumbling by too sudden heating. The experiments of Mr. Edison on the electric light have been in progress several years, in which time he has used various substances for the incandescent material. He commenced with platinum, and employed a device by which the galvanic current would be reduced when the metal approached the melting-point. This device consisted chiefly in placing within the fine platinum spiral a rod of the same metal which would be moved, on the principle of the pyrometer, one way or the other by a lever, and thus cool by its presence the incandescent spiral when it became too hot. But this device did not prove successful. Another arrangement employed heated air acting upon a diaphragm as the regulating power. The various metals which he used soon became oxidized and rendered useless. He then gave his attention to perfecting the vacuum employed by Lodyguine in 1873. Edison's platinum lamp as perfected consists



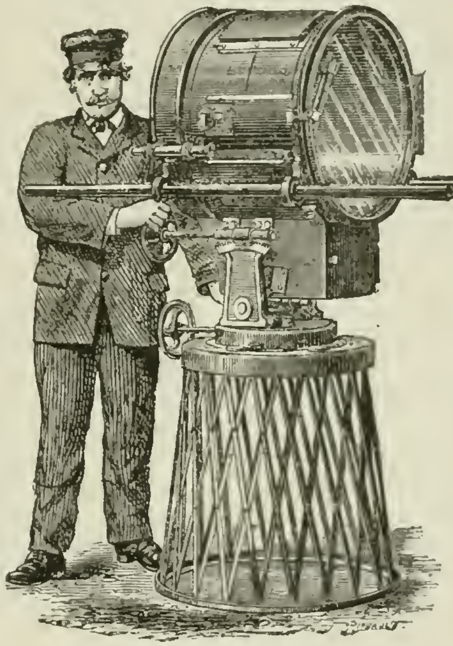
Electric Light Regulator.

of a long coil of platinum coated with calcined magnesia, supported by a platinum rod within a glass vacuum-tube, which rests upon a metal frame containing the regulating apparatus. It is claimed that Edison has produced a vacuum more perfect than any other, so that only one millionth of an atmosphere remains. His attention was called from the use of platinum to that of small threads of carbon, made by charring cotton thread in a vacuum with the electric current. Light of great intensity was obtained in this way. He experimented with various forms of woody fiber, but finally found that nothing gave more satisfactory results than charred paper. Bristol card-board is cut in the shape of a horseshoe, the strips being about two inches long, and an eighth of an inch wide, and laid upon one another in an iron mold, being separated by tissue-paper. When the mold is packed, it is placed in an oven and gradually heated to 600°; afterwards in a furnace to a white heat. The carbonized product is then carefully removed and placed in a small glass globe, and made the resisting portion of the galvanic circuit; the globe is then exhausted and sealed air-tight. The drawing represents the most approved electric-light regulator, with double clockwork, after Foucault's arrangement. See *Electric Light*.

ELECTRIC LIGHT.—Powerful electric lights have become exceedingly important as engines of war, and the soldier and sailor vie with each other in the development of apparatus suited to their special needs. Enormous increase in the power of single lights has been obtained during the past few years by the great improvements which have attended the introduction of electricity as an illuminating agent. This has benefited the defense more than the attack, whether the operations be on land or sea; for, usually, the main functions of a powerful light are to guard against surprise, to give the defenders a timely warning, and thus enable them to aim at the advancing forces. The defense can, moreover, employ the most powerful lights, the machinery for which is ponderous and not suited to the mobility required by the attack. Nevertheless the use of a powerful light may frequently aid the attacking forces very materially. Thus at the attack on Charleston, during the War of Secession, the Southerners were prevented from repairing the breach in Fort Sumter by night on account of a deadly shrapnel fire which was directed upon the breach by the aid of a lime-light, which is so inferior to the light now obtainable by means of the electric arc. Again, in an advance over obstacles, it has been found that the attacking party will often receive great assistance even from the electric lights of the defense. As before stated, however, the balance of advantage appears to be considerably on the side of the defenders. In all descriptions of siege-operations the employment of the electric light has become a matter of considerable importance, many operations which it has hitherto been customary to perform under the cover of darkness being no longer possible, and other operations, such as the bridging of rivers, which formerly could only be carried on during daylight, being now possible on the darkest night.

The two important war-services for which powerful electric lights have been provided, in England, are: 1. As search-lights for the vessels of the Royal Navy. 2. As search-lights to act in unison with the artillery and submarine mining defenses of ports and harbors. In the one case the machinery is carried on board the large men-of-war, and in the other case is erected inside the forts. In each of these positions the machinery can be placed practically out of reach of an enemy's shot and shell; but the protection of the projector, and of the men who manipulate it, can never be so satisfactorily provided for, and the subject has consequently received a good deal of attention, both in the army and navy. The subject has especially been worked at by the Royal Engineers, and has been attacked in two ways: 1. By attempts to place the projector and manipulator out of the direct fire of an enemy, and to use a mirror for the final projection of the ray of light in his direction, such mirror being exposed to the fire, but being arranged so that it can be easily and quickly replaced. 2. By attempts to greatly decrease the cost of the projector, and to arrange the optical portions so that they can be expeditiously replaced if broken. The projectors at first used were large metallic reflectors, either spherical or parabolic; but a lighter, smaller, and equally powerful arrangement was found in the Fresnel lens, now called a spherical holophote. It consists of a central lens, generally in three elements, with a focal distance of .15 meter, and which receives dioptrically the light-rays in a cone of about 60 degrees. The catadioptric portion is composed of five or six annular rings so placed that the principal focus of each ring coincides with that of the dioptric portion. There is also sometimes added a small spherical metallic mirror, placed behind the focus, so as to catch and throw forward again the rays from the back of the arc-light. Owing to the short focal distance, it is very difficult to focus the light properly in these costly projectors, and the glass rings are frequently cracked by the flame and radiation from the electric arc. For short ranges, however, they are efficient.

These projectors have given place to a most effective arrangement designed by Colonel Mangin, of the Corps du Génie (French army), and which consists of a reflecting lens ground on the inner side to a spherical surface of somewhat shorter radius than the outer spherical surface, the glass of the reflector being, therefore, thicker at the sides than at the center. In fact, the projector is a spherical catoptric apparatus, the divergence of which is rectified dioptrically. The drawing represents a smaller Mangin projector,



Mangin Projector.

.60 meter in diameter, which differs in a few of the mechanical details from the larger sizes. It is fitted with two bars, and can thus be moved about by two men, the lattice-work stand being moved separately. All these projectors are costly, and to place them so as to look over the parapets of our forts or the bulwarks of our ships is to invite their speedy destruction by an enemy's fire. To meet this difficulty arrangements were made and tried at Chatham in accordance with suggestions made by Major Sale, R. E., C.M.G., in 1876–7, then Secretary R. E. Committee, to place the projector in a splinter-proof pit, and direct the beam of light on to a plane mirror placed a short distance off, and alone exposed to the enemy's fire. The results were encouraging, but difficulties were encountered in the fixing and manipulation of the mirrors, the apparatus tried being so weak that the wind moved the mirror unduly. In these designs the projector and the mirror or mirrors were placed nearly in the same horizontal plane, and there was a loss of light when the mirror was approaching at extreme angles of training. Moreover, the range was limited, and unless two mirrors were used (in some situations not convenient, and in others not possible) on opposite sides of the light, the portion of the whole circle illuminated was limited. And in some situations the length of parapet required could not be spared.

In April, 1880, Captain Bucknill, R. E., proposed the following arrangement: 1. To work the ray of light to the zenith, either directly or by means of a mirror. 2. To deflect this ray by an upper mirror carried in a framework or funnel. 3. To carry the funnel or tube that supports the upper mirror upon a ring, and this again upon rollers and another ring clamped or fixed to the inner wall or walls of a fort. A slow-motion screw, a worm, etc., would then move the funnel in azimuth at pleasure, and consequently the ray of light from the mirror. 4. To move the upper mirror by a slow-motion screw actuated by a light grip-wheel on the axle of such screw, which wheel can be turned by an endless cord from below, by a man who would take his orders through a speaking-tube from an observer in the firing station. The only commands required would be "Up," "Down," "Right," "Left," "Fast," "Slow," "Stop." Such a tube could be taken down at daybreak and put up again in the evening in a few seconds by an arrangement like that used in raising and lowering Thames steamboat funnels. It is difficult to work a light-ray direct to the zenith, especially with a Mangin projector, as the burnt pieces of hot carbon fall on the glass of the projector at the thinnest part (the center) and perhaps crack it. The vertical ray can, however, be readily obtained by means of a lower mirror. It should be noted that this arrangement provides for reflection at about 45 degrees, a very small angular movement of the upper plane mirror producing a large vertical motion of the ray of light. See *Dynamo-electric Machine* and *Electric Lamps*.

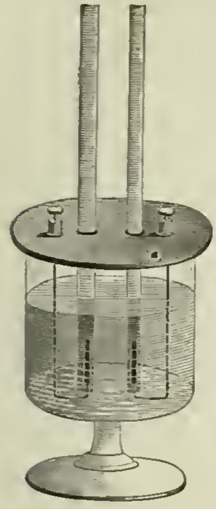
ELECTRIC PRIMER.—This primer consists of the long tube of the service friction-primer, split at one end to receive a large piece of brass tube, to which it is soldered. The larger tube incloses a cylindrical piece of hard wood, slotted midway of its length, and perforated at each end to receive short pieces of copper wire, which are connected across the slot by a coiled piece of fine platinum wire. The outer ends of the copper wires project a few inches to connect the wires of the primer with the terminal wires of the battery. When thus connected, the battery-current, by reason of the resistance met with in passing through the platinum wire, heats this wire sufficiently to ignite a small piece of loose gun-cotton which, together with the platinum wire, occupies the slotted portion of the wooden cylinder. The ignited gun-cotton commmunicates its flame to the powder in the long tube. The open ends of the large tube are turned down on the wooden plug to prevent blowing out. These and the open ends of the small tube are closed and dipped in varnish, as described for the friction-primers. The platinum wire is coiled to increase its length between the copper ends. By this means the absorption of heat by the latter is overcome. The coil is also less liable to be broken by any slight displacement of the copper wires. With the standard length of one inch and thickness .003 inch for the platinum wire, the resistance of this primer is about 7 ohm cold and 1.2 ohm at explosion. Fulminate of mercury may be used instead of gun-cotton. The latter is preferred, however, as being equally serviceable and less dangerous. See *Friction-primers*.

ELECTRO-BALLISTIC MACHINES.—The accurate determination of the *velocity* of a projectile at any point of its trajectory has been one of the most difficult problems in the science of gunnery. It has exercised the talents and ingenuity of the best scientific minds of the age, and has given rise to much interesting discussion and many valuable experiments. The wondrous mechanical skill of the day, and our mastery over the powers of electricity, have, however, recently given us instruments which, in their results, more than realize the brightest dreams of the experimenters of a century ago. Their bulky, unwieldy, and expensive machines have given place to the neat and compact chronoscope, which, with its pencil of electric light, now notes with unerring certainty infinitesimal intervals of time. Besides the electro-ballistic machines, a great variety of instruments have been invented to determine directly the initial velocity of a projectile, the most reliable of which are the *gun-pendulum* and the *ballistic pendulum*. In the first the velocity of the projectile is determined by suspending the piece as a pendulum, and measuring the recoil impressed on it by the discharge; the expression for the velocity is deduced from the fact that the quantity of motion communicated to the pendulum is equal to that communicated to the projectile, charge of powder, and the air. The second apparatus is a pendulum the bob of which is made strong and heavy, to receive the impact of the projectile; and the expression for the velocity of the projectile is deduced from the fact that the quantity of motion of the projectile before impact is equal to that of the pendulum and projectile after impact. These machines have been carried to great perfection both in this country and France, and very accurate and important results have been obtained by them; but they are very expensive and cannot be easily adapted to the various wants of the service.

The employment of electricity to determine the velocity of projectiles was first suggested by Wheatstone in 1840. The application depends on the very great velocity of electricity, which for minute distances may be considered instantaneous. The general method of applying this agent is by means of galvanic currents, or wires, supported on target-frames placed in the path of the projectile, and communicating with a delicate time-keeper. The successive ruptures of the wires mark on the time-keeper the instant that the projectile passes each wire, and knowing the distance of the wires apart, the mean velocities, or velocities at the middle points, can be obtained by the relation, $\text{velocity} = \frac{\text{space}}{\text{time}}$. The various plans in use differ only in the manner of recording and keeping the time of flight; one of the simplest and most common instruments employed is the pendulum. The ballistic machine of Captain Navéz, of the Belgian service, has been tried in this country, but has been found too delicate and complicated for general purposes. See *Chronoscope* and *Electric Clepsydra*.

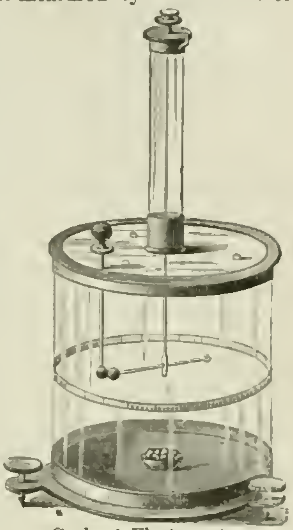
ELECTRO-CHRONOGRAPH.—An instrument used for recording time and occurrences in the instant and order of their time, as in noting transits in observatories. A paper marked for seconds is placed on the surface of a revolving drum, over which is a stylus operated by electro-magnetic action when the circuit is closed by the telegraph-key in the hand of the operator, who is also the observer at the transit instrument. A mark is thus made on the time-paper at the instant of the occurrence of the transit. See *Chronograph*.

ELECTROLYSIS.—That division of the science of galvanism which treats of the laws and conditions of electro-chemical decomposition. As this decomposition is generally attended by electro-chemical combination, it is sometimes difficult to distinguish electrolysis from the more general subject of *electro-chemistry*, which embraces all chemical changes resulting in or from the galvanic current. In one case, however, the application of the term is strictly correct—viz., where decompositions are effected by electrodes which are not attacked by the elements of the electrolyte (the substance decomposed) discharged at them. No substance is decomposed by the current so long as it is in a solid or gaseous state, and it must first be brought to a liquid state, either by solution or fusion, before the current acts on it. The decomposition of water by platinum plates is always taken as the type of electrolytic action. In a very convenient apparatus for the purpose, a glass basin is made so as to admit a cork below, through which two wires pass having slips of platinum plate soldered to them above. Two glass tubes, open below, are hung over the plates, to hooks projecting from an upright support. The bowl is filled with acidulated water; and the tubes, after being filled with the same, are inverted, and hung with their lower ends inclosing the plates. When the wires projecting downward from the cork are connected with the poles of the battery, hydrogen rises from the negative, and oxygen from the positive electrode, to fill each its separate tube. As the decomposition proceeds, twice as much hydrogen is liberated as oxygen. When the tubes are filled, they may be removed and examined. The oxygen thus obtained smells strongly of ozone. Hydrogen is here the type of the metals or other electro-positive substances (cations), which, during electrolysis, are always disengaged at the negative electrode; and oxygen of the salt radicals, chlorine, iodine, sulphur, etc., which, being electro-negative (anions), always appear at the positive pole. Moreover, the proportions of the volumes of the two gases being that of their chemical combining volumes, reminds us that, when a body is decomposed, its components are always separated in the proportions in which they were united, viz., those of their chemical equivalents. If the tubes of this apparatus were graduated, it would serve for a voltameter. If, instead of one such voltameter included in the circuit, we had several, we should find that, whatever amount of gas was liberated in one of these would be liberated in all, and that independent of the size of the plates and amount of acid in each. We learn, therefore, that the chemical power of the current is the same at every point of the circuit where it is manifested. From numerous experiments it has been concluded that electrolytes are resolved under the action of the current into anions and cations which appear at their respective electrodes in the proportion of their atomic weight, or multiples of their atomic weights. It is not only in cells exterior to the battery that this law holds, but in the cells of the battery itself. If the battery which effected the above decomposition consisted of six cells, for the equivalent atoms of hydrogen, tin, and lead separated without the battery, equivalent atoms of zinc in each cell would have been dissolved, and an equivalent disengagement of atoms of hydrogen at each of the copper plates, if the cells were one fluid. The above law holds not only for compounds whose elements enter into combination with their usual atomicity, but for those in which the elements, through the same, change their atomic equivalents. Thus, if the same current pass through two decomposing cells, one containing a solution of the cuprous chloride (CuCl), and the other of the cupric chloride ($CuCl_2$), the same quantity of chlorine will be disengaged in both, but twice as much copper is deposited in the first as in the second. Here the copper alone changes its atomicity, hence the change in the amount of it in the consecutive cells. The accuracy of the electrolytic law is somewhat compromised by the fact that liquids possess, to a certain extent, the power of conducting, physically, electricity without electrolytic action, so that all that passes in this way is chemically lost. Fortunately the error thus introduced is very small, and can be therefore practically disregarded. The drawing represents an improved water decomposing apparatus, consisting of a glass goblet, with binding-screws, platinum electrodes, and finely graduated bell-tubes for the gases. See *Galvanism.*



Decomposing Apparatus.

ELECTROMETER.—An instrument to measure the amount of electrical force. In Coulomb's torsion-electrometer, shown in the drawing, the force opposed to that of electricity is the resistance to twisting offered by an elastic thread. In Henly's quadrant-electrometer the electric force is measured by the amount of repulsion which it produces upon a pith-ball attached to a silk fiber suspended from the center of a graduated arc. Sir William Thomson's and Varley's electrometers are the most delicate of all, and are used in reading the insulating power of telegraph-cables. The quadrant-electrometer consists of a conducting-rod, generally of box-wood or brass, with a graduated semicircle attached above, in the center of which is a pivot for the rotation of a straw carrying a pith-ball at its outer end. It is used for a charge of high potential, such as that of the electric machine. When placed on the prime conductor of the machine, the whole becomes charged with + electricity, and the ball is repelled first by the electricity of the rod, and then by that of the prime conductor, the height to which it rises being seen on the semicircle. This is not an electrometer in the strict sense of the word, for although it tells us, by the straw rising and falling, when one potential is greater or less than another, it does not tell us by how much, the conditions of its repulsion being too complicated for simple mathematical expression. It can show us, however, by the indicator standing at the same point, when the electric potential of the machine is the same at one time as at another. The strength of the electric force excited by the rubbing of glass, sulphur, amber, wax, resin, etc., was measured by Gilbert by means of an iron needle moving freely on a point, *versorium electricum;* very similar to the apparatus employed by Haüy and Brewster in trying the electricity excited in different minerals by warmth and friction. See *Electricity.*



Coulomb Electrometer.

ELECTROPHONE.—An instrument devised by Dr. Strethill Wright for producing sound by electric currents of high tension. In its simplest form the electrophone consists of two metallic plates separated by a sheet of cartridge-paper, the whole being closely pressed together by a heavy weight or screw. Such an instrument, when its plates are connected with the terminals of a small induction-coil, forms a sonorous condenser, the note of which varies with the rapidity of action in the electrotome, or contact-breaker. The more complicated electrophone communicated to the Royal Scottish Society of Arts, 25th April, 1864, by Dr. Wright, is composed of four curved plates of the thinnest sheet-zinc, each 2 by 4 feet, and each separated from its neighbor by a double layer of imitation silvered paper, the silvered sides being in apposition to the zinc. The first and third, and second and fourth plates are connected by fine wires, which also connect the instrument with the induction-coil. When this instrument is connected with a small coil, the terminals of which afford a spark almost inaudible, it becomes charged and discharged with each impulse of current, each charge being attended by a sonorous tap given out by the whole mass of metal thrown into vibration, and the rapid succession of taps producing a prolonged trumpet-note, the power of which may be increased by adding battery-power to the coil. The electrophone has been recommended by its author for use as a telegraphic relay capable of giving two or four signs with a single wire, with the advantage over other relays that perfection of contact is not necessary to its working. Fig. 1 shows the mode of working the electrophone as a double relay with four signals and the galvanometer of Thomson; A represents the needle of the galvanometer, B and C the wires communicating with an electrophone. When the needle is deflected to the right, it falls on the points B and C, and sounds the electrophone through B, A, C. The signals are produced by long and short contacts, as in the code of Morse. The second set of signals are produced by the reversal of the line-current, which throws the needle on the points of the arrangement D connected with a second electrophone of different tone.

FIG. 1.

The electrophone has been employed as a lecture-table instrument to report to a large audience results of processes which can only be rendered sensible by the most delicate galvanometric apparatus. Fig. 2 shows the adaptation of the electrophone to the galvanometer. AB represents the needle of the galvanometer suspended by a silk fiber, C; D is a small vessel of mercury communicating by a fine wire with the center of the needle; while a similar wire, attached to the end of the needle B, dips into the curved trough EF, containing distilled water. The wires inserted into D and F connect the coil with the electrophone, the current passing through F, E, B, D. When the needle is deflected, the tract of water between E and F is shortened, and the electrophone gives forth a gradually increasing sound. By a delicate system of levers attached to the wrist, as in the sphygmograph,

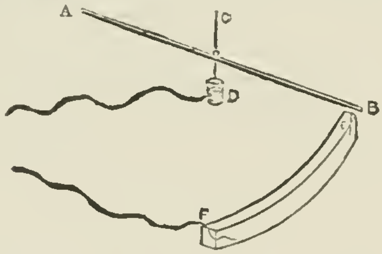


FIG. 2.

the rhythm and character of the human pulse, and its variation in disease, may be indicated to the class by the physician. Further, the electrophone may be adapted to the telephone by making the telephone-membrane act the part of a make-and-break for the current circulating in the primary wire of induction-coil. This can easily be done by leading the current through the membrane, and through a spring carrying a platinum point, which presses lightly against a piece of platinum attached to the center of the membrane. If the sounds uttered into the telephone be sufficiently strong to make the membrane so to vibrate as to cause actual separation between the platinum surfaces, they will be reproduced with great loudness in the electrophone; but if, as in the case of speaking, they be merely able to cause variations of pressure at the surfaces, they will be but imperfectly heard. Hence the electrophone succeeds best with singing, and a song gently sung in one place may be repeated in trumpet-tones in another hundreds of yards distant.

ELECTROSCOPE.—An instrument for detecting electrical excitation. In its usual form it consists of a glass jar with a wooden bottom, a brass wire passing through the cork and surmounted by a ball of the same metal; to the lower end of the wire are gummed two depending strips of gold leaf. The gold-leaf electroscope is a handy instrument for estimating roughly medium potentials. One of its best forms has a glass ball, about 4 inches in diameter, resting on a brass tripod, and its neck, about an inch in diameter, is inclosed by a brass collar fixed with shellac. A brass plate, with a hole ¼ inch in diameter in the middle of it, can be screwed air-tight into the collar. Before it is so fitted, a brass rod, ¼ inch in diameter, is fixed by shellac or sealing-wax into the hole in the middle, so as to be perfectly insulated from it. The upper end of the rod ends in a brass ball, and the lower end is filed on each side, to allow of two strips of gold-leaf, an inch in length, being attached to it. Before the plate and leaves are finally fixed, the interior of the ball is thoroughly dried, by passing hot dry air into it, so that the ball contains no moisture to carry away the charge of the leaves. When the plate is screwed to the collar, there is no communication between the included and external air. The insulation of the leaves is complete; and they keep their charge, in dry weather, for hours together. When the instrument is used, it may be charged directly, by contact being established with the ball and the body whose electricity we would examine, or a charge may be carried to it by the proof-plane, when the leaves diverge according to the charge communicated. When we would ascertain simply the kind of electricity with which a body is charged, we proceed in the following way: A glass tube is rubbed, and brought into the neighborhood of the brass knob; the leaves diverge by induction, and, when so diverged, the knob is touched with the finger, and the leaves fall to their original position, for they are then out of the line of action. In this state, — electricity is fixed by the action of the + electricity of the tube on the side of the knob next it, and the corresponding + electricity is lost in the ground. When the finger is removed, the + electricity is cut off, while the — electricity remains in the knob; and its presence is manifested by the leaves diverging permanently after the removal of the tube. If, now, a positively electrified body be brought near the knob, it draws away the — electricity from the leaves, and they consequently fall in; but if a negatively electrified body be brought near, it sends the — electricity more to the leaves, so that they diverge further. We are thus enabled to distinguish between a + and a — charge. See *Electrometer*.

ELEMENTS.—In a military sense, the first principles of tactics, fortification, and gunnery.

ELEPHANT.—The ancient Carthaginians and other nations employed elephants in war, not only as beasts of burden, but as combatants. These animals formed part of the army which Hannibal led across the Alps, and they are said to have decided the victory at the battle of Trebia. For a long time the elephant was as important an arm of war as the artillery of modern nations, and first became known in Europe from its employment in the wars of the East. They have been taught to cut and thrust with a kind of scimitar carried in the trunk, and it was formerly usual for them to be sent into battle, covered with armor, and bearing towers on their backs, which contained warriors. But the principal use of the elephant in war is for carrying baggage and for dragging guns. An elephant will apply his forehead to a cannon, and urge it through a bog through which it would be almost impossible for men and cattle to drag it; or he will wind his trunk round it and lift it up, whilst horses or cattle drag it forwards. They are extensively used, in India, for the draught of siege-trains, and in mountainous countries to carry mountain-guns on their backs. They are more sure-footed and serviceable than either horses or mules, in difficult mountain-roads. On the very steepest declivities an elephant works his way down pretty rapidly, even with a *howdah* and its occupants upon his back, his chest and belly on the ground, and each fore-foot employed in making a hole for itself, into which the hind-foot afterwards follows it, and to which the weight may be trusted, that another step may be ventured with safety. The load for steady work varies from 1700 to 2200 pounds, and the pace is from 3 to 3½ miles per hour. See *Pack-animals*.

ELEVATED BATTERIES.—Batteries in which the platforms of the guns are on the natural surface of the ground, or above it. These batteries are more simple in construction than any of the other kinds, because the arming of the batteries can be made independent of the execution of the parapet. Enfilading-batteries should have their crests as nearly as possible perpendicular to the prolongation of the line to be swept by their fire; counter-batteries should have their crests nearly parallel to the line subjected to their fire. These conditions, when fulfilled, will save a great deal of labor in the construction of embrasures. Embrasure-batteries are to be preferred to barbette, but the embrasures must be hidden, if possible. Various devices are given by means of which the embrasures are concealed, and the gunners screened from the fire directed upon them. The general principles governing the construction of field-works and trenches apply to the construction of batteries. It is to be remembered that artillery-fire draws artillery-fire; hence a greater thickness is requisite for parapets and epaulements sheltering artillery than is required for the simpler works. The batteries forming the first artillery position may have weaker profiles than those of the second position. See *Batteries*.

ELEVATING-ARC.—The elevating-arc is used for such guns as the 10-inch and 15-inch. This consists of a strip of brass attached to the base of the breech parallel to the ratchets. It is graduated into degrees and parts of degrees, and a pointer, attached to the ratchet-post, indicates the elevation or depression of the piece. When the pointer is at zero, the axis of the piece is horizontal. Besides the graduation on the arc, the ranges in yards for the ordinary charges for shot and shell are given. In batteries for garrison and sea-coast defense, where the platforms are fixed, the line of metal may be considered as permanent; but with siege-guns, mounted on traveling-carriages, the wheels are liable to vary in position from unevenness of ground or unequal settling in newly-constructed platforms. This line is constantly changing, and approximates the higher wheel in proportion to the difference of level between the wheels; hence, to secure accuracy of fire, allowance must be made by observing where the shots strike and correcting the aim accordingly. Deviation from this cause is always towards the side of the lower wheel. All range-tables are made out with reference to the horizontal plane passing through the axis of the trunnions; when the object to be fired at is situated on a plane lower than this, an allowance must be made for this difference of level by deducting from the elevation laid down in the table of ranges.

The following table is calculated for cases in which the piece is *above* the object; it will also serve with sufficient degree of approximation for cases in which the piece is *below* the object, by simply reversing the method of application; i.e., by adding, instead of subtracting, the quantity due to the height and distance:

Distance.	Height.							
	1 Ft.	2 Ft.	4 Ft.	8 Ft.	16 Ft.	32 Ft.	64 Ft.	96 Ft.
Yds.	° ′	° ′	° ′	° ′	° ′	° ′	° ′	° ′

5,000..	.2	.5	.9	1.8	3.7	7.3	14.7	22

When the height of the piece above the water or horizontal plane is known, the angle of depression for different distances can be found thus: Find the angle for any height not given in the table, as follows: divide the given height into parts, which are found in the table, using the largest numbers possible; and add the angles corresponding to those parts, for the required distance. See *Pointing*.

ELEVATING-BAR.—A stout bar of iron with one end squared and made to fit into the ratchets on the breech of the piece for the purpose of giving elevation. It is operated as a lever, the fulcrum being the ratchet-posts of the carriage.

ELEVATING-EYE.—To facilitate the elevation and depression of the Armstrong land-service guns, an *elevating-eye* is screwed into the under side of the breech, at a suitable distance from the trunnions, for the adjustment of the gun, by means of an elevating-screw; the 40-pounder, however, has a somewhat different arrangement, having an elevating-screw and quoin.

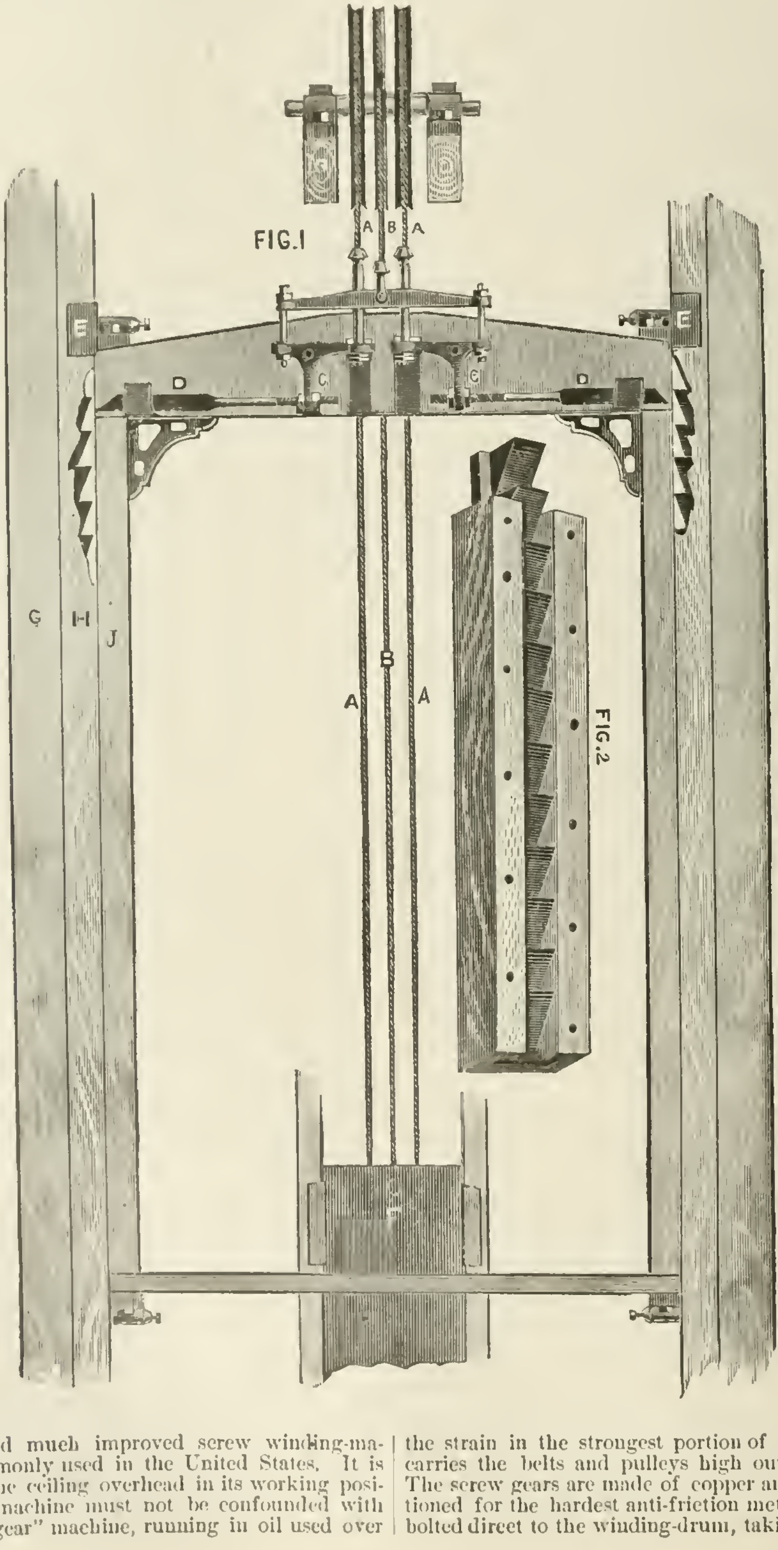
ELEVATING-GEAR.—Gearing variously contrived for elevating the breech of a gun. In the Gatling gun it consists of a screw whose lower part rests upon the trail of the gun, and whose upper part ends in a ball, working in a socket, on the under side of a brass casting. On the upper surface of the casting is a rib which works in a corresponding slot in a square brass plate screwed to the under side of the breech-casing. See *Traversing-gear*.

ELEVATING-SCREW.—A screw beneath the breech of a piece of ordnance to give the elevation or vertical direction to the piece. In field-pieces it is bedded in the stock immediately under the base-ring of the gun, which rests on the top of the screw. The screw is turned by four handles. The elevating-screw attached to the new iron carriages in England is known as the Whitworth pattern. Heavy gun-carriages, such as the wrought-iron standing or rear chock carriages, have the "ratchet-head and lever," with a modification in the chock-carriages, which have an oscillating instead of a fixed nut. In theodolites and other geodetical and astronomical instruments a similar contrivance is used for leveling the instrument.

ELEVATING-SIGHT.—The back sight of a gun or rifle which is raised, when it is found necessary, to elevate the piece.

ELEVATION.—In gunnery, the raising of the axis of the piece sufficiently high to enable the shot to range the required distance. In firing at a given object, the axis of the gun must necessarily be directed upon a point at a sufficiently vertical distance above the object to allow for the action of gravity, which causes the ball continually to descend after leaving the bore of the piece. The elevation of the axis of a gun is generally regulated by means of a tangent-scale, which is graduated in such a manner that the divisions on it correspond with the various ranges required from the gun. In geometrical and fortification drawing, *elevation* is the projection of the face of a work on a vertical plane by horizontal rays. It shows the height or depth of a work, and also its length, when the plane of projection is parallel to its face.

ELEVATOR.—Freight-elevators are now regarded as a business necessity by all manufacturers using several floors. They double the value of the upper stories for storage and other purposes, enable them to handle goods with much less help and in less time, and reduce the cost of manufacturing in the same proportion. These advantages are so self-evident that their use has become the rule in commercial centers. As a matter of safety, in all elevators, whether geared, screw, or hydraulic, all the essential parts, winding-machine connections and platform, should be stronger than the driving power, so that if the platform or its carelessly loaded freight should come in contact with a floor, or any unyielding obstruction, nothing will break, but the belts will slip or run off and do no harm; if a hydraulic elevator, the piston will stop in the cylinder. The power for hoisting may be obtained from various sources. As most foundries and construction-works are supplied with an abundance of steam or other power, they employ steel screw machines of sufficient lifting capacities, again and filled with dirt and accumulations to grind out the parts. The drive-shaft and screw are made from a solid cast-steel forging, cut and finished by special tools. The screw is run above (not under, as usual) the worm-gear, and thus concentrates all



A recent and much improved screw winding-machine is commonly used in the United States. It is secured to the ceiling overhead in its working position. This machine must not be confounded with the "worm-gear" machine, running in oil used over the strain in the strongest portion of the frame and carries the belts and pulleys high out of the way. The screw gears are made of copper and tin, proportioned for the hardest anti-friction metal. They are bolted direct to the winding-drum, taking no chances on the breakage of the shaft, or keys or set-screws getting loose. They are also fitted with an automatic stop-motion, which is adjusted to the height of the building, and prevents the winding-drum from making more than the number of revolutions required for the platform or car to travel from bottom to top, where it is stopped automatically, without any connection with the shifting-ropes. With the belt-shifter one belt only is moved at a time, which is much easier to operate and with less wear upon the belts than where both belts are shipped across wide pulleys, as is usually the case. The loose pulleys have long bearings lined with composition sleeves, and have large self-oiling chambers.

In a locality supplied with a system of water-works at a sufficient pressure, the hydraulic elevator presents many advantages over any other. The first cost is much less when compared with that of putting in steam-boiler and engine; the cost of running is much less than the cost of fuel and the services of an engineer; the objections to steam-boilers are avoided; the elevator is always ready, night and day; there is no waiting to get up steam, nor noise from fast-running engines, belting, or machinery. The hydraulic engine is very simple, strong, and durable, slow and noiseless in its movements, and requires little attention or repair. In localities not supplied with water-works an independent water-pressure may be provided on what is known as the "tank system." A water-tank of suitable size, made of tank-iron or cedar, is placed upon the roof of the building. Another of similar size is placed in the basement. Water from the upper tank is conducted by wrought-iron pipes direct to the hydraulic valve and engine below, the pressure of which supplies the power to raise the car. When the car descends, the water is discharged into the tank below. Here the problem of power comes in: to return the water again to the upper tank, using the same water over and over again. This is usually done by a steam-pump, working perfectly automatic, the steam being admitted and shut off according to the requirements of the elevator by the height of the water in the lower tank. In this system (as the pressure is invariably due to the height) buildings of four stories or more high will give the most satisfactory results.

The drawing shows what is known as the "gravity safety," a counter-weight provided for elevators subjected to heavy loads. Its principle consists in making the weight, used to balance the car, serve the purpose of safety also, by attaching it directly to the safety-pawls, ready to throw them out to engage the safety-ratchets, if the lifting rope or ropes should break. A A, Fig. 1, are two lifting-ropes. B is the rope attached to the weight, F. C C are two wrought-iron crank-levers, which swing on pivots and engage the two safety-pawls, D D. E E are the two guide-shoes, which run on the safety guide-ways, H. G is the guide-post.

It will be seen that, as the two lifting-ropes are attached to extremes of the crank-levers, C C, and the weight-rope to the other extremes (connected by the cross-lever), so long as the lifting-ropes maintain their hold they will keep the levers and pawls in the position shown in the drawing by the superior weight of the car; but should one or both of the lifting-ropes break or lose hold upon the weight-rope, always ready to act, it would instantly throw out the pawls to engage the safety-ratchets on the guide-posts, and lock the car.

Fig. 2 is an enlarged view of a section of the safety ratcheted guide-way, shown also at H, Fig. 1, with a portion of the wood casing cut away to show the iron ratchets. The object of this invention is to provide a smooth, even, noiseless guide or track for the platform or car while moving up and down; also to retain and hold the flanged iron safety-ratchets with increased strength and safety. By incasing the iron ratchets in or between the hard wood by the iron flanges as shown, and the wood screwed or bolted to the guide-posts, it forms the noiseless guide-way, and so holds, strengthens, and retains the latter that should it be broken it could not separate from the wood, but would still serve the purpose of safety-stops for the car. It might be found desirable to form the casing in two or more strips, united and placed, with relation to the ratchet sections, in any convenient or suitable manner.

The shaft to receive an elevator should always be constructed from four to six inches wider upon each side than the bottom of the car. This gives ample room for guide-ways, cables, counter-weights, etc. The shaft should extend through the roof and be lighted from the top, especially in passenger-elevators. All projections (in the shape of door-sills or pipes) into the shaft should be avoided; they are always elements of danger. The inside of the shaft should be as plumb and smooth as possible. Whenever the shaft is built of wood, the studding should be 2×6 feet, if possible, and 12 inches from centers, well and firmly bridged, and corners well tied together. The door-openings to the shaft, upon each floor, should be the width of inside of the car. This is necessary in freight-elevators to give ample access to car or platform. In passenger-elevators this space should be occupied by one stationary and one sliding door, with the upper panels of doors furnished with plate glass or wire screens. This gives a prominence to the elevator-entrance, and a much more pleasant appearance from without or within the car. The doors should slide as nearly flush with the inside of the car as possible, and be opened only from the inside by the attendant in the car.

In planning the position of an elevator, it is always advisable to enter the car from the same side on each floor, having but one door opening into the car, if possible. Cars with two door-openings, at right angles, calling for corner guide-posts, are more expensive, not so strong, and more liable to accidents.

ELF-ARROW-HEADS.—A name popularly given in the British Islands to the arrow-heads of flint which were in use at an early period among the barbarous tribes of Europe generally, as they are still in use among the American Indians, the Esquimaux of the arctic regions, and the inhabitants of some of the Islands in the Pacific Ocean. It was believed that elves or fairies, hovering in the air, shot these barbs of flint at cattle, and occasionally even at men. Thus, Robert Gordon, of Straloch, an accomplished country gentleman of Scotland, writing in 1654, tells how one of his friends, traveling on horseback, found an elf-arrow-head in the top of his boot, and how a gentlewoman of his acquaintance, when out riding, discovered one in the breast of her habit. He remarks that, although they are got by chance in the fields and on the highways, one who goes to look for them on purpose will search in vain. He adds that they are most commonly met with after showers—a circumstance which probably helped them in Germany to their names of "thunder-bolts" and "thunder-stones," and is easily enough explained. The rain, by washing away the earth in which they have been imbedded, makes them more readily perceptible to the eye, especially if the sunshine happens to fall upon them. Cattle dying suddenly in the fields were believed to have been struck by elf-arrows—a belief which yet lingers in Ireland, and perhaps in some secluded parts of Scotland. The elf-arrow-head was occasionally set in silver, so as to be worn on the person as a talisman, or had a hole drilled through it, so that it might be dipped in water, which, being thus endowed with healing virtue, was used sometimes as a wash, more commonly as a draught. As a talisman, the elf-arrow-head was believed to be most efficacious as a preservative from poison and witchcraft. The ascription of the flint arrow-head to the elves or fairies

Elf-arrow-head.

is but one of several instances of the disposition of a people to elevate or degrade the earlier races whom they vanquished or dispossessed into mythical beings, better or worse than mankind. Thus, in Greece and Italy the remains of the rude strongholds built by the Pelasgi came to be regarded as works of the fabled Cyclops, or one-eyed giants. So also, in Scotland, the sepulchral mounds of the aboriginal inhabitants were called "elf-hillocks;" and the vestiges of ancient plowshares which may be traced on heaths and hill-tops were called "elfin-furrows." Examples of elf-arrow-heads may be seen in most Museums of Antiquities. They fall to be more particularly described in a following page, under the head of FLINT IMPLEMENTS AND WEAPONS.

ELLIOT CARTRIDGE-BOX.—This box consists of two metallic plates mounted side by side on a common pivot, by which they are secured in a skeleton metallic frame covered with leather. They are fluted radially for the reception of twenty-four musket-cartridges, caliber .45. These flutings are so arranged that the heads of the cartridges may lie in an almost continuous row, while the points overlap each other in such a manner that the cartridges are mutually supported by the ends of their cases, the weight being thus taken off the point of the ball, and removing its liability to be driven into the cartridge by the repeated shaking of transportation. The box when used is to be worn over the left breast. When charged, it is rotated for firing by bringing with the fingers each cartridge in succession to an open notch in the periphery of the frame, beyond which it is kept from going by the interposition of the end of the rim, which is here turned down into a flap and serves to stop its further motion in this direction. Its return is prevented by a spring-pawl on the under side of a slide on the circumference of the frame. This slide, when pulled out, keeps the cartridge beneath it from accidentally falling out, and yet allows it to be used as a means of rotating the box, as soon as the cartridge next preceding has been picked out through the space left for its ready removal.

ELLIOT GUN.—A breech-loading small-arm having a fixed chamber closed by a movable breech-block, which rotates about a horizontal axis at 90° to the axis of the barrel, lying above the axis of the barrel and in rear, being moved from above. By cocking the hammer, it operates as a lever on the breech-block pawl, and at each movement alternately pushes and pulls against the lower arm of the breech-block and opens and closes the piece. After opening the piece the hammer falls forward, and resting upon the pawl prevents any motion of the block until the piece is closed, which is done by again bringing the hammer to the full-cock, where it is held by the rear end of the trigger. The piece is locked by the position of the breech-block and by its friction against the head of the cartridge when firing. It is also braced by the hammer falling behind a shoulder on the pawl, to prevent its movement as in opening. It is fired by the usual center-lock and a firing-pin in two sections, one of which moves with the block and the other remains in the frame. Extraction is accomplished by a lever pivoted below the chamber and worked through the intervening extractor-link by the movement of the hammer on the pawl. Ejection is effected by an auxiliary spring playing on a friction-roller eccentrically placed in the extractor. The guard is hinged at its rear end so as to afford a ready means of inspecting or cleaning the mechanism, and the lock is so constructed that the hammer cannot be let down slowly upon the firing-pin with the thumb.

This arm has been modified so that extraction may be caused by a bent lever of the usual form, and operated by the descent of the breech-block. In this modification the breech-block pawl is single and works within the cheeks of a slit hammer.

ELLIOT MAGAZINE-GUN.—This arm is provided with a reciprocating and rotating bolt for closing and locking the cartridge chamber by means of a handle in the usual way. It is also provided with a double tubular magazine, located in the butt-stock, the tubular chambers being arranged one over the other, and each provided with independent cartridge-propelling devices. The upper end of the revolving pawl is bent inward and works in a longitudinal groove cut in the side of the bolt; and where the bolt is rotated in locking and unlocking the arm it gives a vertical movement to the revolving pawl, which, being actuated by a suitable spring, causes the disk or ratchet to revolve one notch. On the face of the disk and over each alternate ratchet-tooth there is a cam. These cams and the free ends of a double feed-pawl are so arranged in relation to each other that the cams pass under and raise the ends of the feed-pawl alternately. Each time one of the ends of the feed-pawl is raised the line of cartridges under it is permitted to move forward until the ball of the first cartridge lodges in the recess between the carrier and bolt. In this position of parts the head of the first cartridge remains a little way in the mouth of the magazine, and the second one has not yet engaged the point of the feed-pawl. When the bolt is drawn back after firing, the magazine-spring forces the whole column of cartridges forward until the feed-pawl engages the head of the second one, and the first one is landed upon the carrier. When the backward movement of the bolt is completed the first cartridge is raised into the receiving-chamber by the carrier-spring. By this arrangement of parts the shock of arresting the forward movement of the column of cartridges is taken upon the carrier and bolt. In addition to the ordinary spiral magazine-spring there is an auxiliary spring in the bottom of each tubular space, the object of which is to cushion the blow of the column of cartridges upon the bottom of the magazine in case of heavy recoil or jolting when the magazine is full or nearly so, and thus prevent accidental explosions. The tubular spaces are provided with projections or shoulders on each side. These projections are so arranged that the cartridge-heads strike them alternately on each side, which causes the heads to vibrate laterally and prevents the cartridges from moving, from any cause, with dangerous rapidity, whereby accidental explosion is avoided. The butt-stock and tip-stock are made in separate pieces, being supported at their inner ends by cheek-pieces, under which they project. The handle of the bolt is attached to the rear end and has six curves, as follows: Backward and downward, which carry the handle back within reach of the thumb, while the index-finger is on the trigger; also curves downward, outward, and upward, to form a bed for the thumb to rest in. The end of the handle has also a downward curve over the side of the hand. During the manipulation of the arm the handle is grasped between the thumb and the side of the hand above the index-finger, from which it is not at any time released. At the moment of firing the bolt is held in the locked position by the thumb on the handle. In withdrawing the bolt the thumb is bent down a little forward of the lower end of the handle, and the act of returning and locking the bolt carries the index-finger back to the trigger, and the other three fingers to the wrist of the arm. See *Magazine-gun*.

ELLIPSE.—The name of a figure in geometry important from its being the approximate shape of the planetary orbits, and frequently appearing in the problems of gunnery. It is a curve of the second order, and is a conic section, formed by cutting a right cone by a plane passing obliquely through its opposite sides. It may be defined as a curve the sum of the distances of every point in which from two fixed points within the curve is always the same. These two fixed points are called the foci; and the diameter drawn through them is the major axis; the minor axis bisects the major at right angles. The distance of either focus from the middle of the major axis is the *eccentricity*. The less the eccentricity is compared with the axis, the nearer the figure approaches to a circle; and a circle may be considered as an ellipse in which the foci coincide.

There are various contrivances for describing an ellipse, called *ellipsagraphs* or *elliptic compasses*. The simplest method of description is to fix on a plane the two ends of a thread with pins in the foci, and make a pencil move on the plane, keeping the thread constantly stretched. The end of the pencil will trace an ellipse whose major axis is equal to the length of the thread.

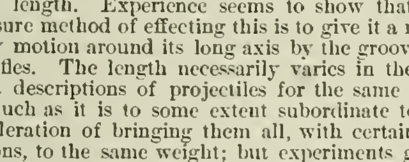
The equation to an ellipse, referred to its center as origin, and to its major and minor axes as rectangular axes, is $\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1$, where a and b are the semi-major and semi-minor axes respectively. From this equation it may be shown by the integral calculus that the area of an ellipse is equal to πab, or is got by multiplying the product of the semi-major and semi-minor axis by 3.1416. It may also be shown that the length of the circumference of an ellipse is got by multiplying the major axis by the quantity

$$\pi\left(1 - \frac{d^2}{2^2} - \frac{3d^2}{2^2.4^2} - \frac{3^2.5d^2}{2^2.4^2.5^2} - \text{etc.}\right),$$

where $d = \frac{1 - 4b^2}{4a^2}$.

ELONGATED PROJECTILES.—The great improvements which have been made of late, in the accuracy and range of cannon, consist simply in the use of the elongated instead of the spherical form of projectile. To attain accuracy of flight and increase of range with an elongated projectile, it is necessary that it should move through the air in the direction of its length. Experience seems to show that the only sure method of effecting this is to give it a rapid rotary motion around its long axis by the grooves of the rifles. The length necessarily varies in the different descriptions of projectiles for the same gun, inasmuch as it is to some extent subordinate to the consideration of bringing them all, with certain exceptions, to the same weight; but experiments go to prove that a length of two calibers at least is necessary for very accurate firing, and it is desirable for good *vis viva*, or destructive effect on impact at any but very short ranges, to have the weight great in proportion to the caliber, or, in fact, to the surface of resistance, and of course this is favored by an increased length of projectile. As a rule, the best length for accurate firing with any ordinary twist has been found to be from two to three calibers.

The form of head is governed by two considerations, *flight* and *penetration*. The latter gives different forms in different instances. The question of flight affects all equally, and on this many experiments have been made, which have resulted in the general adoption of what is termed an *ogival* head, or figure generated by the revolution of an ogival or pointed arch about its axis. It has been found that the total pressure on a nine-inch spherical projectile, moving with a velocity of 1150 feet per second, is about 555 lbs. ANBM representing the spherical nine-inch projectile, and the total pressure on a hemi-



spherical-headed, elongated projectile of the same diameter represented by ACDBM, and moving with the same velocity, is 487 lbs., thus showing a difference of 68 lbs. total pressure. Now supposing the elongated projectile to move steadily, point first, the pressure on the respective heads, A, M, B, must be the same; therefore the difference of the total pressure, viz., 68 lbs., must be due to the difference of *minus pressure* on the bases ANB, ACDB respectively, thus showing that the form of base of a projectile materially influences the total pressure which it meets with when moving through the air at a high velocity. The total pressure on an ordinary ogival-headed projectile of 9 inches diameter, represented by ACDBM′, is only 389 lbs., thus showing the great difference of pressure, viz., 166 lbs., on an elongated ogilval-headed projectile and a spherical projectile of the same diameter when moving at the same velocity through the air. Another great advantage which the elongated projectile possesses over the spherical is that, for the same caliber, the momentum of the former is much greater, varying, of course, in proportion to their respective weights, which would be nearly three to one, depending on the length of the elongated projectile. Piobert says that the figure experiencing the least resistance from the air has a length five times its greatest diameter, with its largest section placed $\frac{2}{5}$ of the length from the hind part. The shapes of some of the Whitworth projectiles approach more nearly to this form than those of any elongated projectiles hitherto used. See *Projectiles*.

ELSWICK COMPRESSOR.—An arrangement for compressing friction-plates used to take up the recoil of gun-carriages upon their slides. The seven friction-plates arranged longitudinally under the carriage and attached to its lowest part have alternating between them six long flat bars attached at their ends to the slide by bolts passing through them, but allowing them a side motion. The plates and bars are tightly clamped by short rocking levers, the lower ends of which act on the outside plates. The levers are worked by collars on a threaded shaft, which catch their upper ends. The shaft is called the compressor-shaft, and has a handle or crank on the outside of each cheek or bracket; one is called the *adjusting-lever*, the other the *compressor-lever*. The first is used to give an initial compression to suit the charge, the other is operated by the recoil being forced down by a tripper on the slide.

ELSWICK GUN-WORKS.—The Elswick Works of Sir William Armstrong, at Newcastle-upon-Tyne, have produced the largest constructions in England of their well-known type, and from which sprang the modified form known as the Woolwich gun. We cannot here attempt to give a description of the Works in any general sense, but merely to notice a few features such as characterize them, or should be noticed by visitors to Elswick, especially engineers. We suppose the works to be traversed in the order adopted, as far as we understand, on the last Public Day.

Commencing at the northeast corner of the Works, the first objects of interest are the 6-inch and 40-ton breech-loading gun mounted in barbette. It is well to observe the system in action and the cover afforded to the detachment. Close to these guns is a shrinking-pit for ordnance from the 100-ton gun downwards, also nineteen gas-producers for furnaces. The shops then may be taken in the following order·

Coiling.—The largest section of bar has been 12 by 10 inches; length of coiling-furnace, 180 feet; gas-furnace for heating barrels, also for tempering, with an oil-well 50 feet deep, over which stands a hydraulic hoist.

Forge.—The large hammer here, made by Thwaites & Carbutt, Bradford, has a 48-inch cylinder and 12 feet stroke; weight of piston and hammer-head, 35 tons. Blast smelting-furnaces, one furnace building, two in work, and running from 900 to 1000 tons a week, chiefly No. 1, 2, and 3 pig, made from Spanish and Elba ores, most of it sold for steel-making. The blast is at present heated by horseshoe pipes, but Cowper's heating-stoves are in course of erection; temperature of blast, from 750 to 800 —about the melting-point of zinc. The engine for the furnaces is made by the firm.

Carriage-shed.—There are band-saws cutting iron which may be noticed, and Albini carriage on short recoil and self-running-up system.

Projectile-store.—Containing the finished projectiles. These are chiefly made with bands only up to full diameter, which saves work, and leaves to the projectile the strength of the uninjured skin of the casting. The Palliser chilled projectiles will be generally found with sharp-pointed heads struck with two diameters ogival.

Foundry.—Containing the ten cupola-furnaces, of which four are generally in work. Forty tons is about the maximum weight of casting made in the foundry—a much larger one, such as the bed of the steam-hammer, weighing 137 tons, being cast on its own ground. The system of hydraulic cranes should be noticed. They are fixed so as to work in pairs, or three together, for heavy work.

Engines.—Near this are the engines for the East Works, and also those for the West Ordnance-works. Horizontal double Corliss engines are employed, with four boilers; three working at a time. Juke's bars and system of stoking is applied to all. The *Jetty* may probably be conveniently visited next, near which are more horizontal engines, 100 horse-power, working on the accumulators; the water-pressure maintained is about 700 pounds per square inch. Five or six locomotives are generally employed in the works. On the east end of the jetty are two fixed hydraulic cranes for lifting 5 tons and 30 hundredweight; and between them large hydraulic shears, made by Day & Summers, worked by a direct-acting hydraulic cylinder, 40 feet stroke, lifting 120 tons. The bag-leg moves so as to bring the lifting-cylinder about 30 feet out, 15 feet inboard of a vessel. The foot is moved by a screw 50 feet long, with hydraulic engine and gear, with three different powers. Along the jetty run pipes with hydrants from 18 to 36 feet apart, on which work five movable cranes, each lifting about 30 hundredweight, being placed in position to suit the holds of the vessels by means of telescope-tubes attached to the nearest hydrants.

The finishing-shop may be taken next in order. The proportions of new-type guns should be noticed also; the breech-loading fittings, and apparatus for firing by electricity and also mechanically. One shop is for small machine-work, completing Gatling machine-guns, hydraulic valves, etc. Another contains planing-machines, etc. Others are constructed for turning, finishing, and boring work, commencing on the solid ingot. At the east end guns are bored vertically in a pit 23 feet deep. The finest lathe is one of Whitworth's for turning, boring, screw-cutting, and rifling, taking a job 44 feet in length, 36-inch centers. There is also a convenient one made by Fairbairn, Kennedy & Naylor, modified at Elswick, taking a chuck job 20 feet in diameter, 4 feet 6 inches long, or a job 34 feet long and 8 feet in diameter. It is fitted with slide-rests on independent beds. There are also chambering and rifling machines. In another shop, crank-shaft and gun work, coil-welding, etc., are performed. The steam-hammers, from 24 tons to 15 hundredweight, are chiefly Morrison's make. There is a great variety of small machinery, for turning and boring out short coils; also a large endless band-saw, 1¾ inch wide, which cuts directly through iron cylindrical work about 16 inches in diameter. Its speed is from 76 feet to 129 feet per minute.

It will be seen that the facilities of these works are ample in every respect for ordnance-constructions; and when we come to consider the decidedly advanced progress in the adaptation of steel in its strongest form—ribboned—in gun-constructions of light weight combined with great power, it must be admitted that in the pure question of the building up of guns to resist the drafts upon them, especially by tangential strains, far beyond standard limits in England, Sir William Armstrong & Co. are farthest advanced as the pioneers in Great Britain of a system destined, probably, to solve in the most satisfactory manner the problemn of all heavy gun-construction, in the present state of the art, in producing the metals deemed most suitable for making sound and reliable ordnance. See *Armstrong Gun* and *Ordnance.*

EMBAR.—The command, in heavy-artillery practice, directing that the handspikes be placed in positions for moving the piece and the carriage; as, for example, when it is wished to move a mortar *in battery*, the four cannoneers face towards the epaulement and EMBAR: Nos. 1 and 2 under the front maneuvering-bolts, and Nos. 3 and 4 under those in rear, engaging the butts of their handspikes about three inches; Nos. 1 and 3 hold the small end of their handspikes in the left hand, Nos. 2 and 4 theirs in their right. All being ready, the gunner commands, HEAVE, and repeats it as often as may be necessary. As soon as the piece is on the middle of the platform, he commands, HALT: all unbar, and resume their posts.

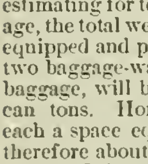
EMBARGO.—A temporary order to prevent the arrival or departure of ships. It may apply to vessels and goods, or to specified goods only; it may be general or special; it may apply to the entering only, to the departure only, or to both entering and departure of ships from particular ports; and lastly, although issued by the Admiralty in England, it would be equally an embargo if issued by any other competent authority. Such embargoes are generally connected in some way or other with a state of war between two countries.

EMBARKATION.—In loading vessels with stores for a military expedition, the cargo of each should be composed of an assortment of such stores as may be available for service in case of the non-arrival of others; and they should be placed on board in such a manner that they may be easily reached in the order in which they are required for service. Each storeship should be marked, at the bow and stern, on both sides, in large characters, with a distinctive letter and number. A list is to be made of the stores on board of each vessel, and of the place where they are to be found in it; a copy of this list to be sent to the chief officer of the proper department in the expedition, or at the place of destination. If the disembarkation is to be performed in front of the enemy, some of the field-pieces should be so placed that they can be disembarked immediately with their carriages, implements, and ammunition; also the tools and materials for throwing up temporary intrenchments on landing. Some vessels, distinguished by particular signal, should be laden solely with such powder and ammunition as may not be required for the immediate service of the pieces. Boats of proper capacity must be provided for the disembarkation, according to the circumstances in each case. It may be necessary to establish temporary wharves on trestles, and to erect shears, cranes, or derricks. On a smooth sandy beach heavy pieces, etc., may be landed by rolling them overboard as soon as the boats ground, and hauling them up with sling-carts. When the embarkation takes place from a wharf, and the vessel is not too high, it is best to use gang-planks and lead the horses on board. The gang-plank leading up from the wharf to the gunwale should be about 20 feet long by 10 feet wide, and be made very strong. This width admits of its being used for gun-carriages. It should be provided with ropes at the corners, rollers, side-rails, and boards upon the sides to prevent the horses from getting their feet over the edges. Another similar gang-plank, but not so long, leads from the gunwale to the deck, the two being securely fastened together by their ropes. These gang-planks should be carried by the vessel, ready for disembarking. Every provision for this latter operation should be thoroughly looked after before starting on the voyage. When it is not practicable to use gang-planks, the horses are hoisted on board by means of a sling and lifting-tackle. Five men are required to sling a horse quickly and well. One man holds the head-guy, which is attached to a neck-collar; two men, one on each side of the horse, pass the sling under his belly; both then hold up the ends over his back, passing the long loop through the shorter one and hooking on the eye of the former to the lifting-tackle, continuing to hold up the sling until the horse's legs leave the ground; another man stands at the breast and fastens the breast-rope, while the fifth stands at his rump and fastens the breech-rope. The officer superintending commands, "Hoist away." The first man slacks away at the guy-rope, holding it just sufficiently taut to keep the horse's head steady. When hoisting, no delay should be permitted; it should be done in the shortest time compatible with safety. At the commencement, after a certainty that all is right, it should be done rapidly, to raise the horse off his feet and free him from surrounding objects before he has time to do any injury by kicking. After attaining the necessary height, he is carefully and steadily lowered to the deck. Care should be taken to have two or three careful and active men stationed to seize the horse and prevent his plunging until the slings are removed. While one holds him by the head-stall, another rapidly unhooks the tackle-purchase, and two others let loose the breech and breast bands or ropes. When the horses are to be lowered through a hatch to a deck below, the combings of the hatch, as well as stanchions about it, should be well padded. As an additional precaution, a head-collar should be provided, with a large pad on top to prevent injury should the horse strike his head against the deck-beams when lighting on his feet. Everything being in readiness and skillfully managed, an average lot of one hundred horses can be hoisted on board in from two to three hours. Hatches for horses must be at least 10 by 10 feet.

Allowing 1100 pounds as the average weight of artillery-horses and 150 pounds as that of men, and estimating for ten days' supply of food, water, and forage, the total weight of a field-battery of six pieces, fully equipped and provided for field-service, and including two baggage-wagons loaded with camp-equipage and baggage, will be 329,000 pounds, or about 165 American tons. Horses embarked without stalls require each a space equal to 3.5 tons, marine measurement; therefore about 550 tons will be required for the horses alone. It is thus seen that the actual weight of a battery forms but a small proportion of the shipping tonnage required for it. The class of seagoing steamers usually chartered for transportation service are those that ply between points along the seaboard. They are generally propellers, and vary in tonnage from one to two thousand tons. Owing to the fact that a considerable part of their room is usually taken up with passenger accommodations, they are seldom able to carry more than one full battery. A steamer of 2000 tons burden, with a free spar and main deck, is capable of carrying two complete batteries. See *Transports*.

EMBATERION.—A war-song of the Spartans, accompanied by flutes, which they sung marching in time, and rushing on the enemy. The origin of the *embaterion* is lost in antiquity.

EMBATTLE.—To arrange in order of the battle; to draw up in array, as troops for battle; to furnish with battlements.



Embattled.

EMBATTLED.—*Embattled*, or *imbattled* (called also *crenellé*), is one of the partition-lines in Heraldry, traced in the form of the battlements of a castle or tower. A bordure embattled is often given as a difference to any member of a family who is, or has been, a soldier. See *Heraldry*.

EMBEZZLEMENT.—Any person in the military service of the United States who makes or causes to be made any claim against the United States, or any officer thereof, knowing such claim to be false or fraudulent; or who presents or causes to be presented to any person in the civil or military service thereof, for approval or payment, any claim against the United States or any officer thereof, knowing such claim to be false or fraudulent; or who enters into any agreement or conspiracy to defraud the United States by obtaining, or aiding others to obtain, the allowance or payment of any false or fraudulent claim; or who, for the purpose of obtaining, or aiding others to obtain, the approval, allowance, or payment of any claim against the United States or against any officer thereof, makes or uses, or procures or advises the making or use of, any writing, or other paper, knowing the same to contain any false or fraudulent statement; or who, for the purpose of obtaining, or aiding others to obtain, the approval, allowance, or payment of any claim against the United States or any officer thereof, makes, or procures or advises the making of, any oath to any fact or to any writing or other paper, knowing such oath to be false; or who, for the purpose of obtaining, or aiding others to obtain, the approval, allowance, or payment of any claim against the United States or any officer thereof, forges or counterfeits, or procures or advises the forging or counterfeiting of, any signature upon any writing or other paper, or uses, or procures or advises the use of, any such signature, knowing the same to be forged or counterfeited; or who, having charge, possession, custody, or control of any money or other property of the United States, furnished or intended for the military service thereof, knowingly delivers, or causes to be delivered, to any persons having authority to receive the same, any amount thereof less than that for which he receives a certificate or receipt; or who, being authorized to make or deliver any paper certifying the receipt of any property of the United States, furnished or intended for the military service thereof, makes, or delivers to any person, such writing, without having full knowledge of the truth of the statements therein contained, and with intent to defraud the United States; or who steals, embezzles, knowingly and willfully misappropriates, applies to his own use or benefit, or wrongfully or knowingly sells or disposes of any ordnance, arms, equipments, ammunition, clothing, subsistence stores, money, or other property of the United States, furnished or intended for the military service thereof; or who knowingly purchases, or receives in pledge for any obligation or indebtedness, from any soldier, officer, or other person who is a part of or employed in said forces or service, any ordnance, arms, equipments, ammunition, clothing, subsistence stores, or other property of the United States, such soldier, officer, or other person not having lawful right to sell or pledge the same, shall, on conviction thereof, be punished by fine or imprisonment, or by such other punishment as a Court-Martial may adjudge. And if any person, being guilty of any of the offenses aforesaid, while in the military service of the United States, receives his discharge, or is dismissed from the service, he shall continue to be liable to be arrested and held for trial and sentence by a Court-Martial, in the same manner and to the same extent as if he had not received such discharge nor been dismissed.

EMBLEE.—A prompt, sudden, and vigorous attack which is made against the covered-way and outworks of a fortified place.

EMBOSSING.—The art of producing raised figures upon various substances, such as paper, leather, wood, metals, etc. This is usually effected by pressing the substance into a die, the kind of die and mode of applying the pressure being modified according to the nature of the design and the properties of the substance to be embossed. Sheet-metal is embossed by stamping it between a pair of steel dies, one in relief, the other in intaglio. See DIE-SINKING. When the pattern is a deep one, several pairs of dies are used, and several blows given with each, the metal being occasionally annealed. The first stamping produces a crude resemblance to the final design, of moderate depth; successive stampings bringing up more of the details, and giving increased depth. The upper die is usually raised by a rope attached over a pulley to a stirrup, in which the workman places his foot; he draws his foot down to raise the heavy die to the required height, and then suddenly releases the pressure of his foot from the stirrup, when the die descends by its own weight. While thus raising the die with his foot, he adjusts the work in its place with his hands. Smaller work is embossed with a screw-press, the lever of which is turned with one hand, while the work is placed under the dies and removed by the other. Paper and card are embossed in a similar manner, but the dies are frequently of brass, sometimes of copper electro-deposits, suitably backed. The counter-die is commonly made of soft metal, card- or mill-board, pressed into the metal intaglio die until a sharp impression is produced. The paper or card is well damped, and a fly-press is generally used.

EMBOWED.—The heraldic term used for anything which is bent like a bow. A sinister arm couped at

Embowed. Counter-embowed.

the shoulder is *embowed*. When the arm is turned the reverse way it is said to be *counter-embowed*.

EMBRASSEUR.—A piece of iron which grasps the trunnions of a piece of ordnance when it is raised upon the boring-machine to widen its caliber.

EMBRASURE.—The embrasure is an opening made in the parapet for a gun to fire through. The bottom of the embrasure, termed the *sole*, is 2 feet 9 inches, or from 4 to 6 feet above the ground, on which the wheels of the carriage rest, according to the size of the gun and the kind of carriage. It usually slopes outward to allow the gun to be fired at a depression. The base of this slope should never be less than six times the altitude. In most cases it may be horizontal, or even have a slight slope to the rear. The interior opening, termed the *mouth*, is from 18 to 36 inches wide, according to the caliber of the gun, and is of a rectangular or trapezoidal form. The line which bisects the sole in the direction of the line of fire is called the *directrix*. The sides of the embrasure are termed the *cheeks;* these widen out towards the exterior, which widening is termed the *splay*, the inclination upon each side from the directrix being one upon ten. They furthermore have an

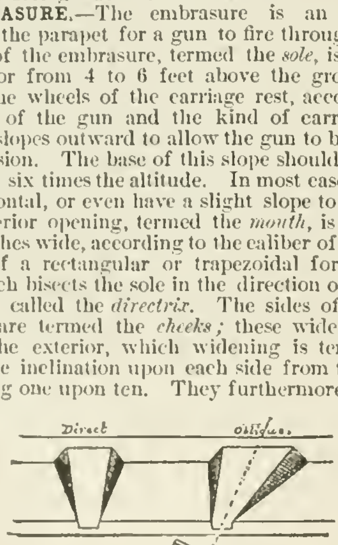


Fig. 1.

inclination outwards from the vertical; this inclination, at the line of the exterior crest, is three upon one. When the directrix is perpendicular to the interior crest, the embrasure is termed *direct;* when oblique, the embrasure is termed *oblique*, Fig. 1. In order that the part of the embrasure which is next to the muzzle of the gun may be nearly of the same width in both the direct and oblique embrasures, the mouth of the latter is wider in proportion to the obliquity. Embrasures are revetted with the same material and in the same manner as the interior slope.

If the exact position for the embrasure is known, it is best to lay it out and make it while the parapet is being constructed. As soon as the latter is built up to the sill of the future embrasure, a light stake is planted in line with the interior slope on each side of the directrix, in such position as to represent the sides of the mouth of the embrasure; a strip is nailed across at the proper height to represent the sill, and another above on the line of the interior crest. The earth being smoothed off to give the desired slope to the sole, the directrix is marked out on it by means of a cord; the splay of the cheeks is obtained by giving the sides an inclination of one tenth with the directrix. These lines being laid off on the sole, the revetment is placed along them and is given an inclination corresponding with the two profile stakes at the mouth, and three upon one at the exterior crest. Should gabions be used for revetting the cheeks, fascines are first partly imbedded along the edges of the sole, and the gabions placed on them in such manner as to obtain the proper flare. The gabions are held in position by being anchored with telegraph-wire to a beam of timber imbedded in the parapet parallel to and about 8 feet from the cheeks of the embrasure. The beams are held by securing stakes. Revetments made of other material are secured in a similar manner. This precaution should be thoroughly looked after in the first instance, because when the revetment is broken by the blast of the gun or the shots of the enemy it is difficult to repair it, and the necessity for repairing would probably come at a time when it could not be done. If the embrasure is to be cut out after the parapet is completed, the mouth is marked off with stakes and strips as before; the earth is removed so as to obtain

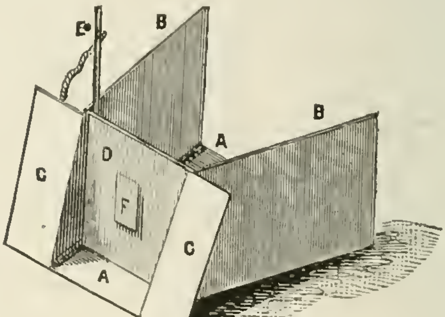

Fig. 2.

Isometrical view of wrought-iron casing for throat of embrasure and door or mantelet of same. A, sole-piece revetted to cheek-pieces, B, at the angles; C, front-pieces; D, door hung on horizontal angle at top; E, Lever with cord attached to pull up the door; F, slot in the door for rammer.

approximately the sole, which is then laid off and the work completed as just described.

The sole of the embrasure should be secured from being worn away by the blast with boards, poles, or some similar material running lengthwise with the embrasure. Raw-hides will greatly assist in preserving the revetments of the cheeks from the effects of abrasion produced by firing. For this purpose the hide, while green, is stretched, with the flesh side outward, over the part to be protected, and is there confined by stakes driven through it into the parapet. The best method, however, for securing the mouth of the embrasure, and the sole and sides for 5 or 6 feet from the mouth, is a lining made of ½-inch boiler-iron, Fig. 2. The plates are cut to the proper form to fit the sole and cheeks, and are fastened together with angle-irons and rivets. Wings, about a foot wide, extend out on each side against the interior slope to prevent the lining from being moved to the front by the blast. A round bar of iron passes across the top about 18 inches from the throat; to this a door of sheet-iron is suspended, forming a mantlet against musketry. In the center of this door is a cut or slot, about a foot high and 6 inches wide, for the double purpose of allowing the rammer to pass through while loading the piece, and for sighting it. A vertical lever of wood or iron is fastened to one side of the door; to this a rope is attached, so that by pulling on it the door is thrown up to allow the piece to be fired.

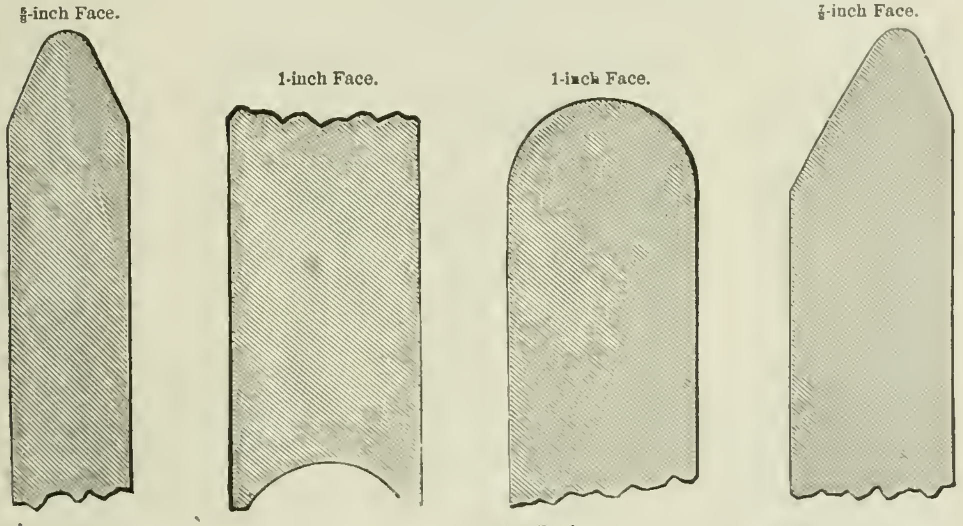
The advantages of embrasures is that the men and guns are less exposed than in a barbette-battery. Their principal defects are: they have a very limited field of fire; they weaken the parapet, and present openings through which the enemy may penetrate in an assault. Owing to their limited field of fire, they are generally used for the protection of particular points, as to flank a ditch, protect a salient, enfilade a road, etc. The most suitable position for them in a work is on the flanks. See *Direct Embrasure* and *Oblique Embrasure*.

EMBROCHER.—A common and vulgar term used among French soldiers to signify the act of running a man through the body; literally, *to spit him*.

EMERY.—A variety of corundum, or of the same mineral species of which corundum and sapphire (with oriental ruby, etc.) are also varieties. It agrees with them very perfectly in composition, hardness, and specific gravity; but is dull, opaque, and not crystallized, sometimes of a grayish black and sometimes of a blue color. It occurs both massive and disseminated. Its masses, although very compact, have a somewhat granular structure. It is found in several parts of Europe, in Asia Minor, Greenland, etc., generally in masses scattered through aqueous deposits, but in one locality in Saxony in beds of steatite in a schistose rock. The emery of commerce is chiefly obtained from the Island of Naxos. Being very hard, it is much used for grinding glass and polishing metals and other hard substances. It is found in lumps, having a granular structure. It is composed of alumina, oxide of iron, and silica, with a little lime, in proportions varying considerably with different specimens. The following may be taken as an average: alumina, 82; oxide of iron, 10; silica, 6; lime, 1½.

It is prepared for use by first breaking it into lumps about the size of a hen's egg, then crushing these to powder by stampers. It is then sifted to various degrees of fineness, which are numbered according to the meshes of the sieve. Plate-glass manufacturers and others separate emery-powder into different degrees of fineness by the method of *elutriation*. A number of copper cylinders of graduated capacities are placed in a row, and filled with water; the emery, churned up with an abundance of water, is admitted by a pipe into the smallest, it then passes to the next in size, and finally flows from the largest; and thus, as a given quantity of water with emery suspended in it passes in equal times through vessels of varying capacities, the amount of agitation will obviously be greatest in the smallest vessel, least in the largest, and in like proportion with the intermediate; the largest particles, therefore, sink in the smaller vessel, and so on till only the very finest will reach the largest vessel. In this manner any number of gradations of fineness may be obtained, according to the number and sizes of the vessels. Elutriation in oil or gum-water is sometimes used on a smaller scale, the emery being stirred up in the liquid, and portions poured off at different intervals of time, the finest being, of course, the last to settle. The use of the oil or gum is to make the subsidence take place more slowly. Emery thus prepared is used for a great many important purposes in the arts. Being next in hardness to diamond-dust and crystalline corundum, the lapidary uses it for cutting and polishing many kinds of stone. Glass stoppers of all kinds are ground into their fittings with it. Plate-glass is ground flat by its means; it is also used in glass-cutting, and in grinding some kinds of metallic fittings. When employed for the polishing of metals it has to be spread on some kind of surface to form a sort of fine file. *Emery-paper*, *emery-cloth*, *emery-sticks*, *emery-cake*, and *emery-stone* are various contrivances for such purposes.

Emery-paper is made by sifting emery over paper which has been covered with a coating of glue. It is used either by wrapping it round a fine file or a stick, or in the hand, according to the form of the work. Emery-cloth is made like emery-paper, with coarse calico substituted for paper. The emery does not adhere so well as to paper, and it is therefore not used by metal-workers, who work emery-paper till smooth with wear, but is chiefly used for purposes where the hand alone is used and paper would tear. Emery-sticks are used for the same purposes as emery-paper wrapped round files; they are made of deal sticks shaped like files, then glued over, and dipped once or twice in a heap of emery. Emery-cake is a compound of beeswax, suet, and emery, melted and well worked together. It is applied to buffing-wheels, etc. Emery-stone is a kind of earthenware mixed with emery, formed by pressing a mixture of clay and emery into

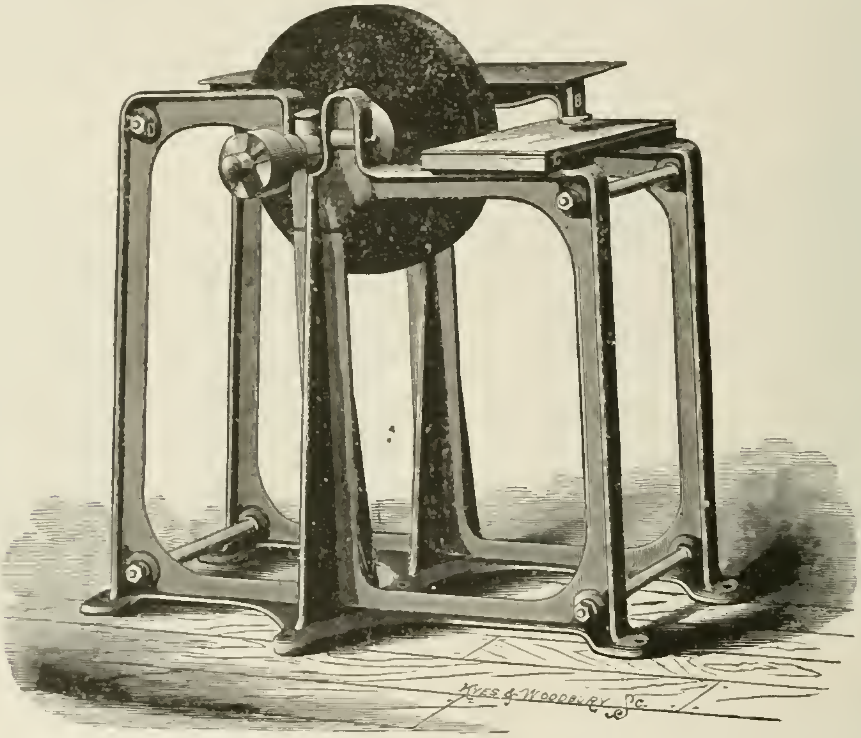


Faces of Tanite Wheels.

suitable molds, and then firing like common earthenware. It is molded into wheels, laps, etc. Its hardness and cutting power are very considerable. See *Polishing*.

EMERY-GRINDER.—An emery-wheel mounted in a stand, to be used as a grindstone. It may be considered as such, indeed, the mineral corundum with a matrix of gum-resin, glue, vulcanite, etc. The Tanite emery-grinding machinery is standard in the United States and Canada. The French, Belgian, Russian, and Australian Governments have also been large consumers, and even in the works of the Chinese and Japanese Governments Tanite emery-wheels and grinding-machines are largely employed.

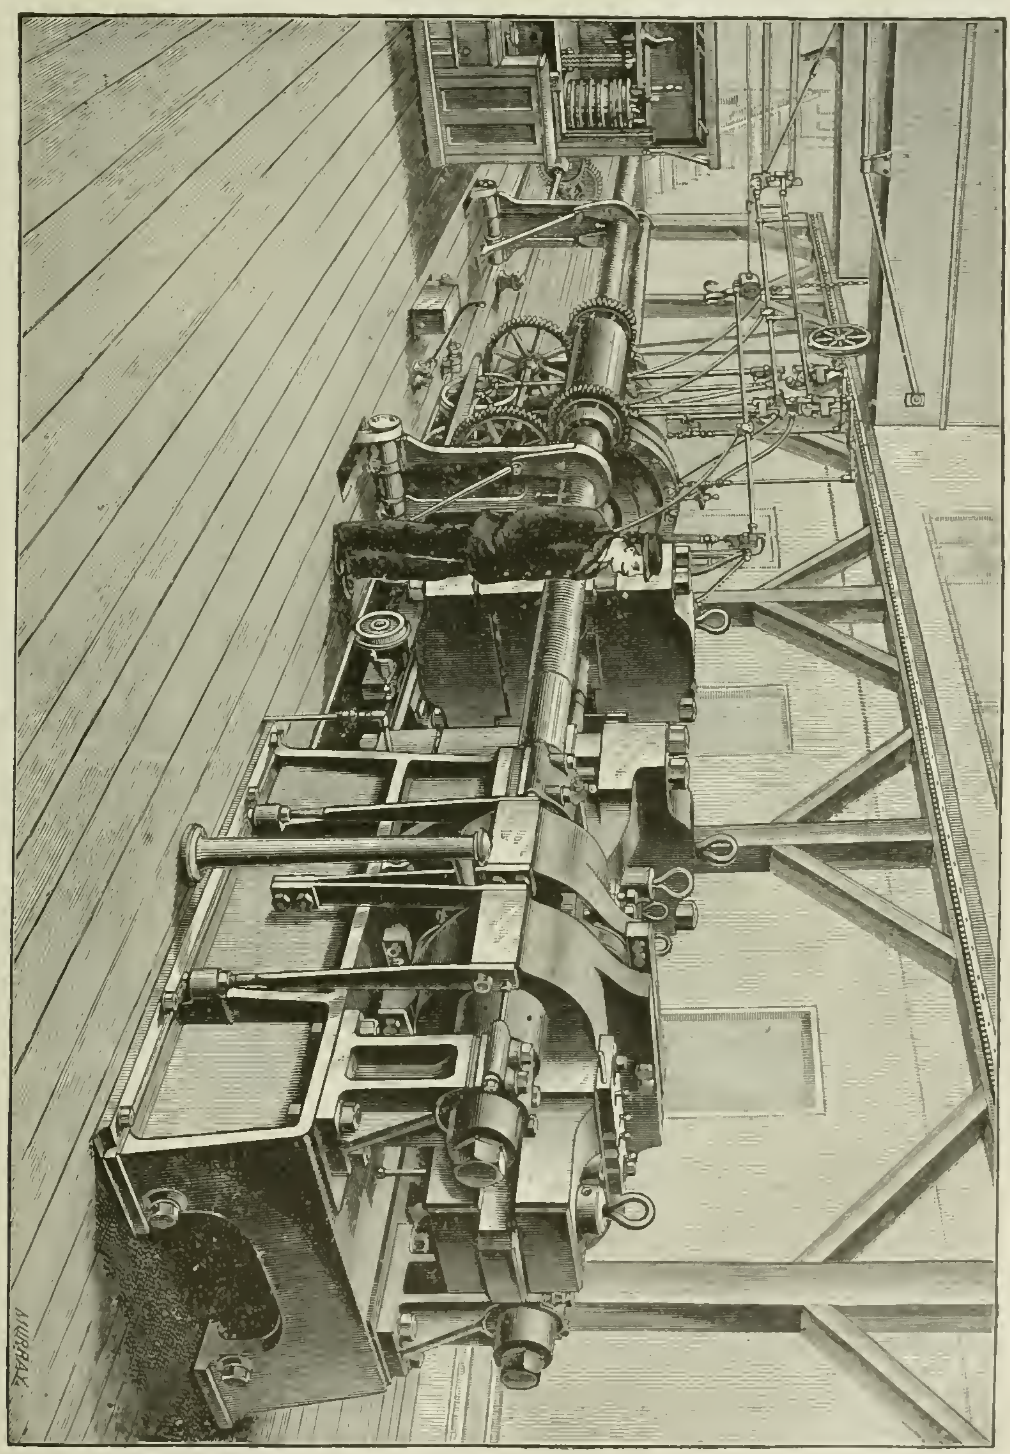
The drawing shows a single-wheel emery-grinder much used in arsenals. Hitherto, among the great variety of such machines, very few have been built to carry exclusively one large wheel. In machines which carry two wheels there is a certain amount of difficulty in providing solid and convenient rests at of these rests are accurately faced with a Tanite wheel running on an emery-planer. The back of the machine stands 5 inches higher than the front, and on the brace rod, D, which connects the upper back corners of the side frames, swings the rest, B, depending for its rear support on the brace-rod, D, and resting in front by a foot on the rest, C. It bridges over the side flange of the emery-wheel, and being a wide, long, substantial rest, allows of work being conveniently held and ground on the flat side of the emery-wheel. Owing to the weight of this rest, B, it remains firmly in position without being held by nuts or set-screws, and as it swings loosely on the brace-rod, D, it can in a moment's time be moved out of the way and be left hanging down at the back of the machine, or lifted up and placed in position. The spindle of the machine is of steel, and is 1¼ inch in diameter at the eye on the mandrel-hole of the wheel. The bearings are long, and are lined with Babbitt-metal. By far the larger proportion of Tan-



Emery-grinder.

the sides of the wheel. This is due to the fact that the emery-wheels overhang the bearings. The special object in designing the machine here illustrated, the manufacturers declare, was to make it equally convenient to use the wheel on the face and on the side. In machines previously built the *side* rests were attached to rest-sockets, and several nuts had to be carefully adjusted before the rests could be secured in their proper position. This grinder is designed to carry an emery-wheel of 20 inches diameter, and of any desired thickness from 1 to 4 inches; 20 by 2½ or 3 inches is the most suitable size. The front of the machine stands at such a height that the rest, C, when laid upon it, brings the metal which is to be worked exactly at the center of the emery-wheel, which is the proper point of contact when the face of the wheel is used as the cutting agent. The rest, C, is of cast-iron, and is 20 inches long by 8 wide. It is shown in the drawing as being faced with a steel plate (saw-steel), which was the original method of making these rests; but more recently all ite wheels are square (or plane) faced. As a rule, the wider-faced ones are used for surface-work, and the narrower for edge work. We give a few diagrams, on page 555, of shapes most frequently used in the arsenal. Of course wheels of any desired face can be made any diameter; but wheels so thin as ⅜-inch face should not be more than 12 inches in diameter, nor wheels of ¼-inch face more than 8 inches diameter. It is difficult to get wheels so thin of even temper if of a larger diameter; moreover, they are liable to warp, and to be broken by heavy side pressure. These shapes are easily obtained by turning square-faced wheels with diamond tools. See *Brass-fitting Machine, Exhauster, Grinding-machine, Gummer*, and *Pony Planer*.

EMERY TESTING-MACHINE.—This machine, the like of which for capacity, accuracy, durability, and general perfection of details is not known, is in possession of the United States Government, and is placed at the Watertown Arsenal in Massachusetts. The engraving on the opposite page shows a perspective view of the machine, and will aid in giving an exact understanding of its construction and the manner of operation. The problem before the inventor of this famous machine was one of no small difficulty. Briefly stated, it was:



Emery Testing-machine.

1. To construct a machine with the capacity of testing specimens for tension or compression up to a breaking-strain of 800,000 lbs., while at the same time the machine should be of such delicacy as to accurately show the strain required to break specimens no stronger than a single horse hair. 2. That the machine should have the capacity of seizing and giving the necessary strains to the specimens, from the minutest to the greatest, without the construction of a multitude of special appliances to suit the numerous changes of form and size in which materials to be tested are presented. 3. That the machine should be

able to give these strains and receive the shocks of recoil produced by the rupture of the specimen without injury. The difficulty of this requirement may be appreciated by considering that when a test to the full capacity of the machine is made, the scale, upon the breaking of the specimen, receives by recoil an *instantaneous load of* 800,000 *pounds*. The machine and scale must be so constructed as to bear this load placed upon it instantaneously, and bear it so perfectly that the next moment it will correctly show a load of a pound without any adjustment whatever. 4. That the machine should be so constructed that the specimen, while undergoing strain, may be readily accessible for the purpose of observing minutely the care being used in general throughout the whole machine.

In the article WEIGHING-MACHINE will be noticed the means which Mr. Emery employed in indicating loads or strains of all descriptions with an accuracy hitherto unknown. In this article we will see how a system of diaphragms can be applied to the weighing of the work of a testing-machine, and also notice what means the designer has adopted to obtain a machine entirely free from back-lash when the specimen breaks. The apparatus consists of two parts. The first is the machinery for putting strain upon the specimen, whether of compression or tension. In its essential features this consists of two screws carrying

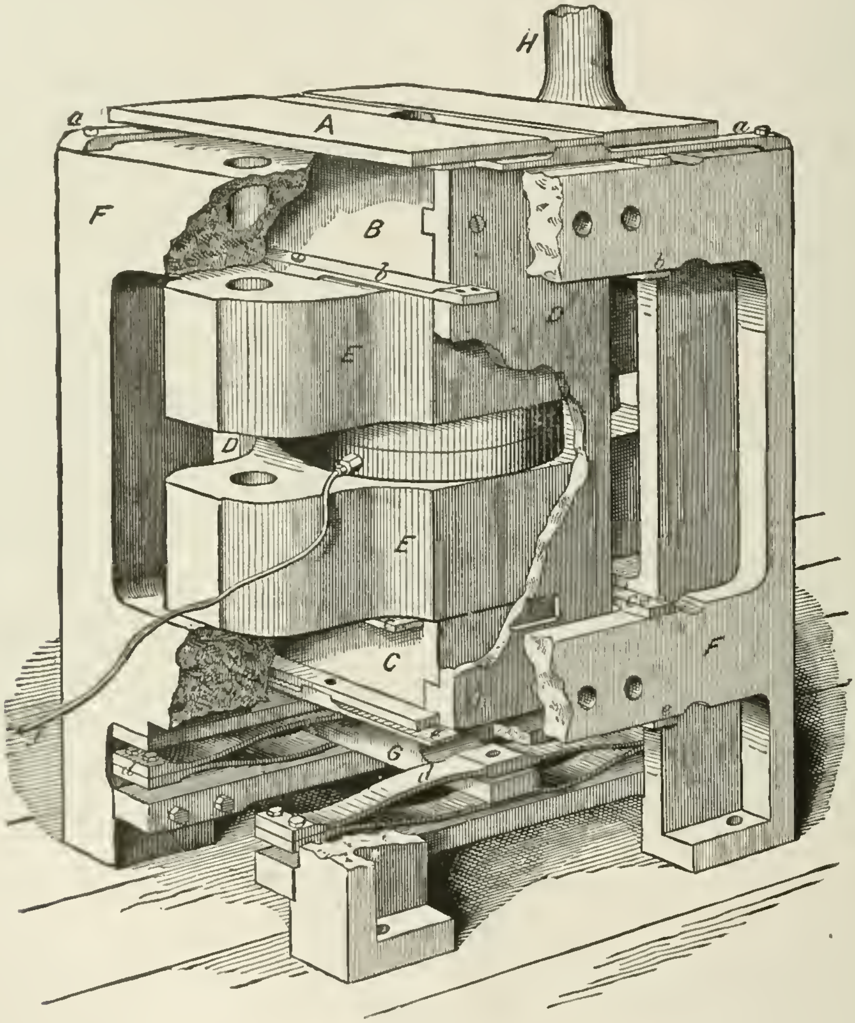


FIG. 1.

changes taking place with the changes of the strains or loads applied to the specimen. 5. That the machine should be so constructed as to be readily operated without excessive cost. The machine, after being erected, had applied to it a test-load of one million pounds, which it seemed to bear with the utmost ease. Before describing the machine, it is well to remark that all the working parts in general were at their working bearings, fitted to gauges to within less than one thousandth of an inch. For instance, the main screws, which are 48 feet long, were dressed to gauges throughout their whole length, and then the threads on them cut to gauges, the threads in the nuts being carefully gauged to match them, the same a straining-beam, to which a hydraulic cylinder is attached. This cylinder furnishes the power for compression or extension. These screws are attached to a frame in which a pair of beams are placed to furnish the abutments for resisting the power. Whether the strain is tensile or compressive, it results in compressing the liquid in the hydraulic support between these beams, which constitute alternately the platform and bed of the scale. The second part of the apparatus of the weighing mechanism comprises a system of levers and a scale-beam with suitable weights, and a pressure-column with its diaphragms, to which the pressure exerted in the testing-machine is transferred by a suitable tube. The liquid in the support between the beams, being compressed, is forced against the pressure-diaphragm of the pressure-column. The amount of force exerted here is then weighed, and the indication read from the scale-beam and the pointer which is atached to it. The reader should bear in mind carefully the distinction between the two pieces of apparatus. One is in and of itself essentially for testing. It gives no indications of the amount of strain applied, and is a perfectly independent and disconnected apparatus. The other is an indicating mechanism, and might be adjusted to a platform-scale, a weighing-lock, a track-scale, or, in fact, to a thousand and one other uses if necessary, its office being solely to register or indicate the amount of force exerted upon the system of levers which it contains. Although resembling to a certain extent the ordinary scale-beam, it differs not only in the nature of its connections, but also in the method of putting on and taking off its weights. This feature alone is entirely different from anything of which we have any account, and adds very materially to the ease and speed of weighing. One of the features which, not only in chemical but also in large balances, is inherent in Mr. Emery's system of weighing, is the fact that the motion of the load is so small, and the consequent momentum so insignificant, that the beam or pointer can come to rest quickly without a long series of vibrations on each side of the zero.

The construction of the apparatus will be better understood by a reference to Fig. 1, showing the base of the machine and framework, with portions broken away to show the more important features. Bearing in mind that whether the strains be those of tension or compression—that is, whether in an upward or downward direction—they must result in compressing the liquid in the pressure-support, the reader is prepared to understand the method of operation. The resistance, or the final abutment, is found in the frame, F, which is of cast-iron and very heavy. This frame surrounds the two beams, E E, which constitute the bed and platform of the scale, and between which is placed the hydraulic pressure-support. When the strain takes an upward direction these pieces are forced against the upper member of the frame. When the pressure is downward they rest on the lower portion of this frame. They have between them, in the pressure-support, a pair of diaphragms inclosing a quantity of fluid, which, by means of the slender tube, *f*, communicates with the pressure-column of the weighing apparatus. These pieces, E E, are surrounded by a yoke, B D C D, in which they are perfectly free and with which they have no rigid connection. The strain of the load is taken by this outside yoke entirely, and through it communicated to the abutment-pieces, E E. These two pieces, with the diaphragm between them and its inclosing rings, are finished to such a thickness that they just fill the space between the two members of the frame to within, say, $\frac{5}{1000}$ inch. This is the maximum amount of motion which is permitted. Having this arrangement of yoke and abutment-pieces, it becomes necessary to hold it in position and prevent it from any lateral motion, and at the same time allow it perfect freedom in a vertical direction. This is accomplished by a most ingenious modification of the flexible plate or metal fulcrums. For example, the upper beam, E, is held and supported in position and prevented from side motion by the thin bars, *b b*. The vertical motion is so small that the elasticity of these spring-bars, *b b*, allows it to rise and fall with practically no friction.

Similar flexible bars, *c c*, support and fix in position the lower scale-beam, E, against horizontal motion and allow freedom of motion vertically. The yoke is in like manner firmly fixed against horizontal motion at its top and bottom by four pairs of spring plates, two of which, *a a* and *a′ a′*, at the top, are attached at right angles to each other to the upper beam, A B, of the yoke and to the frame, F, while the other two pairs at the bottom, *e e* and *e′ e′*, also at right angles to each other, are fixed to the lower beam, C, of the yoke, and to the frame, F. They allow perfect freedom in a vertical direction, while compelling the whole movable portion to work in a vertical line. A beam, G, is bolted to the bottom, beam, C, of the yoke, and has its two ends extended between two pairs of initial load springs, marked *d d*. The yoke, B C D D, and its contained scale-beams, E E, being suspended in the air by the six pairs of fixing-springs, as before mentioned, is now carried firmly against the beams, E E, by the full pressure of the load-springs, *d d*, by means of two pairs of screws not here shown, one pair of screws acting to apply the load of these springs, *d d*, in an upward direction, and the other in a downward direction. When these springs are made to bear upward against G, the yoke is resting against the lower scale-beam, E, transmitting the load of the springs, *d d*, through the pressure-support to the upper beam, E, which now becomes the bed of the scale, with its outer ends resting against the frame, F, at the top, while the lower beam, E, acts as a free platform, and the scale is then balanced ready for use with strains of tension. If strains of compression or transverse loads are desired, the load-springs, *d d*, are made to act downward on the beam, G, the upper beam, E, now acting as the free platform, and the lower beam, E, as the bed of the scale. The acting area of the diaphragm in this apparatus, where a strain of 75 tons is to be exerted, is 13.6 inches in diameter.

The testing-machine is arranged for transverse strains by putting a heavy bar across the top of the table, A, which carries at its two ends suitable supports with hemispherical bearings on which the specimen rests. The outer ends of these bars are supported by braces, the lower ends of which enter the slot shown near the base of D in Fig. 1. Immediately under the ram is shown a gauge for reading the deflection. The cross-head which carries the hydraulic ram is arranged in a very neat but somewhat peculiar manner. It is carried by two screws, the nuts of which have, both above and below, a pair of gear-wheels. A pair of intermediate gears transmit the motion from one to the other, and the whole is moved up and down by means of a crank at the left hand of the machine. This crank, through a pair of bevel-gears, works the vertical shaft on the left-hand side with its two pinions, thus revolving the nuts. The shaft is provided with the usual slot and feather. This makes the matter of adjustment for different lengths of specimens comparatively easy, and, at the same time, simple. The cylinder is a double-acting one, and is connected with the force-pump by means of two telescopic tubes, shown at the right-hand side, and connecting with the cylinder itself by small bent copper pipes. These telescopic tubes are arranged in such a way that no changes in the connections are needed in any part of the stroke. For extension a peculiar form of jaw screws into the bottom of the piston-rod or ram, and also into a hole in the beam A B. The weighing mechanism itself consists of a weight-beam, somewhat similar to that shown in Fig. 5 in the article WEIGHING-MACHINE, with its indicator-rod and a series of suspension-rods for carrying weights. This beam in the scale shown is not connected directly to a pressure-column, but is moved by a large steel beam 2.5 inches deep by 10 inches in width, pivoted with plate fulcrums and moved by a pressure-column. Just above the block is the case containing the small pressure-chamber which is connected with that in the support between the scale-beams. The method by which weights are put on and taken off is in this case so entirely novel and different from anything that has been employed in ordinary weighing-machines that we give it in detail. Fig. 2, on a large scale, shows the weights with their rod. The rod D carries on its front side a number of lugs, and is supported by a plate from the beam, the suspension-spring being shown at the point marked D. The rods A and B also carry on their faces a number of lugs, and are supported by the cross-head, C, attached to one end of a rod which is operated by a lever below; *a, b, c, . . . k* are the weights. The problem is to successively throw these weights upon the beam. This is accomplished by a downward movement of the rods A and B. The lugs not being evenly spaced,

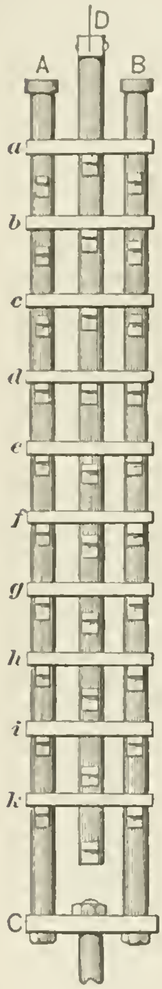

FIG. 2.

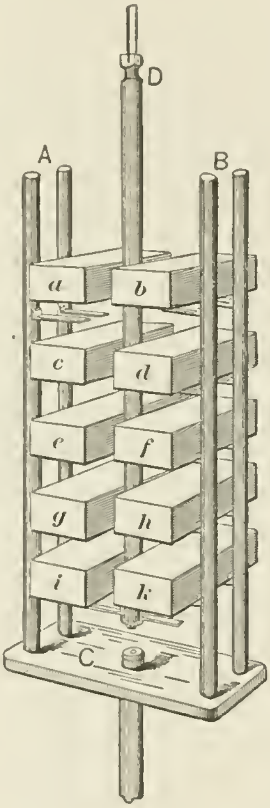

FIG. 3.

this downward motion brings the top weight, *a*, in contact with the uppermost lug on the rod D. If the motion is continued, *b* is next dropped on the rod, and *c* follows. In the engraving *a, b, c* have already been left by the downward motion of A B on the rod D. The weight *d* is bearing not only on the center, but also on the side rods, and any further downward motion of A B would allow it to rest upon D. The other weights would be in succession deposited on the central rod by a continuance of the downward motion. On the front of the beam there are three sets of these rods, each one of them carrying a carefully adjusted set of weights, 10 in number. When all of one set are upon the beam the next set is added, and so on, gradually increasing the weights until the limit of capacity is reached. The weights are arranged to add tens, hundreds, and thousands of pounds to the balancing-load. At the outward end of the beam, however, it is desirable to put on still greater weights, and Fig. 3 shows how these large weights are arranged. As in the previous case, there are 10 of them, but they are carried by two sets of rods fastened to the cross-head, C. The rod D has arms projecting from it. One pair of these arms is shown at its bottom just below the weights *i* and *k*. By the lowering of A B, the weight *a* is first picked up by the rod D, then *b* follows, and so on, until all are carried by D. When the cross-head, C, is raised the weights are lifted from D in a reverse order. In the front of the case which covers the beam four handles are seen. These handles, by motion up and down, move, by means of levers, the weight-frames, and put on or take off the weights. At the same time they raise or lower a series of pointers, and thus indicate just how many weights have been placed on the beam. In starting to weigh, all the handles are moved so as bring the pointers to zero. See *Testing-machines* and *Weighing-machine.*

EMINENCE.—A high or rising ground which overlooks and commands the low places about it. Such places within cannon-shot of any fortified place are a great disadvantage if the besiegers become masters of them.
